Abbreviation: MSA, metropolitan statistical area.

Notes: Trivariate probit model of any nonspecialty visit, any specialty visit, and any antidepressant fill estimated by simulated likelihood using the Stata routine MVPROBIT. Estimated correlation between nonspecialty and specialty visits is 0.501 (0.017), between nonspecialty and antidepressant use is 0.678 (0.016), and between specialty and antidepressant use is 0.654 (0.018). Any treatment is computed at the union of any nonspecialty visit, any specialty visit, and any antidepressant fill using the estimated multivariate normal distribution. Standard errors in parentheses computed using the method of Balanced Repeated Replication (128 half replicates using a Fay's adjustment of 0.5) which accounts for the stratified and clustered design of the MEPS and correlation in observations across families and individuals.

school days lost and bed days, and a number of other adult health measures as well as measures specific to children and adolescents. Good arguments could be made for including any one of a number of them. The main reason for sticking with just chronic conditions, SF-12, and perceived health status is parsimony. Together they do a reasonable job of representing physical health and capture many of the same dimensions of the other measures in this context.

Mental health status

Conceptually, we might think mental health is the most important determinant of demand. If you are depression free, why seek treatment? Thus, the 2-item Patient Health Questionnaire (PHQ-2), a well-validated depression screener taken from the Adult SAQ, is included. The PHQ-2 asks "Over the last 2 weeks, how often have you been bothered by any of the following problems?" "Feeling down, depressed, or hopeless," and "little interest or pleasure in doing things." Responses ranged from "not at all" (0) to "nearly every day" (3). A score of 3 or higher is suggested as a cut-point for depression screening. The linear PHQ-2 scale (0–6) is used because it measures both probable clinical depression (PHQ-2 $\geq$ 3) and severity. For example, each increment in the 0–6 scale is associated with a 2.6% point increase in antidepressant use.

The mental health analog of perceived physical health status is also included. Even controlling for symptoms of depression, we find that perceived poor or fair mental health increases nonspecialty use by 8.2% points, specialty use by 9.7% points, antidepressant use by 11.7% points, and any treatment by 18.3% points compared to those with better mental health.

Two concerns with the PHQ-2 and perceived mental health measures are noted. Most importantly, the first information we get about depressive symptoms occurs later in the first year a person enters the MEPS, and the PHQ-2 scale asks only about symptoms in the past 2 weeks. If a person sought treatment in the past because of depression, assuming treatment works, he/she may be symptom free by then. This will tend to reduce the impact of depression estimated. Like physical health, an alternative has been tested using only the second year of data for each person substituting their first year PHQ-2 measurement and perceived mental health status. Surprisingly, no appreciable differences in the effects on treatment use have been found. This may be because, although depression is a chronic illness, it is also episodic. It is also possible that reverse causality bias is offset by people with depression in the first year who do not carry symptoms into the second year and do not need treatment. However, as with physical health status, when the demand models were reestimated to explicitly account for endogeneity bias, the effects of mental health status were substantially reduced.

Second, although the PHQ-2 does a nice job for a two-item scale, it is not as sensitive to depression severity as its longer cousin the PHQ-9 or other depression instruments. A more sensitive depression measure would reduce the potential for our health insurance and demographic determinants to be confounded with unobserved severity of mental health.

Sociodemographic Determinants: Specification, Results, and Interpretation

Age

Age is represented by four binary indicators: ages 19–29, 30–44, 45–54, and the omitted category 55–64 years. For specialty and nonspecialty care, there is an upside down U-shaped relationship between age and use with the peak in the age 30–44 years range. In both, those aged 30–44 years are 1.3% points more likely to use treatment compared to those aged 55–64 years and approximately 1.0% points more likely than those aged 19–29 years. Antidepressant use showed a different pattern with respect to age with use peaking in the 45–54 year old group.

What do these U-shaped relationships mean? Age, in part, serves as a proxy for health and mental health not captured in our health measures. But other explanations are plausible. Young adults cumulatively have less exposure to the health care system, and thus, less time for providers to detect depression and recommend treatment. Tastes and preferences may change as young adults mature, or alternatively, they may suffer for years before seeking treatment. Cohort effects may also be at play here with stigma likely greater in older groups.

Sex

Sex is usually included in demand models to reflect biological differences in the prevalence, course, and severity of disease. Women, for example, are much more likely to have depression. However, controlling for symptoms of depression as much as possible in the MEPS, we find that women are still much more likely than men to use treatment, especially antidepressants. Whether this is due to unmeasured differences in depression between men and women or differences in preferences over treatment or stigma we cannot say.

Race and ethnicity

A standard representation of race and ethnicity was used in dividing the population into the following groups: non-Hispanic Whites (the omitted group), Hispanic ethnicity, Black race, and others including those of Asian and mixed race ancestry. Hispanics, Blacks, and others are substantially less likely to have nonspecialty and specialty mental health visits but proportionately even less likely to use antidepressants than Whites. For example, Blacks are almost 8% points less likely than Whites to use antidepressants controlling for other determinants. It is hard to see how unmeasured differences in depression severity might explain these magnitudes. More likely, it reflects unmeasured differences in attitudes and differential access to care. Here measures related to immigration and citizenship status have not been included because they are not available on the MEPS public use files, but they substantially reduce the magnitude of the effects for Hispanics on treatment use (not shown).

Marital status and household composition

Following standard practice (Table 1), a measure of whether the person was married at the time of their round 1 MEPS interview is included. Counts of the number of household

members between the ages of 0–5, 6–17, 18–64, and 65 years and older are also included. One reason for including household composition variables is the potential protective health benefits of marriage. Another is that increasing family size may reduce resources available, both money and time, to any one particular adult in the family for treatment. Consistent with both rationales, the measures were negatively correlated with different types of treatment use, with the exception of a small positive effect of marriage on antidepressant use. But interpretation here is difficult. Depression may also lead to divorce and family dissolution (reverse causality) reducing the magnitudes of the effects which have been observed. Family composition may also be related to unmeasured preferences for depression treatment.

Education

A series of binary indicators corresponding to degrees obtained is obtained: less than high-school diploma (omitted), high-school diploma or equivalent, some college, bachelors, and advanced degree (Masters, MD, JD, PhD). This simultaneously allows for a nonlinear relationship between education and treatment as well as potential 'degree' effects. That is, more than just another year or 2 years of college separates someone with some college from someone who earned their bachelor's degree. Certainly, this is true in the labor market but may extend to preferences over treatment through its effects on social class and norms.

The regression results show substantial differences by education, even controlling for symptoms of depression. Those with a high-school diploma or less are substantially less likely to seek treatment than their better educated counterparts. Interestingly, there is little difference in use of nonspecialists and antidepressants among those with some college, bachelor's, or graduate degree. However, there is a strong gradient for specialists, with use increasing sharply with education.

Clearly education is strongly related to depression treatment, but is it a determinant in a causal sense? Educated consumers might understand better the importance of adherence with antidepressant medication schedules. Or they may have higher quality interactions with therapists providing cognitive behavioral therapy (CBT). In both cases, better educated consumers might derive greater benefits and thus more likely to continue treatment. They may also be more likely to initiate treatment if they better understand potential benefits. However, we cannot help but suspect that unmeasured preferences and social class norms drive much of the educational differences we observe. It is hard to understand why those with graduate degrees would be so much more efficient than those with bachelor's degree in the production of CBT and other talk therapies but not with antidepressant medication. More likely, the stigma surrounding seeing psychiatrists, psychologists, and other specialists is lower among those with graduate degrees.

Reverse causality is potentially a problem with our education measures. Depression may begin in adolescence leading to lower educational achievement through decreased motivation. Such bias would tend to reduce the magnitude of educational effects measured. In the opposite direction, higher education may be correlated with greater economic resources available to pay for treatment.

Geography

Indicators for each of the four Census Regions in the United States (Northeast, Midwest, South, and West) and whether the person resided in a Census Bureau defined Metropolitan Statistical Area, a measure of whether the person lives in an urban or rural area have been included. These are likely correlated with tastes for treatment. For example, stigma for mental health treatment is thought to be stronger in rural areas and in the South. They are also attractive proxies because bias from reverse causality (health causes location) is probably small. Indeed, we find that those in urban areas are more likely to use specialists, whereas those in the South are somewhat less likely. Geography may also be correlated with availability of health care services, but it is also likely that supply follows demand (more doctors in areas where people like to use services). A growing literature also suggests substantial local variations in medical provider practices. In this context, there may be variations in preferences among psychiatrists to treat patients with talk therapy instead of medicating depressed patients.

Proxy

The MEPS is a household survey with one person responding for all household members (the Adult SAQ is one exception). Although MEPS requests that this be the person most knowledgeable about health and health care in the family, there may still be issues with proxy responses. For example, a wife may not be aware that her husband sought depression treatment. To account for the potential for underestimating treatment use obtained by proxy, an indicator is included for whether the MEPS sample member is the respondent (proxy = 0) or not (proxy = 1). Consistent with this worry, the regression results show that proxy respondents are approximately 1% point less likely to use each of the three types of treatment. Of course, proxy status could be correlated with other unmeasured aspects of individuals related to treatment.

Trend

To account for the possibility that demand increased between 2004 and 2009, two time-trend variables were included. The first is linear term for survey year (minus 2004 to normalize to 0). The second term squares the first allowing for nonconstant changes in demand. In fact, there is no discernable trend in overall demand using this or any number of alternative specifications between 2004 and 2009. This would not have been true in the late 1980s and 1990s when demand grew rapidly with the introduction of new classes of antidepressants.

Excluded Determinants

A number of potential determinants do not appear in this empirical example. Employment status, occupation, and industry have been excluded because of their direct potential for reverse causality and uncertain effects on demand. Ideally, time price would be included, but direct measures of travel and time costs as well as suitable proxies are lacked.

The MEPS Adult SAQ contains four items designed to represent individual attitudes and beliefs. However, the correlation between first and second year responses was lower than expected suggesting responses may be endogenous with current health and health care use. Good arguments could be made either way for including smoking status, but it has been excluded as lacking a clear a priori hypothesis about its effects. Although clearly relevant to depression, alcohol and drug behaviors are not available. A number of available access measures believed to be endogenous have been omitted. Finally, Local area supply side and market characteristics that can be merged onto MEPS for similar reasons have been omitted.

Need Versus Demand: Illustrating with the Empirical Example

Policymakers and advocates often speak of 'unmet need' for treatment for diseases such as diabetes, heart disease, and depression. In this context, need is some norm that is being applied to groups of individuals defined by illness and then determining the extent to which they actually receive care. In the example given, if a diagnosis of depression is used as the determinant of need then it is being said that all individuals with depression should receive treatment. Those without it have unmet need. If one prefers, the definition can be made more restrictive, as many have proposed, to include additional functional impairment criteria, but regardless we are still applying some external norm. Alternatively, the actual use of individuals in one group (say high income) as a norm for other groups can be used.

As introduced earlier, economists view demand strictly through the eyes of the individual. Even in demand–supply graphs, market demand curves are simply the sum of individual demands. The authors talk about 'need' variables being included in demand models, but individuals take this more into account than just their health in determining whether and how much care to consume. An individual with depression may or may not perceive that they need treatment at all. Some depressed individuals may not seek treatment even if their out-of-pocket price is zero. For others, whether they seek treatment may depend critically on price.

Survey data such as MEPS gives us the opportunity to study measures of 'need' as distinct from demand and use. If we look at the descriptive statistics on Table 2, we see that only 40% of people with a current PHQ-2 score of 3 or greater (suggesting probable depression and the need for further screening) receive treatment. If we use this cut-point as our norm for treatment need, it suggests that more than half of currently depressed individuals do not receive treatment and therefore have unmet need. Conversely, 12% of those not meeting our hypothetical norm for need consume treatment. The empirical model can be used to simulate the effect that changing a key determinant has on changing the relationship between our norm for need and actual demand. Health insurance coverage, because it is so amenable to policy changes, is the obvious choice. Here, the model implies that providing public coverage to all of the uninsured would reduce the gap between need and demand in the uninsured from 78% to 65% and among all adults aged 18–64 years from 60% to 57%.

Conclusion

Specifying and interpreting the empirical determinants of health care demand is as much art as science. As seen from the author's review of recent empirical studies, there is not only widespread agreement about some determinants such as age, sex, health status, and education but also wide variation in the treatment of other characteristics that might be correlated with health care use. Researchers are confronted with tough trade-offs among competing concerns in selecting and specifying determinants they think relevant in demand models. Formal models of health care demand can help guide us about the treatment of variables such as health status, income, and price. Theory also guides us in the choice of proxies and, also using statistical principles, how to best specify these proxies to represent unmeasured aspects of health and treatment seeking preferences. As seen from the empirical illustration, proxies such as education are often powerful predictors of demand. These same economic and statistical principles also aid us in interpreting our empirical determinants. But in a world where unobserved preferences and health play such a key role, we will always face some uncertainty about how to model the empirical determinants of health care demand.

Health Econometrics: Overview

A Basu, University of Washington, Seattle, WA, USA
J Mullahy, University of Wisconsin-Madison, Madison, USA

Empirical analysis of data describing relationships involving health – health econometrics – arises in a wide variety of important scholarly and policy contexts. The econometric analysis of data on topics as diverse as health insurance, substance use, provider behavior, chronic disease, evaluation, market structures, regulation, medical technologies, labor supply, and others is encountered routinely in every issue of leading field journals like the *Journal of Health Economics*, *Health Economics*, and others.

Reflecting the increased prominence of both conceptual and applied health econometrics research is an increasing array of professional activities devoted specifically to health econometrics. For over 20 years, researchers at the University of York and local sites all across the European Union have organized annual meetings on health economics and health econometrics. More recently, specialized health econometrics conferences and workshops have regularly been organized in the US, Italy, and elsewhere. Beyond these, sessions and pre-conference courses dedicated to health econometrics have been among the most popular and well-attended activities at meetings of major health economics organizations like the International Association of Health Economics, the American Society of Health Economists, and others.

The methods of health econometrics are deployed to address a wide variety of questions. At their essence, many are concerned with the estimation of treatment effects, broadly construed. These can arise in narrow small-N contexts like the evaluation of clinical interventions as well as in broad population or large-N contexts like the implementation of tax, regulatory, or other public policy interventions. Recent emphases on 'comparative effectiveness' and the empirical methods used to understand the relative value of interventions have underscored the importance of linking relevant decision-making contexts to reliable and robust analytical methods that can be deployed to inform such decisions.

How to deliver informative estimates of treatment effects in the light of observational data often utilized in the service of such questions is one of the central problems of applied health econometrics. Such observational data are now drawn from an increasingly wide set of sources: Population and community surveys, administrative data describing program participation, electronic medical records, and others. Regardless of the particular data, there is widespread recognition that many of the treatments at issue are endogenous with respect to the outcomes of interest (i.e., are correlated with unobserved determinants of such outcomes, known as 'confounding' in the epidemiological literature). To circumvent the problems that arise with endogenous treatments, quasi-experimental methods are often utilized. Instrumental variable methods, longitudinal or panel data analyses, and others are deployed with assumptions sufficient to generate consistent estimates of parameters of interest (whether the assumptions are reasonable and/or holds in the context of the particular study are separate but important questions). One such assumption is the correct specification of a model for the data at hand. Economic theory, or any other theory for that matter, often has a hard time predicting directions of covariate effects. It does not provide much guidance as to the appropriate functional form for the data at hand. Therefore, a good deal of health econometrics literature has focussed on ascertaining appropriate models using various goodness of fit measures. A good discussion of these issues can be found in the chapter by Manning on modeling healthcare expenditures that are known for their idiosyncracies. Appropriate specification of a model is then followed by identification of the parameter of interest, often a treatment effect parameter. Geographic variation in constraint sets has been one prominent identification strategy (Rosenzweig and Schultz, 1983), and indeed was – to our knowledge – the approach that introduced instrumental variable analysis to clinical and related audiences (McClellan *et al.*, 1994, in the context of differential distance instruments). More recently, approaches like propensity score or control function methods have become popular in health services research even though the extent to which such methods fail to circumvent problems arising from confounding is often underappreciated.

In this context it is often useful to bear in mind that the 'gold standard' of the randomized clinical trial against which observational data analysis is frequently held is itself an emperor that often wears little clothing. Within-trial behaviors like attrition, non-adherence, etc. (Efron and Feldman, 1991; Lamiraud and Geoffard, 2007) will typically jeopardize both the internal and external validity of results and inferences based on such data. Floras are typically compliant with treatment protocols, but human fauna will often fail to be. Whereas randomized trial provides a solid conceptual foundation for thinking about an ideal data-generating experiment (Permutt and Hebel, 1989, for a specific example executed in an instrumental variable context), its actual implementation often falls short of the ideal. When contemplating the analysis of health (or any other) data, it can generally be more helpful to appreciate that such data are themselves often generated by purposive decisions of data suppliers and demanders (Philipson, 1997).

In many instances, the particular nature of the data to be analyzed by health econometricians sets health econometrics apart from other domains of applied econometrics. Many of the measurement and sampling approaches used to describe health-related phenomena as well as the consumer, producer, and market decisions and processes from which such data arise are more or less unique to health economics. Econometric methods used to analyze such outcomes data – censored, bounded, discrete, ordered, etc. – have often been developed by analysts working primarily in health economics (Newhouse, 1987). Even so, health econometricians have sometimes failed to be sufficiently sensitive to the fundamental measurement features of the data they analyze, e.g.,

estimating moments of ordinal scale outcomes like self-reported health status obtained using Likert scale or analogous strategies (Stevens, 1946).

Regardless of the particular questions at hand, the ability to move from conceptualizing such analysis to implementing it has required both individual-level (or micro-) data describing the choices and outcomes of health producing consumers and suppliers observed over space, over time, or both, as well as a rapid evolution of analytical and data management that has permitted such data to be analyzed using state of the art methodologies (e.g., Stata, Limdep, R, and others; Renfro, 2004 for a general discussion). Given the sensitive nature of many topics with which health economists deal at the household, institution, market, and population levels, ideal data may sometimes not be available for analysis owing to a variety of privacy protection protocols that have legal standing in most countries. Nonetheless, the progress that has been made in advancing empirical understanding of such phenomena is remarkable.

Interested readers may find as a useful starting point Andrew Jones's (2000) seminal and comprehensive overview of health econometrics topics. The articles in this section complement in some respects Jones's overview and, in the light of the ongoing rapid pace of conceptual and methodological developments in the field, bring some of the topics he addressed over 10 years ago into newer light.

While the articles in this section cover a broad swath of topics in health econometrics, it could also be pointed out for context several topics that are not accorded article-length treatment in this Encyclopedia although, in some instances, they are treated in part in various articles. Among such topics of interest to health economists include specific treatment of outcome measurement, econometric analysis of experiments, prediction and forecasting, and multivariate outcomes. Also to be noted with considerable sadness is that a article on the econometric analysis of clinical trial data was planned by Prof. Tom Ten Have and was in early stages of preparation when he died of multiple myeloma at a rather young age in 2011.

Health Insurance and Health

A Dor and E Umapathi, George Washington University, Washington, DC, USA

Introduction

Most developed countries provide universal or near-universal health insurance coverage. The US has lagged behind with 49.9 million individuals, or 16.3% of the population, reportedly uninsured as recently as 2010. Policy debates in the US, where proponents of universal coverage have argued that extending coverage to the uninsured would result in better access to health care, improved health outcomes, and ultimately lower costs, have culminated in the enactment of the Patient Protection and Affordable Care Act and the Health Care and Education Reconciliation Act (collectively referred to as the ACA) in 2010. In tandem with the policy debate, health economists have explored the impact of health insurance on health outcomes using empirical methods. Nevertheless, the evidence so far remains inconclusive. Both those favoring universal coverage and those arguing for limited steps were able to find some support for their respective positions, albeit on a selective basis. Although supporters of the legislation claim that the phased implementation of the ACA will dramatically reduce the ranks of the uninsured, millions of Americans are expected to remain without any coverage. Gaining a better understanding of what the health economics literature offers to this policy discussion thus remains highly relevant.

Economic theory suggests that health insurance can serve a dual purpose of protecting people against the financial burden of illness and of increasing access to care to meet unmet health care needs. Conventional expected utility theory, which is widely applied to evaluate the demand of health insurance, considers any medical expenditure to be a loss of income. In view of this theory, the purchase of health insurance or medical care reduces a consumer's wealth. For the research question at hand that investigates whether health insurance improves health, medical expenditures may instead be considered an input in the health production function (Grossman model). Accordingly, the stock of health can be improved by investments in medical care which the purchase of insurance enables. Most of the relevant literature assumes such a model, at least implicitly. At the same time, the benefits of health insurance coverage may be partially offset by the effects of ex-ante moral hazard (Moral Hazard is the change in behavior that occurs as a result of becoming insured. Ex-ante moral refers to the change in the probability of illness or injury. Ex-post moral hazard refers to the size of the loss (medical expenditures) after the illness/injury occurred.). Accordingly, people with health insurance coverage may have less financial incentives to engage in healthy behaviors that prevent injury and illness.

A body of existing research supports a negative association between the lack of health insurance and access to care, and in turn, a positive association between access to care and health outcomes. Descriptive studies report that in the US the uninsured have less access to health care, higher risks of unmet health needs, and poorer health outcomes. For example, research has shown that uninsured adults use 60% less ambulatory health services and 30% less inpatient health services than insured adults. In addition, the uninsured are more likely to delay seeking care, to report not being able to see a physician due to costs, and to require costly emergency care. Even among patients that did see a clinician, only 18% of uninsured patients received all recommended follow-up treatment in comparison to 30% of insured patients. In comparison to insured adults, the uninsured are also more likely to have a lower self-reported health status and are more likely to be diagnosed at an advanced stage of cancer, suffer from cardiovascular diseases, exhibit worse glycemic control, and experience higher in-hospital mortality rates.

Although the positive association between health insurance coverage and health outcomes appears to be convincing, the issue has been a matter of considerable controversy among empirical economists. Mere associations may mask the fact that healthier individuals tend to be better equipped to obtain health insurance, leading one to overstate the actual contribution of insurance to health, a problem related to reverse causality and simultaneity in econometric estimation. To address this general concern different methodological approaches have been undertaken, perhaps contributing to occasionally conflicting results. In addition, this literature encounters measurement issues which merit further scrutiny.

In this article, the aim is to shed light on the nuances in the literature on the causal effect of health insurance on health outcomes. The objective here is to clarify the limitations of this literature and to provide a deeper understanding of the causal pathways between insurance and health, ultimately to better inform the policy debate. As will be seen, certain patterns have emerged: Lack of insurance may be more of an adverse factor for mortality and generic health outcomes although its effects on condition-specific measures are more complex. In addition, interruptions in insurance coverage can be just as harmful as the complete lack of insurance. This review focuses primarily on the US, and its private segment of the market, where the acquisition of insurance has largely been a matter of individual choice, at least before the implementation of ACA. However, inferences are also drawn from the literature on government sponsored insurance, namely, Medicare and Medicaid, where insurance coverage is simply assigned to individuals based on age and income, and the state in which the individual resides.

The remainder of this article is divided into five sections. First, there is a brief description of the characteristics of the US uninsured population and the anticipated changes for health insurance coverage under the ACA. Second, the methodological challenges related to estimating the impact of insurance on health are discussed. Third, the methods used in the source literature are illustrated. Fourth, general findings in the source literature are presented. Finally, challenges for future research are discussed and emerging implications of the ACA comes in as conclusion.

The Uninsured and the US Health Care System

In the US, historically, the elderly and the disabled have received public insurance coverage through Medicare, whereas the poor received public insurance through Medicaid. Otherwise, health insurance coverage has effectively been tied to employment with 90% of all privately insured individuals receiving their coverage through their employers. Roughly 50% of employees participate in employer-sponsored health insurance coverage and consequently a large portion of employees, especially temporary and part-time employees, lack insurance. Not surprisingly, the contraction in the labor market that accompanied the Great Recession in the early twenty-first century also contributed to the rising number of the uninsured. Between 2008 and 2010, nearly one-quarter of working-age adults reported that they or their spouse had lost their job and more than 50% of these people became uninsured. Historically, a significant portion of the uninsured population consisted of relatively vulnerable groups such as the near poor and near elderly. Individuals belonging to these groups are more likely to experience unemployment compared with higher income or young people, and are also more likely to suffer from adverse health events. Yet, income and age restrictions precluded these individuals from enrolling in public insurance programs such as Medicaid or Medicare, leaving them at a higher risk of remaining uninsured.

The ACA is expected to greatly reduce the number of uninsured. Under the ACA, most US citizens and legal residents will be required to have health insurance, a number of states will expand Medicaid to include the nonelderly population at 133% of the federal poverty line, and states are engaging in setting up health insurance 'exchanges' offering plan choices to previously underserved individuals. In addition, federal subsidies will be made available to small firms and individuals for the purchase of insurance. Nevertheless, the ACA will only reduce the number of uninsured by half. The Congressional Budget Office estimated that by 2019, 23 million Americans will remain uninsured even if the ACA is fully and successfully implemented. The small penalties levied against those opting out of the system, the so-called 'mandates,' may not be sufficient to outweigh the incentives not to join. Moreover, certain population groups are exempted.

Methodological Challenges

In this section, methodological challenges facing research estimating the causal effect of insurance on health are discussed, starting with identifying the uninsured, defining health outcomes, and addressing endogeneity bias.

Identifying the Insured and Uninsured

Identifying the uninsured is a difficult task. In most household surveys, individuals tend to misclassify themselves as being insured or uninsured due to the way health coverage is defined. Misclassification occurs mainly around changes in employment status, due to confusion about receiving coverage through another family member, or simply because of poor recall when survey questions require longer retrospective periods. Another type of misclassification occurs when Medicaid enrollees or beneficiaries of other public programs do not recognize these programs to be a form of health insurance, leading some to erroneously identify themselves as uninsured. Indeed, comparisons of survey data with administrative data have demonstrated that surveys consistently underestimate insurance coverage. Underreporting of insurance coverage has been proven to be a particular problem for Medicaid with specific evidence of underreporting available for all Medicaid beneficiaries in California and Maryland, and nationwide for child beneficiaries. As a result, the estimated prevalence of uninsurance varies somewhat between surveys. For instance, a comparison of the Health Retirement Survey (HRS) and the Medical Expenditure Panel Survey (MEPS) in 2006 yielded an uninsurance rate of 10% and 12%, respectively.

Another form of measurement error occurs when continuity of coverage is of interest. The majority of studies reviewed used insurance coverage at the time of interview as the key explanatory variable. However, in the US, particularly in the private sector, people frequently gain and lose health insurance coverage, a phenomenon also known as churning. Between 1998 and 2002, churning affected 22% of the population. Much like the complete absence of insurance, churning may adversely affect health due to discontinuity of care and delays in treatment. Among children and adults, loss of insurance is associated with a lower likelihood of having a primary care provider, getting check-ups, or receiving the recommended follow-up care. Intermittent health insurance coverage may thus affect health outcomes in a similar fashion as the lack of health insurance coverage. A number of nationally representative surveys including the HRS, the MEPS, and the National Health and Nutrition Examination Survey (NHANES) ask respondents to report their health insurance status retrospectively for a 3–18-month period. Several studies made use of this feature to define insurance in terms of frequency of changes or to draw comparisons between the continuously insured, the intermittently insured, and those lacking insurance coverage over a fixed period.

Although this article focuses only on the provision of insurance, note that health insurance is heterogeneous and variations in generosity of health insurance benefits can occur not only between general insurance categories such as Medicaid, Medicare, and private, but also within such groupings. The lack of information about insurance generosity in household surveys creates a major practical limitation for related research. The literature reviewed here is generally silent on this issue.

Measuring Health Outcomes

The source literature assessed the impact of health insurance on three broad categories of health outcomes: mortality, condition-specific morbidity, and generic health measures. The majority of studies relied on mortality-based measures, such as all-cause mortality, disease-specific mortality, or survival rates. Condition-specific morbidity measures pertain to the clinical status of a given illness or medical condition.

Examples from the literature include low birth weight, obesity, and cancer disease stage.

The term 'generic health measures' is used to describe aspects of functioning in health related daily activities which are not necessarily disease specific. Generic health measures can be either unidimensional or multidimensional. Unidimensional measures include self-reported health indicators, such as one's overall ranking or the number of chronic conditions. Multidimensional measures combine several subjective indicators of physical and mental health into a single additive scale.

Expert research in the psychosocial literature has validated the use of self-reported health rankings. In addition, the health services research literature offers well developed and validated methodologies to construct multidimensional health indices, such as the Short Form-36 (SF-36). Data elements that comprise these indices are now routinely included in nationally representative surveys such as the National Health Interview Survey and the HRS. For example, Dor *et al.* (2006) and McWilliams *et al.* (2007) combined self-reported general health, the number of physical limitations, and pain into a modified SF-36 health index. **Table 1** provides

Table 1 Overview of source studies by payer category

Author (year)	*Method*	*Insurance*	*Health outcome*	*Results*
Bhattacharya *et al.* (2003)	IV model uses state Medicaid eligibility and employer-sponsored insurance	Uninsured, private insurance, and public insurance	Mortality	Insurance reduced risks of dying, private insurance more than public insurance
Bhattacharya *et al.* (2011)	IV model uses state percentage of workers working in medium and large size firms and Medicaid eligibility	Uninsured versus insured	Obesity	Provision of public and private insurance to the uninsured increases body weight, with slightly larger effects for public insurance
Courtemanche and Zapata (2012)	DD compares Massachusetts to other states before and after health reform in Massachusetts	Massachusetts reform	Self-reported, physical and mental health, functional limitations, joint disorders, BMI and physical activity	The Massachusetts health reform improved all health outcomes
Dor *et al.* (2006)	IV model uses state marginal tax rates, average unemployment rate, and average rate of unionization	Uninsured versus privately insured	SF-36 type health index	Insurance improved health status by 10–11%. Separate regressions for people with asymptomatic conditions, chronic conditions, or nonchronic conditions found no substantial differences in health.
Hadley and Waidmann (2006)	IV model uses spousal union membership, immigrant status, and involuntary job loss in the past 5 years	Continuity of insurance coverage	Health index and mortality	Continuous coverage from age 55 onward reduces mortality and increases health
Kaestner (1999)	IV model uses state dummies, interaction between state dummies and high income, and mother's employment status	Uninsured, Medicaid, and privately insured	Low birth weight	Insurance coverage did not improve birth weight
Pauly (2005)	IV model uses firm size and/or marital status	Uninsured versus privately insured	Self-reported health and number of chronic conditions	Insurance status does not affect health outcomes
Thornton and Rice (2008)	IV model uses state percentage of firms with more than 20 employees and the percentage of union workers with state FE	Extending private insurance to the uninsured	Mortality	Insurance reduced mortality.
Weathers and Stegman (2012)	IV model uses randomized assignment to health insurance	Uninsured versus privately insured	Self-reported, physical, and mental health, depression, disability and mortality	Private insurance improved self-reported, mental and physical health 1 year following health insurance enrollment, but did not reduce mortality within 2–3 years of enrollment.

a brief description of the literature used in this article. Although this article focuses primarily on private insurance a summary of the evidence on the causal effect of Medicaid and Medicare is available in Table 1.

Although each of the above health outcome categories offers certain advantages, they are also affected by certain measurement issues and interpretation problems. An obvious advantage of using mortality as a summary measure of adverse outcomes is that death is completely unambiguous, and it is easily verifiable in most data systems. Thus, mortality is susceptible to minimal measurement error. However, although mortality reflects the lowest boundary of health, it does not capture the path of declining health over the individual's life cycle. In contrast, condition-specific measures may capture the stage and severity of illness, but targeting a narrowly defined condition may lead researchers to overlook other important dimensions of health. Moreover, most surveys rely on self-reporting of morbidity indicators, and thus require respondents to possess specific and time sensitive knowledge of their own disease.

Generic health measures provide a broader view of health that transcends any single condition. Because general health measures are based on a person's functioning, they can be used for more general population groupings than the above. Another advantage is that most household surveys provide validation of respondents' replies to questionnaires. However, by trading off specificity generic measures may mask insurance 'treatment' effects that might apply to certain conditions but not others. Further adding to measurement error, interpretations of good functioning may vary by respondents' age, gender, and other groupings. However, the health services literature suggests that combining several unrelated aspects of health helps mitigate reporting error in multidimensional indices. Finally, generic health measures may reflect health status changes, with a time-lag, rather than responding instantaneously.

In summary, both insurance coverage and health status indicators, excluding mortality, are subject to measurement error. In regression analysis measurement error in the dependent variable (health status) increases standard errors but does not produce a biased estimator. However, measurement error in the explanatory variable (insurance) biases the coefficient estimates, although the direction of the bias is predictable (toward zero) as long as measurement error does not appear in any other independent variables in the model.

Endogeneity of Insurance in Health

Selection, reverse causality, and omitted variable bias pose other methodological challenges. Each one of these issues presents a special case of endogeneity, whereby ordinary least square estimates of the effect of insurance on health may be biased due to a correlation between a regressor and the regression residual. A myriad of institutional and behavioral processes underlie endogeneity, making it difficult to ascertain whether the bias occurs in an upward or downward direction.

The private insurance market is affected by selection problems, which arise when there is information asymmetry between insurers and insured. Adverse selection occurs when insurance companies attract sick people who are more likely to need and use health care, and when healthy people, who do not anticipate incurring high medical expenses, choose cheaper but less generous plans or opt out of insurance altogether. Adverse selection would bias the estimated relationship between insurance and health downwards. Auspicious selection occurs when insurers try to attract the good risks (e.g., healthy or young individuals), while making plans unattractive for bad risks (e.g., those with preexisting conditions). Auspicious selection would bias the estimated relationship upwards. Both adverse and auspicious selection, and related estimation biases, will be even worse when insurance risks are experienced rated (as in the individual insurance markets) rather than community rated (group insurance).

Reverse causality occurs when health affects health insurance status. The direction of this bias is also unknown. People in poor health are more likely to buy health insurance (or purchase more generous coverage) than healthy people, as they anticipate a greater need for care. Conversely, in the mostly employer-based private segment of the US market, poor health tends to be associated with job loss and hence loss of insurance, particularly in periods of high unemployment.

Finally, a type of omitted variable bias occurs when the individual's insurance choice is determined by some traits that also affect health but are unobservable to the researcher. For example, risk-averse individuals are more likely to hedge the risk of income loss by purchasing insurance, although simultaneously displaying risk-avoiding health behaviors. Similarly, certain people are better equipped to asses both insurance and health care information and act preventively, an unobservable trait sometimes referred to as health ability. Reliable measures of risk aversion, health ability, and underlying health behavior are rarely available in observational datasets. Consequently, in classic regression analysis included explanatory variables may be correlated with the error term.

Estimation Methods

Three different approaches to measuring the causal effect of insurance on health as they appear in the literature is discussed: Studies using instrumental variable (IV) techniques, studies using quasi-experimental designs, and randomized experiments. (Quasi-experiments encompass both the natural experiments and IV studies that are discussed. For the purpose of this article, natural experiments and IV approaches are discussed separately because natural experiments rely on exogenous source of variation in the treatment assignment, whereas the IV approach uses a continuous probability distribution of the treatment assignment.) In the context of private markets, most studies used IV approaches to address the endogeneity issue previously discussed, allowing for probability distributions of the insurance choices made by individuals. In the context of government programs where insurance coverage is simply assigned to individuals based on an arbitrary (exogenous) criterion, quasi-experimental techniques are more relevant. Although the primary interest is in the private segment of the market, some attention is devoted to quasi-experimental evaluations of Medicare and Medicaid in order to draw inferences for future research directions given

the recent enactment of private mandates in the US. Finally, the very limited but important literature on controlled experiments that allow for random assignment of individuals into insured and uninsured states is discussed.

Instrumental Variable Estimation

The issue of endogeneity can be addressed by simultaneous estimation of insurance choice and a health outcome using IVs. Briefly, IVs would be included in the insurance equation but excluded from the health equation based on the following criteria: First, the instrument must be uncorrelated with the error in the health equation. As this is not easily verified, researchers' choice of IVs must rely on economic theory and solid reasoning when choosing appropriate instruments. Second, the instrument must be strongly correlated with insurance choice (the latter can easily be tested).

A variety of instruments have been used, but their validity has been repeatedly called into question. Examples include state-level variables, firm-level variables, certain individual-level variables, or some combination of all of the above (source studies and their instruments are described in **Table 1**). A number of studies employed indirect tests that provide a modicum of confidence. For instance, arguing that state-level Medicaid eligibility and average firm size are independent of health (mortality) but affect the ease with which people obtain Medicaid or employer-sponsored insurance, Bhattacharya *et al.* (2003) examine their strength and relevance as instruments when estimating the effects of public and private insurance on health among human immunodeficiency virus (HIV) patients, using data from the HIV Costs and Services Utilization Study. The authors report a strong correlation between their instruments and insurance coverage based on statistical tests (e.g., the Wald statistic), and a high degree of relevance, based on a reasonable falsification test. (The instruments would be irrelevant if they were to predict health outcomes for an unrelated population. Using a sample of Medicare beneficiaries as an alternative to the original sample of HIV patients, Bhattacharya *et al*. show this is not the case, suggesting that their instruments are valid.)

In a related example, Dor *et al.* (2006) used state marginal tax rates, average unemployment rate, and average unionization rates to instrument insurance. The study population included adults age 45–64 from the 1992 to 1996 HRS surveys. Substantial literature suggests that state-level tax burden is uncorrelated with health but to be positively correlated with insurance participation. Similarly, union membership is positively correlated with being offered insurance coverage, whereas unemployment is negatively correlated with private health insurance coverage. However, the use of marginal tax rates in the first stage results were only weakly correlated with health insurance. Some critics raised questions about the validity of unemployment as an instrument, arguing that macroeconomic downturns may affect health not only through insurance loss but also because they affect health behaviors such as drinking and exercise. It should be noted, however, that previous versions of the study used county-level firm sizes as an instrument, yielding essentially the same results for the effect of insurance on health (Dor *et al.*, 2003).

Various combinations of person-level variables have also been used to instrument insurance. Among these are employer size, marital status, spousal union membership, immigrant status, involuntary job loss, and self-employment status (**Table 1**). Again, the validity of any of these variables can be questioned, given that is unlikely that they do not affect health in some indirect way. For instance, for some people job loss may lead to depression or loss of physical activity, leading to deterioration in overall health; foreign-born workers from poor countries may have worse health status than native-born US workers, suggesting that immigration status is and negatively correlated with health. Spousal union membership may be the most appealing variable in terms of avoiding systematic correlation between the instrument and the subject's health. However, any study to date that has attempted to test the validity of this instrument by itself is unheard of.

Quasi-Experiments

Quasi-experimental methods including difference-in-difference (DD) models and Regression Discontinuity Design (RDD) models have been used to get around the difficulties of modeling endogeneity and selecting appropriate IVs. These models, which borrow from the more general program evaluation literature, rely on finding cases where insurance can be treated as an exogenous intervention. In DD models, a treatment group and a comparison group are identified and the impact of the treatment is inferred from the difference between the changes experienced by the two groups over time; DD models have been widely used to evaluate Medicaid expansions and outcomes in US states, whereas RDD models are more readily applied to evaluations of Medicare (**Table 1**). In an innovative study, Polsky *et al.* (2009) employ DD to Medicare by comparing health status for the previously uninsured and continuously insured before and after enrollment at age 65.

RDD models exploit exogenous policy rules, yielding a comparison of individuals above and below a fixed cutoff point. A critical assumption for RDD models is that by tracking individuals closely around the cut off trends unrelated to the policy are essentially filtered out. RDD models are commonly used to evaluate Medicare because of its generally arbitrary eligibility criterion which assigns individuals to the program at age 65. For example, using the 1991–2002 Behavioral Risk Factor Surveillance System, Decker (2005) estimated the effect of Medicare eligibility on breast cancer stage and survival. To ensure that other age-related changes such as retirement were not erroneously captured in her eligibility indicator, Decker also controlled for employment status; although this additional variable was statistically significant in her model, it did not alter the estimated Medicare effect. In a variant of RDD, McWilliams *et al.* (2007) used a linear spline regression to compare health outcomes for people before and after acquiring Medicare.

Randomized Controlled Experiments

Given the difficulty posed by endogeneity and concerns over nonsymmetry between treated and controls in quasi-experimental studies, ideally, the impact of insurance on

health would be inferred from randomized controlled trials (RCT) whereby people are randomly assigned to separate categories of those receiving health care coverage and those without any insurance. However, RCTs are virtually impossible to implement due to both practical and ethical reasons. Nevertheless, two recent policy experiments offer close approximations; the first was carried out by the US Social Security Administration (SSA), and the second was implemented by the state of Oregon.

Focusing on Social Security Disability Insurance (SSDI) beneficiaries, the SSA experiment was designed to test whether making medical benefits available to these beneficiaries immediately, rather than requiring a mandatory 2 year waiting period improves health outcomes. Accordingly, between October 2007 and November 2008, a subset of newly enrolled SSDI beneficiaries was asked to participate in the Accelerated Benefits (AB) demonstration. Those that agreed to participate were randomly assigned to groups receiving a relatively generous health insurance plan versus remaining uninsured for 2 more years. The AB demonstration thus provided a unique opportunity to test whether having insurance improves short-term health outcomes (Weathers and Stegman, 2012).

In 2008, Oregon had enough funding to expand enrollment to 10 000 low-income adults. Later dubbed the Oregon health insurance experiment (Oregon HIE), beneficiaries were randomly chosen by lottery from the pool of eligible candidates, thereby creating two groups of covered and noncovered individuals. The origins of the Oregon HIE can be traced to the RAND Corporation Health Insurance Experiment of the late 1970s. However, the RAND Corporation study focused on cost sharing levels with insurance rather than outright withdrawal of insurance.

Analysis of the first year's results offers valuable insights, but also highlights limitations of RCTs and their approximations (Finkelstein *et al.* 2011). At the end of the year, insurance coverage appeared to improve participants' self-reported physical and mental health in comparison to the uninsured control group. However, when the timing of these improvements was examined more carefully, the researchers found that they occurred before the actual initiation of health care. This may suggest a type of placebo effect whereby the mere availability of health insurance provides the individuals with a sense of well-being and a heightened perception of health status.

Results: Health Insurance Effects by Type of Health Measure and Study Population

Having noted methods, studies can be further classified by type of health outcome measure and type of population studied. Results are summarized accordingly:

Health Outcomes

Overall, the large majority of studies agree that health insurance coverage reduces the risk of mortality. For example, using state-level panel data from 1990 to 2000 and firm size and union membership to instrument insurance, Thornton and Rice (2008) concluded that extending private insurance to the uninsured would reduce adult mortality and save more than 75 000 lives annually. Similarly, using union membership, immigrant status, and involuntary job loss as instruments for insurance, Hadley and Waidmann (2006) concluded that extending insurance coverage to all Americans between the ages of 55 and 64 would reduce mortality in this age group. Furthermore, Bhattacharya *et al.* (2003), using the 1996–1998 HIV Cost and Services Utilization Study, concluded that HIV patients with private health insurance coverage had a 79% lower relative risk of dying than HIV patients without insurance. And, HIV patients with public health insurance had a 66% lower relative risk of mortality than HIV patients without insurance. Weathers and Stegman (2012) is the only study to find no effect of insurance coverage on mortality; their brief follow-up of 3 years did not allow for identification of longer term effects in their experimental data.

Similarly, a majority of studies found positive effects of health insurance on generic health measures. Weathers II and Stegman found that insurance improved self-reported mental and physical health of SSDI beneficiaries one year after receiving health insurance. Using the 1992–1996 HRS, both Dor *et al.* (2006) and Hadley and Waidmann (2006) found that insurance improved health as proxied by SF-36 type health indices. Similarly, Courtemanche and Zapata (2012) concluded that the Massachusetts health care reform legislation improved a number of health outcomes, including self-reported general health, physical limitations, and a health index. An exception can be found; Pauly (2005) found no significant effect on self-reported general health or the number of adult chronic conditions using the 1996 MEPS.

In contrast, insurance effects vary across condition-specific measures. Private insurance did not reduce the share of infants with low birth weights (Kaestner, 1999) and coverage did not benefit people with chronic conditions more than people without (Dor *et al.*, 2006) while initiation of Medicare coverage improved outcomes for women with breast cancer. In one interesting case, private insurance coverage actually increased obesity prevalence (Bhattacharya *et al.* 2011). One way to reconcile seemingly contradictory results would be to assume that ex-ante moral hazard (in this case more eating, less physical activity and the like) affects some conditions more than others and that the adoption of risky behaviors offsets the health benefits of insurance unequally. The association between health insurance and health behaviors was not explicitly treated in the literature surveyed in this article. Although informative, these findings may not necessarily generalize to other settings given that the efficacy of medical treatment, which insurance enables, is not the same for all medical conditions and diagnoses.

Reconciling Competing Health Measures

Using the setting of transitions into Medicare, an important discussion on the relationship between mortality and generic health measures took place through two interrelated studies (McWilliams *et al.*, 2007; Polsky *et al.*, 2009). In much of the previous literature summarized in **Table 1**, condition-specific outcomes, and generic health measures were treated as mutually exclusive outcomes. A point of agreement in both of these studies is the need to account for censoring due to mortality even when other health outcomes are of interest,

particularly when longitudinal data are employed. Indeed, the two studies using essentially the same database report that attrition due to mortality was responsible for a 15% reduction in sample size during a 13-year period for a population of people around Medicare eligibility. However, although Polsky *et al*. and McWilliams *et al*. agreed on the problem, they disagreed on the methods needed to address it, leading them to engage in a lively debate in subsequent articles.

Although both studies used similar quasi-experimental designs (DD and RDD, respectively, see Section Estimation Methods) and share some findings, their results differ for some outcome measures; the differences have been attributed to the way the authors deal with mortality-related censoring. Both studies compared previously uninsured to insured before and after entering Medicare, and both studies drew the same years and health outcomes from longitudinal HRS data (**Table 1**). Both studies found no significant effect on self-reported health status, mobility, and pain, but differed in their findings for agility and symptoms of depression. In addition, the effect of health insurance was significant for an index of health outcomes only in the McWilliams study. To attenuate sample attrition, McWilliams *et al*. used an inverse probability weighting technique to assign higher weights to individuals who had died on the basis of antecedent health trends, insurance coverage before age 65, and demographic and socioeconomic characteristics. However, this approach may not be accurate given that death is not a random event. To address the nonrandomness issue Polsky *et al*. used a novel approach simulating the predicted probability of health state transitions, with death as one of the included health states. Interestingly, when Polsky *et al*. incorporated inverse probability weighting into their original DD design they found similar results as McWilliams *et al*. This suggests that disparate results were caused by the different ways of accounting for mortality, rather than choice of general technique. The discussion underscores the need for researchers to continue to design innovative and more complete measures of health outcomes.

Vulnerable and Special Populations

The health effects of insurance vary for populations stratified by medical conditions or vulnerability, with vulnerable people benefiting more from health insurance than others. For example, although the RAND Corporation experiment did not find an effect of insurance generosity on the health status of the average adult, insurance generosity did have a positive effect on health for individuals with high blood pressure (Keeler *et al*., 1985). Similarly, private insurance positively affected the health of HIV patients (Bhattacharya *et al*., 2003), Medicaid health benefits were larger when provided at early childhood than at later childhood (Currie *et al*., 2008), and adult patients nearing the Medicare enrollment age with cardiovascular disease or diabetes benefited more from insurance coverage compared with their counterparts with any health condition (McWilliams *et al*., 2007). More generally, Weathers and Stegman (2012) attributed the larger effect of health insurance in the AB demonstration as compared with the Oregon lottery to the relatively poorer health and disability status of persons in the former cases. Further research is needed to identify which patient populations would benefit most from insurance coverage.

Continuity of Coverage: Effect of Churning

A few studies sought to go beyond the simple insured/uninsured dichotomy and evaluated the effects of discontinuities in insurance coverage over time (churning). These begin with a comparative, but mostly descriptive study, (Baker *et al*. 2001), followed by a more rigorous study by Hadley and Waidmann (2006); both studies found that adults who were continuously insured had better health outcomes, as measured by summary health scores, compared to those with intermittent private insurance. Hadley and Waidmann (2006) followed preretirement age adults up to eight years before reaching the Medicare eligibility age of 65, and analyzed the impact of health insurance on health status at that point. Insurance coverage was defined as percentage of time a person has insurance over the observation period before age 65. Although this created certain lumpiness in their insurance measure (the Health and Retirement Study, from which they draw their data, is a biannual survey thus requiring the assumption that people remain in the same insurance category in between survey years) it allowed the authors to estimate effects of continuous insurance versus intermittent insurance. They used similar IVs as those described in Section Estimation Methods to purge their insurance variables from endogeneity bias. McWilliams *et al*. (2007) also report that continuous insurance coverage appears preferable to intermittent coverage for a host of health outcomes. Despite progress made in modeling the dynamic impacts of insurance on health, there appears to be a need for additional research on the intertemporal effects of insurance.

Conclusion

This article highlights the myriad of methods used to estimate the impact of health insurance on health and their limitations. Despite the wide variation in research designs and methods applied, and in particular, the difficulty of identifying valid instruments, a number of common themes can be found. First, it appears that insurance coverage impacts mortality and generic health outcomes more significantly than most condition-specific outcomes, at least in the studies reviewed. Second, certain vulnerable populations such as infants, the disabled, and HIV/acquired immune deficiency syndrome patients appear to benefit from insurance more than the general population. Third, despite the availability of a yet small and largely descriptive body of research on the intertemporal dynamics of insurance, there is compelling evidence to suggest that continuity of health insurance coverage is particularly effective in maintaining health, and that having sporadic coverage offers little protection over little protection over having no coverage at all.

Relevance for Health Reform

With the advent of health care reform, the US appears to be moving closer to universal coverage, albeit not fully. The full

effect of reforms, in terms of reducing the ranks of the uninsured, remains to be seen. A major hurdle in the implementation of the reforms was crossed when the Supreme Court's ruling of June 2012 largely upheld the constitutionality of two major provisions of the ACA: First, the individual mandate and second, the Medicaid expansion (expanding Medicaid eligibility to almost all people under age 65 with incomes at or below 138% of the Federal Poverty Line). The individual mandate requires most people to maintain a minimum level of health insurance coverage starting in 2014; however, the ACA contains several exemptions to the mandate, which allow several millions of Americans to remain uninsured by choice. Moreover, the court's ruling made Medicaid expansion in the ACA optional for the states, and despite the availability of generous federal matching funds, some states have opted not to expand their Medicaid programs. The next hurdle in the path of health care reform and the ACA in terms of moving closer to universal coverage is the design and implementation of state insurance marketplaces (exchanges) that are meant to pool and subsidize employees of small of firms and the self-insured. These marketplaces are intended to be fully functional by early 2014. However, delays are anticipated in many states and participation rates remain to be seen.

Thus, in all likelihood, the debate regarding the value of extending coverage to the uninsured will continue to rage even after the implementation of the ACA. From a methodological perspective, studies on the relationship between insurance availability and health outcomes in the private segment of the US market were hampered by statistical identification issue, making it difficult to ascertain the precise contribution of coverage to health. The anticipated broad expansions of insurance coverage in the US should provide future researchers, opportunities to conduct quasi-experimental studies of private expansions, much like has been done previously in the context of Medicaid and Medicare. It is noted that the debate over this issue is not limited to the effects on health. Other important arguments for providing insurance include efficient use of resources, cost containment, equal access to care, and social protection. These are treated elsewhere in this volume.

Health Insurance in Developed Countries, History of

JE Murray, Rhodes College, Memphis, TN, USA

Introduction

Institutional arrangements for health insurance long predate efficacious courses of therapy or even accurate diagnostic techniques. Let health insurance be a type of insurance in which the benefit payment is triggered by an adverse health event. Nowadays the payment is generally intended to pay the costs of health care: physicians and nurses, equipment, drugs, and hospital care. In the more distant past, the primary cost of ill-health was lost income due to the inability to work. Thus, the initial health insurance schemes set out to replace a sick or injured worker's pay, occasionally paid for medical care, and often included death or burial benefits for survivors. Throughout Europe, workers formed sickness funds to execute these sorts of risk management measures. They bound themselves into mutual aid societies that required of them regular payments into a jointly kept fund, from which they were eligible to draw benefits when incapacitated and unable to work. Details of such funds differed according to trade, nationality or region, and over time, but their numbers and the number of members they covered grew until the advent of state-sponsored health insurance in the later nineteenth century.

The Medieval and Early Modern Periods

The first health insurance schemes were established in the late middle ages. Because miners endured the greatest risk of accident and death at work, it was reasonable for them to found the earliest sickness funds. The earliest record of a miners' fund dates back probably to the year of 1300 during the reign of King Wenceslas II of Bohemia. A few early *Knappschaftskassen* (miner society funds) maintained hospitals for members and townsfolk in mining communities, but most aimed to care for widows and orphans of members killed in accidents. Medical care and short-term sick pay, for four to six weeks, generally came from mine owners. There were exceptions, however, such as the mining law for the region surrounding Trier (1546), which called for a fund managed according to insurance principles of compulsory premium and entitled benefit payments. These benefits financed care and sick pay for up to four weeks.

Miners' funds continued to grow into the early modern period, aided by complementary legal developments. Twelve German states made membership in *Knappschaften* compulsory, for example, as in the Prussian *Knappschaftsgesetz* (miner society law) of 1767. A later Prussian law required poor relief claimants in mining regions to exhaust all available benefits from *Knappschaftskassen* before receiving any government benefits. Thus began the connection between private (if government aided) health insurance and state entitlements.

Through locally based guilds, other trades also developed sickness funds in the early modern era. Dutch guilds, for example, established separate relief funds for members in the seventeenth century to protect their general operations from unexpected demands during epidemics. These funds took on the structure that characterized private sickness funds for much of the next three centuries. Although these guilds accepted donations, sickness funds required regular contributions from masters, who in turn were compelled to join the guild in order to practice their trade in a particular location. Guild members, that is, masters, who were sick and temporarily unable to work, claimed a small replacement payment to carry them through their illness. Elderly and otherwise needy guildsmen, widows, and orphans were not entitled to assistance, but might receive some aid when there was enough money in the coffers. Journeymen and apprentices were not eligible for such aid as they were to be supported by the master as long as they lived under his roof. Some guilds developed separate funds for apprentices. As early as 1608 in Antwerp, separate apprentice funds appeared for milliners' and clothmakers' apprentices and journeymen – and Louvain, Brussels, Ghent, and Bruges soon followed. In a few places, Austria in particular, apprentice and journeymen funds survived into the twentieth century. Compulsory membership in apprentice funds ensured a steady flow of new, young, and relatively healthy members into a guild of fund.

In addition to miners and skilled tradesmen in guilds, voluntary occupation-based relief funds appeared as early as the sixteenth century in Amsterdam, Delft, and Leiden, covering the great majority of journeymen and apprentices. The seventeenth and eighteenth centuries saw rapid growth in these funds as well as increasing labor mobility among their members. To prevent financial destabilization and with the aid of local authorities, many local, occupationally based funds instituted compulsory membership; these appear to have been a minority, perhaps between 10% and 20% of apprentice funds. In a nutshell, a substantial share of workers enjoyed membership in sickness funds by the end of the eighteenth century. In Amsterdam, the proportion was approximately one-third, whereas in other northwestern European cities, it ranged between 25% and 30%.

Friendly societies, as sickness funds were known in Great Britain, covered a variety of workers. They also appeared under the name of 'box clubs' to indicate the means of collecting premiums, with a box set to one side of a pub or office. For one century from the later part of seventeenth century, their effectiveness led the elite of the country to call for more such societies to enable care of the poor apart from the provisions of the Poor Laws. Daniel Defoe proposed that the sailors' mutual aid society in Chatham could be taken as a model. By two contemporary estimates, between 7000 and 10 000 friendly societies covered approximately 700 000 members by the year of 1800, or almost one-third of the adult male population. Although all of these friendly societies paid benefits to members, some paid only burial or widows' benefits and not sickness benefits.

Nineteenth Century until 1880

The most celebrated event in the history of government-sponsored health insurance occurred late in the nineteenth century: the German adoption of compulsory insurance. This development did not occur in a vacuum. Throughout the nineteenth century, the evolution of the legal environment and the secular expansion of mutual aid society membership set the stage for direct government intervention. The Napoleonic Wars spread the French Revolutionary animus against guild activity through continental Europe. For example, during the French occupation in Ghent, journeymen's aid societies operated in secret, and they were later joined by elite textile workers' secret funds. When they were allowed to operate openly in 1827, one-third of craft workers were linked to sickness funds. The number of Dutch mutual aid societies grew at this time as well, by 50% from 1800 to 1820, and the number had doubled again by 1850. For profit, commercial insurance, with benefits that replaced pay during sickness or that paid for medical costs, or both, began at this time to cover families having no members in sickness funds. Even before 1842, when physicians themselves started and operated insurance funds that enrolled their patients, nearly one-fourth of Amsterdam's population was insured against medical expenses.

In Great Britain, the friendly societies proved to be popular among all parts of the working class, both skilled and unskilled. At times, the government wished to encourage this trend, but in general active and prospective members resisted this intrusion, managing and expanding their ranks voluntarily. Early in the nineteenth century efforts to encourage county or 'patronized' friendly societies under gentry management came to naught; in 1825, the House of Commons Select Committee on Friendly Societies observed that "people themselves [prefer] clubs managed by themselves." The societies acted creatively to ensure enrollment of future workers. After the 1820s and 1830s, when some Sunday schools organized sickness funds for students as well as teachers, the Oddfellows and Foresters formed juvenile sickness funds from which, they hoped, full members of their societies would emerge.

In the New Poor Law of 1834, Parliament gave an indirect boost to voluntary enrollments of friendly societies. One intention of Poor Law reformers was to encourage the near poor to attain some degree of financial independence through membership in friendly societies. That is, ideally workers would save for hard times rather than hope for relief from Poor Law related institutions such as parish apprenticeship for unwanted children. The reform seems to have had the intended effect, as the number of societies and the number of members rose in the decade after enactment; thus workers do seem to have been saving more. However, the causative role of the New Poor Law in this trend is open to debate. Grim New Poor Law institutions such as Dickensian workhouses bore no less stigma than parish-level outdoor relief under the old Poor Law; both provided substantial incentives to the working class to avoid public assistance.

Friendly societies grew in geographic extent, membership, and operational sophistication through the midthird of the nineteenth century. Regional and national groups of societies known as affiliated orders emerged from individual societies and box clubs. There were 163 such federations by 1877, the largest two of which, the Manchester Unity of Oddfellows and the Ancient Order of Foresters, enrolled some 800 000 men in total. Centralization accompanied the process of growth and affiliation, and central offices began to require the submission of data on sickness claims. From here, it was a relatively easy task to engage in actuarial research to produce tables of claim rates and thus expected probabilities of claim rates and benefit payments in the future. The latter part of the century saw societies moving from customary levels of membership dues to actuarially determined rates, in particular rates being differentiated by age. The ability of societies – or alleged lack thereof – to assess sufficient rates to cover their liabilities became a political issue not put to rest until the 1911 National Health Insurance Act, by which the state financed these liabilities. Notwithstanding the advent of an objective actuarial science, the culture of the societies being closely tied to the local pub and its working-class bonhomie, bound members in a truly mutual fashion to examine their own claims and those of their fellows carefully. Societies sent committees of members out to examine claimants, forbade those claimants from entering pubs, and thereby reminded each man of his obligation to the society as a whole. This solidarity was one characteristic of friendly societies that could not carry on past 1911.

Despite occasional efforts to recruit women and children, the primary aim of friendly societies in nineteenth-century Britain was to cover adult men. Exactly which adult men, in class terms, has been a subject of debate. Earlier historians, such as Eric Hobsbawm, had claimed that premium levels were high enough to discourage unskilled workers from joining, so that the membership by and large consisted of skilled workers – the so-called labor aristocracy. Although more skilled and better paid workers may have composed the majority of friendly society members in the first half of the century, recent microstudies of local club membership rosters have found a broader membership base from mid-century onwards. James Riley compared distributions of occupations of Oddfellows to those of Englishmen as a whole late in the century and found a close correspondence. The representativeness of friendly society membership to British society as a whole was perhaps not evident to historians who relied on official and printed sources, and awaited those local historians who were willing to dig into the manuscript record. In any case probably, the large share of the British population who enjoyed friendly society sickness benefits did not differ in any substantial way from the uninsured population.

Later Nineteenth Century until the Great War

In cultural terms, the German situation was worlds away from that of Great Britain. The English societies had formed out of a tradition of voluntary association whereas the Prussian provident funds, or *Hilfskassen*, stemmed from compulsory organization of artisan trades through the guilds. That compulsion signals the importance of the state in the development of German funds. Care for ailing and injured journeymen played a particularly important role in the German case. Journeymen had neither the access to resources that masters had nor were they under the responsibility of a particular

master, unlike apprentices. As the German states disabled guild influence over members, they required guilds to provide closer assistance to journeymen in need. For example, the Prussian industrial code of 1845 included enabling laws that permitted local authorities to require all journeymen in their jurisdiction to belong to journeymen's sickness funds. The growth of other workers' funds was limited to opportunities left open by the lack of state action. In Germany, as in Britain, workers' sickness funds interacted with Poor Law institutions. One reason for the 1845 enabling law was the Prussian Poor Law legislation of 1842, which shifted the focus of benefit payments from the person's original place of settlement to his current place of residence. As local communities could no longer rely on guilds to care for distressed journeymen, they were granted powers by the 1845 law to shift that obligation back to the guilds. Between 1849 and 1853, some 226 Prussian municipalities made joining a sickness fund mandatory for workers. Although compulsory membership in sickness funds appears in the historiography as a reaction to the tumult of 1848, it is noteworthy that legal requirements to join these funds have predated the events of that year. A later law, the Emergency Ordinance of 1849, allowed local governments to compel factory workers to join provident funds, to which factory owners were required to contribute, thus placing artisans and factory hands on roughly similar legal footing. Again, the main concern was protecting local poor relief institutions.

Changes in the legal environment around the middle of nineteenth century affected all manner of sickness funds. A rising tide of internal migration, especially well documented in the lower Rhine region surrounding Düsseldorf, concerned local authorities who feared the newcomers would end up on their own poor rolls. The central Prussian government, however, committed itself to freedom of movement. Rather than restrict labor mobility, in 1854 it allowed local communal funds to bill the commune of birth or previous residence of a poor relief recipient for up to a year. The number of funds grew as a consequence. At the same time, the Prussian government dramatically changed its laws regarding property rights to underground resources, with consequences for the miners' funds, the *Knappschaften*. Mine owners, rather than the state, would control the disposition of assets and hold the ability to hire and fire miners and to determine their pay rates. Miners' funds could now set member contributions either as a flat percentage rate, or as a flat rate within a set of fixed categories corresponding to earnings. The rise of Liberal political influence in the 1860s led to the founding of labor union provident funds, which continued under Social Democratic influence. These funds were eager to be treated as others were; that is, to keep their members from being compulsorily enrolled in guild, factory, or communal funds, and thus paying twice over for their insurance. After the 1866 Prussian annexation of territories into the North German Confederation, the *Reichstag* did in fact issue an Industrial Code in which compulsory membership requirements could be met by joining a 'free' or voluntary membership fund, such as those operated by labor unions.

Over the course of the 1860s, the status of voluntary and compulsory funds, those 'free' of government regulation and others overseen by local government or business officials, those operated by trade unions that permitted member mobility and communal funds that did not, became muddled. Court opinions contradicted one another, and the confusion led communal authorities to cease requiring residents to join provident funds. The central government found the wide range of premiums, benefits, and claim requirements unsatisfactory, but politically untouchable at that time. One result of this relatively *laissez faire* approach to insurance regulation was the outburst of growth in both the number of funds and the number of workers they covered. Between 1860 and 1870, the number of funds for skilled craft workers rose by 29% whereas the number of covered craft workers rose by half. Over the same period, the number of funds for factory workers doubled, as did the number of such workers who were covered.

In 1876, the central government of what was then the German Empire finally achieved its goal of standardization through the Law on Provident Funds. At least nominally, the legal requirements of similar benefits, and thus similar premiums to pay for them, among the voluntary funds meant that they could not be used as an expedient method of avoiding the higher-priced, higher-benefit level compulsory funds. To do this, the central government created a new category of registered funds, membership in which might be either compulsory or voluntary, and benefits from which were strictly regulated within certain minimum and maximum time periods and levels. In addition, these funds were required to end their provision of benefits for anything other than sickness and injury, such as death benefits for widows and orphans, or partial pay benefits for striking members. Besides forbidding fund members to participate in strikes, this law also forbade investments of fund reserves in the sponsoring firm, thus detaching the funds from both workers and employers in one stroke.

For various reasons, the state's interest in health insurance regulation did not end there. In a strategic view, Bismarck wished to soften the blow of the first Anti-Socialist Law of 1878 among the working classes, and to co-opt them into believing that the state, rather than removing their political voice, was providing for them materially. This explains Bismarck's initial efforts to fund compulsory insurance through employer contributions and taxes: "If the worker must pay, the effect on him is lost," he said, because then the worker could see that he himself and not the state had produced the resources that paid for the benefits. From a more tactical perspective, the need for widespread (but not universal) compulsory health insurance arose from gaps in the current state of accident insurance that stemmed from the Accident Liability Law of 1871. Efforts to update the state of accident insurance stalled in the 1882–83 session of the *Reichstag*, and so the relatively uncontroversial provisions for health insurance were removed and placed in a separate bill. With accident insurance to be made compulsory across the Empire by a bill that assigned responsibility for the first several weeks of disability to the sickness insurance funds, it would not do to have pockets of worker autonomy concerning sickness insurance. Hence, the 1883 Sickness Insurance Law entered the books before the 1884 Accident Insurance Law.

The new Sickness Insurance Law built on the existing network of small sickness funds. It made membership in a

sickness fund compulsory for a large class of workers who earned less than 2000 marks per year. In addition, employers contributed to sickness funds at a rate of one mark for every two paid as dues by the employee, but there was to be no state funding. By inspecting employer records, cross-checking fund membership lists, and threatening employers of uninsured workers with fines, the state effectively enforced coverage requirements. For workers who toiled in other sectors, such as agricultural laborers and domestic servants, and for those workers who earned more than 2000 marks annually, membership was voluntary. Registered aid and state-registered aid funds covered those outside the compulsory system who chose to join voluntarily. The network of health insurance funds covered a large share of the working class though not immediately. Enrollment in 1885 numbered some 4.5 million, or almost a tenth of the population; by 1906, the covered share of the nonagricultural labor force (not population) had risen to approximately 70%.

Despite the broad extent of coverage, the systems still confronted problems of moral hazard and physician agency. The statutory minimum wage replacement rate was one-half, but many funds paid 60% or 70% of a worker's usual earnings to disabled members. One consequence was a steadily increasing number of missed workdays due to sickness absence. In 1885, the first year with comprehensive statistical data, the average covered worker missed six days of work due to ill-health. By 1908, that number had risen to nine days per year, an increase of 50 percent. Over this time, workers did not change the rate at which they submitted claims, so the increase in sick time was due to longer spells of sickness. For example, in establishment funds operated by particular firms, the average duration of illness rose from 12.5 days in 1885 to more than 18 days in 1908, an increase of nearly a week per sickness event. The upward trend was not affected by the 1903 law that increased the mandatory maximum duration of insured sick time from 13 to 26 weeks. Among funds in which membership was compulsory, both the frequency of sickness spells and their duration were strongly and positively associated with the level of sick pay, suggesting a moral hazard in which the availability of sick pay increased the time spent off work. Indeed, the German-American statistician Frederick Hoffman proposed that the fundamental problem behind increasing absenteeism among insured German workers was not their worsening health but rather their 'dishonesty, deception, and dissimulation' regarding missed work time.

Similar problems appeared in miners' sickness funds. Up to the turn of the twentieth century, miners had averaged between six and eight days per year of absence, but after 1900 or so, that figure jumped to as high as 12 days per year. As one observer noted, "[F]requent malingering…in the Ruhr area led to a great increase in costs." In response, *Knappschaften* ended sick pay for Sundays and introduced waiting periods that acted as a kind of deductible. Still, here too, later research found a strong, positive, and significant correlation between sick pay and absenteeism rates.

To deal with these problems, the system developed an elaborate process of obtaining second opinions. To receive sick pay benefits in the first place, a worker's claim needed to be approved by a physician associated with the fund. In German funds that offered free choice of physician, fund-employed doctors monitored independent physicians by performing second examinations. Both funds and their members enjoyed the right to demand a second opinion from a variety of 'confidential medical advisors,' either fund-employed physicians or committees were composed of physicians' and insurers' representatives. The results of the second opinions suggested that the physician-agent's diagnosis depended on the identity of the principal. Given free choice of physician paid by capitation, as in most compulsory funds, patients were the principals, and physicians who gave initial diagnoses of incapacitation were their agents. Medical advisors who monitored the primary physicians, on the other hand, were agents of the insurers. Probabilities of claim approval reflected these relationships. A report of fund groups in several northern cities during 1909 and 1910 indicated that whereas initial consultations tended to favor the worker, second examinations favored the fund. Between one-eighth and one-third of workers who had obtained statements from their own physician attesting to their incapacitation returned to work rather than be examined by a fund doctor. These workers either recovered quickly or lacked confidence in the veracity of their claims. German workers, physicians, and their supervisors all understood the implications of agency. Physicians wanted to keep even their most annoying patients, who frequently presented with dubious symptoms, in order to maintain the capitation fees that accompanied them. Contemporary observers asserted that personal physicians thus gamed the system by approving questionable claims. The fund's medical advisors then routinely rejected the claims at the second opinion stage, thereby keeping the fund financially healthy and the attending physician's pay intact, while allowing him to blame the second physician for the rejection.

During the later nineteenth century, other forms of health insurance expanded their coverage in continental Europe. With the exception of sickness funds for miners in France, membership in them was voluntary rather than compulsory. And that membership grew. French membership in adult funds, which accepted a measure of government supervision, tripled to 2.5 million from 1886 to 1905, whereas free funds, which operated without such oversight, grew by more than a third to 425 000. Similarly in Belgium, recognized funds under government oversight grew nearly ten-fold to a quarter-million members from 1885 to 1904. In Denmark sickness societies, heavily subsidized by the government, tripled their enrollments between 1895 and 1905, with another 20 percent growth by 1907.

These sickness funds managed a different set of problems from the compulsory German sickness societies previously discussed. All voluntary funds faced the threat of adverse selection, including the voluntary German funds that descended most directly from Poor Law institutions. To manage the problem of cultural differences in determining whether a worker was too sick to work, absence records from both voluntary and compulsory funds within Germany were compared to each other in the region of Leipzig. Here, membership rolls in the voluntary funds skewed older than those in compulsory funds, which suggested selection biases into membership. But then controlling for the age categories of members, voluntary funds had much higher absenteeism rates than compulsory funds among same-aged workers, which suggests that the

voluntary funds were especially attractive to those in poorer health at every age. Members of voluntary funds who were in their early 20s had extraordinarily high sickness rates, nearly as great as those of men in their 60s. A contemporary German observer has explained the reason in a classic adverse selection statement: "Practically all the male population, including the weaker and those who are physically less valuable, are sent to work in the earlier ages [i.e., and then they join compulsory funds]; in a few years, however, the weaker persons must give up the occupations in which they are engaged, but realizing their need for insurance, continue their membership as voluntary members."

In voluntary French and Belgian funds, such difficulties were compounded by the financial need for 'honorary' members. These were civic-minded men of the bourgeoisie whose membership required them to contribute premium payments but did not allow them to claim benefits. Their presence in sickness associations diluted the solidarity among rank and file members that was necessary for them to function efficiently. Both France and Belgium relied on mutual aid societies to care for sick workers through their benefit funds, with the few workers employed by large firms enrolled in establishment funds. A manual for sickness fund managers addressed a widespread concern with selection bias by recommending rejection of all applicants over the age of 40 due to "the risk of illness [being] considerably augmented after that age." French benefits were in line with those elsewhere. A large fund for store clerks in Paris charged its members two francs per month in dues and offered sick pay benefits of two francs per day for not more than 60 days plus the attention of a physician employed by the fund. Belgian funds were less generous. One coal mining company fund replaced only 22% of a miner's pay, but paid these benefits for the first six months of illness. Dependence on scarce honorary members kept Belgian dues relatively high, leading a contemporary to complain, "It is the élite of the working class alone that can stand the cost of sick insurance."

Financial problems plagued French and Belgian sickness funds as memberships aged and claim rates rose beyond the ability of fund assets to service. French establishment funds became even more dependent on subsidies from sponsoring firms. Among all French funds, the value of assets per participating member (excluding honorary members) fell by one-quarter from 1898 to 1905, whereas this measure rose by 10% among compulsory German funds. The historian Theodore Zeldin summarized the situation of the French societies thus: "Ignorance of the principles governing insurance was common, methods of administration amateur in the extreme….The most serious omission was that the whole movement was never established on an actuarial basis." Similarly, Belgian funds endured chronic financial difficulties due to their lack of actuarial soundness. A government official at the time conceded that the societies' sick funds could, in theory, "be scientifically managed," but in fact "the mutual sick-benefit societies do not fulfill the necessary requirements of a safe and rational organization." These difficulties led Catholic and Socialist legislators to agree on the need for compulsory insurance in 1912.

Consequences of sickness insurance benefits varied according to the voluntary or compulsory nature of membership. As noted above, availability of sick pay seemed to induce German workers to take additional days off, and the pattern of increasing sickness time appeared in other compulsory funds as well: in Austria and among German and French miners. Whether those days were truly evidence of malingering, or whether workers could finally afford to take necessary time off work to recover, cannot be determined from statistical analysis. Among workers who belonged to voluntary funds in France, Belgium, and Denmark, however, after about 1890 paid absenteeism began a slow and steady decline for some years. This trend is unlikely to have been caused by improving worker health. Rather, it stemmed from the financial inability of these funds to support previous levels of absenteeism benefits. French physicians, employed directly by sickness societies, ceased to approve absence benefits so readily after being ordered by fund managers to cut costs. Later, in the 1930s, Belgian funds adopted denial of benefits as an explicit policy to keep their accounts in balance. Statistically, greater expenditures per sick day on medical benefits were associated with briefer spells of absence, which may have been due to physician visits resulting in orders to return to work, at least among the voluntary funds. The French physician and statistician Jacques Bertillon wrote in 1892:

> The fact is that when these societies grant compensation they attach less importance to their regulations than to the state of their till. A rich society gives its help more liberally than a poor one; and this is absolutely the sole cause of the large English societies, which are often very old and generally rich, granting more daily indemnities than the French (for instance), who are obliged to exercise the strictest economy.

Given the limited efficacy of therapeutics in the late ninteenth and early twentieth century, the primary benefit of sickness insurance coverage was the sick pay benefit that enabled workers to take time off to recuperate. This rest enabled workers to recover from illness and injury sufficiently regularly to influence mortality rates. Various studies had found that more expansive sickness insurance coverage, whether compulsory or voluntary, was associated with reductions in mortality rates in general. In particular, infant mortality rates were also lower as coverage expanded, probably as a result of confinement benefits. Those benefits also led to relative increases in fertility rates. Finally, persuasive evidence has been adduced to show that the availability of sickness insurance in Germany had reduced the rates of emigration at the turn of the century. Thus, health insurance had measurable influences on all manner of demographic measures throughout early twentieth-century Europe.

Growth of health insurance (as it came to be called) in Great Britain trod its own path quite different from developments on the European continent. The German government was committed to elaborate intervention into, but not subsidies for, health insurance markets, and the French were equally committed to upholding a worker's choice of joining a benefit society or not. In the British case, a far larger share of working class men belonged to friendly societies than in France or even in Germany before 1883, which mitigated the perception that government action was needed to insure workers and also created a formidable political barrier to such action. The Liberal government launched its welfare reforms

only in 1906, because until that time the great concern had been to care for the elderly who had simultaneously been pushed out of the labor force by younger workers and pushed into the embarrassment of outdoor relief. How exactly to deal with the deserving aged poor remained a conundrum until the 1908 Old Age Pensions Act provided tax-financed pensions to the elderly. This landmark Act thus moved the responsibility for care of the elderly from local Poor Law Guardians to the national government.

The unusual calls for two general elections in 1910 gave the government time and space to consider the next step of compulsory health insurance. In 1907, a young William Beveridge suggested that provision of unemployment insurance could potentially mitigate a great deal of poverty, and then in 1908 after passage of the Old Age Pensions Act, David Lloyd George visited Germany for five days to study the possibilities for a similar national health insurance program in Britain. The combination of these two events led to the National Insurance Act of 1911. The health insurance aspect of the Act, as distinguished from its unemployment insurance provisions, was to be funded by weekly contributions. Unlike in the German system, these contributions were fixed as flat rates, thus imposing more of a burden on lower-paid workers. Employed men paid four pence, employed women three pence, their employers three pence, and the state two pence weekly. Coverage automatically applied to all manual laborers and to all over age 16 who earned less than £160 per year, the equivalent of 3200 marks. Insured workers could obtain free medical care from a physician who belonged to a local medical committee. Workers were eligible for a sick benefit of 10 shillings per week for men (seven shillings sixpence for women) for up to 26 weeks. After 26 weeks, an ill or injured worker might apply for a disability benefit of five shillings per week.

As the Bill proceeded through Parliament, it changed considerably. Originally, Lloyd George had intended for friendly societies to perform much of the administration of this insurance, but concluding that commercial insurers were much sounder in actuarial terms, he shifted the load of management toward them. During consideration of the National Health Insurance Bill in 1911, the British Medical Association persuaded the government to allow free choice of physician as part of a larger development that excluded more approved friendly societies from the system. Thus the great distinction today between German management of health care finance, where insurance funds determine the levels and distribution of expenditure on health care, and the British method, wherein such decisions are made by the state, is one that dates back to the early twentieth century.

After 1918

The British economy staggered out of its victory in World War I into an uneasy peace. In 1919, the earnings limit for mandatory insurance increased to £250, almost keeping pace with wartime inflation. The next year contributions rose to five pence for both men and women, and the standard benefit was increased to 15 shillings per week for men and to 12 shillings for women. Over the entire interwar period, the share of the male population entitled to benefits rose steadily from 51% to 63%; the associated share of women rose from 23% to 30%. During the high unemployment era of the 1930s, the sick pay benefit offered through the national health insurance program began to look better for workers when the comparable benefits available through unemployment insurance and workmen's compensation (accident insurance) expired. One result was that workers who became unemployed tended to make claims of ill-health against the national health insurance plan when their unemployment benefits ended. Thus, as unemployment rose during this period, so did sickness claims. From 1921 to 1927, sickness claims by men rose by almost half, as did long-term disability claims. In actuarial terms, the ratio of actual to expected costs of disability benefits for men increased by 80% in Britain between 1922 and 1935. The possible substitution of sick for unemployment benefits produced an acute strain on the insurance program's finances.

In May 1940, the Chamberlain government fell after the loss of Norway to the Germans. Only a year later, the coalition government led by Winston Churchill appointed William Beveridge to chair a new committee on the reform of social insurance. Beveridge's famous report of 1942 determined the course of the British welfare state for a generation after the war. It aimed to create a unified system of social insurance for the entire population, and not just manual workers. The safety net was to cover workers and their dependents against ill-health, unemployment, and old age, and was to be financed through general taxation funds. In the wake of successive reports from the Committee on Medical Insurance and Allied Services (1920), the Royal Commission on National Health Insurance (1926), and the British Medical Association (1930 and 1938) that emphasized the shortcomings of the existing arrangements, the Beveridge Report recommended replacing compulsory insurance for most workers with a comprehensive national health service for the entire population. British physicians fought the imposition of a salaried state medical service right up to the formal establishment of the national health service in 1948.

In France, settlement of the Great War undermined French notions of individual choice of insurance from within. After the Franco Prussian War of 1870–71 the German Empire annexed the former French Alsace-Lorraine. Inhabitants of the region were integrated with the German project of compulsory sickness insurance from its start, and by the time of the Treaty of Versailles, they were in no hurry to return to the status quo of 1870. In response to the threat of an independence movement, the French government promised Alsatian labor unions that it would maintain health, disability, and old age insurance substantially as they had been, and hinted at even using these arrangements as a potential model for the rest of France. French physicians aimed to prevent such developments, but eventually they compromised with the government and allowed the first form of compulsory insurance to be established in 1930. This insurance reimbursed patients for 80% of their medical bills. The downside of this agreement was that individual physicians felt no compulsion to abide by fee schedules negotiated on their behalf by medical groups. The share of covered population (not labor force) rose to almost 25%, but unexpected expenses and denials of benefits increased political discontent with the scheme.

The next step in French insurance policy occurred during World War II. It was conceived not in France itself but by the

Free French government in London, and then enacted in 1945. The necessary relationship between employment and insurance coverage ended, thereby enrolling greater numbers of the insured. In qualitative terms, this expansion of the *Sécurité Sociale* also proposed to limit increases in physician billing rates. By some accounts, this represented a missed opportunity to do away with fee for service medicine altogether and leap ahead to the system that began to be implemented after the 1960 reforms. Still, the postwar reforms succeeded in bringing 'the quasi-totality of the population' under coverage – a Gallicism meaning almost three-fourths, roughly same as the share of Americans with hospital insurance. But again, costs rose faster than expected, making it impossible to keep the French budgets in balance.

The Dutch interwar experience offered a fine example of the ability of a totalitarian government to break legislative deadlocks and impose politically unpopular compulsory insurance. By the end of the nineteenth century, a wide variety of sickness insurance funds was operating in the Netherlands: some formed as mutuals by groups of workers, others sponsored by employers or trade unions, still others by local governments, a few operated by commercial insurers, and a unique set of funds were operated by physicians. And here things stayed due to Parliamentary impasses. From the Great War onwards, every effort to enlarge the government's presence in health insurance markets halted due to unwanted amendments, parliamentary deadlock, dissolved governments, and other flotsam of a democratic polity. The arrival of Nazi occupation forces ended the stalemate. To bring the Netherlands in conformity with the German example, the occupiers promulgated a compulsory sickness fund decree that broke through the parliamentary clutter and established government health insurance once and for all. As for Belgium, the Allied breakout from Normandy caused the Germans to put Nazifying health insurance on hold. But soon after liberation, the Belgians too enacted compulsory insurance. Thus in the Low Countries, both occupiers and the occupied looked upon government health insurance as an idea whose time had arrived by the mid-twentieth century.

Elsewhere in the world, the rise of government intervention in health insurance markets awaited the second half of the twentieth century. In the middle of this century, the Canadian situation was in flux. Canadian physicians had become more sympathetic than their American counterparts to the prospect of state action, and the Canadian Medical Association was participating in the reform process. Creation of government insurance occurred first in the West, where Saskatchewan, British Columbia, and Alberta had adopted a tax-funded hospital insurance program. Newfoundland had already created a health insurance program that covered half the population by the time it entered the Confederation in 1949. The success of government hospital insurance in these provinces led to the Hospital Insurance and Diagnostic Services Act of 1957, by which the federal government subsidized hospital insurance in all the provinces. Pushing the principle of state insurance further, the provincial government of Saskatchewan established Medicare, as the Canadian single payer medical insurance system came to be known, in 1962. This triggered a bitter and ultimately unsuccessful strike by the province's physicians. The strike's failure caused a loss of political capital by the most important opponents of an expanded government role, and this in turn opened the door to further state intervention. The pressure for national health insurance became so great that even the physicians did not want to be seen in opposition to it, and they again moved to work with governments on the shape of insurance policy. Pushing the principle of state insurance further, the provincial government of Saskatchewan established Medicare, as the Canadian single payer medical insurance system came to be known, in 1962.

Nor has the notion of health insurance been restricted to only Europeans and their descendants. Compulsory health insurance for industrial workers began in 1950 in Taiwan, in part as a political effort to improve the protection from the risk of ill-health enjoyed by Taiwanese workers relative to those in the People's Republic. From its initial remit of coverage for workers in public factories and mines, the government expanded this health insurance to workers in private in private industry, smaller manufactories, and fisheries by 1953. Beginning in 1958, it extended compulsion to government workers and teachers, and then all industrial workers, and eventually nearly all workers, including those in agriculture. By the time of national health insurance in 1995, there were few uninsured Taiwanese remaining.

In Latin America, the more prosperous countries have succeeded in enrolling a large share of the population in health insurance of some kind. By 1986, Argentina, Brazil, Costa Rica, Mexico, Panama, Uruguay, and Venezuela offered medical care coverage to 71% of their combined populations. The covered populations tended to be city-dwellers, who were relatively easy to reach and relatively able to afford the premiums. Five of these countries covered spouses and children of the insured, and of the remaining two, Uruguay provided maternity and pediatric care whereas Panama excluded only hospital care from coverage. The origins of these programs date to much earlier in the twentieth century. For example, in the 1920s, Brazil created a variety of social insurance funds for various kinds of workers in different parts of the country. Over the next several decades, legally mandated amalgamation reduced the number of social insurance funds to seven large funds that represented major occupational groups, including rural workers.

Health Insurance in Historical Perspective, I: Foundations of Historical Analysis

EM Melhado, University of Illinois at Urbana–Champaign, Urbana, IL, USA

Introduction

Although the US, in comparison with other Western countries, was a latecomer to social insurance and the public provision of insurance for health services, it was largely in the America of the 1960s that formal economic analysis of health care first began to take root, and American ideas and practices have long since dominated health economics; hence American ideas are the focus of this and the next article. The efflorescence of American health economics emerged from (and helped alter the course of) antecedent traditions of American thought about health insurance, which began in the early-twentieth century. For a bit more than the first-half of its history, ideas about health insurance took form in and evolved from the work of two overlapping groups of analysts: a broader one, whose members took a normative perspective animated by questions of social politics; and a smaller group whose members aimed more specifically to improve public health. Figures in both were reformers and activists; they hoped to advance what they understood to be the public interest. Their normative vision little exploited formal economic analysis, which, at least in its modern, mathematized mode, was at that time only incompletely developed and thus unavailable to reformers as a basis for analyzing health policy; but the aspirations of the emergent social sciences often informed their vision.

Only during the 1960s, under the then prevailing liberal dispensation, when a significant social surplus was available to sustain expanded forms of collective provision, did formal economics of a sort more familiar to modern practitioners begin to make itself felt in application to public policy. Economists developed formal rationales for governmental involvement in the economy and articulated the principles that should govern public programs. In the case of health policy, figures such as economist Kenneth Arrow (1921–) held that much of health care qualifies as a special set of services that require collective subsidy (if not indeed public provision). This agenda gradually fractured, however, as diverse forces, both inside and outside economics, undermined a once broad faith in the value and propriety of governmental intervention in the economy, in the capacity of experts (particularly those in governmental employ) to achieve desirable goals, in the utility of regulatory regimes, and in the capacity of society to gain consensus about the goals of public policy. Convictions wavered even about the value of health services, at least at the margin. As economics developed and honed the tools to analyze public policy, analysts toned down, but did not abandon, normative orientations, and the role of the economist and expert became less that of reformer and more that of the servant of diverse interests well beyond the traditional ranks of policymakers. Gradually, the major concern became markets, at first as the best means to realize broad social goals, and later, as commitments shifted away from fostering collective provision, to serve and facilitate individual choice.

Advocates of older normative views have hardly disappeared, but their approaches, reflecting social and cultural traditions that had been eroding since especially the 1970s, have been routinely contested by advocates – both within economics and without – of markets and limited government. The public debates that preceded the Obama reforms, i.e., the Patient Protection and Affordable Care Act (PL 111–148, as amended by the Health Care and Education Reconciliation Act, P.L. 111–152; henceforth, ACA), passed at the end of March, 2010, and the persistence thereafter of pervasive disagreement in health care about the goals of public policy and the roles of government, show that both economists and Americans broadly remain profoundly divided about these questions. Many economists, by professional interest and training concerned with markets, have often presented themselves as representing a value-free perspective on questions of public policy; yet many of their critics, including other economists more rooted in traditional approaches to policymaking, find that their colleagues' claimed neutrality implicitly harbors values inimical to those rooted in older approaches, that they still sought to honor as collective commitments. Economic analysts of health insurance and related areas, despite the drift of the profession in favor of markets, still reflect the diversity of values and beliefs about the proper goals and means of public policy; neither health economics writ large nor the parts of it most directly connected with insurance have eliminated this diversity, but they have provided powerful and influential frameworks for defining, discussing, and analyzing the issues.

This article opens with discussion of several historical frameworks useful in exploring the history of American thought about health insurance and provides elements of a taxonomy of both researchers and advocates of various forms of health insurance. It then describes the earlier history of thought and advocacy in the context of the social politics that emerged in the early-twentieth century and persisted until the late-1960s and early-1970s. It takes up underlying notions of social solidarity, their tensions, and their relevance to health insurance. It next exhibits the emergence of a market-oriented perspective and its corrosive effects on ideas about social solidarity. The following article explores the two principal bodies of thought that called for market-based approaches to health care, notes their early connection with calls in the late-1960s and 1970s for expanded public insurance, elicits the main elements of these traditions, and links discussion with contemporary developments, particularly in the light of the evolution of markets on the ground. The article concludes that in America health economics has done much to enable analysts to formulate and analyze policy questions, but that policy

discussion about health insurance remains highly contested. What is clear is that the US, despite recent reforms, is not moving toward a uniform system of National Health Insurance (NHI), but continues to fragment care and coverage, organizing subsidies by income, race (through the proxy of poverty), and age. What is at stake for the future is thus not this fragmentation; but the extent to which recent reforms that aim to expand entitlement and improve benefits will survive the vagaries of administrative complexities and future political developments. Economists, meanwhile, continue to dominate analysis of these policy questions.

Historical and Conceptual Frameworks

Various frameworks have been proposed for understanding the history of health insurance in the US; this section takes up three of them. In one, Daniel M. Fox has characterized three normative models for research on health care and health policy, social conflict, collective welfare, and economizing, this last having eclipsed the former two, especially since the 1980s. In another, Paul Starr divided the field into three eras during the twentieth century, according to the ways in which advocates of health insurance addressed the costs of sickness, direct and indirect, individual and social; and in his recent book, he has revised this model in the light of subsequent developments. In a third, Deborah Stone drew attention to persistent conflicts in American insurance arrangements between 'the solidarity principle' and 'actuarial fairness,' that is, in terms that describe the opposing social and economic functions that insurance has been taken to perform.

Advocates of the two older models in Fox's scheme were those possessing knowledge of the nascent social sciences and used them in support of expanding health services and improving access to them. Under social conflict, researchers held that health services, like food, clothing, and shelter, are essential; but that those better-off (or dominant) tend to withhold them from those less well-off (or belonging to socially subordinate or marginal groups). Expanding access and improving benefits under social conflict therefore became the subject of struggle on behalf of the poor and vulnerable; research aimed, inter alia, to document lack of access, its causes, and its consequences. Under collective welfare, researchers regarded health services as special, because they determine personal wellbeing if not indeed survival, and that attitudes of social solidarity, rather than conflict, require cultivation to bring more of the benefits of medicine to more people. Research tended to exhibit, inter alia, the consequences for health of diverse levels and goals of expenditure. Both models reflected not only a conviction, owing to the scientific innovations that began in the late-nineteenth century, that health services were effective, but also a commitment to social politics to provide citizens with shelter, in policy areas thought of fundamental importance, from the market arrangements that otherwise prevailed in economy and society.

Under the recently ascendant economizing model, in contrast, researchers have thought of care as largely similar to other commodities, best organized through markets, and they have regarded research as best conducted by exploiting economics (and several other sciences, especially epidemiology and biostatistics). Research has concerned the effectiveness of services, the functionality of reimbursement mechanisms and institutional arrangements, and the means to minimize the costs of expensive programs and to structure and fine-tune markets to improve efficiency and opportunities for choice. Under the economizing model, researchers have adopted a less openly normative posture, aiming less to press for new programs than to analyze for policymakers what exists and how (in the light of policymakers' values) it might be improved. In shifting from the older models to the economizing one, researchers, as Fox had once put it, moved from reform to relativism.

The two older of Fox's models dominated the first two of the three eras that Starr marks out in the history of health insurance. The earliest, that of 'Progressive Health Insurance,' represents the body of ideas that was prominent in the American Progressive Era (roughly, 1900–20) and that focused on sickness as one cause of poverty (via the consequent interruption of wages to workers and their families), as well as on the social causes of sickness. 'Sickness insurance,' as it was initially called, to be provided on the state level, would serve workers as a cushion against lost wages and, through its financing, create incentives to exploit public-health measures and industrial reforms that would reduce the extent of sickness and thereby improve national efficiency. Starr's 'Expansionary Health Insurance,' dominant in the period from the 1930s to the 1960s, marked a redirection of researchers' concern from lost income and public health to the direct costs of care. Introduced especially by the work of the Committee on the Costs of Medical Care (CCMC), active from 1927 to 1932 under philanthropic support, they focused on the rising costs of medical care (especially hospital services), owing to scientific innovation, and on the inability of both working and middle classes to meet them (particularly in view of their highly unequal incidence); but, in view of the benefits of care, called for insurance both to cover costs and to expand the health system.

This same period witnessed the first appearance in the US of significant programs of voluntary health insurance. These programs, did not, however, stop reformers from pressing for NHI in the 1940s and beyond. Around 1930, Blue Cross plans, fostered by the American Hospital Association, provided hospitalization insurance initially to employee groups and, starting roughly a decade later, Blue Shield plans, under the control of medical societies, provided insurance for physicians' services. Governmental policies emerging in the war years encouraged the spread of voluntary insurance (inter alia by permitting collective bargaining over fringe benefits, by making health insurance a fringe benefit untaxed for employees, and by allowing employers to deduct the costs of insurance from their taxable incomes). The labor movement, although in principle committed to public provision, nevertheless preferred this privatized form of the welfare state. Reformers still nurtured hopes of creating NHI, and especially from the 1940s they repeatedly tried and failed to secure it. Only in 1965 did they achieve a partial victory with the passage of Medicare (a federal program that provided health insurance for the elderly) and Medicaid (a federal-state program that provided insurance for some of the poor), as new titles under the Social Security Act of 1935. Medicare largely

reflected a social-insurance approach, but Medicaid, enacted as a reform of antecedent welfare programs, lay in the world of welfare and public assistance.

Although the partnership of social insurance with public health that marked American interest in health insurance from the beginnings persisted into the 1940s, the concern for health insurance gradually grew more fully allied with social insurance and its advocacy became associated more with the founders, architects, and administrators of the Social Security system than with experts in public health. In envisioning health policy for the postwar years, the Public Health Service developed proposals for federal support of medical education and research as well as planned hospital construction and expansion of personal health services under public-health auspices. Some features of this program, albeit in forms that accommodated medical and other interests, did emerge in the postwar years, but as a potential site for public provision, especially for the poor, public-health institutions gained little support. At the same time, figures from public health grew less active in pressing for either direct public provision of services or insurance. Meanwhile, a mixed public–private system grew dominant, consisting of nonprofit Blue plans, their for-profit competitors, and the two large governmental programs, Medicare and Medicaid, created by legislation of 1965.

These two public programs have worked under different administrative arrangements and operated in different policy environments. Administratively, Medicare lay under the Social Security Administration until 1977, when President Carter's incoming Secretary of the then Department of Health, Education, and Welfare (HEW), Joseph A. Califano, Jr. (1931–), moved it, together with Medicaid, into his newly created Health Care Financing Administration (HCFA; becoming in 2001 the Center for Medicare and Medicaid Services). Medicaid had been lodged in the welfare bureaucracy of HEW, where it had its own bureau, something it lost at HCFA, where it was overshadowed, morally and substantively, by Medicare. These administrative changes reflected Califano's goal of gaining administrative control over health and other programs in HEW and preparing the ground for NHI. Indeed, champions of Medicaid had generally aimed to sever its links with welfare and worked to render it a suitable vehicle for NHI by reducing state-by-state variations in the program and imposing broad standards of eligibility, benefits, funding levels, and accountability. However, whenever NHI was on the table, Medicaid received little attention, seen either as a thing to be dismantled under NHI or absorbed into it. Medicaid thus became no foundation for NHI but a large, diverse, and complex program for certain uninsurable people, for several categories of the poor, for the frail elderly, and for some of the disabled. Its opponents, however, tried to undermine its character as an entitlement and pressed for devolution of its administration and management to the states. Under the ACA, Medicaid is to serve as one element not in a broad system of NHI but as one enhanced and streamlined element of the larger health system, affording coverage to most of the poor, whereas other elements, public (especially Medicare) and private, continue to cover other groups. The ACA thus crowns an incremental strategy that preserves and reforms diverse preexisting forms of health insurance and financing, thereby perpetuating the difference between the poor and those with private coverage or social insurance.

Reformers saw Medicare and Medicaid as only a way-station on the route to NHI and, at the end of the 1960s, they renewed their push, hoping to cover those still uninsured (then approximately 10% of the population) and improving what often appeared to be inadequate benefits. Expansionary thinking persisted, though the gradually dawning implications of Medicare and Medicaid, which lodged large and rapidly escalating costs in the public purse, inspired the idea that NHI would provide the levers to rationalize the health system and rein in costs. Reform of the health system, dependent on governmental supervision and regulatory measures, would render affordable the expansion of entitlement. At least as late as the mid-1970s, passage of NHI, understood in this spirit, looked imminent; its failure, however, and the recession of 1974–75, which ended the long, postwar economic expansion that had fueled diverse public programs, now gave wider scope to novel ideas about health care policy. The prevailing consensus that had sustained standard modes of organizing and financing care, via fee-for-service payment of largely free-standing hospitals and solo or very small group physician practices, began to break down. So, too, did the conviction that NHI would have to take the form of a single system, governmentally mandated, planned, and regulated. New, and often conservative, voices had begun to suggest that market-based approaches to care could offer public policies that were efficient and accountable, and liberals pressing reform began to heed this advice, while persisting in emphasizing redistributive concerns, social equity, and (for some time) planning the organization of care.

Thus in the 1970s, began Starr's third era, that of '(Cost-) Containment Health Insurance,' whereas at the same time, policymakers and the researchers they financed, employed, or consulted felt the pull and fostered the growth of Fox's economizing model. Concern with expansion of entitlement persisted but in a manner that could foster rationalization of the health system and rein in cost escalation. As Starr remarks, pressure for and resistance to NHI had become competing versions of 'comprehensive reform' of the health system. From the conservative side, comprehensive reform revolved around diminishing traditional regulatory and other barriers to the functioning of markets in health care, application of stricter antitrust enforcement (especially to rein in the anticompetitive powers of the medical profession), and support for novel organizational arrangements such as 'health maintenance organizations' (HMOs). On the liberal side, comprehensive reform still meant universal coverage but, as the actions of Senator Edward M. Kennedy (1932–2009) increasingly revealed, involved a willingness to abandon demands for a single public system (like Medicare), to incorporate private innovation in the organization and supply of health services, and to exploit the power of competition to foster efficiency. In the hope of devising system-oriented reforms, economists and other researchers began to focus on market-oriented precedents and innovations.

Two new groups of reformers emerged, the one consisting chiefly economists like Mark V. Pauly (1941–), Martin Feldstein (1939–), and Joseph P. Newhouse (1942–); and the other, comprising a diverse group of professionals, including Paul M. Ellwood, Jr. (1926–, a physician with background in rehabilitation medicine); Ellwood's associate, Walter McClure

(1937–, who came to health policy from physics); Alain C. Enthoven (1930–, an economist with background, inter alia, in defense policy); and Clark C. Havighurst (1933–, a professor of law deeply interested in antitrust). Both groups hoped to exploit the persistent interest in improving entitlement to foster a more frankly market-based system. The former group aimed to create supply-side measures that would enable consumer choice in a market setting, relying on consumer sovereignty at the point of service to discipline the supply side and using income-graduated subsidies to bring the poor into the market; the latter, while exploiting similar thinking, also believed that the problems of health care could be remedied only by transforming the supply side of the market through HMOs to apply incentives directly to physicians and competition at the point of enrollment and prospective payment by capitation to encourage efficient practice. These newer approaches to public policy, although initially exotic-seeming to policymakers and to most earlier experts, gradually grew familiar, and market-based health care, as analyzed and explored by economists such as these and those receptive to their influence, became the dominant mode of thinking about health policy. The very intellectual foundations for thinking about public policy had been transformed.

Stone's classification also exploits historical analysis but it takes up a different set of the social and economic functions of insurance from those Starr emphasized. Her central question is how one should regard medical care: as something to which citizens have a right or as merely another commodity available to consumers through markets. This bifurcation has manifested itself between the divergent appeal of equity as understood in the commercial insurance industry ('actuarial fairness' being Stone's term for risk-rating of insurance) and equity as understood among advocates of social conflict and collective welfare as providing for need medically defined (Stone's 'solidarity principle'). Actuarial fairness operates by fragmenting communities into ever narrower risk groups, by emphasizing the differences among groups and by fostering the perception that individuals are responsible primarily for themselves and far less for others. Taken to its logical conclusion, actuarial fairness could shrink the risk group to the individual level, ending the mutual aid provided by insurance. Overall, actuarial fairness distributes care in inverse relation to need (however conceived), and it undermines among citizens a sense of participation in community and a conviction that community members possess mutual obligations.

In this analysis, the solidarity principle acts in the opposite direction, by broadening risk pools, by emphasizing shared traits among members of groups and members' reciprocal responsibilities and by assuring that the healthy subsidize the sick. The solidarity principle thus preserves mutual aid through the mechanism of social insurance. The historical dimension of Stone's study lies in its recounting the emergence, development, and deployment within the life-insurance industry of underwriting as a means to reduce subsidies across risk classes; the entry of underwriting into commercial health-insurance markets; and the appearance of its diverse forms of exploitation in health-insurance mechanisms. The study also points to developments current as of when she wrote that had conspired to expose to scrutiny the propriety of actuarial fairness; however, Stone finds actuarial fairness so deeply rooted in American culture that she ends her discussion on a pessimistic note about the prospects for health reform, than becoming a reinvigorated topic. However, recent reforms that aimed to expand entitlement indeed have entailed limits on underwriting. The ACA rests on the principle that price, efficiency, and generally value for money should be the focus of competition among insurers rather than characteristics of individuals, such as their preexisting conditions and health status.

If Stone's analysis emphasizes subsidies across risk groups, so that the healthy subsidize the sick, Starr's emphasizes a different social function of insurance, subsidy across income classes, so that the rich (or the better-off) subsidize the poor (or less well-off). Because in both cases financial obstacles loom large (in the latter because the poor lack ability to pay and in the former because serious illness can entail major economic loss), discussion of 'ability-to-pay' can obscure the distinction between the two kinds of subsidies. The earlier history of health insurance in America separated them fairly clearly, later they grew blurred, but in the ACA they have again become more distinct. The early Blue Cross plans, which emerged in the 1930s to provide the working and middle classes with hospital insurance, usually as a fringe benefit of employment, rested on community rating; i.e., they charged the same premium to subscribers regardless of risk class. The healthy subsidized the ill, but the extent of redistribution was modest, given that most subscribers, being of working age and employed, were largely healthy. The appearance of competing commercial insurers, which exploited experience rating, forced the Blue Cross plans to constrain or abandon community rating, thus squeezing out the subsidy across risk classes. The rise and development of managed care, especially in the 1990s, reinstated the subsidy across risk classes, in that managed care plans promised comprehensive benefits on a capitated basis to all members of an insured employment group for the same premium. However, the 'managed-care backlash' of the late-1990s, which rested in great measure on the perception that the utilization controls exerted by managed care organizations were a back-door way to renege on the commitment to provide comprehensive benefits with low copayments, led employers and insurers to back off from utilization controls and employ a diversity of more or less flexible, networked products to cater to the wishes of both employers and employees. One result was new constraints on the subsidy across risk classes.

In the case of the American Medicare Program, the basic program, Part A, hospitalization insurance for the elderly (who had not participated in the Blue plans) took wing as a way to provide the elderly a governmentally financed version of Blue Cross. However, in this case, the boundary between the two kinds of subsidy grew blurred. In part, the elderly, having left the work force, lacked income to pay for insurance; the program therefore subsidized those who were less well-off financially. However, it was the actuarial practices of commercial insurance, the exclusion of the elderly from the community rating offered by Blue Cross and the eventual departure of Blue Cross from community rating that had in effect turned a risk class – the elderly are sicker and, with purchasing power, would use more care – into an income class. By fragmenting risk pools, private underwriting made

health insurance and thus care unaffordable to many of the elderly. Similarly, any groups facing high prices because of high risk or no prices because underwriters had labeled them 'uninsurable' could not afford (or perhaps even find a venue in which to consider the possibility of affording) to pay. A risk group becomes an income group needing a subsidy. The Medicaid program, for the poor, primarily subsidizes an income group, but to the extent that its beneficiaries have lower health status than the rest of the population and thus constitute a risk group, the program subsidizes across risk groups, i.e., healthy (and better-off) taxpayers subsidize care for the unhealthy poor; the same effect can be seen among the low-income elderly on Medicare. The diversity of programs in other advanced countries also exhibit many such complexities in the nature of the subsidies that social insurance provides.

In the US, convolutions of this kind have made for difficulty in maintaining the political stability of public programs. Neither its supporters nor its opponents thought of Medicare as an end point or irrevocable commitment in social policy; rather its opponents have continued to criticize it and attempted reforms that would reduce its costs, its economic prominence, and its character as an entitlement, whereas its defenders have seen it as an expression of social-insurance principles that they have sought to extend to the entire population. However, persistent lack of a coherent rationale for the Medicare program, whether in the failure to tailor its benefits to its target populations or to provide cogent justification for it as an element of social policy, has made it possible for diverse interpretations to come to bear on it that continue to fuel debates about its future and its reform, particularly as its costs have continued to grow. Although its proponents have seen it as a partial realization of a right to care, some analysts have argued that a different sort of stability is what had anchored health care entitlements in America: programmatic rights. Controversial programs have often found stability less in a clear rationale in social policy than in the persistence of existing programs on the ground; in their support by activist courts, congressional entrepreneurs, and activists who looked to the federal government (and not the states) for leadership in social policy; and in the expectations accumulating since the New Deal among beneficiaries (current and future) that government bears responsibility for alleviating social problems. Sometimes controversial programs like Medicare thus became invested with 'programmatic rights' that stabilized their politics. Medicare may indeed have become cloaked in such rights, particularly insofar as it had been sold by its founders as a form of insurance for which beneficiaries, while in the labor force, paid through payroll deduction. However, in the current policy environment – characterized by the high cost of governmental programs and large, governmental deficits – programmatic rights seem unlikely to sustain support for these two large public health care insurance programs. If advocates are to preserve them, clear articulation of rationale and reforms in financing and may become essential.

A similar analysis clarifies the ACA. It offers both kinds of subsidy that Starr and Stone discuss: across risk groups (and hence the importance of risk adjustment under its provisions; and across income classes (as embodied in its reforms of Medicaid and in the construction of state insurance exchanges for subsidized purchase of insurance by those not covered under employment-related or public-insurance programs). The two functions of social insurance have thus become more evident under the ACA (although persistent fragmentation of risk pools still keeps them less than fully distinct). The public, however, little understands the provisions of the act. Although the gradual implementation of its provisions would likely clarify its meaning and elicit support from its beneficiaries, its political viability, in view of the controversy surrounding it, seems dependent on the success of its advocates in articulating for it a clear rationale; in tuning its provisions to suit its target populations; and in assuring a worried public still focused on programmatic rights and confused about assaults on the legitimacy of entitlements that hitherto favored programs will not erode; and in parrying claims that budgetary imperatives must entail transformation, as opposed to reform, of costly public programs. Because many cost-control measures employed in other advanced countries have thus far proven politically unacceptable in the US, advocates of public programs have struggled to find means to rein in costs while upholding the legitimacy of continued, high levels of spending in public programs of health insurance.

Social Politics and Social Science: Securing Refuge from the Market

Analysis of health insurance began in the context of thought about social politics. From the late-nineteenth century through the end of the New Deal, American analysts of social problems participated in a largely North-Atlantic culture of social politics, in which shared conceptions of social vulnerability to the transformations wrought by industrial capitalism inspired a cluster of convictions about social policy. Thus, industrializing nations needed broadly similar policies, less to achieve specific, shared goals or a common form of polity (e.g., a welfare state or a social-insurance state) than to shelter some features of social and communal life from the reign of the market. There was also a sense that some countries had moved farther or faster in that direction than other, lagging ones (especially America) and an expectation that experiences in one country could be studied for their utility to others and perhaps imported with modifications. In America, reformers felt the appeal of European experience and hoped to import foreign ideas and modify them to suit American conditions. To analyze both European experience and American possibilities, many reformers aspired to exploit the then nascent social sciences. Some possessed either formal training in the social sciences or, in their capacities as journalists, social critics, rationalizers of business and intellectual brokers, substantive knowledge of them. A major element in the emergence of the social sciences was the tension between the participation of social scientists in reform and advocacy on the one hand and, on the other, their exercise of dispassionate scientific objectivity to gain fundamental scientific knowledge, i.e., the tension between Fox's reform and relativism. Those early health reformers who came from the ranks of social scientists and from public health clearly understood themselves as exploiting their

scientific knowledge in the service of social reform. Although their reformism eventually moderated and narrowed, the change was gradual and never complete. Only beginning in the late-1950s and especially in the 1960s, did analysts harness formal and recognizably modern economic analysis to health policy, and in that context as well, normative considerations, while circumscribed, have marked even the most ostensibly positive analyses.

Thus Starr's Progressive Health Insurance had much in common with later thinking about health insurance, but it articulated more explicitly than later proposals the rationale for distributive justice. Capitalist development, as reformers saw it, having imposed most of its costs but few of its benefits on labor, left workers facing primarily four risks, unemployment, accident, illness and old age, all of which portended the impoverishment and immiseration of workers and their families. To remedy the problems resultant from the realization of these risks, reformers recommended social insurance and, specifically in the case of health care, they pressed for 'sickness insurance' primarily to cover its indirect costs, especially loss of income. They understood that such measures would require political support and exerted themselves in various ways to achieve it. Reformers like Isaac Max Rubinow (1875–1936) aimed to enroll fellow reformers into a coalition, to which they hoped to recruit leaders of the major interests (business, labor, the medical profession). A reform tradition descending from John R. Commons (1862–1945) at the University of Wisconsin hoped to create support by showing that the workers, industry, and the public possessed shared interests in workers' well-being. Reformers aimed, in a word, to create a broad sense of social solidarity that would undergird reform coalitions. However, these reformers failed to parry opposition from diverse, well-organized interests, and, in the Progressive Era, their efforts came to naught.

In Starr's expansionary era, however, advocates again pressed for health insurance, this time emphasizing the direct costs of medical care and the social costs resulting from deficiencies in its accessibility and limitations on its availability. In doing so, however, they rarely let notions of social justice take center stage. Instead, reformers and advocates emphasized two things: the efficacy of care and the peculiar economic features of health care and the health sector. With regard to the first, reformers became deeply impressed with the advances in medical science during the late-nineteenth and early-twentieth centuries and convinced that care was of tremendous value. They therefore articulated the notion of need, urged from the outset of the expansionary era in the work of the CCMC. The committee invoked insurance not only as a mechanism to enhance access to needed services, but, out of the conviction that the health sector was inadequately developed to meet the needs of even those who could afford care, also as a method to finance the expansion of health resources (hospitals, clinics, technology, and trained personnel).

Not only efficacy suggested the importance of care but also the apparent implications emergent from early economic analysis of health care and the health sector. Analysts repeatedly identified and characterized the poor fit of health care, as opposed to most conventional commodities, with the standard tools and procedures of economic analysis, and these economic peculiarities seemed, in advocates' minds, to reflect the special moral and social significance of health and health care. Thus, analysts showed that health care differed from other commodities in several economically significant ways – in modern terms, that the demand for health care is derived from the demand for health; that health care exhibits externalities (costs or benefits involving parties outside of a transaction); that providers and patients-qua-consumers exhibit informational asymmetries (i.e., consumers are ignorant of what had recently become a recondite and technical field of scientific medicine inaccessible to those without long and arduous training); and that patients experience uncertainty regarding both the need for and effectiveness of care. In its simultaneous possession of these economically distinguishing characteristics, health care, in the eyes of reformers, was very nearly unique. In the light of these peculiarities, society had limited the extent to which market principles applied to health care, for example, through professional self-regulation, nonprofit organization of hospitals, support for programs to enlarge the health sector and to facilitate access to it; and charitable and philanthropic arrangements that served both poor and the middle class. As seen by advocates of insurance, the economic peculiarities of care, precisely because of its often little-articulated moral significance, had given rise to social arrangements that replaced standard market arrangements and thereby expressed underlying commitments to social justice.

However, corrosive forces were at work. These elicited more explicit articulation of noneconomic rationales for distributing care equitably. From the early-1970s and lasting in significant measure to the present, some voices, concerned about costs and mindful of the lack of knowledge about the effectiveness of care, expressed skepticism about the value of especially high-technology care, at least at the margin. Notions of need, that is, having begun to grow intellectually exiguous, newer analysts such as Mark Pauly began to suggest that consumers, as opposed to experts, should be allowed to exercise choice in a relatively unfettered market. In response to such growing uncertainty about the value of health care and its implications that markets need not be constrained, some proponents of redistributive policies found an additional rationale for the nonmarket arrangements prevalent in the health sector – they directly express the existence and value of social cohesiveness, of inclusive sentiments about the poor and the sick, of a will to maintain and preserve the dignity of all citizens, and of a tendency to evaluate positively lives that are not conventionally economically productive (children, the elderly, and the disabled). Figures holding these views sometimes accorded the intangible features expressed in redistributive measures in health care a priority that equaled or exceeded that of the substantive economic benefits (reduction of individual and social costs) that access to care could bring. More recent analysts, responding to the eclipse of distributional rationales for public programs under pressure of market-based health policy, have taken a similar approach, to exhibit and therefore justify perpetuating the solidarity foundations that public programs seemed to them to possess even beyond the value of the concrete medical benefits they confer.

The Eroding Aura of Medicine and the Opening to Market-Based Thinking

Cultural developments, emergent or newly prominent after World War II, exerted corrosive effects on the notion, long animating reformers, that health care and its providers possessed special qualities. Paradoxically, the organized medical profession itself was one agent of this change: while defending itself against governmental intrusion into medical care aimed at advancing entitlement to coverage, the profession portrayed the purchase of medical care as just another consumption decision, one often overshadowed by consumers' preferences for other goods and services. Lack of ability to pay seemed beside the point; supposedly unmet need, from this perspective, should be regarded not as a reflection of deficient public policy but as an anticipated outcome of a consumer society in which demand (not need) dictated the distribution of care. Health care, as another commodity, belonged not in the purview of redistributive policies, but in that of the market, where consumers could take of it what they wanted. Of course, for physicians the market was the one they had helped create and preserve, but upholding it in the face of consumerism would prove more and more difficult, for if the services that physicians purveyed were not so special, neither were the purveyors. Factors that diminished the personal ties in physician–patient relationships and substituted a remote professionalism led patients to take a more dispassionate view of their doctors. An increasingly well-insured suburban middle class viewed medical care as it did other, especially professional services, that is, as routinely available for purchase and subject to scrutiny with a consumer's eye. Social scientists, moreover, had revealed with some surprise that the high-minded professionalism of medicine seemed to cover professionally self-interested behavior. Culturally, health care formed part of the broader changes in the culture of consumption and individualism that gave precedence to the market ahead of government and politics and that gave priority to free choice over paternalism and sentiments of social solidarity and inclusiveness. Consumers increasingly expected to make market choices for services that reflected their own sense of what they wanted and needed.

This was the state of affairs that emerged in the beginning of the 1970s and set the stage for the appearance of market-based health policy: traditional reformers pressed for a governmental program of NHI in the light of their conceptions of solidarity and social justice; cost escalation, particularly under Medicare and Medicaid, suggested the need for systemic reform; medicine and its practitioners itself suffered loss of prestige; some newer voices began to doubt prevailing notions of need, thought of care as a commodity, and claimed that health care should be allowed to operate in the market; and traditional advocates of NHI responded by emphasizing that broadened entitlement to care can express and foster solidarity and social justice. Meanwhile, the social sciences, especially economics, began to suggest novel policy ideas that, their practitioners held, could accomplish system reform and redistributive goals better than further application of prevailing policy methods. The next article takes up the immediate cultural and intellectual developments that gave scope to market-based notions of health policy, it pursues the intellectual history of market-oriented health care, and it suggests how the evolution of markets have both reflected and affected novel policy positions.

Health Insurance in Historical Perspective, II: The Rise of Market-Oriented Health Policy and Healthcare

EM Melhado, University of Illinois at Urbana–Champaign, Urbana, IL, USA

Introduction

Health Insurance in Historical Perspective, Part I explored several frameworks for understanding the evolution of American thought about health insurance; examined the belief of traditional reformers that health insurance should serve as one of a cluster of measures designed to secure citizens from the risks posed by capitalistic markets; suggested that, in an environment of escalating healthcare costs, doubts about the value of healthcare had led some reformers to stress its significance less for its substantive benefits than for its utility as an expression of social solidarity; noted the factors that undermined the special status of medicine and medical care; and indicated that medical care, in the eyes of diverse analysts, increasingly resembled other commodities traded in conventional markets. This article opens by characterizing the two broad forms that American proposals for market-based health policy initially assumed: one resting on modern economic analysis of the demand side of healthcare markets and the other, initially depending far less heavily on formal economic analysis, but reflecting the conviction that public purposes could better be realized through supply-side reforms. The article reveals the extent to which some of the founding ideas and concerns of health economics arose through analysis of the health sector when national health insurance (NHI) seemed imminent; and it briefly explores the consequences of these developments for the history of ideas about health insurance and for the development of healthcare markets on the ground. It offers conclusions about both the kinds of reform measures that American health policy has generated and role of economists in health policy.

From Advocating Care to Reforming Health Insurance

More than changing cultural perceptions of medicine helped elicit market-based thinking in health policy. From the late 1960s, and especially in the light of cost escalation that followed the introduction of Medicare and Medicaid, American healthcare became the subject of scrutiny that began to reveal shortcomings that would have to be remedied under any system of NHI. Cost escalation, the most pressing, was in a sense only a symptom of increasingly nonfunctional features of American healthcare. The health sector appeared to be an uncoordinated profusion of chiefly solo or small-group physician practices; freestanding, independent hospitals; and a diversity of public and private insurance programs. The fragmentation of the health sector, its maldistribution of resources, and its inability to tailor resources to needs on a community level or services to individuals in and among local institutions constituted a set of problems that experts as well as the public hoped to remedy. Pressure for NHI, that is, had become transformed into pressure for broad reform of the health system.

Until the end of the 1970s, NHI had seemed imminent, although in retrospect the apparently close but still abortive effort to achieve it in 1974 brought its short-term prospects to an end. For many traditional reformers, planning and regulation that they expected to take root under NHI would provide the levers to rationalize the distribution and deployment of resources and rein in costs; the resultant efficiency gains would provide the resources to expand and improve entitlements to health services. In their view, system reform amounted to more extensive and more thorough-going application of traditional policy means. However, other analysts of cost escalation and fragmentation exploited the prevailing interest in NHI as a vehicle to introduce novel ideas about the utility of markets and competition to solve the problems of healthcare. Two clusters of proposals emerged from their efforts: Reform of the demand side of the market through the imposition of increased cost-sharing under insurance (that is, increased out-of-pocket expenditures for insured individuals and families), combined with subsidies, graduated inversely with income, to insure the poor; and reform of the supply side of the market by creation of health maintenance organizations (HMOs) or other health plans that combined the delivery of healthcare and the insurance mechanisms to finance it. The roles of economics (and some other social sciences) in early studies of health insurance can be examined by tracing the emergence of these two categories of proposals.

Income-Graduated Cost-Sharing

Within economics it was the application of formal doctrines that increasingly subsumed healthcare under the rubric 'commodity.' The implications of the change emerged in at least two stages, one in which traditional advocates of NHI began to apply to healthcare (among other areas of policy) formal rationales for governmental provision and a second, in which skepticism about governmental provision combined with economic analyses to undermine the case for the specialness of care and therefore suggest the propriety of its subordination to market arrangements.

The first stage is represented by the tradition of public-expenditure analysis, which emerged in the 1960s as part of the effort to rationalize governmental financing or provision of public services. Whereas an economist like Seymour E. Harris (1897–1974), in his study of American medicine, exemplified traditional advocacy for increasing the quantity, improving the quality, and rationalizing the distribution of health services, Herbert Klarman (1917–99), in a major, early review of health economics, maintained that only those health programs that made better use of resources than alternative ones could find economic justification. However,

 doi:10.1016/B978-0-12-375678-7.00926-3

this orientation did not deflect needs-based analyses. Animated by concern for the social costs of lack of care, analysts regarded care as an investment in human capital and exploited the cost-benefit principles previously developed in analyzing governmental investments in water projects. Needs-based thinking had supposed that the demand for care depended all but exclusively on epidemiological, scientific, and technological factors; but a more dispassionate economic analysis provided evidence that care resembles other commodities in that its demand also depended on the economic variables of income and price (i.e., demand for care exhibited income and price elasticities). Nevertheless, from a needs-based perspective, such evidence could be reinterpreted: to recognize that insurance (a price subsidy) improves access to care is less to acknowledge the price elasticity of demand than to welcome the shift brought by insurance of a deprived population into the ranks of those able to acquire one of the necessities of life. Similarly, income effects among the insured wealthy need not have been taken to imply the dependence of demand on price. The wealthy buy more services because they have more education and appreciate more the value of care. From a needs-based standpoint, evidence for the commodity-like behavior of care therefore carried little weight, and it authorized reliance not on novel markets but on planning. Indeed, one of the economically characteristic features of healthcare, informational asymmetries, and the consequent dependence of patients on experts, only reinforced the conviction that nonmarket arrangements were preferred, if not indeed necessary.

Although cultural changes noted in the previous article helped divest care of its special characteristics, developments within the social sciences fostered a reorientation among formal analysts of public policy. A novel and powerful approach to analyzing both politics and policy, known as 'public choice,' particularly as undertaken by one of its founders and leading lights, James M. Buchanan (1919–2013), suggested that the virtues of public provision had been overrated. In a study of public goods, Buchanan revised the case for special social arrangements, especially public provision and production of certain goods. Acknowledging the desire of some citizens to increase the consumption of particular goods by all citizens, he could treat the individual's consumption as enhanced by an external benefit. His analysis suggested, moreover, that unlike cases such as national defense or fire and police protection, such 'externalities in consumption' need imply no monolithic supply, for example, governmental provision. Externalities in consumption could be provided in conventional markets by private producers so long as the community participates (through financing) in purchasing the goods or services. Buchanan's position departed from that represented by Paul Samuelson (1915–2009), one of the major analysts of public goods, whose approach Buchanan regarded as excessively prescriptive (i.e., paternalistic). Buchanan thus provided a path for analyzing healthcare that opened the door to subsuming it under more conventional market arrangements.

It was Buchanan's student, Mark V. Pauly (1941–), eventually to become one of the most distinguished of American health economists, who first took that path (1971), although Martin S. Feldstein (1939–), having undertaken an econometric analysis of the British National Health Service, was working along similar lines in the early 1970s; indeed, the two exerted a mutual influence. Although some others had in principle reduced calls for NHI to externalities in consumption, it was Pauly who first unequivocally translated notions about the specialness of care into support for a tax-financed program of subsidies. Pauly's question was how to optimize the subsidy. His analysis took the unequal distribution of income as given, assumed that demand for care responds to price and income – i.e., he accepted frankly that price and income elasticities suggested that care is an ordinary commodity – and anticipated that different consumers would have different levels of care. This last point also departed from traditional social justice rationales for care, which largely anticipated that NHI would provide a uniform standard of care. His analysis led him to propose 'variable subsidy insurance' (VSI). For the poorest it would prove comprehensive coverage at low or zero premium cost; for those with middle incomes, it would subsidize demand by paying part of the premium cost (perhaps to an extent that varies inversely with income) and impose deductibles and/or coinsurance that would increase with income; for the wealthy, it would supply a catastrophic policy, i.e., one that would pay only for the most expensive forms of care. The cost-sharing provisions would constrain utilization (and thus respond to growing concerns, intensified by talk of NHI, about cost escalation). Almost simultaneously, Feldstein offered a similar proposal for 'major risk insurance' (MRI).

These proposals carried important implications both for improving public policy and for exhibiting the value of economics – and some implications of its use – as a means for analyzing policy. In regard primarily to the substance of policy, several features stand out. In acknowledging the desire of some citizens to increase consumption of care by others, the proposals gave expression to social solidarity. They do so, moreover, by assuring taxpayer sovereignty: the taxpayers decide what services to subsidize, for whom, and to what extent. In recognizing that diverse consumers (because of differences in their 'tastes' for care and in their income) would exhibit diverse levels of demand for care and in according a minimal role to expert determination of need, the proposals expressed consumer sovereignty. In granting the poor, as traditional reformers had wanted, the same rights as those better-off to make choices from among the same providers in the same private markets, the proposals emphasized that aspect of social solidarity that focused on inclusiveness and mutual regard across income classes. However, in rejecting a universal standard of care, the proposals drew back from the distributive imperatives underlying older notions of solidarity. This result followed in part from the economic tools that underlay the proposals. The optimization procedures of welfare economics aimed to enhance allocative efficiency – the efficiency with which resources are distributed among consumers - in that a system of graduated subsidies under cost-sharing would achieve a reasonably tight match between the income of consumers and the socially desired enhancement to their consumption of care. In addition, any market operating under these proposals would help constrain social costs by fostering productive efficiency: In competing for the business of patients with purchasing power, healthcare providers would have to show themselves frugal in using the funds brought to

healthcare transactions by insured consumers who would have to foot a significant part of the bill. Providers would seek either to produce a given level of care more efficiently or offer services of perhaps reduced (but still positive) benefit but at lower cost. Physicians and hospitals, that is, would have to become the financial, as well as the medical fiduciaries of their patients. Finally, because the proposals left market mechanisms largely undisturbed (except to the extent the supply side would evolve on its own under such a system of subsidies and cost-sharing), they offered a means to resolve controversy among economists about separating efficiency in the allocation of health services (achieved through the exercise of consumer choice under cost-sharing) from distributional equity in access to health services (achieved through income-graduated public subsidies).

Two additional features of the work by Pauly and Feldstein merit attention. One is their discussion of 'moral hazard,' the tendency of insurance itself to foster the occurrence of the risks against which it provides protection, so named by the insurance industry to signal the 'abuse' of insurance by policy holders. In the case of healthcare, under an insurance scheme that, absent cost-sharing, affords a zero price at the point of service, the insured will purchase more care than otherwise. Pauly regarded the effect not as morally dubious but as rational. It implies that a taxation scheme that compels citizens to pay for insurance against certain risks is inefficient, because, under the scheme, some consumers would have to pay more than they would want to; some consumers, in a word, would benefit from purchasing a lower standard of care. Moreover, cost-sharing, by reducing demand and thus constraining utilization, would reduce the premium of insurance and therefore could make desirable a policy otherwise unattractive to some consumers. The effect of coinsurance, for example, depends on the elasticity of demand, which varies among consumers; an optimal policy would thus similarly vary. Hence, the utility of such schemes as VSI: Income-graduate subsidy would encourage socially desired utilization (i.e., the increased consumption by some consumers that others desired); and income-graduated cost-sharing would improve the efficiency of the resultant allocation.

Feldstein, responding to Pauly's view of moral hazard, showed in the case of the hospital industry that the stimulation of demand that insurance occasions has a special characteristic: it results in increased prices, which in turn elicit more insurance, i.e., it produces a circular effect that, although not explosive, provided strong evidence in support of cost-sharing. Moreover, the government further stimulates demand via the tax treatment of health insurance (primarily, that the health benefits that employers provide employees are exempt from employees' income tax), from which Feldstein drew two conclusions: (1) tax subsidies make the net cost of an insurance premium fall below the expected value of the benefits; and (2) they encourage employees to substitute for taxable wages more comprehensive (but shallow) insurance. Insurance then provides first-dollar coverage for modest expenses, but little coverage for catastrophic ones. It was in the light of these concerns that Feldstein devised MRI. Health insurance, previously seen as a solution to the problem of achieving access to health services, itself now became the source of two problems: intensive price inflation and inappropriate forms of coverage. Older advocates of health insurance had insisted on universal, comprehensive benefits as following from the high social valuation of healthcare; now, their approach seemed to be an artifact of faulty policies. In the newer view, allowing some consumers to purchase a lower standard of care would not only serve the cause of efficiency but it might also help overcome the political obstacles to NHI. As Pauly observed after over a decade of discussion about the virtues of NHI and of its possible forms, advocates of comprehensive NHI had kept the poor and those suffering from catastrophic illness from obtaining a standard of care that, if lower, was nevertheless, for them, more desirable.

These concerns lay in the background to the RAND health insurance experiment (HIE), one of the most ambitious social experiments ever undertaken. Conducted over the period from about 1974 to about 1982 by the RAND Corporation, a nonprofit organization that contracts with diverse organizations to carry out research and policy analysis, the experiment emerged from the War on Poverty amid discussions of how to arrange financing of care for the poor. The principal issue around which it took form was the lack of consensus about the effects of increased demand (through expanded entitlement and improvement of benefits) and about the effects of cost-sharing, on both utilization and health, in constraining demand. This is not the place to discuss either its origins and evolution or underlying economic concepts; for present purposes, only some of its conclusions merit attention. The experiment indicated a price elasticity of -0.1 to -0.3 for most kinds of health services (i.e., an increase in price of 1% would decrease quantity demanded from between 0.1% and 0.3%). Although the measured elasticities were modest, the experiment seemed to show that consumers do adjust usage to price; that excessive insurance does seem to result from moral hazard; that cost-sharing does constrain use, even for hospitalization; that these changes, for all but the sick poor, had little effect on health; and that therefore cost-sharing can serve as a sound instrument of public policy that aims to constrain costs. The implication seems to have been that much of the care provided to most consumers lay on what Alain C. Enthoven (1930–), a prominent advocate of healthcare markets, called the 'flat-of-the-curve' (i.e., where the initially upward graph of benefits of care as a function of their costs flattens, indicating that additional expenditures on care provide no health benefits).

However, in constraining use, cost-sharing did not, as its advocates hoped, limit chiefly ineffective care. Cost-sharing was therefore a blunt instrument, but its impact, at least on the nonpoor, seemed positive, for the reduction of utilization it achieved did not have an adverse effect on health. Pauly and Feldstein had justified consumer sovereignty with reference to lack of knowledge about the outcomes of care. The RAND group, which had classified forms of care into the categories of 'effective' and 'ineffective,' now argued that the failure, even of care it classified as effective, to affect health under a variety of insurance schemes that fostered reduced utilization authorized the same conclusion.

Cost-Sharing, the Poor, and the Value of Services

However, the message issuing from the experiment was not univocal. The HIE revealed that, in regard to the poor,

especially the ill poor, cost-sharing could entrain adverse effects on health; that is, the failure of the poor, under cost-sharing, to obtain some effective services led to reductions in their health status. Diverse policy responses could be devised to bring such services to the poor. One would establish targeted programs to supply specific services to the poor, although not all services are amenable to this approach. Others might exploit screening programs, but in large populations their costs exceed their benefits. Moreover, as critics of market-based care have argued, the likely confinement of this measure to public programs risks offense to standards of equity and the dignity of the poor. Yet another would supply insurance but exempt the poor from cost-sharing, as Pauly had suggested and as, under Medicaid, they largely had been, although maintaining a separate Medicaid program rather than the imposition of a general income-graduated cost-sharing would continue to stigmatize the poor, which is indeed the approach taken by the Obama reforms under the Affordable Care Act (ACA, i.e., the Patient Protection and ACA, PL 111–148; as amended by the Health Care and Education Reconciliation Act, P.L. 111–152, passed in March 2010). Another approach, also taken under the ACA, would impose on individuals and families a modest level of income-graduated cost-sharing and provide income-graduated subsidies, as the likes of Pauly, Feldstein, and the RAND group had been discussing. Yet another measure would be to structure coinsurance so as to foster coverage of effective services, an approach that draws strength from recent research on the effectiveness of care, although the still small proportion of services that have been evaluated limits the usefulness of this practice.

Other policy responses might be devised; however, more important than the prospect of modest cost-sharing in any version of NHI, the experimenters acknowledged, was the difference between some insurance and none. Nevertheless, in regard to the poor, the RAND group was reticent, leaving to policymakers to decide whether the experimental results should authorize public provision of care to the sick poor. The normative case for cost-sharing for the nonpoor, in other words, was for the researchers overwhelming; but for the poor they aimed only to narrow public debate by providing concrete experimental results, not to propose whether and if so how to expand entitlement to services. For the poor, if not for the better-off, relativism, not reform, is what characterized analysts of health policy.

The experiment has exerted an enduring influence in American health policy, particularly in its emphasis on the utility of demand-side measures – which have received far greater application in America than in other advanced countries – to constrain utilization. However, subsequent developments have changed the context for assessing its implications. A growing body of more recent research has suggested much more strongly than the HIE that uninsurance and underinsurance, especially for the poor, entrains poor health outcomes and that improving Medicaid and other kinds of coverage entails positive health benefits. By strengthening previously attenuated convictions about the effectiveness of care, these results have enhanced the case for redistribution to cover effective services, whether routine and inexpensive (such as blood pressure monitoring and in general management of chronic diseases) or less frequent but much more costly (such as organ transplants or care for heart disease or cancer), especially but not only for the sick poor.

Indeed, Nyman argues that advocates of cost-sharing have failed to understand a point that reformers have been making since early in the past century: insurance is needed to secure access to forms of care that are not affordable even by the middle class and that are medically valuable, even life-saving; insurance, that is, possesses what Nyman dubs its 'access value.' In these cases, the exercise of moral hazard, that is, the purchase of more care than would be purchased without insurance, is precisely the point, for it gives access to valuable services that would otherwise be inaccessible. Because the payoff from insurance amounts to an increment to income, Nyman argues, the purchasing decisions of a seriously ill person with insurance reflect not a shift along the demand curve, as most economists assume, but a shift of the curve outward. Discouraging consumption through cost-sharing of services that are valuable and expensive is therefore welfare reducing, because it limits the access value; at the same time, excessive consumption of less urgently needed or less valuable care may be a relatively minor effect of insurance. Pauly, a major architect of the moral-hazard argument, eventually recognized that its applicability to the seriously ill and the services they need had not been adequately studied. The HIE therefore provides little assistance for policymakers in deciding the extent to which especially expensive services should become available to Americans, both poor and better-off.

These reflections, which result from new research that occasioned reevaluation of the RAND HIE, clearly implicate both sides of the market, although the HIE itself had focused on the demand side. The figures such as Pauly and Feldstein who had suggested demand-side reforms at first actively opposed reconstruction of the supply side of the market. Reconstruction would require a major role for government, but the newer approaches to public policy took inspiration precisely from what their advocates regarded as governmental failures, especially under traditional regulatory regimes (which had been under attack since the Carter administration). By contrast, incentive-based reforms, to which Charles L. Schultze (1924–) later gave systematic articulation, sidestepped any meddlesome and likely counterproductive governmental intrusion into the economy, and it reduced the risk of antagonizing the major interests, especially the providers of healthcare. Instead of what Schultze called the 'command-and-control' characteristic of regulatory regimes and the 'perverse incentives' operating under them – terms that helped put much wind in the sails of Schultze's ideas – incentives that aligned the interests of actors with public purposes could serve public policy more efficiently in both economic and political senses. Moreover, economists believed that demand-side reforms that responded to concerns for the inflationary effects of insurance (e.g., reducing the tax subsidies of health insurance), could achieve with reasonable promptness and certainty the savings anticipated by theorists, whereas ambitious structural reforms might not work and entail severe unintended consequences. Supply-side innovations, nevertheless, had their advocates, and the evolution of markets on the ground has taken place in a context defined by their concerns and their vocabulary.

Healthcare Plans

Indeed, it was roughly simultaneously with demand-side analyses that an alternative, supply-side approach emerged. It called for combining insurance with the provision of care through competing large, bureaucratic institutions (healthcare plans, initially, chiefly the HMO). The early proponents of this approach shared some views with advocates of cost-sharing, especially that healthcare is a commodity suitable for sale to consumers in markets, and a commitment to an incentives-oriented approach to public policy as preferable to regulation; but they departed from advocates of cost-sharing by calling for government to assist in reorganizing the supply side of the market and then to withdraw and let it evolve. Moreover, unlike advocacy of cost-sharing, the call for reform of the supply side did not at first result chiefly from applications of economic theory.

Reforming the Market

Instead, their views arose from at least three convictions: (1) although under cost-sharing physicians would have to compete on economic as well as medical grounds, aiming to serve as fiduciaries of patients' money as well as their health, incentives toward economy could become truly effective only if they were made to bear more directly on physicians; (2) large bureaucratic organizations could accomplish this task in ways not possible under market conditions characterized by solo practice and freestanding hospitals; and (3) traditional healthcare policy, which relied on professional self-regulation, planning, and regulation of institutions, especially hospitals – the very features of healthcare markets that, for older theorists, distinguished them from conventional markets and reflected the unusual characteristics and fundamental importance of healthcare – if carried out effectively, would either lock-in the causes of dysfunction in healthcare or, because draconian, erode in the face of opposition from patients and providers. In a period when cost escalation elicited characterizations of complex problems facing the health sector, when calls for NHI grew coupled with calls for the reform of health system itself, and when traditional forms of governmental regulation were in decline, the market solution, based on new organizations, seemed to cut through the Gordian knot that advocates of traditional NHI then still hoped to unravel by strengthening established practices.

Hence Paul M. Ellwood, Jr. (1926–) and his colleagues, in their classic summary of the 'health maintenance strategy' Ellwood *et al.* (1971), held that the "health system is performing poorly because its structure and incentives do not encourage [systemic] self-regulation" and that "[m]arket mechanisms, such as competition and informed consumer demand, which might provide a check on the provision of unnecessary services, inflation, and inequitable distribution, do not exist in the health industry." Their conclusion (p. 298) was as simple as it was bold:

> The emergence of a free-market economy could stimulate a course of change in the health industry that would have some of the classical aspects of the industrial revolution - conversion to larger units of production, technological innovation, division of labor, substitution of capital for labor, vigorous competition, and profitability as the mandatory condition of survival. Under these conditions, HMOs would have a vested interest in regulating output, performance, and costs in the public interest, with minimal intervention by the federal government.

To sharpen the contrast between prevailing arrangements and the market-based system, Ellwood, from 1972, invoked a locution that until then had been little exploited in discussions of healthcare, 'cottage industry.' In the early 1970s, it allowed him, together with his colleagues and allies, to epitomize the inadequacy of what they perceived to be a still preindustrial health sector; and it has remained a handy resource that has enabled them and their successors to deprecate subtly traditional healthcare policy and practice, while enhancing the legitimacy of the novel, market-based ones and buoying their prospects.

The confidence evident in the preceding quotation rested far less on economic theory than on enthusiasm for a textbook notion of competition and from the knowledge that the archetype of the HMO, the prepaid group practice (PPG) – of which a few then existed, several having emerged especially from the 1930s – had successfully provided high-quality care more cheaply. Their principal tools were capitation payments (per head or per family) from plan members and either the staff or group model of provider organizations – in the former, the plan itself employs physicians, whom it pays a salary; in the latter, the plan pays the physician group, which pays its physicians a salary. In both kinds of plans the incentive structure of fee-for-service medicine had been reversed – for example, as Enthoven saw it, of Schultze's call for reform of perverse incentives – as neither plans nor physicians benefited from increased utilization. Moreover, by owning or contracting with hospitals paid on a global budget, the plans had incentives to provide hospital care efficiently. Yet the numbers and market penetration of such organizations was small and, in areas in which patients did have choice of insurers, the success of health plans may well have reflected their case mix and the tastes of their clienteles. Moreover, early analysis of their performance suggested that their economies resulted primarily from limiting hospitalization rather than from constraining the other aspects of practice that exposure to a fully competitive market might have led plans to target. In other words, as a model for a competitive health system, the HMO was suggestive but hardly compelling. To call for expanding these modest precedents to dominate the entire health system and create a novel, competitive market was thus to pose an enormous gamble (as advocates of cost-sharing under fee-for-service had believed). Proponents found it appealing because, in the face of the complex problems of the health sector, competing health plans seemed a conceptually simple approach, one as yet little encumbered with a body of experience and a long history in the policy sphere. In comparison with what market advocates saw an apparently exhausted tradition of regulation and planning, markets populated on the supply side by competing, large, capital-intensive organizations looked fresh and promising.

However, there was some pertinent history in the policy sphere. The modest degree of market penetration that bureaucratic practices had attained by the end of the 1960s

reflected in part the successes of the organized medical profession in controlling not only the narrow dimensions of medical practice and training but also the organization and financing of healthcare. PPGs had long been a target of the profession, which had generally succeeded in constraining their growth and proliferation. To assist him in taking on this legacy of professional control, Ellwood coined the term, 'HMO.' It expressed not only the hope that he, as a rehabilitation physician, entertained about the importance of prevention (especially regarding chronic disease) and its utility in an anticipated cost-control regime but also his expectation that additional organizational forms beyond the traditional PPGs could serve the purposes that advocates of plans envisioned. However, the new term recommended itself chiefly as a way to appeal to physicians without eliciting memories of the history of conflict over the organization of medical care. Like earlier reformers, who saw that social and economic developments presaged transformations of healthcare and called on the medical profession both to lead and, by so doing, protect its interests, Ellwood hoped to engage physicians and enroll them in his project of reform. However, another advocate of market-based reforms, the law professor Clark C. Havighurst (1933–), took a more adversarial stance toward the profession, holding that professional self-regulation underlay the profession's anticompetitive practices. The cottage industry was the profession's creature; it existed to serve the interests of the profession, not those of patients or polity. From the standpoint of his concern for antitrust, he believed that reorganizing the supply side would break the back of medical dominance over the market for healthcare, permit the evolution of large provider organizations that the profession had long succeeded in inhibiting, and expose physicians to market discipline. Even more important, he took on the role of policy entrepreneur who disseminated his views among those able to make decisions and act in practical circumstances. A major goal for his activity was to establish the market as a realm for the exercise of choice by consumers.

The Evolution of Healthcare Markets

From the mid-1980s, the reduction of constraints on supply-side innovation resulting from antitrust activity; the diminished threat, after the failure of the Clinton health-reform plan, of increased federal regulation; and the restraints on state regulation resulting from federal preemption, under the federal Employee Retirement Income Security Act of 1974 (P.L. 93–406), of state regulatory powers in healthcare, helped open the door to the rapid evolution of healthcare markets on the ground. A new coinage, 'managed care,' emerged in the late 1970s and became commonplace from about the mid-1980s to encompass the early emergence of diverse and novel supply-side arrangements in addition to HMOs as originally conceived. Under that term, analysts included organizations and practices that supposedly generated efficiency gains (and thus cost-controls and quality improvements) through corporate control over the practice of medicine and that supposedly fostered competition among managed care entities and between them and conventional fee-for-service practice. From the late 1990s, with the 'managed care backlash,' the apparent consensus on the virtues of managed care had dissolved, but dynamic evolution continues.

That dynamism is one of several themes that emerges from the growth of markets. In both extent and degree, the dynamism of healthcare markets has surely exceeded the expectations of most of their early advocates. An industry formerly heavily sheltered from market forces now, under the profit motive – and the resultant imperative for nonprofit entities to emulate for-profit ones – has become subject to chaotic impulses that have created, reconstructed, and destroyed novel organizations and managerial and professional practices, as well as built and upended institutions and relationships among employers, insurers, providers, and patients. Indeed, so rapid have markets evolved that scholars have been in continuous struggle to keep up with events, characterize changes, and assess their implications. Such changes arouse concern not only with the services that healthcare markets provide but also likely more so the economic advantages and the profits that issue from them. A focus on market share and profit making is surely what anyone expects of markets; but roiling market dynamics seems incompatible with the stability that patients and consumers would hope for in a system intended to provide services of an often intimate nature and existential import.

Nevertheless, the concern of market-oriented analysts and policymakers to widen the scope of consumer choice is a second theme in the evolution of markets. The managed care backlash seemed to suggest that consumers were disillusioned with paternalism, whether of employers or providers, and that they wanted to exercise choice in an environment that made the relationship of costs, benefits, and accessibility more evident than the combination of community rating and sub-rosa utilization controls that managed care had created. Private insurers backed off trying to influence physicians (the fundamental goal of managed care), aimed instead to influence patients in an environment of diverse choice, and tried to appeal to employers who sought to offer employees a menu of options rather than to select plans for them. Under such arrangements, the consumer would have greater room for making choices and greater responsibility for exercising them. 'Consumer-driven healthcare,' a particular set of financial and insurance arrangements, is perhaps the fullest expression thus far of this trend. It reflects the appearance of the middle-class shopper given to evaluating professional services, a phenomenon that market advocates had favorably anticipated. However, studies have shown that the extent to which consumers enjoy clear choices and, where they do, the extent to which they take advantage of them, have been highly limited.

A third theme has been the tendency of market advocacy and attention to market evolution to eclipse the public-interest goals of traditional reformers. After policymakers grew convinced that not only NHI but system reform was also necessary, after Senator Edward M. Kennedy (1932–2009) altered his thinking about healthcare reform to accommodate private markets, and after the failed Clinton plan marked a new check in the work of reformers to achieve NHI and opened the floodgates to dynamic market change, conceptions of the purposes of healthcare markets that depart from traditional collective thinking gained increasing prominence. Indeed, many have argued that the growth and growing

familiarity of markets and the continual rehearsal of their anticipated virtues have entailed consequences many of which were foreseen with apprehension by the earliest critics of markets: Diminished interest in entitlement, access to care, continuity of care; waning of patients' trust in providers; and loss of interest in fragmentation of the health system. What advocates of markets have deemed most important is enhancing efficiency, constraining cost escalation, avoiding paternalism, fostering choice, all without 'rationing care,' long demonized as paternalistic, unaccountable, and simply dangerous. This approach comports with recent cultural developments that have rendered 'the market' an idealization that lacks historical or social content or context. In the minds of their advocates, healthcare markets have not yet reflected or achieved an ideal state, but confident that such a state can be attained, they persist in searching for it.

Accordingly - and here is a fourth theme in the evolution of markets - policymakers' focus on efficiency and consumer choice has compelled reformers oriented to traditional public-interest goals to continually rehearse them and insist on their pertinence and viability. Even early advocates of markets like Pauly and Enthoven, for all their emphasis on care as a set of commodities and markets as the best way to distribute them, held to Schultze's notion that markets existed (or should be created where they did not) to serve articulated public purposes, in the case of healthcare, not only efficiency and cost-control but also improved entitlement; and they stuck with the conviction that the same markets that served the better-off should also accommodate the poor, albeit to buy a lesser standard of care. Moreover, Enthoven originally proposed that governmental regulation was needed to organize a market so as to meet public goals, and therefore he called early for 'procompetitive regulation'. Later he substituted 'managed competition' – not to be confused with 'managed care,' i.e., provision of care by cost-efficiency-oriented bureaucratic organizations – as a means to avoid such problems as risk-selection (e.g., selling insurance to the well and avoiding the ill) and product differentiation that hinders consumers from making comparisons and circumnavigates price competition. He and others held, in brief, that markets required regulation or management to keep their evolution in conformity with public purposes. That such concerns have managed to persist in the face of enthusiasts who reject governmental intervention in markets find testimony in the ACA, which both expands entitlement and organizes markets. The controversy that this legislation has aroused, however, shows that the struggle between market enthusiasts and advocates of traditional public-interest goals has scarcely ended.

These last two themes contrast sharply with experience in most other advanced countries. There, the traditional focus of policymakers lay on regulating or constraining the supply side of the market. Cost-constraining measures in advanced countries have included lower levels of funding; upstream limits on capital; planning; limits on the exploitation of technology; constraints on the size of the medical profession, its composition by specialty, and its geographic distribution; limits on professional fees; global budgets; bargaining among 'peak associations' (i.e., national-level interest groups); gatekeeper systems; explicit rationing and waiting lists; price controls (e.g., on pharmaceuticals); and simpler administrative and payment mechanisms, all of them practices to which the American polity has thus far been vastly less hospitable. Moreover, even the recent experiments that other advanced countries have undertaken with competitive measures – on both demand and supply sides – to foster choice and with it improve efficiency often have been accompanied by regulatory measures to keep their healthcare systems in conformity with underlying solidaristic values. In America, pressure in support of efficiency and choice pose a constant threat to traditional public-interest goals. However, regulation, which market advocates had seen as impediments to the achievement of efficiency and securing of choice, constantly returns through the back door. As diverse market arrangements provoke dissatisfaction from consumers-cum-voters, they demand and get piecemeal protective regulation from the sequelae of market operations. However, few policymakers draw the conclusion that their focus on the efficiency of markets may fail to serve the public and thus require something resembling the practice in other advanced economies of subordinating market arrangements to other social values; rather, they suppose that the ultimate in market arrangements remains to be found.

Concluding Reflections

The themes that this and Health Insurance in Historical Perspective I develop suggest that the ACA is a profoundly American product, tempering as it does the traditional goals of social policy with support for markets and consumer choice. It aims to cover most of the hitherto uninsured, and it preserves and reforms existing market arrangements and adds new ones; but it does not transform the healthcare system into a version of uniform entitlement to comprehensive benefits that traditional reformers long desired. Given the persistence under the ACA of employer-based insurance, of the diversity across employers in costs and levels of coverage, of regressive tax subsidies for private insurance, of Medicare, of Medicaid and its variations across states, of safety-net institutions devised for the poor; and the appearance of new provisions for income-graduated subsidy and cost-sharing, the US has clearly decided to persist in subsidizing care according (primarily) to income, and thereby also (by proxy) according to race, and (secondarily) according to age. Proponents of reducing health disparities (i.e., different levels of health status prevalent among different ethnic and income groups) have recently come to apply the term 'fragmentation' – formerly employed with regard to such things as the 'cottage-industry' structure of the health sector, its lack of focus on the patient, and its inability to coordinate care – to the distinctions drawn in our health system by race, class, gender, and income. These distinctions find expression in the differentials that persist across social groups in access to care, extent and depth of coverage, magnitude of reimbursement, and the kinds and numbers of accessible insurers and providers. Although other health systems in advanced countries also took form with references to such social categories, they persist in the American system to a far greater extent. The ACA offers not a uniform system of NHI, no 'Medicare for all' that some have advocated – HR 646, first introduced into the 111th Congress – no reckoning of care as a prerogative or right attached to citizenship to be equitably

assured, but a system that expresses differential degrees of social success and approval, that affords differential degrees of freedom and responsibility in seeking and gaining access to care, and that provides differential access to care according to socioeconomic status and ethnic and gender identity. Americans have not utterly eschewed a sense of collective responsibility and social solidarity; but their choice of a market-based system seems entirely consonant with their persistence in classifying and discriminating citizens from one another, their privileging the goals of choice and efficiency over social protection, and their seeking in the market an exalted path to realizing and expressing personal autonomy and responsibility.

What role has economics played in the evolution of American health insurance? In no sense has it been determinative of policy choices, in part because economists came to see themselves much more as servants of their masters, public and private, than as reformers or decision makers. Yet economists have scarcely been strictly neutral analysts, for like those for whom they work, they reflect (and in turn have reinforced) the broader cultural and social changes that have helped give rise since the end of the 1960s to a polity and to a population of policymakers more attuned to the values associated with the market – the home turf of economists – and more hostile to government, professional expertise, and paternalism (whether public or private) – than the concerns that traditional policymakers still strive to uphold. If economists have been more influential than in the past, it is the result, in great measure, of this convergence of values. However, their influence also reflected developments in the capacity to analyze public programs that economics as a discipline had begun to show in the late 1950s and 1960s. In a context marked by the problems emergent in the health sector under traditional policy, by the growing concern about cost escalation, and by the fear that expanding access to health services through NHI by extrapolating previous approaches to policy would be too expensive, economists applied to public policy their increasingly mathematized and powerful intellectual tools that had matured in the postwar era. From there flowed the influence of their fundamental individualism, of their arguments about the failures of traditional health insurance, about moral hazard, and about cost-sharing. Moreover, through efforts of this kind, they gave rise to the subdiscipline of health economics and heavily informed the emergent, interdisciplinary field of health services research.

As for analysis of the supply side, the push for competing health plans, rather than only for competition inside a traditional cottage industry, was less an argument of economists than the harnessing of modest institutional precedents by a new set of analysts to remedy the problems in healthcare that cost escalation had rendered acute. Yet as markets involving novel organizations and practices emerged and grew, their development provided grist for the economists' mill. The efficiency of integrated insurers-cum-providers, their incentive-structures, their marketing methods and market shares, their access to capital, their likelihood of serving goals increasingly defined by market-oriented sensibilities (and decreasingly defined by collective sentiments), all this and much more proved amenable to economic study and analysis. Even if the pace of events has often outrun the ability of economists and other health services researchers to keep up, the dynamism of markets and their capacity to serve the preferences of payers, of individuals, and the goals of mostly market-oriented policymakers have opened a vast field for economic analysis. There, too, economists will not and cannot make the value-based decisions that drive policy; but their powerful tools, their professional argot, and the market orientation they share with their employers and many policymakers assure that their will remain influential voices.

Health Insurance in the United States, History of

T Stoltzfus Jost, Washington and Lee University, Harrisonburg, VA, USA

Glossary

Adverse selection A situation that arises when high-risk individuals are more likely than low-risk individuals to purchase insurance. As a result, the average riskiness of people who buy insurance exceeds the average riskiness of the population as a whole. Low risk individuals may choose not to insure at all.

Community rating The setting of health care insurance premia according to the utilization of a broad population (e.g., one defined by employer type or geography).

Experience rating Setting premiums based on an individual or group's claims history.

Introduction

Given the central role that health insurance plays in the American healthcare systems, it is remarkable how short a time it has been with us. Many Americans alive today were born before modern health insurance became available in the United States around 1930. Although brief, the history of health insurance in the United States is sharply contested.

The history of health insurance in the United States is often presented as a narrative of missteps and missed opportunities. Indeed, two contending narratives of policy failure dominate much of the literature describing this history.

The predominant narrative, both in terms of the length of the tradition and volume of scholarship it has produced, emphasizes the failure of the United States to join other developed nations in embracing universal care coverage. Time and again, during the progressive period, in the New Deal, during the Truman Administration in the 1960s and 1970s, and during the Clinton Administration, efforts to establish a universal national health insurance program had come to naught. There were certainly victories along the way – most notably, the enactment of Medicare and Medicaid in 1965. But repeatedly, national health insurance proposals had gone down in defeat.

There is, however, also an alternative narrative of failure, favored by opponents of government intervention in healthcare finance. According to this narrative, repeated unwarranted government intervention in our healthcare system through regulation and subsidies has resulted in excessive cost, inadequate quality, and limitation on choice. Our biggest policy failure has been our refusal to unshackle the free market to work its magic on our healthcare system.

This article recounts both narratives. It will then, however, offer yet another alternative narrative – a story of 'muddling through' and of modest success. In fact, throughout the second half of the twentieth century, the vast majority of Americans were insured. The number of Americans covered by employment-based health insurance expanded very rapidly during the 1940s and 1950s, whereas the scope and extent of coverage continued to expand until the 1980s. Beginning with the 1960s, the Medicare, Medicaid, and State Children's Health Insurance Programs in the 1990s filled the most serious gaps in private coverage. Besides noninsurance 'safety net' programs, the Emergency Medical Treatment and Active Labor Act, which requires hospitals to provide emergency treatment regardless of ability to pay (although not for free), filled yet another gaps. Only with contractions of private coverage in the 1990s, greatly accelerated in the 2000s, did this patchwork of insurance coverage become truly unsustainable.

The article concludes with an analysis of the Patient Protection and Affordable Care Act of 2010, which attempts to build on the United States' unique mix of private and public health insurance to fill the growing gaps in coverage that have become apparent at the beginning of the twenty-first century. The extent to which this fix, in fact, succeeds, certainly, remains to be seen.

A History of Political Failure: Attempts to Achieve Universal Coverage

The dominant account of the history of health insurance in the United States focuses on failed attempts to create universal health coverage. The first attempt to establish universal health coverage in the United States was led by the progressive movement in the late 1910s. Germany had inaugurated a social health insurance program in 1883, followed by a number of other European countries in the 1890s and early 1900s. The success of the efforts of the progressives to expand social welfare programs at the state level led the American Association for Labor Legislation (AALL) to believe that a national sickness insurance program might also succeed. The AALL marshaled a coalition of progressive academics and enlightened business leaders, who pushed for reform based largely on the German model. By 1917, the AALL's standard health insurance bill was being considered in 15 state legislatures.

Then everything fell apart. Some labor leaders opposed the government taking over the provision of welfare benefits to workers, a role that they coveted for themselves. Business leaders consolidated their opposition to the legislation. After a brief initial period of openness to change, organized medicine retreated to a stance of obdurate and highly effective opposition, which it assumed toward public health insurance for decades thereafter. Insurance companies, which as of yet sold little health insurance but had developed a substantial market

 doi:10.1016/B978-0-12-375678-7.00903-2

for industrial life insurance policies, opposed the proposal, which would have offered burial policies as part of the sickness benefit. Finally, as America was drawn into the First World War, enthusiasm for German things quickly waned. Compulsory health insurance legislation was defeated in California and New York, and by 1918, social health insurance was no longer on the table.

The possibility of a national health insurance program flickered to life again briefly during the 1930s. The severe economic dislocation of the Great Depression quickly overwhelmed state, local, and private relief efforts. The Social Security Act enacted in 1935 created a national social insurance retirement income program for the elderly and offered federal subsidies for state cash assistance program for the poor elderly, dependent children, and the blind. Although there was considerable support for a federal program that would provide health benefits, fervent opposition led by organized medicine threatened to bring down the entire social insurance program if health insurance was a part of it. President Roosevelt ultimately abandoned social health insurance.

Repeated attempts to create a universal social health in the aftermath of war also proved unsuccessful. Although President Truman campaigned for a national health insurance program more vigorously than what Roosevelt did before him, the United States turned rightward following the war, electing a Republican congressional majority. The most important parts of Truman's program that survived Congressional debate were the Hill-Burton hospital construction program (which between 1947 and 1971 disbursed US$3.7 billion in federal funds for hospital construction, contributing up to 30% of all hospital projects during the period) and a heavy federal commitment to healthcare research. There was also quiet expansion of healthcare for the poor. The Social Security Act Amendments of 1950 for the first time committed the federal government to match, to a very limited extent, state expenditures for in-kind medical services through the matching fund provisions of the federal/state public assistance programs for the elderly, blind, and disabled, as well as families with dependent children. Federal assistance for state indigent healthcare plans program was further expanded by the Social Security Act Amendments of 1960, which created the Kerr-Mills program to provide federal matching funds for a medically needy elderly.

The anticommunism of the late 1940s and early 1950s and continued opposition from organized medicine put a hold on any further attempts to create a national health insurance program. Nevertheless, pressure for national health insurance was quietly building among organized labor and the elderly, who adapted strategically scaling back their expectations by limiting their immediate goals to cover only social security beneficiaries with social health insurance, and by 1960, to the coverage of hospital care.

With the election of President Kennedy in 1960, efforts to provide healthcare for the elderly were redoubled. The landslide election of President Johnson and of a liberal Democratic Congress following the assassination of Kennedy finally made health reform inevitable. In 1965, Congress created the Medicare program to insure hospital and medical services for the elderly as well as the Medicaid program to pay for healthcare services for public assistance recipients and the medically needy.

Social insurance advocates had hoped that the enactment of Medicare and Medicaid would be followed up by expansion of public insurance to the entire population. The 1970s, however, brought little progress as Democrats in Congress failed to reach agreement with the Nixon administration regarding the way forward, and the Carter administration focused (largely unsuccessfully) on cost control rather than on coverage expansion. Medicare coverage was expanded to the disabled, but no further.

Although the 1980s saw expansion in the Medicaid program, universal health coverage was off the agenda during the Reagan administration. The election of Bill Clinton in 1992, who campaigned for healthcare reform in the light of a growing number of uninsured Americans and rapidly increasing healthcare costs, brought new hope to reform advocates. However, Clinton administration stumbled politically. It took a year and a half to craft a reform plan in secret, giving interest groups and political opponents time to rally opposition and devising at last a plan that was too complex and could not gain traction. The late 1990s saw the creation of the State Children's Health Insurance program, followed by the expansion of Medicare to cover outpatient prescription drugs in 2003, without which another two decades were likely to be lost in the quest for universal coverage.

Analysts offer a variety of explanations for America's inability to adopt universal coverage. These include a national ideological aversion to strong government, powerful interest groups that benefit from the status quo, the absence of a strong political left, political institutions that make it far easier to block than accomplish change, and path dependency. Each of these explanations explains part of the problem, although the saliency of any particular explanation varies from one decade to another.

The 'failed attempts to adopt universal coverage' narrative would seem to be an accurate description of the history of health insurance coverage in the United States as far as it goes but does not fully acknowledge the remarkable expansion of private health insurance, which has played a more central role in the United States than it has in most other developed nations (Switzerland and, more recently, the Netherlands being the main exceptions). It is to that story to which the authors will shortly turn. The author will also consider whether the adoption of the 2010 Affordable Care Act provides a happy ending to the narrative of failure. But first, the free market advocate alternative for 'history of failure' narrative will be considered.

The 'Government Interference with Health Care Markets' Narrative: A Narrative of Economic Failure

Although the failure of universal coverage narrative focuses on the plight of uninsured and underinsured Americans, the government interference narrative contends that Americans are 'overinsured.' Americans have too much insurance because of government policies that have encouraged private insurance for routine as well as catastrophic medical costs, thus resulting in severe moral hazard (as well as too much public health insurance and government regulation).

The history of American overinsurance begins, according to this narrative, with the exemption of fringe benefits in wage-price controls during World War II, thus stimulating the former's growth. Also dating from the 1940s, are tax subsidies for employment-related insurance that have encouraged the provision of excessive health insurance coverage for most Americans. Because insurance premiums have largely been covered by employers, the true cost of health insurance has been concealed from Americans. Because the predominant forms of health insurance have imposed little costsharing, the true cost of healthcare has been concealed as well. Finally, the Medicare and Medicaid programs have driven up healthcare prices and utilization, limited choices for the elderly, and discouraged provider innovation. Repeated attempts by the government to fix health insurance market failures have only worsened the situation.

There is some truth in this narrative despite offering only a partial picture of American developments. In fact, labor was scarce during World War II and excess profit taxes were very high, up to 85%. The Stabilization Act of 1942 did allow the National War Labor Board (NWLB) to exclude a 'reasonable amount' of insurance benefits from wage controls. An IRS administrative ruling of 1943 also allowed businesses to deduct payments toward health and welfare funds as business expenses, contending that these benefits would not be taxable to employees.

Yet, there is reason to be skeptical of the oft-repeated claim that wage policy was the primary reason for the expansion of health insurance coverage during the War. First and foremost, health insurance as an employee benefit was already well established and rapidly growing before the war began, as described below. Second, most of the growth in wartime employment and health insurance coverage took place before the NWLB policies came into effect in 1943. American industry had been gearing up for the looming war since 1939, and while the number of American employees insured through commercial plans (the plans most likely to be paid for in part by the employer) increased from 960 000 in 1939 to 4.3 million in 1943, it only increased to another 71 000 between 1943 and 1945. Employment-related insurance coverage increased again rapidly after wage price stabilization controls expired in 1946, suggesting yet again that expansion was not driven primarily by wage stabilization policy. The wage stabilization policy was in any event routinely circumvented, as it allowed wage increases in conjunction with promotions, which quickly became common. Finally, throughout the war, Blue Cross coverage, the most common form of health insurance, continued to be paid for largely by employees rather than employers. By the end of the war, only 7.6% of Blue Cross enrollees were participants in groups to which employers contributed.

There is more reason to credit the employee benefit tax exclusion and deduction for the increase in health insurance coverage in the United States. The most rapid growth in health insurance coverage, however, took place in the late 1940s and early 1950s before the tax subsidies were enshrined in the 1954 Tax Code, and probably had more to do with aggressive collective bargaining by the unions than tax subsidies. The tax subsidies, however, undoubtedly contributed to the expansion of the scope and depth of health benefits well into the 1990s.

It is also very likely that the expansion of benefits has contributed to the growth in healthcare costs. Free market advocates assert that the Rand Health Insurance Experiment (HIE) conclusively demonstrated that more comprehensive health insurance coverage leads to higher healthcare spending. Although the meaning of the HIE and its relevance to contemporary health policy continue to be debated, the correlation between broader insurance coverage and increased healthcare spending seems plausible. It is also clear that the creation of Medicare and Medicaid has resulted in higher healthcare spending at least due to more people being insured.

Market advocates generally argue for the removal of tax incentives for private health insurance coverage and for the scaling back the operation of government healthcare programs through the use of vouchers to pay for private health insurance. Their most significant legislative victory has been the Medicare Modernization Act of 2003, which provided tax subsidies for health savings accounts coupled with high deductible health plans. High deductible health insurance has spread rapidly during the early 2000s and now dominates the individual market. This has resulted in increased financial difficulty for insured families and reduced access to healthcare. However, increased cost sharing has also arguably had a restraining effect on healthcare costs.

An Alternative Narrative: A Modestly Successful Patchwork of Coverage

The Origins of Modern Health Insurance

There is yet a third narrative of the history of health insurance in the United States that is somewhat more sanguine. Health insurance came into existence in the United States in the first half of the twentieth century as advances in medicine made healthcare of real value and increases in the cost of healthcare rendered it increasingly less affordable to those with serious medical problems. The prestigious Committee on the Costs of Medical Care concluded in its 1932 final report that the high cost of medical care for those most in need necessitated the provision of either private or public insurance, but by that time private insurance was already in use.

Describing the early history of health insurance is problematic because of a different meaning of the term 'health insurance' before the mid-twentieth century. The late nineteenth and early twentieth centuries saw the rapid growth of what was then called health insurance or sickness insurance. This coverage insured against wages lost due to illness. After a short waiting period, an insured individual would be able to collect a fixed amount per week until he (or, rarely, she) was able to return to work or until the benefit was exhausted. This insurance was offered by employer-funded 'establishment funds', labor organization funds, and commercial insurers; as well as by ethnic, religious, and community-based fraternal organizations. Some of these insurers and funds also provided life or burial insurance. Although a few offered insurance to cover medical costs, most did not. Not only was the value of most medical care questionable, fund members were also apparently concerned

that a doctor paid for by the fund might be too eager to certify the member healthy enough to return to work.

Other precursors of health insurance also emerged during the late nineteenth and early twentieth centuries. Some fraternal organizations hired physicians to provide care to their members – the much maligned 'lodge practice'; some even built their own hospitals. Employers in remote areas like in the case of railroad, mining, or logging companies also provided medical services through company doctors or through industrial medical plans.

Modern health insurance was born in 1929. In that year, the first 'hospital service plan' was started by Baylor Hospital in Dallas in 1929. Baylor entered into a contract under which white public school teachers paid 50 cents a month into a prepaid hospital services annual plan with the assurance that they would receive up to 21 days of hospital care, and a one-third discount for the remaining 344 days.

Hospital service plans did spread quickly during the 1930s. In 1936, the American Hospital Association established the Commission on Hospital Services, which ultimately became the Blue Cross Association. This commission encouraged and supported the spread of state and regional Blue Cross plans. By 1937, Blue Cross plans had 894 000 members; by 1943, membership reached almost 12 million.

Blue Cross plan members paid a fixed sum every month for the assurance that their needs would be covered if they had to be hospitalized. Blue Cross plans were available on a community-rated basis, that is, all members paid the same rate, regardless of health status. The plans negotiated 'service benefit' contracts with the hospitals under which the plans would cover up to a fixed number of days of hospitalization for a per diem fee established in the contract. Blue Cross plans also provided either service benefit or indemnity coverage (under which insureds would pay medical providers in cash and then file a claim with the insurer for an indemnity payment) for 'extras' such as emergency and operating room charges, or laboratory tests.

As it became increasingly clear in the late 1930s that there was a substantial market for hospital benefits, private commercial insurers too entered the group insurance market. Whereas only 300 000 Americans were covered by commercial hospitalization policies in 1938, nearly six million had coverage in 1946. Unlike Blue Cross plans, commercial insurance covered hospital care besides offering surgical coverage. By 1945, over five million Americans had commercial surgical coverage. Commercial plans even began to cover medical costs (nonsurgical physician's services) in the hospital. By the late 1950s, home and office visits also began to be covered, especially under individual policies. Commercial health insurance was sold on an indemnity basis. Indemnity payments would be for fixed sums per service, which were set forth beforehand in the insurance contract.

The success of the hospitals in offering prepaid benefits was soon noticed by physicians. In 1939, the first of the physician service benefits plan that came to be known as Blue Shield plans appeared. Blue Shield plans initially covered surgical benefits in hospital, expanding later on to cover in-hospital medical and eventually ambulatory medical benefits.

Blue Shield plans combined the Blue Cross and commercial insurance approaches for providing benefits. Although some plans offered only service benefits or only indemnity coverage, most of them offered both. Doctors agreed to accept negotiated payments from the plans as payment in full for patients whose income fell below a specified level. Members with incomes above such levels, however, received indemnity payments and had to pay the difference between the doctor's charge and the indemnity amount. Blue Shield plans were initially community-rated, but over time moved to experience rating like the commercial insurers.

The year of 1929 saw the birth of other models of health insurance as well. In that year, the first consumer's cooperative providing prepaid medical care was created in Elk City, Oklahoma, whereas the Ross-Loos Clinic, a physicians' cooperative, began offering a prepayment plan for an employment-related group in Los Angeles. During the 1930s and 1940s, other models of health care coverage appeared based on comprehensive prepayment for healthcare. Some of these, such as the Kaiser plan, were initially industry-sponsored wherease others, like the Washington Group Health Insurance Plan, grew out of consumer-sponsored plans. The Farm Security Administration encouraged consumer cooperatives, which covered 725 000 persons by the early 1940s, but largely disappeared when government support ended. Industry-sponsored plans also continued to exist, covering approximately a million people in 1930.

These precursors of modern staff-model health maintenance organizations (HMOs) were vigorously opposed by organized medicine. Organized medicine preferred cash-and-carry medicine (as it does today), but was willing to tolerate insurance that did not subject doctors to lay control. Lay control of medical practice was unacceptable, and health plans that employed doctors were fought vigorously by the American Medical Association (AMA) through much of the twentieth century, resulting in a criminal conviction of the AMA for antitrust violations in the 1940s. These efforts by the AMA kept prepaid medical practice marginal until the final quarter of the twentieth century.

Initially, Blue Cross, Blue Shield, and commercial plans were sold primarily to groups. It was much less expensive to market health insurance to groups than to individuals. Insuring employment-related groups in particular helped for addressing the problem of adverse selection. Blue Cross plans sold insurance to groups of various types, primarily, however, they contracted with employment-related groups. Employers permitted the sale of group policies to their employees, facilitated the formation of groups, and often deducted the premiums from pay checks through a payroll check-off system.

At the outset, employers themselves rarely contributed to premiums for the Blue Cross plans. As late as 1950, only 12.2% of Blue Cross plan participants received employer contributions. Employer contributions were more common with commercial plans. By 1950 employers contributed approximately half of the 'gross cost' of health insurance for employees and 30% of the cost of dependent coverage. Because employers commonly received rebates from insurers, their actual 'net cost' was in fact much lower, approximately 38.5% for employees and 20% for dependents. A major focus of collective bargaining agreements was to shift more of the cost of the premium to the employer.

Health Insurance in the Mid-Twentieth Century

In the booming American economy following World War II, health insurance coverage expanded dramatically. By 1950, nearly 76.6 million Americans constituting half the American population had hospitalization insurance – 54.2 million had surgical benefits, and 21.6 million had medical benefits. By 1965, when Medicare and Medicaid were adopted, private hospital insurance covered 138.7 million Americans, that is, approximately 71% of the American population.

As coverage expanded, it also became more comprehensive. In the early 1950s, commercial insurers began to offer major medical coverage that provided catastrophic coverage for hospital and medical care. Major medical policies usually supplemented basic hospital and surgical-medical coverage. Comprehensive coverage followed soon on its heels, bundling basic and major medical coverage into a package to provide the most complete coverage available. During the 1950s, Blue Cross and Blue Shield plans began to combine forces to offer similarly comprehensive coverage. Finally, during the 1960s and 1970s, insurance coverage began to expand to cover dental care and pharmaceuticals, with improved coverage for maternity care, mental health, and some preventive services within basic coverage.

Another important trend after the War was the increased employer responsibility for employee health benefits. During the late 1940s and early 1950s, employer contributions to collectively bargained plans increased exponentially. By 1959, employers paid the entire premium for hospital insurance for virtually all unionized employees in multiemployer plans and for 37% of employees subject to collective bargaining agreements in single-employer plans.

Employer contributions to premiums in nonunionized places of employment increased more slowly. By 1964, however, approximately 48% of employees had the total cost of their health insurance covered by their employer. Employer contributions to health insurance expanded even more quickly during the 1970s and 1980s. By 1988, employers covered 90% of the cost of individual coverage and 75% of the cost of family coverage.

Among the several reasons for the impressive postwar expansion in the number of workers covered, the benefits provided, and the level of employer contributions in the third quarter of the twentieth century, the most important one was probably pressure from the labor unions. Unions were at the peak of their strength in the mid-twentieth century. Improved fringe benefits were a high priority for the unions. The National Labor Relations Board clarified in 1949 that employee benefits were included within the 'terms of conditions of employment' subject to collective bargaining under the National Labor Relations Act, giving new impetus to union demands for health benefits.

In the beginning, some of the major unions such as the United Mine Workers had operated their own health benefit funds. The 1947 Taft-Hartley Act prohibited union-run benefit plans, but established multiemployer Taft-Hartley plans, which were operated jointly by labor and management. Most employee benefit plans, however, were established by management. Unions tended to favor Blue Cross and Blue Shield contracts, which offered more comprehensive coverage, but large employers favored commercial insurers that offered more flexibility in the design of plans as well as generous rebates, which substantially reduced the employer's net contribution to premiums. Employers with healthy workforces also favored commercial insurers because they used experience rating and thus could offer lower rates.

Health benefits were not limited to unionized firms. Even firms that were not unionized offered liberal fringe benefits to forestall unionization. Employers also saw health insurance as a means to stabilize employment (by making it more difficult for employees to leave), to keep workers healthy and productive, and to ward off a national social health insurance program.

Another factor underlying the growth of employment-related insurance was the continuing increase in healthcare costs. The proportion of the gross domestic product spent on healthcare grew from 3.6% in 1928–29 to 5.4% in 1958–59. Changes in medical technology were making medical care much more effective and thus more valuable, although medical care was becoming less affordable. The growing burden of healthcare costs led, in turn, to an increased desire to spread costs through insurance and pass it on to employers.

Tax policy also certainly played a role. The 1954 Internal Revenue Code explicitly recognized the nontaxability of employment-related benefits. As more and more Americans began to pay income tax (which was paid primarily by the wealthy before World War II), the tax benefits of health insurance became more important. Tax subsidies played a particularly important role in increasing the share of premiums covered by employers as well as the scope of coverage.

A final factor that drove the expansion of employee coverage was the enactment of the Employee Retirement Income Security Act (ERISA) in 1974, which blocked the application of state insurance regulation and premium taxes to self-insured plans. Self-insurance gave employers increased power to control healthcare costs and the opportunity to receive interest on reserves, as well as protecting them from state premium taxes, insurance mandates (which became common in the early 1980s), capital and reserve requirements, and risk pool contribution requirements. Whereas only 5% of group health claims was paid by self-insured plans in 1975, an estimated 60% of employees were in self-insured plans by 1987.

Although most American employees had hospital coverage (and increasingly surgical and medical coverage) by the 1970s, that coverage was often quite thin. Until the 1980s, commercial insurance was predominantly indemnity coverage and balance billing was very common. Moreover, dollar limits on coverage were often quite conservative. As late as 1959, when 72% of the population had hospital insurance, 18.4% of personal care expenditures was covered by insurance, whereas 56.5% had to be paid. Blue Cross plans offered first-dollar coverage, but initially limited the number of days of hospitalization they would cover, whereas Blue Shield plans often offered indemnity coverage to higher-income enrollees.

Coverage, moreover, did not reach many who were not employed. The one group that was most noticeably left behind during the coverage expansion was the elderly. Retiree health coverage expanded rapidly during the 1950s and 1960s, and many of the elderly purchased individual insurance, yet many

remained uninsured too. Efforts to provide public insurance for this group came to fruition in 1965 with the creation of the Medicare program, described earlier. The Medicaid program too offered supplemental coverage to the elderly and disabled besides basic coverage to impoverished families with dependent children.

Other new programs also began to partially fill other gaps left by private insurance. Community health centers that provide services to lower-income families on a sliding scale basis were launched in 1964. Provisions of the 1949 Hill Burton hospital funding program, requiring grantees to provide free or reduced cost care to those in need, finally began to be enforced in the 1970s. The 1986 Emergency Medical Treatment and Active Labor Act required Medicare-participating hospitals to provide emergency services even to those unable to pay (although not free). The 1986 budget bill also included a provision that allowed persons who lost their employment or their dependency status to purchase continuation coverage for a period of time at full cost (so-called, COBRA continuation coverage).

By 1980, the vast majority of Americans had health insurance coverage through their employment, and this coverage was increasingly comprehensive. 82.4% of the population had private health insurance that year, a proportion not yet repeated. Most employers paid the full premium for individual coverage and the majority of the premium for family coverage. Deductibles and coinsurance remained common, and indeed spread to Blue Cross and Blue Shield plans, but with the advent of major medical and then comprehensive coverage, out-of-pocket expenditures decreased and insured expenses increased in the final quarter of the century. By 1980, the proportion of healthcare costs covered by private health insurance exceeded that covered out-of-pocket, and with the advent of HMOs in the 1980s, cost-sharing virtually disappeared. The United States had apparently solved through private initiative, supplemented by public programs for those whom private markets could never protect, the problem of health security that other nations addressed through social insurance or public provision.

Private Health Insurance Unravels

However, America's health security system began to unravel during the early 1970s. The driving disruptive force was the increase in healthcare costs. Inflation generally was a serious problem during the 1970s, but healthcare costs grew even more rapidly than other costs. Public initiatives were adopted to restrain healthcare cost growth – including health planning, professional standards review organizations, and in some states, hospital rate review – but none achieved great success.

During the 1980s and early 1990s, health insurers responded to cost increases by turning from being passive payers to becoming care managers. Within a decade, conventional indemnity insurance and service benefit plans gave way to plans, initially called HMOs and preferred provider organizations, which offered limited provider networks, attempted to review and control utilization, and experimented with incentive structures that would discourage rather than encourage provision of services. This strategy worked for sometime. By the mid-1960s, healthcare cost growth had declined dramatically, indeed it briefly fell in line with the general growth of the economy.

But cost increases also began to have an impact on coverage. Beginning on with the 1980s, the percentage of Americans with health insurance began to decline. The first to lose coverage were retirees, who fell victims to the declining power of the unions (which had been their strongest champions), to the steady increase in healthcare costs, and to a change in accounting standards after 1990 that required firms to consider the cost of future retiree health obligations as a current liability on their books.

Moreover, small businesses had never covered their employees to the same extent as larger businesses, and as the American economy shifted from a manufacturing to a service-based economy – and concomitantly from large unionized employers to small businesses, the percentage of employees who were insured began to fall further.

Small groups have been underwritten for decades on the basis of expected claims costs of their members, and coverage can be very expensive, even difficult to find, for older groups or groups in hazardous occupations. A number of states took steps in the 1990s to make health insurance more accessible for small groups. This included statutes guaranteeing insurance issue and renewal, limiting variations in rating among groups; and restricting the preexisting condition exclusions. A few even required community rating. The 1996 federal Health Insurance Portability and Accountability Act established guaranteed issue and renewal requirements throughout the country and imposed limits on the preexisting condition exclusions. Administrative costs, however, remained significantly higher for small groups than for large groups and health status underwriting continued for small groups in most states.

Even for larger groups, managed care succeeded in stemming the growth of healthcare costs only temporarily. The more extreme forms of managed care proved intensely unpopular. Although Congress failed to adopt a national managed care bill of rights when the issue came before it in 2001, most states adopted legislation restraining managed care in the late 1990s. As the economy improved in the late 1990s and early 2000s, employers backed off from the most stringent forms of managed care, moving to broader provider networks and away from strict utilization controls.

Healthcare costs began to rise dramatically again by 2000, however. As the economy worsened again in the mid-2000s, the cost of employment-related health insurance began to reach levels that employers found intolerable. Employers reacted primarily by increasing employee cost-sharing, although some employers dropped coverage or increased the employee share of health insurance premiums. Many employers shifted to high-deductible policies, sometimes offering contributions for health savings accounts (held by the employee) or health reimbursement accounts (held by the employee), which received tax subsidies under the 2003 Medicare Modernization Act. As health insurance became more costly and less valuable to employees, more employees passed up employment-related coverage.

Public programs grew steadily for some time, offsetting the decline in private coverage. Employment-related coverage had never covered dependents on the same terms as workers, and many lower income workers could not afford the premiums

required for family coverage if their employers even offered it. Many children, therefore, remained uninsured. Medicaid coverage for children had steadily expanded through the 1980s and 1990s, and in 1996, the State Children's Health Insurance Program was created to cover children in families with incomes up to 200% of the poverty level and above. Medicaid was also expanded after 1981 to cover pregnant women, recognizing the cost-effectiveness of timely prenatal care.

The massive layoffs and economic retrenchment that accompanied the economic decline in 2008 and 2009, however, accelerated the decline in private coverage, overwhelming the expansion of public coverage. Only 55.8% of Americans had employment-based coverage by 2009, down from 63.9% in 1989. The decline of insured retirees had been even steeper. Only 28% of large firms that offered health benefits covered retirees in 2010, down from 66% in 1988.

A small percentage of Americans have always been insured through the individual market. Administrative costs are even higher in the individual non group market than in the small group market, and premiums vary sharply from individual to individual based on health status, age, and other underwriting factors. Individual insurance, however, is often the only alternative available for a growing number of self-employed Americans, including, early retirees, the unemployed, part-time and temporary workers, and individuals who do not have insurance available through their place of employment. A number of states attempted in the 1990s to reform the nongroup market, but in most states reforms were not as ambitious as small group market reforms. The Health Insurance Portability and Accountability Act required only guaranteed renewal and imposed limits on the exclusions of preexisting conditions for individuals who transfer from group insurance or some equivalent public insurance. Many states also established high risk pools for otherwise uninsurable individuals, but risk pool premiums were high and participation was generally low. Individual plans are now predominantly high-deductible plans, with the most common deductible levels in 2009 being US$2500 for individual policies and US$5000 for family policies. The individual market is characterized by high premiums and high turnover, but it is the only coverage currently available to many Americans.

In summary, the history of American health insurance is a story of successes and failures. It is true that healthcare costs have been growing at rates in excess of general inflation almost without interruption for the past half century and that the number of uninsured Americans has now reached critical levels – 50.7 million or 16.7% of the population in 2009. But the vast majority of Americans had access to healthcare for a half century through private health insurance and those who had the most difficult time accessing insurance were covered through public insurance. Can we, however, do better?

The Patient Protection and Affordable Care Act of 2010

The Patient Protection and Affordable Care Act of 2010 (ACA) represents an additional article in each of these three narratives. Some, although not all, of its supporters laud it as finally achieving the long-dreamed of goal of healthcare coverage for all. In fact, if all goes according to plan, the legislation should dramatically expand health insurance coverage and reduce the number of the uninsured. The legislation expands Medicaid to cover all American citizens and long-term legal residents with incomes of up to 138% of the federal poverty level and offers tax credits to help cover the cost of health insurance premiums for Americans and legal residents with incomes of up to 400% of the poverty level. It imposes a penalty on Americans who do not purchase health insurance and penalizes employers who do not offer health insurance or provide inadequate coverage to their employees. The Congressional Budget Office estimates that by 2020, the legislation will reduce the number of the uninsured by 32 million, but it will still leave 23 million Americans (including undocumented aliens) without health insurance. The dream of universal coverage is not yet fulfilled.

Free market advocates loudly criticize the ACA as a 'government takeover' of the healthcare system. They complain that the legislation extends government subsidies for and regulation of the healthcare system even further. They fret that the expansion of health savings and reimbursement accounts that they achieved in the early 2000s will be overturned. They assert that the legislation will result in unconstrained growth in healthcare costs.

The ACA does dramatically expand federal funding and regulation of private health insurance. It does not, however, significantly expand federal regulation of the healthcare delivery system. Fundamentally, moreover, the ACA adopts a market-based approach to healthcare reform. It establishes 'health insurance exchanges' at the state level to organize competition among health plans. It establishes new programs to increase competition by encouraging the extension of multistate private plans to every state and the formation of interstate insurance sales compacts and nonprofit insurance cooperatives. Finally, the legislation has no effect on health savings or reimbursement accounts other than to limit their use for over-the-counter drugs. Indeed, the normal employment-based policy currently has an actuarial value of over 80%, whereas the standard subsidized 'silver' policy under the ACA will have an actuarial value of 70% ('actuarial value' refers to the percentage of total medical costs of a standard population paid for by an insurer, so the lower the actuarial value, the higher the percentage of medical costs borne by the insured. Most current health savings accounts-affiliated high deductible plans will be permissible as 60% actuarial value 'bronze' plans. There is likely to be most, not less, cost-sharing under the ACA.

However, the ACA is best understood finally in terms of the 'patchwork of coverage' narrative. The legislation is in the long American tradition of expanding private health insurance coverage and filling gaps with public coverage. Once the ACA is fully implemented, most Americans will continue to be covered by employment-related health insurance, Medicare, and Medicaid. The ACA significantly expands Medicaid, acknowledging that Americans below 138% of the poverty level simply cannot afford health insurance although the Supreme Court decision limits the number of poor Americans who will benefit from this expansion. Tax credits and cost reduction subsidies are offered to allow Americans earning up to 400% of poverty to purchase health insurance and to limit their

exposure for cost-sharing, thus making insurance affordable to 19 million more Americans.

The biggest change made in the American health insurance is that the legislation outlaws health status underwriting and bans preexisting condition exclusions. Insurers must no longer compete based on risk selection but rather do so based on price and value. The original Blue Cross plans community-rated premiums, and community rating has long been the norm (and required by law since 1996) within employee groups. Outlawing health status reinforces this tradition while rejecting an equally long tradition of health status underwriting. The legislation also prohibits or limits other health insurance practices and policy provisions – some of which, like the imposition of annual limits, date back to the beginning of health insurance, whereas others, like limitations on access to certain specialists, are more recent.

The ACA fits within the narrative of the quest for universal coverage, and can also be understood as imposing additional government regulation and subsidies on healthcare markets (albeit to the prospect of making them function better), but it is best understood as one more article in the ongoing story of helping our patchwork private/public health insurance system to hobble along.

Health Insurance Systems in Developed Countries, Comparisons of

RP Ellis, T Chen, and CE Luscombe, Boston University, Boston, MA, USA

Glossary

Ceiling The limit on the dollar payments or visits covered by a health plan.
Claims The payments for consumer losses covered by health plans.
Coinsurance The proportion of healthcare cost paid by the consumer, for example, 20%.
Complementary insurance Insurance that covers part of the consumers' cost share of their primary plan.
Copayment A fixed-money amount paid per day or unit of service, for example, US$10 per office visit.
Cost-sharing, demand-side The healthcare costs paid by the consumer, which can be copayments, coinsurance, deductibles, or amounts paid above a coverage ceiling.
Cost-sharing, premium The share of premium paid by consumers rather than a sponsor.
Cost-sharing, supply-side The healthcare costs borne by providers.
Deductible An amount up to which the consumer pays the full price for healthcare; hence, the consumer might pay the first US$500 deductible without any copayment.
Duplicate insurance Insurance that provides coverage for benefits already included in the primary insurance program, which may have further benefits, including jumping ahead in a waiting line.
Health savings account A system of self-insurance in which funds are deposited by a consumer or sponsor and available for reimbursing healthcare expenses in the current or future year.
Managed care An insurance program in which utilization constraints are used to control costs.
Pay for performance The payments determined based on some observed measures of providers.
Premium Fixed payment per unit of time (e.g., per year) for a defined set of healthcare services.
Primary insurance The system of insurance used for the dominant group in every country, who are employed workers and their dependents.
Replacement insurance Insurance purchased as an alternative to the primary insurance. It is not clearly defined for the US.
Risk adjustment The use of information to explain variation in healthcare spending, resource utilization, or health outcomes over a fixed period of time.
Secondary insurance Insurance that adds to, or replaces, the coverage provided by primary insurance.
Selective contracting Providers can choose whether to contract with some or all health plans, and health plans can choose whether to contract with only some providers.
Self-insurance Consumers bearing the full risk of health expenditures through savings. Consumers are also their own sponsors.
Social insurance A system of insurance in which benefits are defined by statute, revenue generation is primarily income based, and participation is mandatory.
Specialized insurance The insurance programs designed to serve specialized populations, which could be elderly, children, disabled, or having certain specified chronic conditions or high health costs.
Stoploss A limit on the amount of payment by an agent, such as a consumer or health plan.
Supplementary insurance Insurance that provides coverage for services not covered by the consumer's primary insurance plan.

Introduction

There is an enormous literature evaluating and comparing health insurance systems around the world, which this article attempts to synthesize while emphasizing systems in developed countries. The authors' approach is to provide an overview of the dimensions along which health insurance systems differ and provide immediate comparisons of various countries in tabular form. To organize their analysis, they focus their discussion on coverage for the largest segment of the population in all developed countries: workers under the age of 65 years earning a salary or wage, which they call the primary insurance system. They later touch on the features of special programs to cover the elderly, the poor or uninsured, and those with expensive, chronic conditions. They do this not because these groups are less important, but rather because special programs are often used to generate revenue and provide services to these groups, and including these programs in their discussion adds considerable complexity. For the same reason, they also focus on primary insurance coverage of conventional medical care providers – office-based physicians, hospital-based specialists, general hospitals, and pharmacies – knowing that there are many specialized insurance programs for long-term care, specialty hospitals, informal providers, and certain uncovered specialties.

A key feature of their analysis is that they focus on providing a broad framework for evaluating different systems rather than immediately comparing specific countries. They initially distinguish between the alternative contractual relationships used in different insurance settings and the choices available to each agent or decision maker. They then provide an overview of the alternative dimensions in which healthcare systems are commonly compared, which include the breadth of coverage, revenue generation, revenue redistribution across

 doi:10.1016/B978-0-12-375678-7.00905-6

health plans, cost control strategies, and specialized and secondary insurance.

Throughout the article, the authors use the health insurance systems of Canada, Germany, Japan, Singapore, and the USA. As shown in Table 1, insurance systems in these five countries span much of the diversity exhibited by health insurance systems around the globe. These countries include both: the most expensive system (US) and the least expensive (Singapore); single payer as well as multiple insurer; and government-sponsored and employer-sponsored insurance. Unlike many comparisons, the authors try to emphasize the general nature of the institutions used to provide care rather than the specifics of the institutional arrangements. More unified discussion of each country is reserved until after they characterize the dimensions in which healthcare systems can be compared.

The topics in this article relate to almost every other article in this Encyclopedia, but are particularly relevant for the topics of health insurance, risk adjustment, equity, demand-side incentives, and provider payment.

Agents and Choices

Agents

As summarized in Table 2, it is useful to distinguish six classes of agents in all health insurance markets. Consumers are agents who receive healthcare services, but in some systems they may have other choices to make. Providers actually provide information, goods, and services to consumers and receive payments; the article focuses on providers covered by insurance contracts. Health plans are agents who contract with and pay providers, also known in some countries as sickness funds. The sponsor in a health system serves as an intermediary between consumers and health plans, allowing for consumer contributions for insurance to differ from the ex ante expected cost of healthcare across consumers. In most countries, the sponsor is a government agency, although in the USA and Japan the sponsor for most employed workers is their employer. The key role of the sponsor in most countries is to ensure that the insurance contribution by a consumer with high expected costs (such as someone old, chronically ill, or with a large family) is not many times larger than the contribution of a consumer with low expected costs. Despite the enormous complexity of diverse intermediaries in many health insurance systems, consumers, providers, health plans, and sponsors can be viewed as the fundamental agents in every healthcare market.

Two other types of agents deserve mention. Insurers are agents that bear risk in their expenditures. In a given system, they can be identified by asking who absorbs the extra cost of care from a flu epidemic or accident. The insurer is not always a health plan as many health plans do not actually bear risk, but instead simply contract with and pay providers and pass along the expense to someone else. Insurance (or risk sharing) in a healthcare system can be shared by any of the four main agents in the healthcare system. Finally, regulators set the rules for how the healthcare and insurance market is organized, and this role can be played by sponsors (e.g., government), health plans, or providers (such as the American Medical Association in the US). Sometimes the functions of two or more agents are combined in the same agent. For example, some health plans own hospitals, and hence are simultaneously a health plan and a provider.

Systems of Paying for Healthcare

Fundamentally, there are four different ways of organizing payments and contracts in healthcare systems. Schematic diagrams of these are shown in Figure 1. System I is a private good market, in which consumers buy healthcare services directly from providers. This system is still used in all countries for nonprescription drugs and many developed countries for certain specialized goods (e.g., routine dental and eye care, and elective cosmetic surgery,) but is rare for the majority of

Table 1 Overview of health insurance systems in five countries

Mandatory coverage	Yes	Yes	Yes	Yes	No

Table 2 Six classes of agents in every health insurance system

Consumers: People actually receiving healthcare, and in some countries choosing health plans or sponsors
Providers: Agents actually supplying healthcare services, such as doctors, hospitals, and pharmacies
Health plans: Agents responsible for paying and contracting with healthcare providers
Sponsors: Intermediaries between consumers and health plans who are able to redistribute the ex ante expected financial cost of health care across consumers and among health plans
Insurers: Agents who bear risk (insure), who can be any combination of the consumers, providers, health plans, or sponsors
Regulators: Agents who set the rules for agents in the health-care system

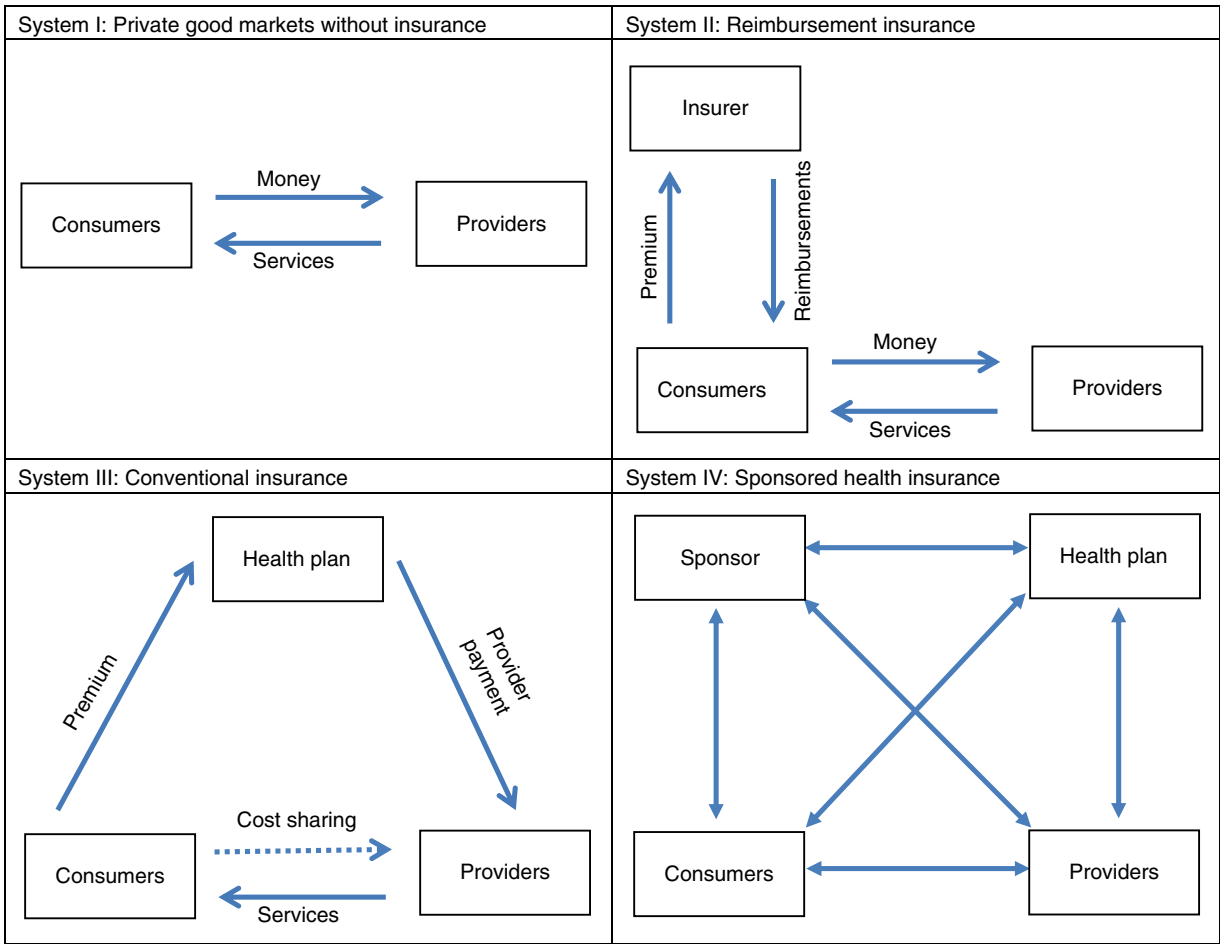

Figure 1 Four structures of healthcare payments.

healthcare services. Most consumers in Singapore and uninsured consumers in the US rely on a private good market, and pay for their healthcare when needed, without insurance.

System II is a reimbursement insurance market, in which consumers pay premiums directly to an insurer in exchange for the right to submit receipts (or 'claims') for reimbursement by the insurer for spending on healthcare. Under a reimbursement insurance system the insurers need not have any contractual relationship with healthcare providers, although the insurers will need rules for what services are covered and how generously. As will be seen, System II is the most common for secondary insurance in developed countries, and it is also widely used for automobile and home insurance.

System III is a conventional insurance market in which the consumer pays a premium to a health plan, which in turn contracts with and pays providers. Although popular in theoretical models of insurance System III is not used for the primary insurance system in any developed country, but is sometimes used for secondary insurance programs. Note the key difference in incentives between these two systems: System II incents the consumer, but not the health plan, to search for low price, high-quality providers, whereas System III does the reverse, reducing consumer incentives but enabling the health plan to negotiate over price and quality.

System IV is a sponsored insurance market in which the revenue is collected from consumers (directly or indirectly) by a sponsor who then contracts with health plans, who in turn contract with and pay providers. All developed countries that were studied involve a sponsor, although in some developing countries the sponsor may be a health plan.

Choices

Each of the line segments shown in Figure 1 reflects a contractual relationship, in which money or services are transacted. These relationships are generally carefully regulated. Countries differ in the extent to which they restrict or allow choice in each of these contractual relationships. Although many comparisons of international insurance systems do not emphasize these choices, they vary across countries significantly. Table 3 summarizes them for the five countries that are the focus of this article.

Every developed country insurance system allows consumers to choose among multiple providers, but only a few allow providers to turn down consumers, or charge fees above the plans' allowed fees (Singapore, the US). In some countries (notably the US, and legal but rare in Germany), health plans may choose which providers they want to contract with, and

providers may in turn choose the health plans they contract with (selective contracting). An especially important dimension of choice is whether the primary system has more than one health plan (Germany, Japan, the US), and how choices among health plans are regulated. In countries like the US and Japan, employers implicitly choose who to sponsor when they hire workers, and hence employers play a key role in redistributing the costs of healthcare between young and old, healthy and sick, or small and large families. In the US, consumers and their sponsors (employers) are allowed to choose not to purchase any insurance at all; some Japanese consumers ignore the mandate and do not purchase insurance, making it similar to the US. The 2010 US Affordable Care Act (ACA) will start imposing tax penalties on consumers and employers in 2014 if they do not purchase insurance, but the system will remain voluntary.

Breadth of Coverage and National Expenses

Breadth of Coverage

With the exception of the US, all developed countries have universal coverage for their own citizens through their primary insurance programs. As shown in the first row of Table 4, insurance coverage approaches 100% of the population in Canada, Germany, Japan, and Singapore, whereas only 83% of the US population has coverage. The 2010 ACA in the US will increase the percentage covered, but there is considerable uncertainty about how much coverage will increase.

Because these measures are often a focal point of international comparisons of healthcare systems, Table 4 also contrasts the dollars per capita and percentage of gross domestic product (GDP) spent on healthcare. US spending of US$8233 per capita (18% of GDP) is by far the highest, whereas Singapore's spending of US$2273 per capita (4% of GDP) is by far the lowest. In recent years, not only has the US been the most expensive, but it has also been experiencing more rapid cost growth relative to a share of its GDP (Figure 2).

Countries differ considerably in the proportion of their healthcare spending done by the public versus the private sector. This dimension is commonly a focus of international comparisons, but the proportion is not a direct choice of the country, rather it is the result of all of the other choices and regulations made in the country. Of greater interest is the percentage of spending by the primary health insurance plan or plans. This ranges from 70% in Canada to 34% in the US. Also of interest is the relative importance of the primary insurance program versus various specialty insurance programs. The US has specialized insurance programs for the elderly, the poor, children, and persons with disabilities, which collectively accounts for 56% of total healthcare spending.

Revenue

Revenue Generation

Developed countries vary significantly in how they generate revenue used to fund health plans (Table 5). In most countries, proportional or progressive taxes earmarked for healthcare are used as the primary source of revenue (e.g., Canada, Germany, Singapore, and Japan), although in some cases general tax revenues predominate. In the US and Japan, because employers are the primary sponsors, revenue comes from premiums paid by each worker. In the US, the premium is typically shared between the employer and the employee with the employer being free to choose the portion of the premium paid by the employee. State and federal tax systems partially subsidize health insurance in the US, by allowing these health insurance contributions to be exempt from income taxes, a widely discussed subsidy of health insurance and potential distortion. In Japan and Germany, premium contributions are set by law at a fixed rate, which is evenly split between employees and employers.

Revenue Redistribution

In countries with a single health plan option, there is no need for redistributing revenue between multiple health plans. However, such systems typically have to allocate budgets among different geographic areas, a similar task to reallocating

Table 4 Measures of health insurance breadth of coverage in five countries

money between competing health plans. In Canada, explicit risk adjustment formulas are used to allocate funds among geographic areas within each province. In systems with multiple competing health plans (i.e., Germany, Japan, the US) risk adjustment is sometimes used to redistribute money away from plans enrolling predominantly healthy enrollees and toward plans that enroll disproportionately sick or high-cost enrollees. (This topic is explored in a separate entry on risk adjustment in this Encyclopedia.) Explicit risk adjustment for this purpose is done only in Germany, where age, gender, and diagnoses are used to reallocate money among competing plans. In the German system, redistribution is done not only to adjust for health status, but also to undo unequal revenues due to the average income of health plan enrollees. This is due

to the fact that plans enrolling predominantly high-income enrollees will have greater revenues than plans with low-income enrollees, as a proportional payroll tax is used as the dominant revenue source.

Despite having multiple competing health plans, Japan and the US do not use risk adjustment to redistribute revenue, although in the US the ACA will expand the use of risk adjustment to the individual and small group markets. Risk adjustment is already used extensively in the various US public programs offered to the elderly and disabled populations and plans serving low-income and high-medical cost consumers.

HealthCare Cost Control

Although every country faces the challenge of controlling healthcare costs, countries vary significantly in their methods for doing so. Fundamentally, there are only four broad strategies for controlling healthcare costs: demand-side cost sharing, or using prices imposed on consumers to encourage them to reduce utilization; supply-side cost sharing, or using prices paid to suppliers to reduce utilization and/or reduce plan payments per unit; nonprice rationing, or setting limits on the quantity of key resources available to provide healthcare, whether done by the government sponsor or by individual health plans; and information provision that influences care provision and demand.

Table 6 summarizes the various cost control features used in the five countries that the article focuses on. It is interesting to note that Japan and the US rely extensively on demand-side cost sharing to control costs, whereas Canada and Germany rely heavily on supply side cost sharing. Singapore utilizes both. A growing number of countries have moved to bundled payment for hospital care, which originated in the US where hospital payments are based on Diagnosis Related Groups

Table 6 Cost containment in five countries

	Canada	*Germany*	*Japan*	*Singapore*	*USA*

(DRGs). This system is now used in Germany, Japan, and many other countries. Experimentation with other forms of bundled payment, such as for primary care and multispecialty clinics, is ongoing but not yet widespread in Canada and the US.

Nonprice rationing techniques are used quite differently in the different countries. In Canada, gatekeepers and provincial-level restrictions on capacity are common. In the US, the government uses these tools very little, though many private health plans use selective contracting and some managed care plans use gatekeepers, though they are rarely mandatory. Gatekeepers are rare in Germany, Japan, and Singapore. Consumer information about hospitals, doctors, and health plans is of growing availability in the US and Japan, but rare or nonexistent elsewhere.

Specialized, Secondary, and Self-Insurance

So far the focus has been on characterizing the primary insurance mechanism used by employed adults in each country. Some countries have separate specialized insurance programs, for which only certain individuals are eligible, such as the elderly, people with a serious disability, children, low-income individuals, individuals with high medical costs, the unemployed, the self-employed, and individuals employed in small firms. In some cases, these programs cover a sizable fraction of the population and an even higher fraction of total healthcare spending. As shown in Table 7, specialized insurance programs are very common in the US and Japan. At the other extreme, Canada, with its universal, largely tax-funded system, does not need any specialized programs for subsets of its population.

In addition to specialized insurance for which only certain individuals are eligible, many countries have secondary insurance programs that reduce the cost to consumers for spending not covered by the primary insurance policy. This can be of four forms: supplementary insurance covers services not covered under the primary insurance; complementary insurance provides additional reimbursement for services not covered by the health plan; duplicate insurance provides coverage for services that are already included in the primary insurance program; and replacement insurance serves as a substitute for primary health insurance coverage. Although conceptually distinct, in some countries, a single insurance policy may have elements of all three. In Australia, for example, a single private policy may cover out-of-pocket costs for some services (complementary), cover new services (supplementary), and also allow the enrollee to opt out of using the public insurance system for a specific hospitalization or service (duplicate). Germany allows specified high-income households to purchase replacement policies instead of the primary policy.

The type of secondary insurance available in a country depends on the regulatory environment and the structure of the primary insurance mechanism. For example, replacement insurance is banned in Canada, but encouraged in the US for elderly or disabled Medicare enrollees. In countries where primary health insurance does not utilize consumer cost sharing, consumers will have no incentive to purchase complementary insurance. Almost every health insurance system will create a demand for supplementary insurance, i.e., coverage for services not covered by the primary policy. Chiropractic care, dental care, optometry, physical therapy, and pharmaceuticals are common examples of services excluded from primary insurance but often covered by supplementary insurance. Coverage for nonhospital-based prescription drug spending is in some cases covered in the primary policy (Germany, Japan, and some Canadian provinces) but not in others (many US plans, Singapore), though in Singapore there is a short list of prescription drugs that can be obtained free of charge from approved providers.

A relatively unusual alternative for insurance is self-insurance, in which consumers are required or encouraged

Table 7 Specialized insurance, secondary insurance, and self-insurance in five countries

Self-insurance programs					
HSAs				√√	√

Note: √, allowed; √√, dominant.

to save for their own current and future medical expenses. Self-insurance is typically encouraged through a tax-exempt health savings account (HSA). This mechanism is particularly important in Singapore, where health spending from HSAs comprises the majority of total healthcare spending. HSAs also received increased tax preference in 2003 in the US, and in 2012 were used by approximately 4% of all Americans. The institutional structure of HSAs varies between the US and Singapore, but both have a common point, in that consumers are encouraged through the tax system to put money in when young. For most consumers the account will grow over time. In some systems (Singapore), unspent money in the account can be used for other household members, or spent on education, housing, or other retirement consumption.

The attraction of self-insurance is that consumers purchase healthcare services with money that is valuable to them, and hence they have more incentive to shop around. The experience of Singapore, discussed further below, provides evidence that the savings can be substantial. However, the challenges of self-insurance are numerous. First, it presupposes that consumers can become enough well informed to shop around intelligently. This is unlikely in most countries where there is inadequate price and quality information for consumer shopping. Countries such as Canada and Germany, which do not use demand-side cost sharing, demonstrate that supply-side incentives can be equally or more effective than demand-side cost sharing. Also of concern is that self-insurance works well only for the 80% or so of the population with below average healthcare costs. Individuals with the highest healthcare costs, particularly those with chronic conditions, will tend to spend all of the money in their HSA, and be severely constrained in their ability to afford healthcare. In effect self-insurance fails these consumers when they need it most. Finally, self-insurance raises equity concerns. Studies show that wealthier households accumulate far more resources than low-income households and the tax-advantaged savings are of much lower value to low-income households. Together, both imply that most of the benefits of HSAs go to relatively healthy, higher-income households.

Country-Specific Comparisons

Canada

Canada has a universal single-payer, sponsored health insurance system called Medicare, which is administered independently by the 13 provinces and territories. Every citizen and permanent resident is automatically covered. The only choice available to consumers in the primary insurance system is a choice of providers. The only provider choice is whether to be in the dominant public system, or be an independent private provider, which is rare of most specialties. As of 2012, Canada spends approximately 11% of GDP on healthcare expenditures. Medicare provides medically necessary hospital and physician services that are free at the point of service for residents, as well as some prescription drug and long-term care subsidies. In addition to Medicare coverage, most employers offer private supplemental insurance as a benefit to attract quality employees, and a few Canadians purchase replacement insurance. Each province/territory is responsible for raising revenue, planning, regulating, and ensuring the delivery of healthcare services, although the federal government regulates certain aspects of prescription drugs and subsidizes the provinces coverage of services to vulnerable populations.

Because all services covered by primary insurance are free at the point of service, medical expenditures in this system are financed primarily through general tax revenue, or in some provinces with small income-based premiums, which together cover 70% of healthcare expenditure. Private supplementary and replacement insurance make up for the remaining 30% of medical expenditure. Employment-based supplementary insurance is the status quo among large employers and tends to cover services such as optometry, dental, and extended prescription drug coverage.

In most provinces, there are no selective contracts, hence the consumers are not limited to any particular network of providers; however, gatekeepers are often used so that consumers must obtain referrals from their family physicians to see specialists. Office-based providers are paid fees for the services. Each province/territory sets its own fee schedule. Bundled DRG payments are used to allocate funds to hospitals in a few provinces (e.g., Ontario), but this system of payments is largely invisible to patients. Whereas providers are able to charge alternative fees, the provincial insurance programs will not pay for any of the services not charged at the regulated rates. This means a provider who does not accept the government's rates must bill the patient, or the patient's secondary insurance, for the full amount of the fee. The patient will not be reimbursed by the government's insurance program for any out-of-pocket expenses. It is important to note under most provincial and territorial laws, private insurers are restricted from offering coverage for the services provided by the government's program.

Although provider shortages and long wait times to receive services push costs down, Canada is also struggling to control rising healthcare costs. The elderly population is increasing in size and it is difficult to maintain the level of benefits Canadian citizens have become accustomed to; cutting covered services is causing frictions in the country.

Germany

The German government sponsors mandatory universal insurance coverage for everyone, including temporary workers residing in Germany. Germany's primary insurance system is a social health insurance system that covers approximately 90% of the population in approximately 200 competing health plans (called Sickness Funds), with the remainder of the population (primarily high-income consumers) purchasing private replacement health insurance system. Although employers play a role in tracking plan enrollment, collecting revenue from employees and passing it along to a quasi-government agency, they are not sponsors: Insurance is not employment based in that all plans are available without regard to where a consumer works. Germany spent approximately 12% of GDP on healthcare in 2009.

Germany's health spending, excluding private insurers, is mostly funded by an income tax. This tax is a fixed portion of

income, usually 10–15%, depending on age, that is the same no matter which health plan an individual is enrolled in, and is shared equally by the employee and employer. Health plans are required to accept all applicants and pay all valid claims. Health plans are free to set premiums but due to strong competition there is almost no variation in price. Germans stop having to pay any payroll tax for healthcare at the age of 65 years even while continuing to receive healthcare benefits. Patients are also expected to pay a quarterly copayment to their primary care doctor. Collection of payroll taxes and premiums is managed by employers, although employers play no role in defining choice options and merely pass along taxes and premiums to an independent government agency. Government subsidies are provided for the unemployed or those with low income. Risk adjustment is used to reallocate funds among the competing health plans, based on age, gender, and diagnoses.

In response to the acceleration of healthcare costs, Germany has implemented various cost-cutting measures. These include accelerating the transition to electronic medical records, introducing quarterly consumer payments to primary care doctors (although visits remain free). Nonprice rationing methods are also used; for example, in order to see a specialist, patients must first be diagnosed and receive a referral from a physician who acts as a gatekeeper. Selective contracting by health plans is allowed, but rare.

The German system uses a unique point-based global budgeting system to control annual healthcare expenditures, whereby the targeted expenditures are achieved by ensuring that total payments to all providers of a given specialty are equal to the total budget for that specialty in a year. The Federal Ministry of Health sets the fee schedule that determines the relative points for every procedure in the country. Each year the total spending on a specialty in a geographic area is divided by the number of procedure 'points' from specialists in that area to calculate the price per point, and each physician in that specialty is paid according to the number of accumulated points, up to quarterly and annual salary caps.

The primary insurance coverage offered through the funds is among the most extensive in Europe, and includes doctors, dentists, chiropractors, physical therapy, prescriptions, end-of-life care, health clubs, and even spa treatment if prescribed. There are also separate mandatory accident and long-term care insurance programs. A majority of consumers also purchase supplemental coverage from private insurers, and the supplemental coverage typically provides patients with dental insurance and access to private hospitals.

Japan

Japan has a mandatory insurance system that comprises an employment-based insurance for salaried employees, and a national health insurance for the uninsured, self-insured and low income, as well as a separate insurance program for the elderly. The employment-based insurance system is the primary insurance program in which employers play a significant role as sponsors and health plans have considerable flexibility in designing their benefit features. Employment-based insurance is of two kinds, distinguished between small and large firms. Health insurers offer employer-based health insurance that provides coverage for employees of companies with more than 5 but fewer than 300 workers and covers almost 30% of the population. Large employers (an additional 30% of the population) sponsor employee coverage through a set of society-managed plans organized by industry and occupation. Employer-based health insurance coverage must include the spouse and dependents. A public national health insurance program covers those not eligible for employer-based insurance, including farmers, self-employed individuals, the unemployed, retirees, and expectant mothers, who together comprise approximately 34% of the population. Health insurance for the elderly covers and provides additional benefits to the elderly and disabled individuals. Finally, any household below the poverty line determined by the government is eligible for welfare support. Altogether Japan spends approximately 9.3% of GDP on healthcare (2011).

Health insurance expenditures in Japan are financed by payroll taxes paid jointly by employers and employees as well as by income-based premiums paid by the self-employed. Fees paid to the healthcare workers and institutions are standardized nationwide by the government according to price lists. The largest share of healthcare financing in Japan is raised by means of compulsory premiums levied on individual subscribers and employers. Premiums vary by income and ability to pay.

Employers have little freedom to alter premium levels, which range from 5.8% to 9.5% of the wage base. Premium contributions are evenly split between employees and employers. Cost-sharing includes a 20% coinsurance for hospital costs and 30% coinsurance for outpatient care. Employer-based insurance is further subdivided into society-managed plans, government-managed plans, and mutual aid associations. Patients may choose their own general practitioners and specialists and have the freedom to visit the doctor whenever they feel they need care. There is no gatekeeper system.

All hospitals and physician's offices are not-for-profit, although 80% of hospitals and 94% of physician's offices are privately operated. Japan has a relatively low rate of hospital admissions, but once hospitalized, patients tend to spend comparatively long periods of time in the hospital, notwithstanding low hospital staffing ratios. In Japan, the average hospital stay is 36 nights compared to just 6 nights in the US. This high average is likely to reflect the inclusion of long-term care stays along with normal hospital stays in the average.

Health insurance benefits designed to provide basic medical care to everyone are similar. They include ambulatory and hospital care, extended care, most dental care, and prescription drugs. Not covered are such items as abortion, cosmetic surgery, most traditional medicine (including acupuncture), certain hospital amenities, some high-tech procedures, and childbirth. Expenses that fall outside the normal boundaries of medical care are either not covered, dealt with on a case-by-case basis, or covered by a separate welfare system.

United States

The US system is at its heart an employment-based health insurance system in which employers play a key role as

sponsors of their employees. By one count, there are over 1200 private insurance companies offering health insurance in the US, which are regulated primarily by the 50 states and not at the federal level. These companies offer tens of thousands of distinct health insurance plans, each with their own premiums, lists of covered services, and cost-sharing features. In addition to this private system, there are also many overlapping public specialized insurance programs designed to cover consumers who are elderly, disabled, or suffering from end-stage renal disease (Medicare program), the poor or medically needy (Medicaid), children, veterans, and the self-employed. Because the US relies on both private and public insurance it is sometimes called a mixed insurance system. As of 2012, approximately 17% of the US population was without primary insurance, although many of these consumers are in fact eligible for Medicaid coverage but do not realize it. Altogether, the US spends nearly 18% of GDP on healthcare, the highest of any developed country.

Although the government acts as the sponsor to all of the public specialized insurance programs, employers are the key sponsor for most Americans. Choice is available to almost every agent in the US system: consumers choose providers, health plans, and sponsors; and employers, health plans and providers can generally turn down consumers who they prefer not to insure/employ, enroll, or provide services to. Employers generally contract with health plans while trying to control costs, but find little competition to hold down prices or control utilization. Many health plans negotiate fee reductions with provider groups, who tend to have substantial market power, but fees for medical care services in the US are with few exceptions the highest in the world. Although the US Medicare program sets provider fees for all regions without negotiation, all health plans must negotiate prices to be paid to providers, and the resulting fees reflect bilateral bargaining with market power.

The 2010 ACA dramatically changed many features of the US healthcare system and should greatly reduce the number of Americans who are uninsured. Starting in 2014 consumers who are without insurance will have to pay a tax penalty, and employers above a certain size will have to offer insurance to their full-time employees or pay a penalty. This US system also entails setting up insurance exchanges to cover the self-employed and small employers, who have the hardest time obtaining insurance in the US. The ACA does relatively little to address cost-containment issues, but does work toward expanding the number covered by insurance. It is unclear whether the national reform will work as well as it has in Massachusetts, where it has reduced the percentage that is uninsured to less than 2% of the population.

Cost containment is a huge issue in the US with such high spending in relation to its income. Demand-side cost sharing is used widely, with copayments, coinsurance, deductibles, coverage ceilings, and tiered payments all being used to deter demand. Many health plans use supply-side cost sharing, such as DRG bundled payments, and some are beginning to bundle primary care payment. Tiered provider payment, a form of 'Value based Insurance,' is also beginning to be used. Recent innovations include capitated provider networks, known as Accountable Care Organizations and reorganizing primary care providers to work and be paid as a Patient Centered Medical Home. Pay for performance systems and electronic medical records are other innovations being tested. It is too early to know which of these systems will be most successful in controlling costs.

Much can be written about the US public insurance programs – Medicare, Medicaid, the Children's Health Insurance Program, and The Department of Veterans Affairs – which also have their own payment systems and cost containment issues. The key point is that there is a huge amount innovation, from which other countries can learn. A positive feature of the US system is the exploration of diverse payment, nonprice, and informational programs to try to control costs. Individual-level healthcare data is more available from the US than from any of the other four countries studied here. Also, consumer information about doctors, hospitals and health plans are all available and can potentially play a role in consumer choice.

With the exception of Singapore, the US healthcare system is arguably the most unfair healthcare system, with consumers who are poor or ill with chronic illnesses paying a high share of their income for medical care. Healthcare spending is a common source of individual bankruptcy.

Singapore

Singapore has a unique-to-the-world healthcare system where the dominant form of insurance is mandatory self-insurance supported by sponsored saving, although complementary and special insurance programs are also central to their system. Remarkably, despite having a per capita GDP of approximately US$60 000 in 2011, Singapore spent a mere 3–4% of GDP on healthcare (2012). The centerpiece of its system is a mandatory income-based individual savings program, known as Medisave, that requires consumers to contribute 6–9% (based on age and up to a maximum of US$41 000 per year) of their income to an HSA. This HSA can be spent on any healthcare services a consumer wishes, including plan premiums. Funds not spent in a consumer's HSA can be carried forward to pay for future healthcare, used to pay for healthcare received by other relatives or friends, or if over the age of 65 years, cashed out to use as additional income, though there are some restrictions. A complementary insurance plan, known as Medishield, is available to cover a percentage of expenses arising from prolonged hospitalization or extended outpatient treatments for specified chronic illnesses, though it excludes consumers with congenital illnesses, severe preexisting conditions and those over the age of 85 years. As of 2011, this specialized program, which is optional, covered approximately 65% of the population. The government also supports a second catastrophic spending insurance program, known as Medifund, which exists to help consumers whose Medisave and Medishield are inadequate. The amount consumers can claim from this catastrophic insurance fund depends on their financial and social status. Singapore's system also includes a privately available, optional insurance program covering long-term care services (called Eldershield), with fixed age of entry-based payments. Consumers are automatically signed up for Eldershield once they reach the age of 40 years but they may opt out if they wish. Subsidies are available for most services, but even after the subsidies consumers must pay something out of pocket for practically all services. Some, but not all,

subsidies depend on the consumer's income, and consumers often have a choice over different levels of subsidy.

Funding for all three of the secondary insurance programs (Medishield, Medifund, and Eldershield) comes from general tax revenue. There are also five private insurance companies offering comparable plans, some of which are complementary to Medishield. Singapore has both public and private providers with the public sector providers serving the majority of inpatient, outpatient, and emergency care visits and the private sector serving the majority of primary and preventative care visits. Singapore's system receives positive publicity for its low percentage of GDP spending on healthcare but has been criticized as not replicable elsewhere. The relatively small population and high GDP per capita allows Singaporeans to avoid some of the costs associated with regulating health insurance in larger, more populous countries. Perhaps Singapore's most substantial criticism is insufficient coverage for postretirement healthcare expenses. Between potentially diminished savings and being cut off from Medishield at the age of 84 years, there is little support for financing catastrophic illnesses. Other criticisms of the country center on fairness concerns. The system favors high-income over low-income households, as they will have much greater funds contributed to their HSA. Also, consumers with high-cost chronic conditions, such as diabetes and mental illness, will repeatedly deplete their HSA and need to fall back on the various secondary insurance programs. Stigma is also an important cost containment mechanism. Finally, although consumers are incented to shop around among providers, as of 2012 there are no readily available report cards or other information sources available to guide consumers to lower cost or high-quality doctors and hospitals.

Concluding Thoughts

From the above descriptions, it is clear that there are an enormous number of ways that healthcare insurance programs vary around the world. Most country systems can be viewed as combinations or variations on the five systems described here. Although it would be wonderful if there were a way of identifying the characteristics of the most effective systems and the most equitable ones, unfortunately doing so in this article would require going beyond the boundaries of what is feasible. There are several excellent surveys of country healthcare systems, notably from the Organization of Economic Cooperation and Development and a series by the Commonwealth Fund that are excellent and are worthy of further reading.

Health Labor Markets in Developing Countries

M Vujicic, Health Policy Resources Center, Chicago, IL, USA

Glossary

Dual job holding The situation where health workers hold more than one job. Typically the primary job is a salaried position within the public sector and the second job is after-hours in a private clinic.

Performance-based pay A method of remuneration that aligns the incentives and rewards provided to health workers with the health outcomes-related objectives of a district or facility employer.

Shortage of health workers When employers are willing to hire more health workers, but there are no health workers available who are willing to accept employment at current wages.

Introduction

Health workers are at the center of health systems, and the health workforce plays a key role in increasing access to health services for populations in developing countries. There are numerous challenges in this critical area of health policy in developing countries. At the global level, a 2006 World Health Organization analysis found that an additional 4.3 million health workers were needed to provide basic health-care services to populations in developing countries. A more recent analysis found that for 31 countries in subSaharan Africa, there will be a needs-based shortage of 800 000 health workers by 2015 and addressing this shortage would require more than 2.5 times the projected financial resources that will be set aside for health worker salaries in these countries. Various global, national, and regional analyses have demonstrated the link between having an adequate number of health workers relative to population and achieving key health service delivery and population health targets. The evidence suggests clearly that having an inadequate number of health workers is limiting the effectiveness of health service delivery in many developing countries.

However, the availability of health workers is not the only health workforce policy challenge in developing countries. In fact, growing empirical evidence would suggest that it is not even the main issue, at least in the short term, in many settings. Geographic maldistribution of health workers is one of the most persistent and widespread issues in developing countries. A recent analysis by the World Health Organization found that one-half of the world's population lives in rural areas, but these areas are served by only 38% of the total nursing workforce and by less than a quarter of the total physicians workforce. Lack of health workers in rural areas is a major constraint to improving health service delivery. Low health worker productivity and quality limit the effectiveness of the existing health workforce. An analysis in five countries found an average health worker absenteeism rate of 35%. A recent review found that in India and Tanzania, doctors completed less than one quarter of the medically required tasks for patients presenting with tuberculosis (TB), diarrhea, or malaria. If these issues of geographic maldistribution, low productivity, and poor quality of care delivered by health workers is resolved, this could often have an immediate impact on health service delivery and population health outcomes in developing countries.

Why is it that countries with relatively similar epidemiological and disease profiles have vastly different numbers of doctors and nurses? Why are there unemployed nurses in countries that have far fewer nurses than needed to deliver basic care? Why do rural areas that often have the highest need for health services have the lowest staffing levels? Why are doctors absent in public facilities yet see patients in their private office? Why do health workers deliver care that is of lower quality than what they are trained to deliver?

As shown in this article, a labor economics perspective is extremely useful in understanding the underlying causes of these and other health workforce challenges developing countries are facing. Specifically, this article reviews the key factors that influence the demand for and supply of health workers and reviews the special features of the health labor market in developing countries. It also discusses how the labor economics perspective is extremely useful for policy makers when designing policy responses to the numerous challenges developing countries face.

A Labor Economics Perspective

A major focus of health workforce policy in developing countries historically has been to identify the 'need' for health workers of various skill sets, in various types of facilities and locations. Need can be defined as the number of health workers required to provide some mix of health services to the population. Need is a completely normative concept and takes into consideration only the epidemiological profile of a population, the preferences of policy makers over disease priorities, and technology considerations such as optimal skill mix, models of care delivery, and the expected productivity of health workers. Determining the need for health workers involves a great deal of priority setting among policy makers, but no economic factors such as prices or budgets enter into the needs discussion. There have been numerous studies that focus on identifying needs-based staffing levels. The World Health Organization estimates that worldwide greater than 4 million additional health workers are needed to deliver basic health services to the population. In Ethiopia an analysis

estimated that 36% more physicians are required in order to expand antiretroviral treatment to target level. To scale up 42 priority health services, Tanzania is estimated to require greater than 100 000 full-time health workers by 2015, compared to a projected availability of less than 30 000.

Demand for health workers is defined according to the standard definition from labor economics: the total amount of labor, or in the simplest sense the total number of health workers, employers are willing to hire at current wages, holding constant other important variables such as health worker productivity, household income levels, political considerations, and government budget levels. The key distinction between need and demand is that many factors other than the health status of the population influence the demand for health workers. In other words, financial, economic, and political factors can be thought of as driving a wedge between the demand and the need for health workers. More importantly, the demand for health workers – and not the need – drives hiring behavior and, as a result, policy makers need to understand employer behavior in order to influence hiring decisions.

In the health sector, particularly in developing countries, there is a diverse set of employers of health workers. The main ones include global nonprofit employers (e.g., multilateral organizations that directly employ health workers), a country's public sector (e.g., national, state, or local government directly or a government-owned hospital), a country's for-profit sector (e.g., for-profit clinics), the nonprofit sector (e.g., mission clinics), and individuals (e.g., sick people who seek care from health workers and pay for their services out of pocket). The factors that influence the demand for health workers within each employer category are different. For the global nonprofit employers, a key factor is the level of resources various bilateral and multilateral agencies provide for health initiatives. For example, the large increases in donor resources for human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) in recent years led to a sharp increase in the demand for health workers who provide HIV care.

The public sector is a significant employer of health workers in both developed and developing countries. Within the public sector, hiring decisions are often influenced as much by political, macroeconomic, and social factors as by the needs of the population. In settings where health workers are employed as civil servants, the demand for health workers is influenced heavily by the total wage bill allocated to the health sector, which, in turn, is often a highly politicized process dependent on macroeconomic and fiscal policy priorities. In developing countries there tend to be constraints, for very sound reasons, on how fast the overall wage bill can expand. For various reasons, these overall wage bill constraints often, but not always, restrict the demand for health workers in the public sector. For example, in Kenya in the mid-2000s the overall wage bill policy of the government limited the Ministry of Health's ability to hire health workers and expand service delivery, leading to high health worker unemployment rates. Even in decentralized settings, fiscal transfers to subnational governments (or even to facilities) are only very loosely based on the health-care needs of populations. As a result, the demand for health workers in the public sector often fluctuates with government (or facility) fiscal conditions, and this has been well documented empirically in both developed and developing countries. As noted in the Introduction section, the fact that addressing the needs-based shortage of health workers in subSaharan Africa would require more than 2.5 times the projected financial resources set aside for health worker salaries helps explain why there are so few health workers (relative to need).

The nonprofit sector operates similar to the public sector, except that specific agencies will focus on particular diseases, populations, or geographic areas. In developing countries this is important because the nonprofit sector is often a major employer of health workers, especially in very poor countries. Moreover, specific to developing countries, if significant levels of donor assistance for health are channeled through nonprofit organizations with little coordination with the government, this further increases the demand for health workers within the nonprofit sector.

In the for-profit sector, the demand for health workers is driven by profit maximization. Among individuals, the demand for health workers is influenced by the demand for health-care services, which is driven by a person's health status, ability to pay, and other factors. In many developing countries, the individual-level market for health services is large, and as a result, individuals and households are a significant source of direct demand for health workers. In a sample of 15 countries in subSaharan Africa, for example, out-of-pocket payments accounted for a low of 6% of the total health spending (Namibia) to a high of 62% (Chad).

The supply of labor in the health sector can be defined as the total amount of labor, or in the simplest sense the number of health workers, willing to work at current wages, holding constant other important variables like working conditions. A more refined definition could incorporate various aspects of effort, including productivity (e.g., hours worked, number of patients treated) and quality (e.g., care provided according to treatment guidelines). It is important to highlight several key decisions that influence the supply of health. These include the migration decision (whether to stay in the country), the labor force participation decision (whether to work or not), and the health-care labor force participation decision (conditional on working, i.e., whether to work in the health sector or in some other field).

Migration of health workers is an important issue in many countries, but especially in developing countries. As much as 70% of the medical workforce in subSaharan African countries eventually migrate. High rates of migration are also found in other regions. Many view migration as the single biggest challenge to strengthening health systems in developing countries. The health-care labor force participation decision is often overlooked by policy makers, yet has important implications. Several studies have shown that even small changes in the health-care labor force participation rate have important effects on the supply of health workers.

Migration and labor force participation decisions determine the supply of health workers within a country. Beyond that, the internal migration decision (which geographic area to work in), the sector decision (whether to work in the public or private sector), and the 'effort' decision (productivity and quality) influence the supply of labor in various settings of interest (e.g., a rural public clinic). When delineated this way,

it is clear that there are intervention points to influence the supply of health workers that go well beyond simply adjusting enrollment levels within education institutions. Too often in developing countries, policy makers overlook several of these critical labor supply decisions.

Just as with the demand for labor, a host of factors unrelated to the health-care needs of the population influence the labor supply decisions of health workers. Migration decisions are influenced by relative wages, working conditions, individual and family characteristics, and preferences. Labor force participation of health workers depends on factors such as wages and working conditions and family income, and the health-care labor force participation decision is influenced by the wages and working conditions of jobs in the health sector compared to relevant jobs outside the health sector. All of these labor supply decisions are also heavily influenced by demographic characteristics such as age, gender, family size, and parental education levels.

It is clear that both the demand for and supply of health workers in developing countries are influenced by a complex set of factors that are unrelated – or at best loosely related – to the health-care needs of the population. This has an extremely important implication: the health labor market – even at market-clearing employment and wage levels – will not necessarily generate health worker employment outcomes that meet the needs of the population. From the policy maker perspective, this provides the rationale for intervening in the health labor market to influence demand, or supply, or both, to move employment outcomes closer to those that promote society's goals with respect to health outcomes.

The Developing Country Context

Several aspects of the health labor market that are, if not unique, at least particularly relevant in the developing country context are worth discussing.

Remuneration is Highly Regulated

In settings where health workers are employed as civil servants, remuneration levels are highly regulated and must be set within civil service regulations. Market forces do not exert a strong influence on health worker remuneration in such settings. Health worker salaries are rarely adjusted in response to actual or projected shortages or surpluses. Rather, they are set relative to other occupations (e.g., teachers) and relative to historical levels. For example, instead of being a function of market conditions, wages for one level of nurse are often set relative to a higher or lower level nurse or relative to another civil service worker with the same number of years of training and experience, such as a teacher. The empirical evidence suggests that remuneration regulations in developing countries – for both legal and political reasons – constrain health worker remuneration changes. In settings where health worker remuneration has been decentralized or removed from the overall civil service, there is much more autonomy for facilities to adjust remuneration in response to market signals.

Salary Is a Dominant Remuneration Method

The way doctors and nurses are paid can provide strong incentives for improving health worker productivity and quality of care. In many low-income countries, health workers in the public sector receive most of their compensation in the form of a salary. Along with weaknesses in governance, this is an important factor contributing to the significant level of health workforce absenteeism and low productivity many developing countries experience. Alternative types of payment mechanisms have the potential to provide stronger incentives to health workers and thereby improve performance and efficiency. Developed countries have a long history of alternative payment mechanisms, including fee-for-service, capitation, and performance-based pay, but only recently have developing countries experimented with innovative compensation policies. The benefit of performance-based pay is that it aligns the incentives and rewards to health workers with the particular objectives of the district or facility where health workers are employed, and several empirical studies have demonstrated this.

Remuneration is Fragmented

Allowances are often a significant component of health worker remuneration. For instance, allowances account for 45% of the overall health wage bill in Kenya and 14% of the overall wage bill in the Dominican Republic. However, allowances are often fragmented and are not used strategically. In Kenya, for instance, the more lucrative housing allowance that accrues to doctors in the Nairobi area has created a disincentive to locate in remote areas. In the Dominican Republic, after a health worker leaves a location, the geographic allowance he or she was receiving turns into a permanent component of the worker's wage. The allowance structure in many developing countries is often not designed to raise remuneration levels in less desirable work settings relative to remuneration in desirable settings. These compensating differentials in remuneration are necessary to recruit health workers to less desirable settings such as rural areas.

Donor Assistance for Health Is Significant

In many developing countries, particularly in subSaharan Africa, there are significant external resources devoted to investments in the health workforce. For example, approximately one-fifth of the UK's support for the health sector in developing countries is channeled to health workforce activities. Although most of these health workforce resources are used to finance in-service training of health workers, agencies such as the Global Fund to Fight AIDS, TB and Malaria and the Global Alliance for Vaccines and Immunization devote significant resources toward health worker remuneration. When there are significant levels of donor assistance for health that are not fully coordinated with the government (through a national health strategy), this poses a challenge for health workforce policy. Nongovernment organizations and other nonprofit organizations are not subject to the same regulations as the government and, as a result,

offer terms of employment that are very different than what is available to health workers in the public sector. This can generate significant movements of health workers across different sectors and can influence greatly the allocation of health workers across various priority programs.

There Are Administrative Inefficiencies in Key Management Functions

Owing to various reasons, including a centralized hiring process, the recruitment process in developing countries is often subject to significant delay and is not targeted to areas with the highest need for staff. For example, in Kenya in the late-2000s, it took an average of 10 months to fill a vacant position once a suitable candidate was found. With reforms to the hiring process, this has recently been reduced to an average of 3 months. In many developing countries, salaries follow people rather than remaining tied to a particular position. In other words, when health workers transfer or move, they often retain their remuneration level. This poses a significant challenge in that it limits the extent to which remuneration can be linked to a specific position (rather than person) and, therefore, the ability of policy makers to generate compensating differentials to attract health workers to less desirable settings. Decentralization, under certain conditions, has the potential to significantly reduce many of these inefficiencies in administrative procedures. For example, when Rwanda devolved remuneration authority to the local level, facilities were able to adjust payment levels to attract health workers to some of the hardest-to-fill positions.

Dual Job Holding Is Extremely Common

In developing countries, health workers often hold more than one job. For example, more than half of doctors in South Africa have additional employment outside of their primary practice. Often, the primary job is a salaried position within the public sector and the second job is after-hours in a private clinic. Although some governments explicitly allow dual job holding through part-time contracts (e.g., Dominican Republic), it is often poorly monitored and regulated. The challenge that dual job holding poses is that it limits the influence policy makers have on total remuneration and, therefore, the incentive structure health workers face within the entire health-care system. Vietnam is a useful illustrative example. In Vietnam, salaries of physicians working in the public sector are set according to Ministry of Health policy and are deliberately set higher in rural areas in order to make rural postings more attractive. This is a sound strategy on the part of the Ministry of Health. However, when all sources of income are taken into consideration, including earnings from dual job holding, the total remuneration in urban areas ends up being much higher than in rural areas. In fact, the effective hourly wage in the second job (in the private sector) is almost double the primary job in the public sector. As a result of dual job holding, there is a considerable earnings disadvantage to locating in rural areas of Vietnam that the Ministry of Health's salary structure did little to reverse.

Using a Labor Economics Perspectives to Guide Policy

The labor economics perspective suggests that to design effective health workforce policies, it is important to understand the overall labor market conditions in the health sector – namely, is the current employment level demand constrained, supply constrained, or at or near equilibrium? For example, when there are surpluses (i.e., few unfilled vacancies and unemployed health workers), it is necessary to stimulate demand in order to increase employment levels. In the public sector, this might be done through lowering wages or increasing resources available for hiring health workers. Negotiating lower wages in the public sector is difficult politically for the various reasons mentioned, but effective wages can be lowered through skill substitution (e.g., shifting tasks away from physicians toward nurses) or contracting with private agencies where total labor costs might be lower. Increasing the level of resources for salaries can be achieved through direct increases in Ministry of Health salary budgets or increased block transfers to districts or facilities (in a decentralized setting). Each strategy has its associated challenges, but there are several examples of countries that have successfully implemented these policies. Reducing the price of health services to households is also an effective way to stimulate demand for health-care and, therefore, for health workers. This can be achieved through reducing or removing user fees or other financial barriers to care. However, policies that aim to increase the supply of health workers are much less appropriate when there are labor surpluses. Increasing the number of graduates, for example, will likely increase health worker unemployment rates when employment levels are demand constrained.

When there are shortages of health workers (i.e., there are unfilled vacancies), a different set of policy options is required in order to change employment levels. In this case, the supply of health workers needs to be targeted. One option is to expand training capacity to increase the number of health workers, provided that graduates remain in the country. Higher wages, improved working conditions, and better continuing education opportunities are some of the interventions that will make jobs more attractive to health workers. Although wages tend to receive the most attention, evidence has shown that improving other job characteristics is often a more cost-effective way to attract workers to vacant posts.

Labor economics also offers some specific quantitative and qualitative analytic tools that can help generate empirical evidence to guide health workforce policy on specific issues. For example, qualitative analysis can be used to identify the critical job characteristics that influence health worker decisions to locate in rural areas and, more broadly, factors that influence health worker motivation and performance. A technique known as discrete choice analysis, in which potential workers are asked to rank jobs with different attributes (including, e.g., wage, location, and training) can be used to quantify the expected impact of alternative policies aimed at recruiting health workers to rural areas. The Government of Liberia recently implemented a rural area incentive program for nurses that directly incorporates findings from a discrete choice analysis. Labor force surveys can be used to

measure current health worker remuneration differentials between different levels of care, specialties, and geographic areas, and the remunerations differentials that would be necessary to entice health workers to change job locations.

Through a better understanding of the underlying behavior of health workers and those that employ them, and how they interact in the health labor market, policy makers can more effectively design health workforce policies. The labor economics paradigm can be an important tool to help address the many health workforce challenges in developing countries and, ultimately, to improve the health of the population.

Health Microinsurance Programs in Developing Countries

DM Dror, Micro Insurance Academy, New Delhi, India, and Erasmus University Rotterdam, Rotterdam, The Netherlands

What is Microinsurance?

Microinsurance does not have a single accepted definition. However, two well-known sources provide high-level definitions and describe salient traits that help establish what microinsurance is and what it is not. These are introduced in this section and used throughout this article to anchor the discussion.

1. Dror and Jacquier's seminal work coined the expression 'microinsurance' and defined it as voluntary, group-based, self-help insurance schemes for which the group designs the premium, benefits, and/or claims to be attractive, relevant, and affordable to excluded populations in the informal sector. This definition departs from classical demand-driven market theory which views the individual as formulating demand, whereas here the group takes that role, and group demand reflects its aptitude to pool both risks and resources in order to provide protection to all members. This definition can be viewed as applying the subsidiarity principle (that decisions should be taken at the lowest level where they can be taken). Hence, both the governance and the utility are mutually determined by those most concerned. And, because microinsurance is typically targeted at low income, poor people (even though this is not a necessary trait), it manifests atypical pooling and risk transfer.
2. The International Association of Insurance Supervisors (IAIS) defines microinsurance as insurance for low-income people provided by a variety of institutions, run in accordance with generally accepted Insurance Core Principles, and funded by premiums proportionate to the likelihood and cost of the risk involved. Microinsurance serves populations in the informal sector that are excluded from or not served by other insurance.

These definitions have much in common:

- microinsurance is insurance (as distinct from savings and credit) and applies principles of risk pooling;
- coverage is always contributory (i.e., schemes that are 100% subsidized would not qualify as 'microinsurance');
- microinsurance is independent of the size of the risk-carrier (can be a local, informal mutual-aid society, or a large national or multinational insurance company);
- microinsurance is independent of the scope of the risk (risks do not become 'micro' when coverage is partial or the insured that experience them are poor);
- microinsurance is independent of the delivery channel (the most common options are small community-based schemes, credit unions, microfinance institutions, or local agencies);
- microinsurance is independent of the class of risk (life, health, crop, livestock, assets, etc.);
- microinsurance targets people in the informal sector;
- microinsurance is suited to people on low incomes (in the second definition this is a defining trait);
- affiliation to microinsurance is voluntary, the first definition makes this explicit and it is generally consistent with the tenor of the second definition.

Although both definitions identify that microinsurance suits poor people with low incomes, and it is an intuitively appealing place to start a definition, including it as a defining trait in the second definition raises operational problems. Measuring low income is complex especially when accounting for the depth of poverty, length of time of being low income, the phase of life (e.g., childhood vs. mid-life), and the comparative deprivation level by reference to the society in which a person lives. Thus, insurers rarely have the knowledge or the motivation to synthesize such complex information that is per se not relevant for underwriting risks. Furthermore, it is also not simple to determine whether premiums are proportionate to the likelihood and cost of the risk involved without specifying the method of premium pricing; this information is not revealed by habitual insurance performance indicators.

There is at least one fundamental difference between the two definitions, vis the role of the group. Because this radically fundamental distinguishes the definitions, the author explores it further.

Communities might variously be area-based, trade-based, faith-based, gender-based, cause-based, ethnicity-based, and other. The core assumption underlying the first definition is that the group is the framework within which cultural, demographic, and general economic factors are shaped in an otherwise unstructured 'informal' environment. The community relies on profound information that is not known outside the community and may have a different logic to that on which commercial insurance decisions are based. Without this group engagement, the market for insurance continues to struggle to establish viable supply and solvent demand for insurance.

Those that accept the second definition believe that commercial or other service providers have the capacity to establish viable supply for which demand can be assumed to exist.

Under both definitions, it is clear that if the scheme is not customized to be relevant to the specific context and needs of the community, it cannot be classified as microinsurance. This has erroneously been taken to mean that national microinsurance programs are not possible. If national programs can be tailored to local needs, they can be described as microinsurance.

How Common is Microinsurance for Health?

Recent overviews of microinsurance activity in poor nations have shown a low penetration rate with some 3% of the poor

 doi:10.1016/B978-0-12-375678-7.00922-6

in the world's 100 poorest nations having some microinsurance in 2007, and only 0.3% having health microinsurance. These figures relate to insurance more consistent with the second definition than the first. Of the 78 million people covered by any microinsurance, only 3.2 million are covered by mutual or community-based organizations that would clearly fit the first definition. Although it is not clear what proportion of these 3.2 million have health microinsurance, it is manifestly apparent that health microinsurance consistent with the author's definition has not reached many of the at least 2.5 billion people who need it. Although a raft of barriers to the growth of microinsurance have been identified, the most fundamental include: poor distribution channels and poor business infrastructure; a history of mandated credit life insurance that builds antagonism among consumers; a prevalence of commercial microinsurance schemes that, although compliant with government requirements, often provide no benefits to the poor; ill-fated attempts to build universal coverage of health insurance where there are neither funds for such a scheme nor adequate available health services. Moreover, regulation remains poor with microinsurance sometimes being ignored by policy and sometimes included without distinction, and the best practice is yet to be identified.

Stated simply, the market (both supply and demand) for health microinsurance remains small or even nonexistent in most settings. If insurance were simply a risk-transfer tool, health microinsurance would theoretically be attractive to low-income populations who are exposed to many and various health risks. Moreover, Nyman's game-changing assertion that health insurance is demanded because it provides an income transfer from the well insured to the sick insured irrespective of risk management, suggests that microinsurance for health would be particularly attractive among the poor who practice reciprocity (rather than state-mandated cross subsidization or solidarity) for their burden of disease. And, notwithstanding the Prospect Theory's challenge to the validity of risk avoidance as a rational motive for insurance, there remains widespread acceptance that the market for insurance in general and health insurance in particular is a market for risk avoidance.

Yet, the typical situation observable everywhere is a dearth of both supply and demand for health insurance at the informal sector in low-income countries, which the private/commercial sector and government are ill-suited to resolve because the economic and behavioral choices in the informal economy differ fundamentally from those prevailing in rich and orderly/rule-based economies. These behaviors and decisions are often regulated or shaped by community interests in ways that may be inconsistent with the expected behavior of a single individual economic actor.

Given that poor excluded populations have great health risk and are in need of income transfer when ill and that they live in communities that can give structure to both the supply and demand side, why then is community-based microinsurance for health not more prevalent? The reason is that successful insurance, even at the community level, requires technical and actuarial knowledge as well as advanced financial literacy, which are sorely missing in the informal sector. Therefore, these barriers to success cannot typically be overcome without external drivers to develop capacity and drive institutional change that will enable markets to establish. In this sense, the lack of a market for micro health insurance is a failure of context rather than market failure.

Typology of Microinsurance Business Models

At least four basic operating models to deliver health microinsurance have been described as 'microinsurance':

1. The partner-agent model in which the role of the insurance company ('the partner') includes designing, pricing and underwriting of products, and responsibility for scheme solvency in the long-term. Distribution/marketing, premium collection, and product servicing are usually delegated to an intermediary ('the agent'), often a person or a for-profit legal entity. Insurance companies usually pay agents a commission on premiums sold. This remuneration method is effective in urban settings and among solvent populations, but less so in the informal sector, where reaching persons may cost much time, and lead to few closed sales. This is why, in Africa and in Asia, insurers have been keen to assign the agency role to bodies that interact frequently with rural and low-income populations, such as nongovernmental organizations (NGOs) or Micro Finance Institutions (MFIs). Where MFIs have identified a need for health insurance (e.g., when illness caused default on repayment of debts), they have sometimes approached insurers to design a suitable insurance product, and suggested the price range that would be acceptable, and pressured providers for better services and claim settlement.

   The partner-agent model could qualify as 'microinsurance' under the second definition if it offered insurance to low-income people, but may not qualify under the first definition as the design decisions are taken by insurers, not by the community. That said, when MFIs acting as agents also involve the community in the bidding process and in priority setting, one could argue that this is a borderline situation that could also meet the requirement of the first definition.
2. The provider-driven model, in which clients pay premiums to the healthcare provider (e.g., hospital, physician), which in turn enables them to consume health services without having to pay out of pocket at the point and time of service. The healthcare provider benefits from this arrangement by creating larger solvent demand for health services, sold mainly by the provider-insurer; and increasing and smoothing the cash flow as it is dissociated from incidence of illness.

   The healthcare providers are responsible for designing, pricing, and underwriting insurance products and for the long-term sustainability of insurance operations.

   The provider-driven model could qualify as microinsurance under the second definition if the client-base of the insurance is composed of poor people. However, it is unclear whether low-premium policies that include rare and expensive surgical procedures would still qualify as 'microinsurance.' Under the first definition, this arrangement would not qualify as 'microinsurance' as the

decisions on pricing, package design, and claims settlement are taken by the provider-insurer according to its commercial interests and capacity to provide, possibly without inputs from, or participation of the community in governance of the insurance. Although there are examples of the healthcare provider investigating need for and willingness to pay (WTP) for health insurance, in all cases the role of the community was limited to passive informant rather than meaningful engagement in decision making.

3. Charitable insurance model (a.k.a. 'full-service' model), in which an external charitable organization, acting as 'insurer,' assumes responsibility for the long-term sustainability of the scheme by supplementing the payment of premiums, because there is an assumption that contributions could never cover all costs of benefits provided. Many charitable insurers are run by NGOs, many are operating not-for-profit, and many may view the insurance as a suitable vehicle to promote their main development, or religious goals. The external donor retains much of the responsibility for product design, pricing, and administering the scheme, in ways that would align with the fundamental objectives of the organization. Thus, there are instances where the charitable insurer fixes premiums below the actuarial cost, or does not enforce the requirement that only paid-up insured can access benefits.

   The charitable insurance model could qualify as 'microinsurance' under the second definition when the financial arrangement protects low-income people against specific perils in exchange for regular premium payments proportionate to the likelihood and cost of the risk involved; it would not qualify as 'microinsurance' when the payment of premium is irregular, and/or when that premium is disproportionate to the risks involved. Under the first definition, charitable insurance would qualify as 'microinsurance' when the community of beneficiaries participates in key decisions and in governance of the scheme, and would not qualify as 'microinsurance' otherwise.

4. Mutual/cooperative insurance model, in which the insured is also the insurer, so that each member of the mutual (or cooperative), together with all other members, is simultaneously benefitting and underwriting at least part of the risk. The community of members is thus responsible for all aspects of the scheme including designing, pricing, and underwriting products and for the long-term solvency of the insurance. The mutual model finds its origins in nineteenth-century Europe, and has been launched, designed, implemented, and administered by and for groups of people without access to the resources and financial techniques of commercial insurance. Being directly in contact with its membership, this insurer can 'disintermediate' the agent role and save agent commissions. As the interests of mutual insurers are identical to those of its members, the first priority is to establish a good fit between the needs of members and the benefit package. Many mutual societies are not only insurance providers, as they function as broader mutual-interest organizations. Some mutual organizations have grown to be very large and have professional management, which can distance the operations from the members, resulting in less social cohesion in large mutuals than in community-based schemes.

   The mutual/cooperative insurance model could qualify as 'microinsurance' under the first and second definitions, provided that the insurance covers low-income people, and the community of beneficiaries participates in key decisions and in governance of the scheme. It is in fact the only model that could satisfy both definitions of 'microinsurance' (Table 1).

In reality, any health microinsurance scheme can have features of multiple models. For example, in Uganda, there are several mission hospitals that run provider-driven insurance schemes, yet they are heavily subsidized, and thus similar to a charitable scheme. Moreover, schemes can start as one model and change over time, as did the Yeshasvini Trust in India, which was initially founded by healthcare providers, and is currently run as a not-for-profit charitable model. The providers largely designed the current benefit package and the trust developed as a mixture between a charitable model and provider-driven model.

Insurance Failures under Microinsurance

There is no principal difference between health microinsurance and any other health insurance in terms of exposure to insurance failures, but there are, or can be, significant differences to exposure under the different business models. The phenomena usually considered as 'insurance failures' include adverse selection, cream skimming, moral hazard, free riding, and fraud.

Adverse selection describes the situation in which an insurer accepts offers of insurance of high-risk persons at rates that do not reflect the actuarial premium attached to their risk class because the insurer does not have full information about the risk that these individuals represent. In response, insurers increase premiums to fund higher costs, which lead to lower participation of people with lower risks, and could even lead to exit of higher risks due to unaffordable premiums. Adverse

Table 1 The fit between the definition of microinsurance and microinsurance business models

Type of business model	*First definition (Dror and Jacquier)*	*Second definition (International Association of Insurance Supervisors)*
Partner-agent model	No, unless motivated to include community decision making	Yes, if client is poor
Provider-driven insurance	No, unless motivated to include community decision making	Yes, if client is poor
Charitable insurance	No, unless motivated to include community decision making	Yes, if client is poor and they pay a premium proportional to risk
Mutual/Cooperative insurance	Yes	Yes

selection is more likely to occur when affiliation is based on individual contracts and is voluntary, and is least likely when affiliation is mandated for a large group. The effective countermeasure to adverse selection is 'en bloc affiliation' of an entire community, even when this is not obligatory.

In the context of health microinsurance, adverse selection is more likely to occur under partner-agent, provider-driven, and charitable models, when they allow voluntary and individual affiliation. En bloc affiliation occurs often under the mutual/cooperative model, and sometimes under the partner-agent model when the agent is a strong NGO that can in fact affiliate an entire community.

Cream skimming, also known as 'preferred risk selection' or 'cherry-picking' (and when it takes the form of nonrenewal it is called 'lemon-dropping'), occurs when an insurer selects only part of a large heterogeneous group which the insurer estimates as being lower-than-average risk (the preferred risks) without discounting the risk-rated premium they are required to pay. The purpose of cream skimming is to enable the insurer to retain profits by reducing the loss ratio.

In the context of health microinsurance, cream skimming occurs when the standard contract includes certain limitations by age (e.g., the insurance is valid only from age 3 to age 60), or by health status (e.g., excluding certain illnesses, chronic conditions etc.), or by benefit types (e.g., cover only a limited list of procedures requiring hospitalizations etc.). Clearly, exposure to this situation is more likely to prevail when the underwriter has free hand in determining the terms of the policy (this is frequently the case in the partner-agent model or the provider-driven insurance) and is less likely to occur when the insured can influence the terms of the policy (as in the mutual/cooperative model).

Moral hazard is the increase in healthcare utilization that occurs when a person becomes insured, which is an insurance failure because insurers pay out more in benefits than was expected when setting premiums. The conventional interpretation is that this additional healthcare utilization represents a loss to other insured people, as they ultimately bear the cost of additional demand. Nyman pointed out that this interpretation is based on the assumption that the extra healthcare is not clinically needed (e.g., cosmetic surgery), but where the extra demand is needed the extra care is a gain to society. Although increased utilization patterns cannot automatically be considered as bad outcomes (as suggested by the term 'hazard'), they are insurance failures when payout exceed actuarial estimates. The conventional remedy for moral hazard is to require consumers to pay part of the cost (i.e., copay) in every case, or that the insurer can legitimately control utilization.

In the context of health microinsurance, given that the target populations chronically underutilize health services, it would be reasonable to expect that health insurance would lead to increased utilization of services covered by the particular health microinsurance scheme. This theoretic welfare gain is borne out by empirical research in India and the Philippines, which indicate a transition from underutilization to normal utilization, as the income transfer overcomes the financial constraints on accessing healthcare. Under the mutual-aid model, where community of insured is simultaneously also the underwriter, the community has very good information on its members when the group size is small. Thus, it can exercise peer pressure to reduce moral hazard.

Moral hazard can also be induced by providers of care that benefit from overtreating insured persons. 'Supply-induced moral hazard'is not easily detected or limited in the context of health microinsurance, but low insurance caps obviously limit not just the cover but also the margin of providers to generate overconsumption. Under the provider-driven insurance model, the provider can exercise better control of supplier-induced moral hazard, but at the same time the provider might be in a situation of conflict of interest to do so.

Free riding arises when a person benefits from the health insurance scheme without paying premiums. This risk is due to imperfect monitoring of those drawing benefits; cashless delivery of services can increase the risk of free riding. The countermeasure for this is to improve monitoring of the system with the view to ensuring that only legitimate beneficiaries will draw benefits. Smart cards and similar electronic devices are increasingly popular aids to monitoring.

In the context of health microinsurance, where there is very little access to IT and where online/real-time access to an management information system (MIS) is rare, it may not be feasible to reduce free riding through automated checks of claims. Rather, the remedy to free riding would consist of creating a counteracting interest to disallow or adjust payments. The mutual/cooperative model has such inherent characteristic, in that all members are simultaneously insurers and insured, share the same informal, local information that circulates informally and free-of-charge (i.e., gossip), and have (or could have) a say in claims adjudication. Thus, they have both the incentive to reduce costs (as excessive payments would translate into higher premiums) and the responsibility to settle claims (and can therefore filter unjustified ones).

Fraud is when someone knowingly provides inaccurate or incomplete information to claim benefits or advantages to which they are not entitled, or someone knowingly denies a benefit to which someone else is entitled and that is due. This issue is similar to free riding (although there may also be provider-induced fraud).

In the context of health microinsurance, the two business models that can reduce the risk of fraud by narrowing the gap between the flow of information and the flow of funds are the provider-driven insurance model and the mutual/cooperative model. This is because the underwriter also has much information on the claimants that can be availed free-of-charge. Provider-insurers in the provider-driven insurance model are in a potentially strong position to undertake provider fraud, which they can avoid only when they refrain from acting on their incentive to maximize profits. Operators in the mutual/cooperative model have no particular access to information on provider fraud, and would have to rely on investigation as would underwriters operating the partner-agent model and the charitable model, which could be disproportionately costly relative to the small sums insured.

Clearly, operators in the mutual/cooperative model have greater access to information that reduces or removes insurance failures arising from asymmetric information, i.e., adverse selection, moral hazard, free riding, and fraud. The exception is information asymmetries on provider-induced moral hazard and provider fraud, for which the insurer-providers in the

provider-driven insurance model have an information advantage. Absence of such information exposes the other business models to greater risk of failure (Table 2).

Application of Specific Actuarial Issues to Microinsurance

It is often stated that insurance is a numbers game relying on the Law of Large Numbers, vis: that the larger the number of independent risks in a pool, the lower the variance of mean losses. Lower variance translates to lower pure risk premium. Yet, most health microinsurance schemes are small, their intrinsic capacity to diversify risks limited, and their exposure to covariate risk is high due to the homogeneity of their clients. Simulation studies have shown that capital loadings to secure solvency are exponentially higher for small schemes. Notwithstanding the financial advantages and potential of lower premiums, pooling of schemes on a voluntary basis has not occurred. Pooling small schemes would be relatively simple if they all had an identical risk profile and shared priorities. In reality, health microinsurance schemes usually cover location-specific risks and priorities, which make pooling schemes more complex because of the differences from scheme to scheme and from community to community. The potential for governments to put in place mechanisms to adjust risks across mandatorily pooled schemes is remote, given the voluntary nature of microinsurance, and the damage such regulatory intervention could have on the role of the community in designing premiums and benefits. A proposal to create reinsurance for microinsurance (labeled 'social reinsurance'), which would provide large pool efficiencies at the reinsurance level, has so far not been implemented.

A paucity of data and its quality with which to determine stochasticity and quantify risks is a perennial problem for microinsurance, particularly health microinsurance. This means that launching a new micro health insurance (MHI) scheme must be preceded by data collection to ensure that premiums reflect rigorous risk estimates, and benefits are customized to address the main risks. Some early movers in the health microinsurance market took a simpler approach to the problem of lack of data by downsizing commercial insurance products that they had developed for the entire country instead of designing specific products with accurate pricing for this market based on a deep understanding of the particular needs of potential customers of microinsurance. The low uptake of such low-cost-low-benefit packages indicates that this approach was not suitable.

Some MHI schemes have introduced innovations in coverage that have actuarial ramifications. For example, in India and Nepal, where entire families share one 'purse,' some schemes have introduced a 'family floater' condition (i.e., a capped benefit which can be used by one or more members of that household) which requires rather sophisticated actuarial calculations to triangulate the estimated loss ratios to the distribution of family size.

In addition to ensuring that the pure risk premium is commensurate with the risk covered, actuaries need to calculate loadings on the premium to cover administrative, operational, and other costs, and, in some business models, profit. Given the high transaction costs associated with business models other than the mutual/cooperative business model, there is rationale to increase premiums, which is at odds with the clients' apparent WTP. In the absence of an acceptable notion of an equitable price, setting the premiums is fraught with uncertainties.

A different approach to explaining the link between premium and coverage has been to say that in microinsurance the price determines the coverage, whereas in other insurance the product determines the price; this point is elaborated in the Section The 'Make-It-Or-Break-It' Factor of Microinsurance: Willingness to Pay.

The 'Make-It-Or-Break-It' Factor of Microinsurance: Willingness to Pay

Under all definitions and types of health microinsurance, prospective clients, who are mostly living and working in the informal economy of low-income countries, affiliate on a voluntary basis. These people cannot be obliged (by governments or others) to pay a premium, even when subsidies cover a share of the expected costs. This means that the WTP of the target population determines the insurance package, rather than the product determining the price, as is typical in insurance. Therefore, WTP is the make-it-or-break-it factor of health microinsurance.

This is why it is essential to estimate WTP before launching the insurance. The most common method for prelaunch estimation of WTP for health microinsurance is contingent valuation (CV), which surveys the target population's responses to hypothetical insurance products and premiums. Respondents are required to think about the contingency (or feasibility) of an actual market for the benefits, and state the maximum they would be willing to pay for them. Over the years, different methods have been developed for the presentation of scenarios and the analysis of the responses.

WTP for health microinsurance is positively associated with income and increases nominally as income rises, but when expressed as a proportion of income, WTP declines as income grows; education; the quality and availability of health services; and recent exposure to healthcare costs. Men are willing to pay higher amounts than women. However, empirical evidence from India and Nigeria show that notwithstanding these variables, WTP is highly location specific, meaning that any temptation to roll out a one-size-fits-all microinsurance (be it in order to capture economies of scale in administering policies, or to establish some kind of a prescribed minimum level of benefits, or to aggregate the risk of more insured persons) may be thwarted. As WTP is location specific, so health microinsurance should be context-relevant in order to succeed. The related question is whether people actually pay the expressed WTP; at this point in time there is not enough published evidence on this question in the context of microinsurance.

The Impact of Health Microinsurance, and Why it is Not More Common

Early attempts to assess the performance of microinsurance for health were limited to measuring several accounting ratios,

Table 2 Summary comparison of the basic features of four microinsurance business models

	Partner-agent model	*Provider-driven insurance*	*Charitable insurance*	*Mutual/Cooperative insurance*
Objective	For commercial underwriter and for-profit agent: main objective is profit. For nonprofit agent (NGO) main objective pooling of health risks. And if NGO is MFI, insurance helps ensure healthier clients – and better loan repayment	For-profit providers: profit. For nonprofit providers: disseminate services and increase access to own services	Provide insurance cover for selected risks at 'affordable' prices and donor's overall purpose	Mutual aid of the members only, by pooling their risks and resources
Product design and pricing	Mainly high-cost and low frequency events	Benefit package designed with the view to increasing utilization of own services	Responding to the donor's perception of prioritizes needs	Responding to the members' prioritized needs and willingness to pay
Rating method	Risk-rating if sold to individuals; community rating if sold through NGOs or MFIs	Experience rating	Community rating	Community rating
Sales	Exclusively through agents (with or without commission)	Direct marketing, through paid or unpaid referrals and/or agents	Use of existing community structures (e.g., SHG, NGOs, etc.)	Use of existing community structures (e.g., cooperatives, SHGs, NGOs, women's associations etc.) and involvement of members
Servicing	Direct claims processing (back office); or through third-party administrators (TPA); in rare cases, agents also contribute to servicing	Servicing through own facilities	NGOs may have a role in claims servicing; otherwise, through back-office functions at providers' facilities (especially when donor arranges cashless access to services)	Both front-office functions (collection of premiums, dissemination of information etc.) and back-office functions; claims processing are done by community members
Sustainability				
Who is responsible?	Responsibility with underwriter	Responsibility with provider	Responsibility with donor	Responsibility with the insured, collectively
Source of income	Income from premiums; income from investment of reserves	Income from premiums; income from other activities of the provider or from subsidy	Income from premiums; income from the donor	Income from premiums
Pricing of premiums	Pricing must ensure underwriter profits (i.e., cover claims costs, marketing and admin costs, operational risk costs, regulatory compliance costs, agent commissions, plus profit).			
What if NGO?	For-profit: Pricing must ensure provider profits for services rendered to the insured; nonprofit: prices must ensure cost of services rendered minus any costs covered by subsidies	Pricing must cover the cost of benefits and admin costs up to the level considered by the donor as 'affordable'	Pricing must cover the cost of benefits plus admin costs	

(*Continued*)

Table 2 Continued

	Partner-agent model	*Provider-driven insurance*	*Charitable insurance*	*Mutual/Cooperative insurance*
Risks to sustainability	Nonrenewal due to client attrition; error in accurate pricing; fraud; moral hazard; provider-induced moral hazard; adverse selection	Nonrenewal due to client attrition; error in accurate pricing; fraud; moral hazard; adverse selection	Donor attrition; low affiliation rate if benefits do not meet clients' priorities; nonrenewal (client attrition); fraud; moral hazard; adverse selection	Error in pricing of premium; exposure to higher-than-expected cost of benefits due to random aggregation of cost-generating events (higher fluctuations due to small risk pools in the absence of reinsurer; nonprofessional management of scheme
Factors contributing to sustainability	Large client-base, high renewal rate, low claims ratio	Contributory factors include: provider attracts the target population (perceived as good, offers the right services etc.)	Contributory factors include: premium perceived as affordable, good fit between clients' and donor's perceived priorities	Contributory factors include: involving insured in benefit-package design and priority setting; good fit between premiums and ability to pay; lower admin costs when front office and back office are managed by the mutual/cooperative locally, at local prices; en bloc affiliation; high renewal rate; low claims ratio; social capital reduces moral hazard
Main conflicts of interest client versus underwriter				
Premium	Yes: the underwriter wants to draw profit NOT IF NFP, and the client wants low premiums and high coverage	Yes: the underwriter wants to draw profit NOT IF NFP, and the client wants low premiums and high coverage	No: donor and client share the wish to have low premium and high coverage	No: the cooperative and the individual client share the wish to have low premium and high coverage
Benefit caps	Yes: insurer prefers a low cap to reduce underwriting exposure; clients prefer high caps to reduce risk of having to pay above-cap OOPS	Yes: insurer prefers a low cap, which reduces underwriting exposure; client would like high caps, which reduce risk of having to pay above-cap OOPS	Yes: insurer prefers a low cap to increase the number of patients served for a given subsidy. Clients prefer high caps, which reduce risk of having to pay above-cap OOPS	No: the cooperative and the individual client share the wish to have caps as low as feasible
Range of benefits	Yes: insurer prefers a narrow range (mainly low probability and high costs); client prefers a broad range of benefits, to enhance likelihood that insurance will cover any event	Yes: insurer prefers a narrow range, limited to the services that the provider can deliver; clients prefer a broad range of benefits, to enhance likelihood that insurance will cover any event	Yes: insurer prefers a range of benefits that are directly linked to the donor's prioritized services; clients prefer a broad range of benefits, to enhance likelihood that insurance will cover any event	No: the cooperative and the individual client share the wish to cover the priorities of the community members

Abbreviations: NFP, not for profit, SHG, self help group.

mostly reflecting financial performance of schemes. More recently, the product, access, cost, and experience (PACE) is used by practitioners to develop a better value-proposition for clients by comparing various microinsurance products to one another and to alternative means of protection from similar risks (including informal mechanisms and social security schemes). However, neither the performance indicators nor the PACE tool offer conclusive and robust insight to three fundamental issues: (1) what difference does the insurance have on utilization of healthcare services among the insured? (2) what difference does the insurance have on the financial exposure/protection of the insured? and, (3) what impact does insurance related improvements in healthcare utilization have on the health of the target populations? These are considered in order as follows:

1. What difference does the insurance have on utilization of healthcare services among the insured? A literature review aimed at answering the question, 'Do clients get value from microinsurance?' suggested that 'value' included three aspects: (1) Expected value – the value clients may get from a product through behavioral incentives and peace of mind, even if claims are not made; (2) Financial value – the value of the product when claims are made compared with other coping strategies; and (3) Service quality value – the externalities created by microinsurance providing access to product-related services of benefit to the client. Answers to these questions were sought in 83 studies on health microinsurance products. According to that report, some 43 studies found that health insurance positively influenced the use of health services. And some 33 studies generally found that insurance led to lower out of pocket spending (OOPS) in case of hospitalization. The major impact of insurance on increasing utilization of health services was confirmed by a different literature review using the randomized controlled trials (RCT) method of measuring impact, and the Cochrane Handbook's characteristics.

   These findings should be put in context. In high-income countries it is often assumed that increased utilization of health services among voluntarily insured persons suggests (or is evidence for) adverse selection (namely, higher propensity to insure among persons who are likely to have above-average healthcare utilization). This assumption is not supported by the findings of studies of healthcare utilization among clients of health microinsurance, where higher frequency of illness was not systematically associated with insurance status, suggesting that in these populations the assumption of adverse selection must be rejected. Rather, it seems that most of the target population for health microinsurance in low-income countries suffers from chronic underutilization of healthcare services, due to the inability to pay for more or better healthcare. Thus, improved utilization of health services among the insured population is an indicator of success in achieving a key objective of health microinsurance, of reducing the limiting factor of unaffordability.

   However, the utopian aspiration that health microinsurance would put in place both more utilization and more equitable distribution of that utilization may be too much to ask, considering the inherent limitation of microinsurance. The poorer the insured person, or the lower the coverage relative to the full cost of services, the more likely it is that insured persons would be unable to pay any copay required to access insured benefits. Thus, the effect of health microinsurance schemes on equality is ambiguous in theory, and in practice, it has been observed to be both positive and negative.
2. What difference does the insurance have on the financial exposure/protection of the insured?One possible indicator of the impact of microinsurance on financial protection is the total OOPS that the insured must bear when accessing insured benefits taking into account also indirect costs and premiums. Although no such analysis has been published, there has been discussion of 'catastrophic' healthcare costs, which have been defined in terms of percentages of household income or disposable income net of subsistence needs. Although such definitions have been used to show significant reductions in the incidence of catastrophic costs among members of health microinsurance schemes, the definitions are insensitive to relative levels of hardship and other healthcare cost-related factors that lead to hardship such as the need to get money quickly, which may necessitate borrowing at high rates and/or selling assets on unfavorable terms. Such 'hardship financing' can be more costly than the healthcare and can throw the sick into poverty. Therefore a more appropriate impact indicator might be the extent to which health microinsurance reduces the frequency or intensity of hardship financing. Studies using this alternative indicator are yet to be carried out.

   The impact on medical expenditure patterns (disregarding indirect costs and premiums) have been studied in various contexts with mixed findings. Some studies have found OOPS (defined as healthcare expenditures net of reimbursement by insurance, either per visit or over the course of an illness) decreasing whereas others found no effect. However, OOPS based measures ignore both premium payments and frequency of visits. Other studies assessed the impact on total annual healthcare spending, either per person or per household, and found an increase in annual health spending because although the cost of individual visits sometimes decreases under health microinsurance, the number of visits typically increases, potentially leading to increased overall expenditure. However, these findings are obscured by the failure of the studies to control for changes in the price of healthcare and changes in household income. Finally, three schemes have been evaluated for their effect on some measure of the socioeconomic status (SES) of insured households. Although two schemes reported a statistically significant increase in SES with higher levels of income growth among households which are insured, and/or reduced likelihood to sell off their food stocks to pay medical bill, the third found no effect of insurance on household income levels, assets levels or self-reports of food sufficiency.

   The literature on estimating or measuring financial protection of microinsurance must be considered with reserve, due to the challenge of obtaining a statistically valid comparison between insured and uninsured cohorts. Most

studies compare utilization of healthcare benefits by the insured with the utilization by persons residing in the same geographical area who are not insured. These comparisons were flawed on several counts: Firstly, they were usually one-off studies following implementation of the microinsurance that did not adequately examine whether the cohorts were different before implementation of the insurance and whether any difference was attributable to the intervention or to an inherent difference between the cohorts. Secondly, a simple comparison of the situation among the insured cohort before and after implementing health microinsurance could be misleading because one cannot exclude the possibility that several changes occurred that were unrelated to the intervention but which had an impact A recent publication explains the methodology elaborated to address such a challenge, following Cluster Randomized Controlled Trial protocol. The method is tested in three waves of microinsurance implementation, ensuring that at the end of the experiment the entire population is offered affiliation with a community-based health microinsurance, but through staggered affiliation. In each wave, villages are grouped into congruous preexisting social clusters; these clusters are randomly assigned to one of the waves of treatment. Before each wave, a baseline evaluation is conducted (using mixed methods, with quantitative, qualitative and spatial evidence collected on the situation). This method assures that the microinsurance schemes operate in an environment replicating a nonexperimental implementation and that all households are offered insurance.

3. What impact does microinsurance have on the health of the target populations? The few studies have explored the health outcomes of health microinsurance have generally found that although healthcare utilization has increased, it is too early to say if the insured have better health. In some cases, there has been a lack of baseline information on health status, making evaluation more difficult. The scant evidence available suggests that any improvement in health outcomes is typically skewed toward the wealthier members of the schemes, possibly because they are better informed about health and have better access to noninsured care and support.

Concluding Note

If health insurance is a 'numbers' game,' and if health microinsurance is the pro-poor variant of health insurance, then it should become the dominant model by virtue of the huge number of persons in the informal sector without health insurance, of whom many are poor. However, progress to develop both supply of and demand for health microinsurance is contingent on developing a workable business model. With most of the target population living and working in the 'informal sector' where governments cannot mandate payment of premiums or apply means-testing for partial subsidization, the implementation of MHI depends on WTP. At the current level of knowledge of how to estimate WTP, it seems that participatory, needs-based, context-relevant, partial, and complementary solutions offer more promise than supply-driven one-size-fits-all products or mandated dissemination models. The partner-agent model remains subject to acute risk of conflicts of interest between underwriter, agent and client, which is never eliminated. Provider-driven supply of health insurance has so far not offered a general formula for scaling. The charitable model, based on delivering subsidized health microinsurance is limited by the funds that the charitable donors can devote in the long term. The mutual/cooperative model, though typically small scale can overcome most barriers to establish a functioning market for health insurance among the poor.

The poor want health insurance and can pay premiums and health microinsurance can operate without subsidy, but possibly not at profit and not with extensive commercial intermediation. The low penetration of health microinsurance can be explained in terms of barriers to the establishment of a market with viable supply and solvent demand in the informal sector. This overall context failure cannot necessarily be solved by the insurance industry offering innovative products through various channels, and cannot necessarily be solved by government regulation, although innovation and regulation are essential if we are to put in place systemic (regulatory and financial) mechanisms to encourage the development of local health microinsurance schemes or to pool risks across schemes, or articulate the relations between local schemes and commercial underwriters and reinsurers. Communities have a central role to play in building capacity and awareness, providing information for actuarial calculations and scheme designs to suit local priorities and service availability, and building the institutional context in which viable supply and solvent demand can be established. That said, local grassroots initiatives are neither willing nor able to scale microinsurance over entire countries.

Preferred Definition of Microinsurance for Health

As a conclusion, the preferred definition of health microinsurance is as follows:

> Health microinsurance is insurance contextualized to the WTP, needs and priorities of people in the informal sector who are excluded from other forms of health insurance. The schemes are voluntary, with premiums suited to people with low incomes. Although health microinsurance is independent of the size of the insurer, the scope of the risk covered, and the delivery channel, it is essential that the scheme is designed to benefit the insured. For practical intents and purposes, this definition implies a central role for the community in at least the design of the scheme, and possibly its operation and governance.

Health Services in Low- and Middle-Income Countries: Financing, Payment, and Provision

A Mills and J Hsu, London School of Hygiene and Tropical Medicine, London, UK

Introduction

A total of 7.6 million children and 287 000 mothers (2010 data) die every year, and approximately 95% of these deaths occurred in 75 countries with the highest burden of maternal and child deaths. Of these, more than two-thirds could be avoided if everyone had access to known effective interventions. Making such interventions available is not just a matter of supplying a drug or vaccine; to ensure effective delivery of interventions, health systems need to be strengthened at all levels, from the community up to the national level.

Economists investigating how health systems can be strengthened in low- and middle-income countries have explored a myriad of issues. This article addresses three core questions:

- How are health services financed?
- What payment methods are used to purchase health services?
- Who are the health service providers?

In each case the concern is to establish the evidence and discuss the implications of current arrangements for efficiency and equity.

There is very active debate on some key policy issues relating to reform of financing, payment, and provision. The second part of this article addresses some of the most contentious issues, notably:

- The appropriate mix of financing sources as countries seek to expand financial protection and move toward universal coverage of health care.
- The role and impact of development assistance for health (DAH) in low- and middle-income countries.
- The desirability of incentive-based payments to health service users and health care providers.
- The role of private sector agencies in health system arrangements (insurance, payment, and provision).

In addressing all low- and middle-income countries, this article considers a very wide range of country circumstances. Health systems differ greatly across low- and middle-income countries, influenced not only by the level of national income but also by countries' colonial history (British, French, Dutch, etc.), political orientation post-independence, degree of openness to market forces both historically and up to the present, income distribution (existence of high income groups with considerable purchasing power), and of course health conditions. To avoid implying that one pattern fits all, it is crucial to recognize this diversity and its implications for appropriate solutions to the many challenging issues facing health systems in these countries.

How are Health Services Financed?

In general, health services in low- and middle-income countries are financed at a much lower level than in high-income countries, and smaller proportion of the total flows through organized sources (i.e., government and insurance intermediaries). Table 1 summarizes health expenditure per capita and the pattern of financing sources and agents by income group and geographical region.

The larger a country's economy, the more it spends on health – high-income countries spend on average US$4660 on health per person compared to US$356 in lower- and upper-middle-income countries combined and US$61 in low-income countries. The level of health expenditure per capita thus mirrors gross national income per capita and the evolution over time can be displayed on Gapminder (hyperlink embedded in Figure 1). Although spending more on health does not necessarily lead to improved health outcomes, a minimum amount of financial resources is required by a health system to deliver essential interventions. It is estimated that spending of US$60 per capita is needed by 2015 for low-income countries to provide the basic package of essential services required to reach the health-related Millennium Development Goals and strengthen underlying health systems. At present, 15 of the 35 low-income countries spend less than the 2015 mark on all health care, and all but two of these countries (Bangladesh and Afghanistan) are located in Sub-Saharan Africa. These figures highlight the challenges faced by low-income countries, particularly those in Africa, in financing essential services for their citizens.

Lower levels of health expenditure are combined with relatively low shares of financing pooled across population groups, indicative of a lack of organized financing arrangements. Low- and middle-income countries usually lack an adequate tax base or large formal employment sector and/or have weaker infrastructure and management capability; some are also suffering from conflict or are in the midst of a political transition such that they have a weak or nonfunctioning state. In contrast, financing agencies in high-income countries are better established, typically following a model where services are funded primarily from general tax or compulsory social insurance. Some middle-income countries have been more successful than others in expanding pooling arrangements: for example, in East Asia and Europe, social security makes up 56% and 47%, respectively, of general government health expenditure. This particularly reflects China, Indonesia, Philippines, and Vietnam where social health insurance is mandated and countries of the former Soviet Republics, which developed social insurance schemes following independence.

The counterpart to relatively low levels of pooling is that countries rely more heavily on private health expenditures,

especially paid out of pocket. Figure 2 shows this reliance to be especially high in low-income countries and in the Sub-Saharan Africa region, and this pattern is also evident over time as displayed in time series data presented in Gapminder (hyperlink embedded in Figure 2). Indeed, private expenditures make up 60% of total spending in low-income countries (compared to 36% in high-income countries) and, within this, out-of-pocket payments represent the majority (i.e., 78% of private health expenditures) and therefore almost half of total health expenditure (Figure 2). High levels of out-of-pocket payments reflect the lack of government ability to collect taxes and provide accessible and good quality health care. Some low-income countries rely heavily on external resources to supplement public financing with donors on average contributing more than a quarter of total health spending in low-income countries. Such high reliance on external funding raises concerns for sustainability of services should these contributions decrease, as well as many other concerns discussed in the Section Development Assistance for Health.

A common criticism of financing patterns in low- and middle-income countries is that financing incidence is regressive – i.e., payments for health care weigh more heavily on lower income households. Recent studies have shed light on this question and are summarized in Table 2.

The mix of health financing sources varies substantially across countries, so it is important to consider the incidence of not only overall health care financing but also the main sources: the incidence of a specific type of tax can vary considerably depending on its design and the country context. For example, indirect taxes (e.g., value-added tax (VAT), fuel levies, and excise duties) are regressive in South Africa but progressive in Ghana and Tanzania, a difference likely be explained by the fact that a larger proportion of the South African population are able to purchase goods and services liable to VAT. In addition, although mandatory insurance is progressive in most countries, it is slightly regressive in the three Asian countries studied with universal insurance systems (i.e., Japan, South Korea, and Taiwan). However, such indices need to be interpreted carefully as in systems with less than universal coverage, the progressive insurance schemes may cover only a select population group composed of formal workers or those who are less poor.

Much of the discussion around appropriate financing mechanisms revolves around the need to protect households from catastrophic payments (i.e., levels of expenditures that are high relative to the amount of resources available to the household to pay for their basic needs, which World Health Organization (WHO) defines catastrophic expenditure as equal to or greater than 40% of nonsubsistence spending). The consequences of lack of financial protection against the costs of health care are abundant. Households may forego expenditures on other necessities such as food, clothing, or education, or they may borrow money or sell valuable household assets in order to pay for health services. They may also choose to simply not seek care at all, potentially exacerbating their illness and risking further adverse effects on their earnings. Catastrophic payments can occur in countries at all levels of economic development, but the incidence is higher where out-of-pocket payments are more than 15% of total health expenditures. Households in 18 low- and middle-income countries are therefore at especially higher risk of facing such costs, and up

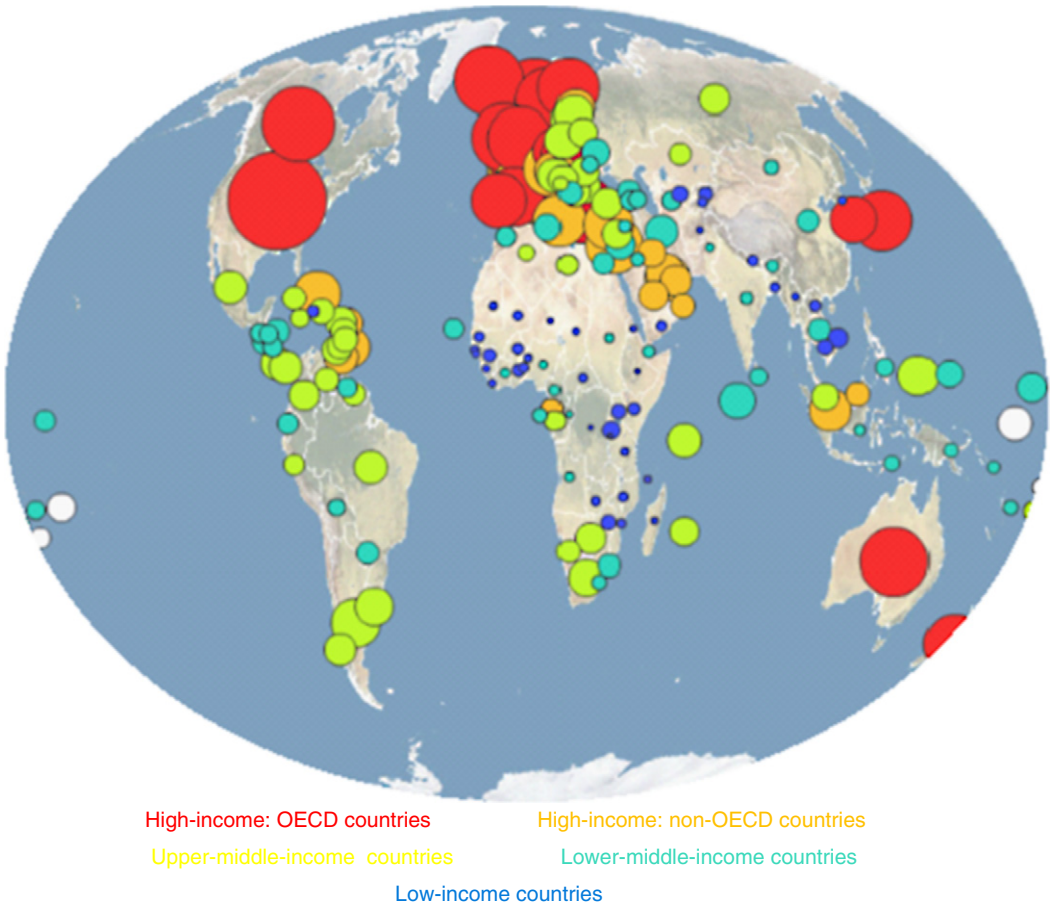

Figure 1 Total health expenditure (international $) per capita by country income group. to 5% of households in those countries' risk being pushed into poverty by health care payments.

Low- and middle-income countries thus face major challenges in financing adequate health services and providing financial protection against catastrophic costs. Characterized by low levels of expenditure, fragmentation, and a reliance on out-of-pocket payments, the financing systems suffer from inequities and inefficiencies. Low- and middle-income countries need to expand forms of prepaid financing and reduce fragmentation in the flow and pooling of funds. Doing so will improve equity by cross-subsidizing risks between the rich and poor and the healthy and sick. It will further increase efficiency by decreasing administrative costs and duplicated coordination efforts required for multiple channels and pools.

However, the equity and efficiency of health financing systems are determined also by many other factors affecting both supply and demand. For example, the low status of women may affect their ability to leave the house to seek care; households may not be aware of the benefits of health care; local health services may lack drugs and qualified health workers or be staffed by health workers who are rarely present or who treat patients with disrespect. Equity and efficiency in financing health services further depend on how funds are used to pay for services and providers – issues covered in the following Sections How are Health Services Paid for? and Who are the Health Service Providers?.

How are Health Services Paid for?

Countries have a choice in deciding how to pay for health services and providers. These choices involve deciding how funding should be channeled from various funding pools (e.g., revenue generated by tax, insurance premiums, and DAH) and payments from individual payers to service providers. There are three principal methods for doing this:

- In relation to inputs (e.g., number of beds, facilities, staff, and items of service).
- In relation to services or outputs (e.g., outpatient numbers and inpatient cases or days).
- In relation to need (e.g., standardized mortality rates).

The payment method used tends to depend on the source of finance. Public funds have traditionally been allocated through hierarchical management structures down to the local

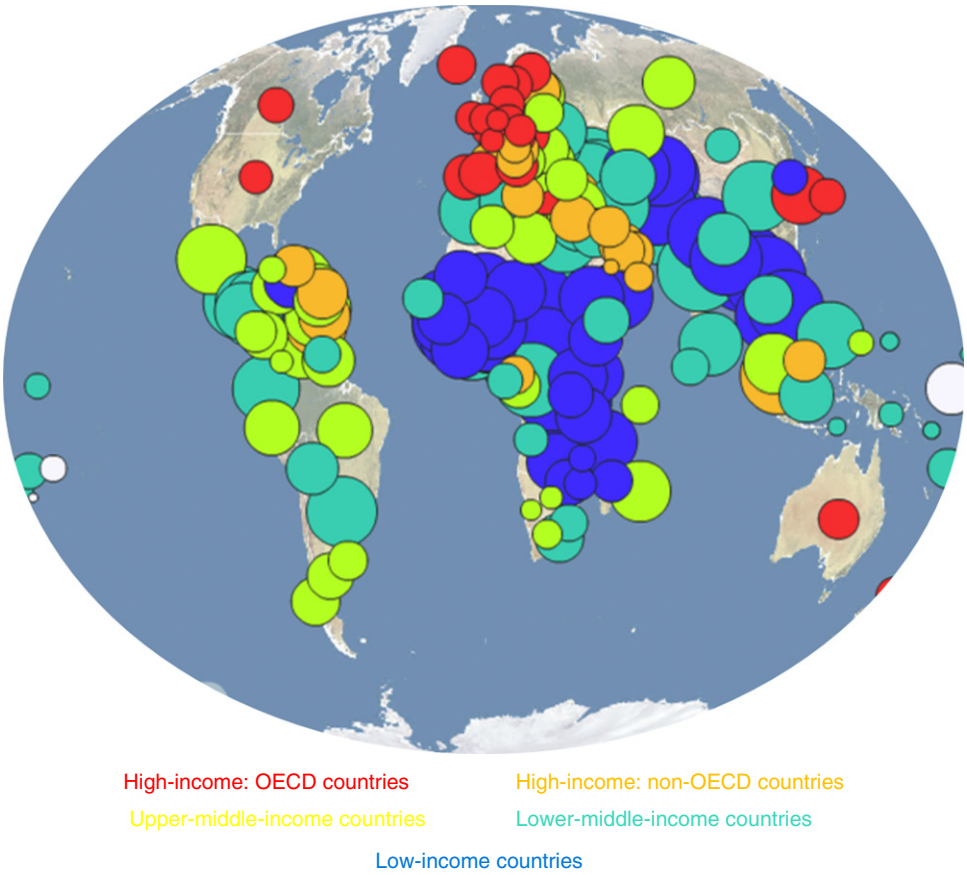

Figure 2 Out-of-pocket expenditure as a percentage of total health expenditure by country income group. service delivery level and are frequently influenced by previous allocations, service or facility volumes and norms, capital developments and associated recurrent expenditure needs, and political influences. Such payment methods tend to assume the historical level of service inputs and outputs is optimal, or at least still appropriate, and does not especially consider efficiency or equity goals. Arrangements may be very inefficient as when more services are purchased than needed, or very fragmented, as in Indonesia where there are multiple channels through which funding flows to the district level. They may also be considered inequitable in that they may not adequately consider health needs, local costs, or income distribution of the recipients for those services.

Following the adoption of similar approaches in richer countries, many low- and middle-income countries have sought to introduce approaches that are population- and/or needs based. For example, Brazil, India, South Africa, India, Thailand, and Nigeria have all sought to improve equity in the allocation of public funds (including the health sector) across geographical areas through resource allocation formulae, which account for provincial variances in factors such as population, socioeconomic status, income levels, health needs, and/or membership in insurance schemes. Such approaches recognize that health services are geographically specific and purchasing should therefore be to some extent decentralized. These approaches are still evolving and commonly struggle to overcome both political influences and historical imbalances in the geographical distribution of the capital stock and related inputs. In Thailand, for example, there was a short-lived experiment with per capita allocation of total Ministry of Health funding; subsequently the salary element was removed and allocate separately, thus severely limiting the ability of the funding mechanism to improve inequality in the distribution of health workers.

Within the public health system, health providers are normally salaried and hospitals allocated an annual budget. More recently, contracts that link payments to the performance of health providers or facilities are increasingly found in the public sector and increasingly used to buy the services of private providers or facilities. These approaches, often termed 'results-based financing,' aim to increase efficiency in the purchasing of services, equity in access to priority services, and quality of service delivery, but evidence of their performance is sparse. Such issues are discussed further in the section Key Issues.

Insurance agencies (whether public or private) normally pay for health services using activity-related measures such as fee-for-service and case payment. The risk, especially with

Equity in financing and use of health care in Ghana, South Africa, and Tanzania: Implications for paths to universal coverage. *Lancet* **380**, 126–133.. doi:10.1016/S0140-6736(12)60357-2; table includes Asian data drawn from O'Donnell, O., van Doorslaer, E., Rannan-Eliya, R. P., *et al.* (2008). Who pays for health care in Asia? *Journal of Health Economics* **27**, 460–475.

fee-for-service payment, is that it encourages an unnecessary expansion in the volume of services and a subsequent increase in expenditure. For example, the fee-for-service payment system has been associated with a rapid increase in expenditure in Thailand (for the Civil Service Medical Benefit Scheme), South Africa (for private insurers), and Taiwan and South Korea (both associated with the implementation of universal health care coverage based on social health insurance). Such cost inflation has encouraged the introduction of payment methods, which do better at containing increases in expenditure. In 2002, the South Korean health system introduced a voluntary prospective payment method for inpatient care based on diagnosis-related groups, resulting in costs of care decreasing by an average of 8.3% in participating health facilities. Reform of the payment system, however, has not been comprehensive as plans to mandate the method were prevented by physician opposition. Thailand, in contrast, drawing on its own experience as well as that of other countries in the region, has had a very successful experience of payment reform with its universal coverage scheme. This pays for inpatient care based on diagnosis-related groups within a global budget and for outpatient care based on capitation payment. This has been relatively successful in extending financial protection while restraining costs: public health expenditure has increased steadily to compensate for increasing levels of utilization, but so far, the share of gross domestic product going to the health sector has not increased.

Household direct payments for care are made in response to fee schedules of providers. Although publicly levied fees may be quite simple in structure (e.g., a flat registration fee), private fees may be per item, with drugs charged separately and often with quite substantial markups. Indeed, practices in the procurement, prescribing and dispensing, and pricing of medicines account for three of the top ten causes of inefficiency identified by WHO in the 2010 World Health Report. In particular, drug dispensing is a major source of inefficiency when linked to prescribing functions as it can represent a significant source of income for private providers (and even public providers) – unofficial estimates indicate up to a 50% profit from drug charges in Taiwan. In response, some countries have sought to break the link between drug prescribing and provider income, a measure adopted some time ago in the rich world. These reforms have often been vehemently opposed with varying government responses and impact on expenditure. For example, Taiwan's 2002 reforms to separate purchasing and dispensing functions were met with strong resistance and a series of protests by the medical profession. To facilitate implementation of the policy, exceptions were made (e.g., rights to dispense were granted to clinics with on-site pharmacists). Such concessions dampened the impact on containment of total health expenditure, although it was successful in reducing drug expenditure. South Korea adopted a different, more rigorous approach in its 2000 pharmaceutical payment reform, breaking the link between prescribing and dispensing, removing all financial incentives, and eliminating profits earned by physicians from drugs. In reaction, however, physicians' fees increased by up to 44% and a greater proportion of brand-name drugs were prescribed.

Different payment methods thus provide different incentives to health providers and their implementation can sometimes have unexpected effects. Countries need to decide which arrangements to use for purchasing health services. These decisions will affect the efficiency, equity, and quality of services provided. For example, fee-for-service can not only

promote responsiveness and productivity but also can lead to inefficiency through supplier-induced demand and cost escalation; capitation and case-based payment can promote efficiency and affordability but may be problematic for quality. The performance of payment systems are determined by the incentives set and how much is being paid, what is being paid for, and who is being paid. In addition, in contexts where capacity to monitor is weak and data limited, there is greater risk of fraud and greater difficulty in fine-tuning payment systems to get the desired results.

Who are the Health Service Providers?

As countries grow richer, a greater share of total health expenditure is publicly financed, as discussed in the Section How are Health Services Financed?, and hence a greater proportion of health care provision is formally organized. The poorer the country, the greater the diversity of types of provider and greater the fragmentation of health services. In general, health service providers can be categorized into seven main groups:

- Government health services for the general public.
- Services run by social health insurance agencies (in countries where they are direct service providers).
- Services run by nongovernment organizations (NGOs) including church organizations.
- Occupational health service providers, both government (e.g., army) and private (e.g., mines and plantations).
- Private for-profit allopathic providers, both individuals and facilities.
- Traditional medicine providers ranging from the more formal (e.g., Ayurveda) to the somewhat less formal (e.g., traditional healers).
- Informal providers such as drug peddlers and unqualified providers (e.g., known as quacks in India).

Data on health providers are much more limited than on health financing. In particular, data on private provision are especially scanty, making it difficult to quantify the relative share of public and private provisions. The 2006 World Health Report stated that approximately 70% of physicians and 50% of other health workers cited their employment as within the public sector; however, the report pointed out that the actual distribution in the public sector is likely to be much lower as the data tend to reflect the health worker's primary employer rather than their main source of income, which in low- and middle-income countries can be significantly higher in the private sector. Evidence on health worker income from Ethiopia and Zambia underscores that the private sector offers much higher remuneration than in the public sector (Figure 3).

Data on utilization patterns can provide additional information on public and private health service providers. Figures 4(a) and (b) show the relative importance of the two sectors in providing health care to women and children in 25 low-income countries. Although there were high levels of variation across individual countries, the use of public health service providers more than half of the time was reported in only four

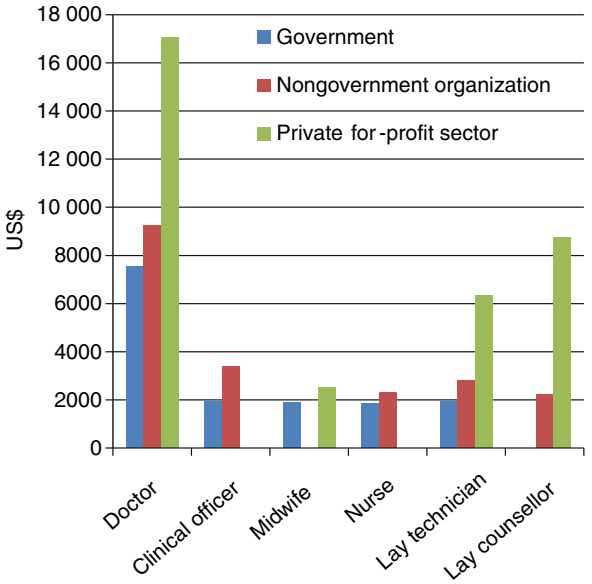

Figure 3 Average annual salaries for health providers in Zambia in 2004. Reproduced from McCoy, D., Bennett, S., Witter, S. *et al.* (2008). Salaries and incomes of health workers in sub-Saharan Africa. *Lancet* **371**, 675–681.

of the countries for deliveries and in only seven of the countries for child fever/cough. In general, adults, especially men, tend to use private facilities more than children, and the probability of using public facilities is higher for inpatient than outpatient care. For example, other cross-country analyses have found that public hospitals account for 73% of inpatient stays in 39 low- and lower-middle-income countries.

The distribution of health expenditures can also give an indication of balance of service provision. With regards to the level of care, hospitals account for approximately 60% of government health expenditures with tertiary hospitals absorbing as much as 45–69%. Such high levels raise efficiency concerns as hospital care tends not to be the most cost-effective when primary care coverage is incomplete. Indeed, inappropriate hospital admissions and excessive lengths of stay, as well as inappropriate hospital size, represent two of WHO's top 10 sources of health care inefficiency. The distribution of Official Development Assistance (ODA) for health indicates the priorities of donors: 40% of 2010 ODA disbursement went to providing HIV care and 19% to controlling infectious diseases with only 15% to basic health care and infrastructure (Figure 5).

Table 3 and Figures 6(a) and (b) provide data on various other dimensions of health service provision across income groups and regions. These show the relative lack of available service inputs and much lower coverage rates of essential interventions in low- and lower-middle-income countries – all of which carry implications for the equity and efficiency of service provision in developing countries. For example, low-income countries have five times fewer physicians per 10 000 individuals and approximately 50% fewer births attended by skilled health personnel and 16% lower coverage of child immunizations when compared to high-income countries. At the regional level, Sub-Saharan Africa has 30 times fewer

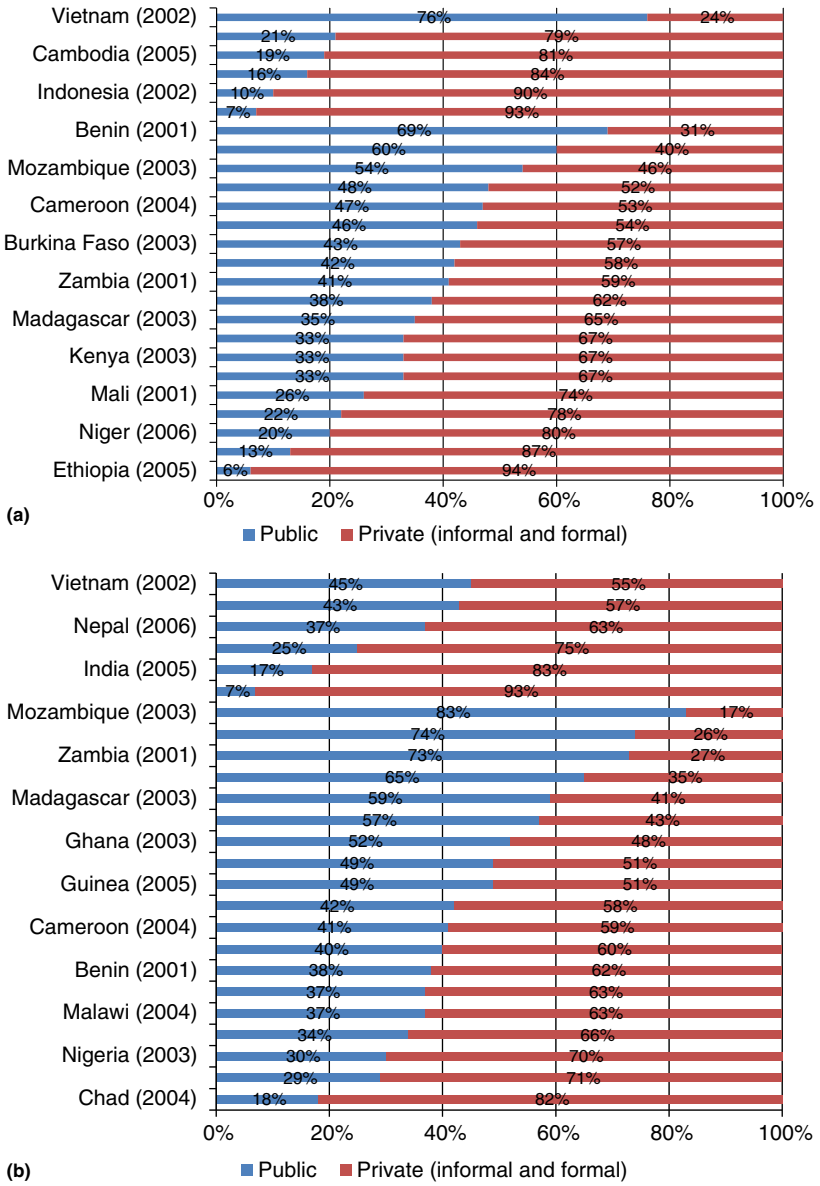

Figure 4 (a) Mothers giving birth in public or private facilities (%); (b) Children treated for fever/cough in public or private facilities (%): Data obtained from 2001 to 2006 demographic and health surveys (DHS). Public sector means health facilities and providers affiliated with the government. Private sector means formal private (e.g., commercial; for-profit hospitals, clinics, or pharmacies; facilities or providers that belong to NGOs or missions) and informal (e.g., traditional healers, drug peddlers or vendors, and shops as well as care provided by friends and relatives and other unspecified providers). Reproduced from Limwattananon (2008). Private–public mix in health care for women and children in low-income countries: an analysis of DHS. Thailand: International Health Policy Program.

physicians per 10 000 individuals and approximately 45% fewer births attended by skilled health personnel and 19% lower coverage of child immunizations when compared to Europe and Central Asia. The health worker shortage in these countries means the insufficient number of providers cannot adequately deliver the care needed in countries with major disease burdens. In the public sector, the mix of doctors and nurses and ratio of health providers to patients are suboptimal, with health workers frequently facing an overwhelming workload and hence delivering low quality of care. It is often for these reasons that the poor seek care in private facilities, which tend to be better staffed and provide more responsive care but often at a higher cost and not necessarily greater effectiveness.

There has been a long-standing debate over the relative efficiency of public and private providers, with claims that private providers are more efficient. However, evidence to support this is scanty and suffers from difficulties in standardizing for type of patients and service models. For example, a study of the provision of primary care in South Africa by various forms of providers (i.e., public clinics, private general practitioners (GPs) contracted to provide free care for poor

patients, private GPs practicing privately, a private clinic chain, and company clinic) found that two of the private sector models were delivering services at comparable cost to the public sector – the contracted GP model and clinic chain. However, the two other private sector models (i.e., independent GPs and company clinic) were delivering services at much higher cost, demonstrating the importance of examining the private sector model by model. Contextual influences, such as payment methods, practice styles, and traditions, also affect performance. Regardless of the type of ownership, investing resources in more efficient providers can result in substantial savings and a great potential to provide more health services within a fixed budget. In Namibia, savings from reducing hospital inefficiency could construct 50 clinics and, in South Africa, represent three times the value of user fee revenue.

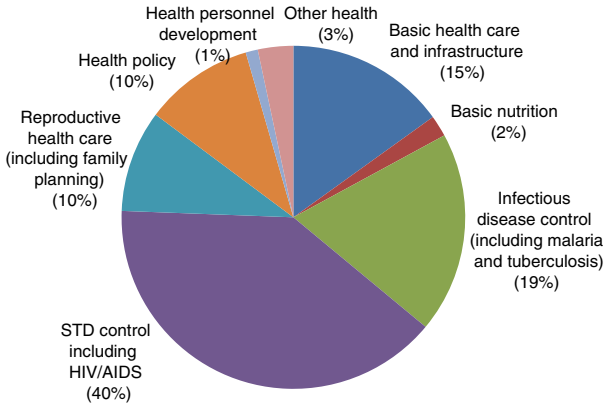

Figure 5 Distribution of 2010 ODA to health in low- and middle-income countries. STD, sexually transmitted diseases. Reproduced from OECD Creditor Reporting System. Available at: http://stats.oecd.org/Index.aspxdatasetcode=CRS1 (accessed 30.04.12).

Another major deficiency is strong evidence on the quality of health services. However, evidence is sufficient to confirm that quality in both public and private sectors is poor, with the private sector tending to perform better in drug availability and aspects of delivery of care, including responsiveness and effort, and possibly being more client orientated. In the case of the South African study referred to above, public clinics tended to offer better technical quality of care than private facilities, but quality as perceived by users was lower due to more crowded facilities and less responsive staff. But there is enormous variation. Many countries, for example, include at one end of the spectrum public and private hospitals offering care of international levels of quality, whereas at the other end of the spectrum are unlicensed and unqualified providers selling drugs, which should be prescription only. Arrangements may be agreed between hospitals and diagnostic laboratories, for example, to refer patients in return for a fee, and regulators may not be independent of the facilities they regulate.

There has been persistent criticism that the use of public services in low- and middle-income countries is inequitable, in that richer groups benefit more than poorer groups. A recent in-depth study of benefit incidence (and financing incidence) in Ghana, South Africa, and Tanzania confirmed this with respect to Ghana and South Africa, although public sector and faith-based organizations' health service benefits in Tanzania were more evenly distributed across the population. Inclusion of private sector services in this benefit incidence

analysis showed even greater disparities in the distribution of benefits. Overall, health services benefited higher income groups despite the greater health needs of lower income groups. The key reasons constraining the access of poorer groups were problems in relation to the availability, affordability, and acceptability of services, particularly health care costs, transport costs, drug stock-outs, insufficient staff numbers, and poor staff attitudes. Such barriers need to be addressed to change the distribution of health services and move toward greater financial protection.

Key Issues

Financing Sources for Universal Coverage

Over the last few years, there has been growing momentum to expand financial protection and set universal coverage as a long-term goal. Evidence has been accumulating from countries such as Thailand that given willingness of governments to support the health care costs of the less well off and design features that constrain cost inflation, universal coverage of a benefit package of reasonable size is possible even for a lower- middle-income country. For example, Thailand achieved universal coverage in 2001 (at a per capita income of US$1900) by introducing a new scheme funded from general taxation to cover the 47 million people who fell outside the preexisting schemes for formal sector workers. Vietnam, Philippines, and Indonesia have now adopted universal coverage as a goal with a timetable for achievement. Both South Africa and India are actively debating plans for universal coverage.

It is clear that a mix of financing sources is needed for progress to be made toward universal coverage – general tax revenues are needed for those too poor to contribute; social health insurance arrangements are of value for enrolling formal sector workers; some degree of contributions from user fees is probably inevitable because even with offer of services free at the point of use, some people will still choose to purchase their care from the private sector. The critical question, over which there is considerable disagreement, is whether those in the informal sector who are not the poorest – often a very substantial number of people – should be covered by general tax funding or enrollment in contributory schemes (with or without government subsidy). Thailand, for example, has chosen general tax funding; Philippines and Indonesia have chosen to seek to extend their social health insurance scheme on a voluntary basis to encompass the informal sector; China has rolled out a massive and highly subsidized rural voluntary insurance scheme covering 835 million people by 2011. Key issues are willingness for the share of government funding to health to increase and the feasibility and management costs of encouraging a high proportion of the target population to enroll voluntarily. The latter concerns have led to a plan in Ghana, where a national health insurance scheme was introduced including voluntary enrollment into district insurance schemes, to move to a 'one time premium,' a largely nominal payment, thus recognizing the de facto situation that the great majority of funding for universal coverage is coming from direct and indirect taxes.

Development Assistance for Health

As shown in the Section How are Health Services Financed?, DAH is a substantial source of health financing in low-income countries – reaching more than a quarter of total health spending. Trend analysis further shows that the total amount of DAH has substantially increased over the last two decades, from an estimated US$5.8 billion in 1990 to US$27.7 billion in 2011 (in 2009 US$). DAH can have a number of economic consequences as well as political implications.

Development assistance has been criticized for fostering donor dependency and hindering economic growth in recipient countries. Indeed, a high reliance on external funding for health raises concerns over the ability of the government to deliver basic health services. Should these contributions decrease – and some recent estimates are showing a decreasing rate of growth of DAH flows since the global financial crisis – it would threaten the delivery of essential health care. Any gap in health financing would need to be covered by the government or private funding. In low- and middle-income country settings, where there are institutional, economic, and fiscal constraints hampering significant government funding increases, the outcome would most likely be higher out-of-pocket payments, further restricting access to health services by the poor.

However, development assistance has also been promoted as a means to empower countries to lead their own development by providing opportunities for strengthening the role of the state and for economic growth. Development assistance can help to build basic health infrastructure, especially in underserved areas or postconflict settings, which can be a visible and important indicator of a functioning state. It may also stimulate improved sector-level policies and strategies, especially when development assistance is channeled through mechanisms such as Sector-Wide Approaches (SWAps).

There has been controversy over whether DAH displaces domestic spending on health. A recent statistical analysis of expenditure data over the period 1995–2006 suggested that for every US$1 of DAH to governments, there was a decrease in government health expenditures by US$0.43–1.14. The analysis further found that when DAH was given to the nongovernmental sector, government health expenditures increased by US$0.58–1.72. However, the evidence for displacement is still inconclusive, not least because of data limitations. Data at the country level, especially in low-income countries, are often missing and estimates frequently vary across institutions (e.g., the degree of correlation between the WHO and International Monetary Fund estimates for government health expenditure is only 65%). In addition, the probability and extent of displacement is likely to vary greatly across countries. For example, in response to increases in DAH, the Democratic Republic of Congo appears to have decreased its domestic health spending by more than 30%, whereas its neighbor, the Central African Republic, increased spending by more than 30%. Factors specific to individual countries, such as donor behavior and domestic policy choices, are likely to be influential. Thus, firm conclusions cannot be drawn, and it is imperative to understand not only whether such effects are occurring but also why. Moreover, the debate underlines the need to understand broader issues such as how domestic spending responds to the volume and type of development assistance.

Additional issues relate to other aspects of the effectiveness of aid. There has been very long-standing concern that health aid flows through far too many channels, is fragmented and excessively tied to specific short-term projects rather than longer term programs and strategies, and is unpredictable. For example, the change in flows of funds from 1 year to the next can create difficulties in implementing sustainable health programs in recipient countries. The volatility in aid given to health over time is shown in time series data presented by Gapminder (hyperlink embedded in Figure 7). Furthermore, the individual reporting requirements of numerous development partners put pressure on already weak financing systems in recipient countries. All of these concerns are reflected in harmonization and alignment principles agreed in the Paris Declaration on Aid Effectiveness and subsequent Accra Agenda for Action. However, much remains to be done. For example, the proportion of ODA to maternal, newborn, and child health, which flows to projects (rather than sector-wide support, for example), has consistently stayed approximately 90% over the 2003–10 period. Various joint donor funding arrangements have sought to coordinate donor support, but many funding flows remain outside coordination mechanisms.

Results-Based Financing to Users and Providers

Results-based financing has recently attracted much attention as a way of implementing agreed priorities through stimulating demand, purchasing services, and encouraging improved health worker productivity and service quality. It is defined as 'a national-level tool for increasing the quantity and quality of health services used or provided based on cash or in-kind payments to providers, payers, and consumers after predetermined health results (outputs or outcomes) have been achieved' (http://www.rbfhealth.org/rbfhealth/about). It is a generic term for a number of different approaches, including:

- Provision of vouchers to enable individuals or households to obtain health care.
- Payment of cash to households conditional on use of specific services and other sorts of financial transfers, for example, to cover transport cost.
- Payment of financial incentives to providers (individual health workers, facilities, or organizations) to supply certain types of services or reach certain quantity or quality targets.
- Agreeing contracts for services with associated performance targets.
- Output-based aid where provision of aid is conditional on achievement of certain targets, such as a minimum immunization coverage level.

Interest in such approaches has grown rapidly over the last few years, with dedicated funding for such projects being provided by the World Bank and bilateral aid agencies. Results-based financing has been introduced in a number of

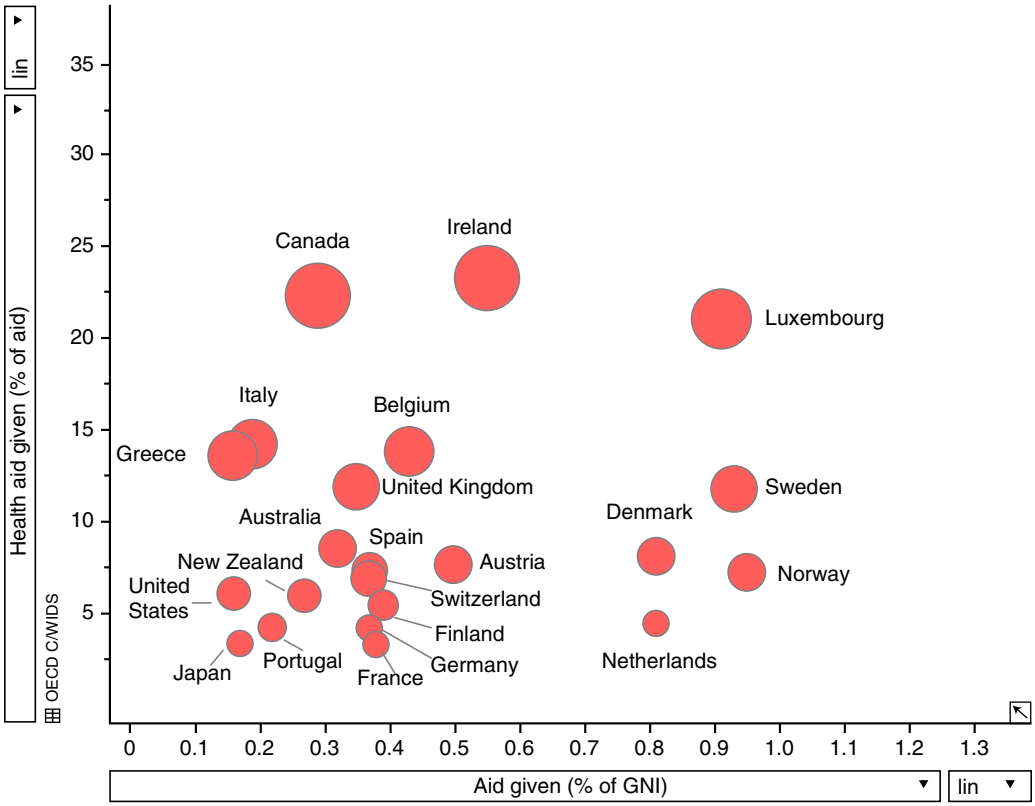

Figure 7 Volatility of aid to health. Data are from 2007 and presented by Gapminder; circles represent high-income country data from the OECD such that the size represents aid given to health as a percentage of total aid. developing countries, particularly in the Latin America and South Asia regions, and frequently for maternal and child health interventions. Although positive results have been reported in several schemes, reliable evidence on effectiveness, especially in low-income countries, is still fairly sparse. There is a gap in understanding how such mechanisms can improve performance and what are the necessary factors to ensure intended effects, and there is virtually no evidence on the cost-effectiveness of such approaches relative to other ways of improving provision of services and increasing the uptake of health care.

Proponents of results-based financing point to available evidence suggesting that such incentives have positively influenced various levels of the system – recipients of health care (individuals and households), providers of health care and facilities, as well as resulted in positive outcomes including higher coverage of key interventions, better service quality, increased efficiency, and/or improved health outcomes. Rwanda has often been cited as an example for its pay-for-performance scheme, and reports often identify increases in uptake of maternal and child health interventions. However, results-based financing may also increase inequities and produce undesirable effects (e.g., reducing the intrinsic motivation of health workers, gaming, cherry picking, neglect of other activities, and corruption). The effectiveness of performance contracts with the private sector has also been questioned as, while there is evidence they have improved access to services, little is known about its impact on the equity, efficiency, and quality of care of the wider health system. Finally, output-based aid can not only accelerate achievement of health targets but has also been criticized for being too narrow and short term in focus. The varied results are a function of the range of results-based financing instruments, their individual design, and implementation in diverse country contexts. Scheme design should be based on an understanding of the underlying problems the scheme is intended to address and on the country context (e.g., taking into account local managerial capacity), and performance indicators must be aligned with the goals of the health system. The impact of results-based financing also depends critically on the ability to implement the scheme effectively and monitor performance.

More broadly, results-based financing is not only argued to improve accountability (allowing for regular reviews of performance) and increase equity (in targeting certain population groups) and efficiency (in improving performance) but it also raises questions over the degree of involvement of donors in scheme initiation, design and implementation, and the sustainability of such arrangements beyond the initial donor funding.

The Role of Private Sector Agencies

Concern about the capacity and performance of governments in both low- and middle-income countries has led to considerable interest in how private sector agencies may perform some roles traditionally assigned to the state. Such roles may include:

- The provision of private insurance.
- The administration of insurance arrangements on behalf of the state.
- The management of drug distribution systems and other elements of public health service management.
- The provision of services.

Debates about private insurance mirror those in high-income countries – namely that it is likely to be neither an efficient nor equitable way of providing financial protection to significant numbers of people. Moreover, there are few countries, which have any sizeable private health insurance sector, given the very limited market of those who can afford to pay. The main potential role is to provide additional cover, to relieve the public health system of the pressure to cater for the highest income group.

A different role for private insurers is to administer state-sponsored financing arrangements. For example in India, the Rashtriya Swasthya Bima Yojana scheme, launched in 2008, targets households below the poverty line. Parastatal and private insurers bid to administer the scheme, which involves receiving a fixed sum of public money per household recruited to the scheme, providing them with a smart card, which is both the evidence of membership and records health care costs up to the allowable maximum per year, signing up hospitals to provide care, and managing payment arrangements. There is annual retendering of the contract, with competition focusing on the fixed sum per household that is requested. This design has permitted very rapid roll out of the scheme across India, with 40 million people covered by 2012. Concerns have focused on low rates of utilization of care by members in some states (hence increasing the profits for the company), fraudulent claims by providers, and in some states incremental creep year by year in the capitation sum.

The management strengths in the private sector have also been drawn on in other areas of health system management. For example, South Africa, which has some considerable private sector capacity, has experience of contracting out drug distribution to hospitals and clinics and also of contracting a private company to manage public hospitals. Evaluations of such arrangements have identified issues similar to those found in high-income countries – the challenges of managing the principal–agent relationship; difficulties of specifying contracts for clinical care; and difficulties public agencies can face in managing contracts well.

Private agencies can play two main roles in service provision. Private providers can directly be contracted to provide services on behalf of the state. Most experience of this model comes from contracts with NGOs, both the international NGOs and indigenous ones, and there is evidence that NGOs working under contract and managing district services have increased service delivery in underserved areas. A second approach is to use a variety of means to improve the quality and reduce the cost of the less formal part of the private sector that is extensively used by poorer groups. Approaches such as accreditation of clinics, franchizing outlets to provide contraception and sexually transmitted diseases treatment, and training of drug sellers can work successfully, although experience is very varied and most approaches have been tried only on a very small scale.

Effective engagement with the private sector is important, but a strong public primary care system has been shown to be

critical in bringing health services to communities and improving health outcomes. For example, the experiences of Ethiopia and Bangladesh in investing in human resources and innovative delivery methods in the public system have resulted in wide reaching and effective primary health care systems (see videos at http://ghlc.lshtm.ac.uk).

Conclusions

This article has covered a very wide canvas in terms of both countries and issues. Echoes are apparent with many of the issues facing high-income countries – the best mix of financing sources, role of out-of-pocket payments, best ways to pay providers, desirability of incentive-based arrangements, and relative roles of public and private sectors. However, the context of low- and middle-income countries means that policy lessons from high-income countries do not necessarily transfer well to all low- and middle-income country settings. Key features that affect the relevance of policies include the very widespread poverty; high proportion of the population in the informal sector; relative weakness of political; and social institutions including governance structures; limited management capacity in the public sector, and vulnerability to influence by agencies external to the country. Numerous studies show that the detailed ways in which policy reforms are designed and implemented in particular contexts play a key role in how they perform, alerting us to the need to be wary of seeking global solutions to health system challenges.

Glossary

Demographic transition Reduction in mortality and fertility rates experienced by most countries in a certain stage of their development process; it is first accompanied by accelerated population growth, then followed by declining rates of population growth.

Epidemiological transition Process of change in the causes of death that accompany the reduction in mortality observed during the demographic transition, from infectious diseases to other causes of death; it is also accompanied by a change in the age distribution of mortality, from early to older ages.

Germ theory Theory according to which certain diseases are caused by microorganisms; became widely accepted starting in the end of the nineteenth century.

Life expectancy Expected years of life if an individual were subject to the age-specific mortality rates observed at a point in time.

Malthusian mechanism/Malthusian response The Malthusian view of population behavior predicts that, in response to improvements in economic conditions, population growth is increased; population expansion, in turn, leads to a deterioration in living standards – through reduced availability of land per capita, wars, and disease – bringing economic conditions back to their original level; in the Malthusian mechanism, population expansions always perform the necessary adjustment, leaving no room for long-run improvements in living standards.

Introduction

Until the seventeenth century, world population behavior was governed by a straightforward Malthusian mechanism: sporadic technical advances and favorable climatic conditions reduced mortality via relaxation of the constraints imposed by the supply of goods; these would then lead to increased population, which would then reverse the movement, bringing standards of living back to the limits of simple reproduction. Mortality rates had great variability with no clear trend and, by the Year 1600, life expectancy was probably about the same as it had been 2000 years before. These Malthusian responses following positive permanent shocks explain a timid but persistent population growth, despite the trendless behaviors of mortality and fertility rates.

This pattern started to break down for some Western European and Scandinavian countries in the eighteenth century. Mortality rates fell (life expectancies increased) without any indication that a countervailing Malthusian mechanism was at work. Population growth for these countries increased, reaching a peak in the mid-nineteenth century, after which, as a consequence of fertility declines, growth rates started coming down. This pattern was followed closely by, among others, the United States and Canada and, by the beginning of the twentieth century, this group of countries had populations larger than they ever had before, together with health and life expectancy levels unprecedented in human history.

This transformation marked the onset of the demographic transition and was an essential part of the process of economic development that continued spreading unabated through most of the world until today. See article by Ebenstein in the same section of the Encyclopedia for a longer discussion of the demographic transition. This revolution, however, took some time to reach the developing countries. It was only after World War I that mortality levels began to decline in the poorer regions of the world. Nevertheless, in these areas, the process took place at a much faster pace and at much lower income levels than it had in Europe and North America. Renewed and persistent mortality reductions throughout most developing regions after World War II changed the face of human societies and led to the population explosion observed during the twentieth century.

These health improvements played a central role in the history of population growth. A strand of theoretical literature also argues that they were a potentially important force determining the reductions in fertility observed at later stages of the demographic transition, as well as the increases in human capital and growth registered thereafter. Nonetheless, the precise causes of the improvements in health and reductions in mortality in the developing world are not yet entirely understood.

In this article, the available evidence on the determinants of health and mortality in developing countries is reviewed. The next Section Patterns of Health and Mortality starts with a discussion of some historical patterns and aggregate studies. Following that, the results from a vast array of studies analyzing various dimensions of potential determinants of health and mortality are summarized. Finally, the Section Discussion concludes with a synthesis of what is known up to now and some general remarks.

Patterns of Health and Mortality

Perhaps the most striking feature of the improvements in health in the developing world is how they became increasingly dissociated from gains in income or overall improvements in individual living conditions. This is most clearly seen in the so-called Preston curve, which portrays the relationship between income per capita and life expectancy across countries. Figure 1

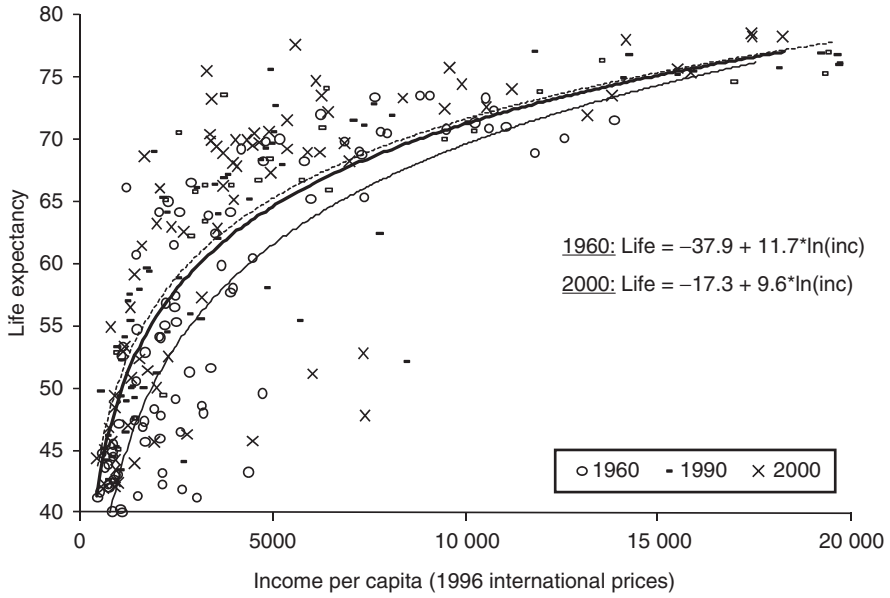

Figure 1 The changing relationship between income and life expectancy; 1960, 1990, and 2000 (Soares, 2007a).

reproduces this curve for the years 1960, 1990, and 2000. There is a positive correlation – close to logarithmic – between income per capita and life expectancy at each point in time. But this relationship has been shifting since the beginning of the twentieth century. This pattern was first noticed by Samuel Preston, who compared data between 1930 and 1960, and has persisted through several decades. In other words, countries at a given income level in 2000 experienced much higher life expectancies than countries at comparable income levels in 1960. From a historical perspective, this amounts to saying that a significant fraction of the gains in life expectancy over the last century were unrelated to changes in income.

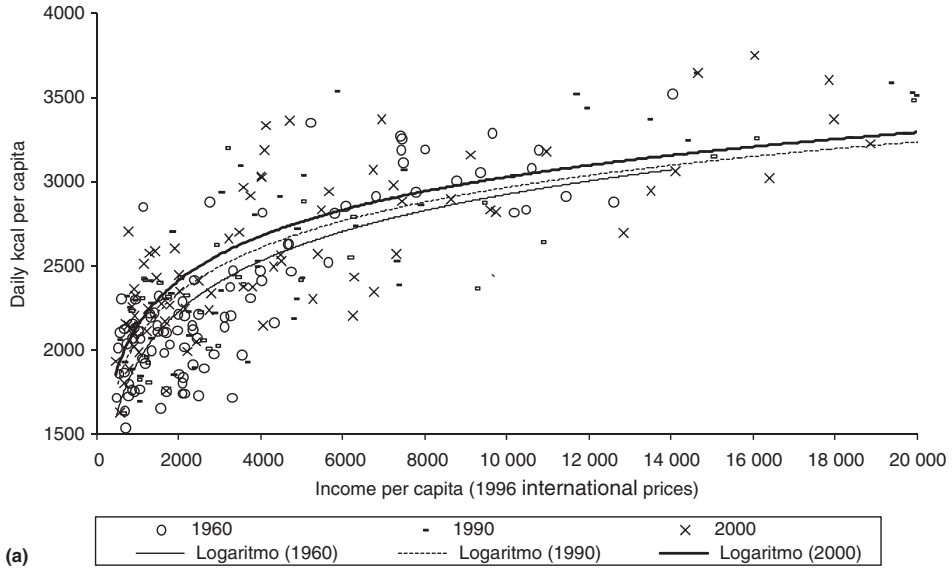
In addition, these gains have been particularly strong for countries at lower income levels. This pattern led to reductions in life expectancy inequality in the postwar period: by any measure, inequality in life expectancy declined substantially after 1960, apart from a mild increase after 1990 due to the arrival of HIV/AIDS. Despite different patterns of access to water, sanitation, education, income, and housing in developing countries, there was a surprising stability and homogeneity in this process of mortality reduction in the postwar period.

The evidence also shows that the shift of the Preston curve is not an artifact of a falling price of food and improved nutrition at constant levels of income. Preston classifies countries in different nutrition and income brackets and compares data from 1940 and 1970. He shows that life expectancy gains took place at constant levels of income and nutrition. Even for the lowest nutrition group (<2100 cal daily), he identifies an increase of 10 years in life expectancy at birth.

Figure 2 shows the same pattern. At constant levels of income, nutrition does seem to have improved slightly between 1960 and 2000. This may be the result of technological improvements and declines in the relative price of food. Nevertheless, it is far from enough to explain the shift in the income–life expectancy profile: the cross-sectional relationship between nutrition and life expectancy at birth shifted in much the same way as the cross-sectional relationship between income and life expectancy. Between 1960 and 1990, at constant nutritional levels, life expectancy at birth rose by as much as 8 years. In a cross-country econometric analysis relating life expectancy improvements to income and caloric consumption, Preston concludes that approximately 50% of the changes in life expectancy between 1940 and 1970 were due to 'structural factors,' unrelated to economic development or nutrition. Other research finds similar results for the period between 1960 and 2000.

The evidence also suggests that this is not an artificial result due to aggregation and within country changes in the distributions of these variables. In the case of Brazil, for example, municipality-level data between 1970 and 2000 show a within country shift in the cross-sectional relationship between income and life expectancy that is similar to that observed across countries. At constant levels of income, life expectancy typically rose by more than 5 years, meaning that at least 55% of the improvements in life expectancy in Brazil during these 30 years seemed to be unrelated to gains in income per capita. Similar evidence is also available for Mexican states.

Analogous conclusions were generated by other studies in very different settings. Mortality changes in Latin America between 1950 and 1990 show that mortality does respond to short-term economic crisis but that these responses are very small and quantitatively irrelevant when compared with historical changes (though morbidity changes may be substantial). The classic concept of 'mortality breakthroughs' itself was based on historical experiences of improvements in health that were not related to growth in income per capita. Several other researchers present various arguments and evidence indicating that the relationship between income, nutrition, and mortality is far from enough to explain the improvements in health and life expectancy observed during the twentieth century.



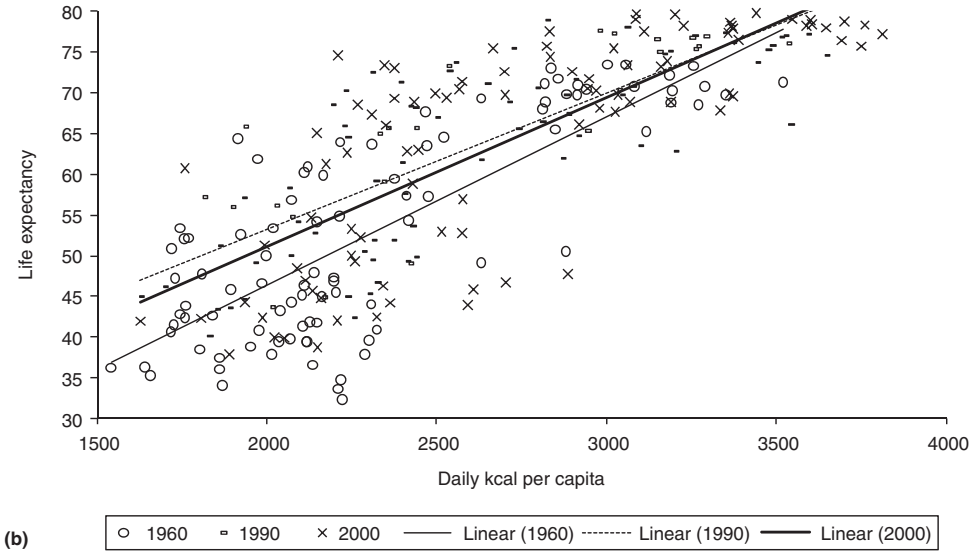


Figure 2 The relantionship between income, nutrition, and life expectancy; 1960, 1990, and 2000 (Soares, 2007a).

The question remains, therefore, as to what were the factors that determined these improvements in health, mostly independently of individual standards of living. Further insight in this matter can be obtained by looking into the profile of changes in the distribution of mortality by age and cause of death. This pattern of changes in the age and cause-distribution of mortality is usually referred to as the 'epidemiological transition,' a term first coined by Abdel Omran. It describes the process of change in leading causes of death, from infectious diseases to chronic nontransmissible diseases, that takes place as mortality reductions progress. There is also an accompanying shift in the age distribution of deaths, from younger to older ages, until child and infant mortalities converge to close to zero.

There is a wealth of information on the epidemiological transition experience of some developed countries. For the nineteenth century US, for example, infectious diseases were responsible for 45% of all deaths between the ages 0 and 4 years, with birth-related and childhood diseases accounting for an additional 30%. Improvements in the period were driven mainly by the acceptance of the germ theory, leading to the boiling of milk and sterilization of bottles, hand washing, isolation of the sick, etc. During the first half of the twentieth century, infectious diseases were still the leading cause of death, and nutrition and public-health infrastructure were the main determinants of improvements in health (reduced deaths from infectious diseases were responsible for three-quarters of the gains in life expectancy in the period). Between 1940 and 1960, infectious diseases continued to play a role, but medical innovations (antibiotics) became increasingly more important (health improvements concentrated on diseases for which new drugs became available). Finally, after

Source: Preston (1975).

1960, mortality reductions shifted toward more sophisticated and technologically intensive medical advances, concentrated at old ages and on conditions such as heart and circulatory diseases.

The historical evidence from England shows a similar pattern. A relatively small number of infectious diseases account for the entire improvement in life expectancy observed in England and Wales between 1837 and 1900. Some interpretations argue that changes in nutrition were the main determinant of changes in susceptibility to these diseases, but others give more credit to public policy (mainly sanitary reforms, perhaps responsible for 25% of the reductions in mortality in the period). Infectious diseases accounted for 68% of the overall reductions in mortality in England up to the 1950s.

A similar path was followed by developing countries in the second half of the twentieth century. Preston was the first to try to map the reductions in mortality in the developing world between 1900 and 1970 into different causes of death. **Table 1** presents the approximate fraction of mortality reductions in less-developed countries accounted for by different diseases. Preston argues that preventive measures associated with public-health programs and infrastructure were probably the main determinants of the changes portrayed in the table (apart from the case of influenza, pneumonia, and bronchitis). Large-scale immunization, cleaning of water systems, and sewage disposal are examples of changes that took place in several less-developed countries throughout the period. This interpretation would suggest that approximately 50% of the life expectancy gains in the period were unrelated to simple improvements in material conditions.

Evidence for Latin America between 1955 and 1973 suggests that dimensions unrelated to living standards were more important in regions where malaria was endemic, and where other infectious diseases were more prevalent. According to this view, approximately 55% of the reductions in mortality would be attributable to factors not directly linked to improvements in living conditions.

The discussion from the previous paragraphs hints at a relationship between mortality by cause of death and available methods of prevention and treatment. Similarly, mortality by cause of death is intimately linked to mortality by age, and to the stage of a specific society in the process of epidemiological transition. At a given historical moment, both of these are associated with the health technologies available and employed in each particular case. For these reasons, the historical profile observed in developed countries is analogous to the cross-country gradient observed in the postwar period.

Analogously, mortality reductions experienced by developing regions in the past 40 years, for example, are very similar to those experienced by the US in the beginning of the twentieth century.

The pattern of cause and age-specific life expectancy gains across different development levels between 1965 and 1995 illustrates this point. In poorer regions (Middle East and North Africa), life expectancy gains are almost entirely concentrated on infectious diseases of the respiratory and digestive tract, and congenital anomalies and perinatal period conditions. As a result, 90% of the mortality reductions are concentrated at younger ages. As the development level increases, mortality shifts continuously from early to old ages (following, in sequence, Latin America and the Caribbean, East Asia and the Pacific, Europe and Central Asia, and North America). For the most developed regions, 60% of the life expectancy gains are due to heart and circulatory diseases and nervous systems and senses organs conditions, all concentrated in old ages.

Historical trends and cross-country profiles within countries suggest a specific process of health improvements and mortality reductions. This process mimics the movement of a country through the different stages of the epidemiological transition. Still, there is no consensus as to the specific factors that determined these improvements in health in each different circumstance. In the next Section Evidence on Determinants of Health Improvements, to shed some light on the issue, the evidence on the determinants of mortality reductions in specific contexts is discussed.

Evidence on Determinants of Health Improvements

The evidence discussed in the Section Patterns of Health and Mortality suggests that 'structural factors,' not directly related to economic development, were responsible for a substantial fraction of the recent reductions in mortality in developing countries. Substantial reductions in mortality were observed at very low income levels and with minimal expenditures on health, so it is believed that diffusion of new technologies must have played a role.

New technologies may come into play as determinants of health through various channels. First, in some dimensions, health is the outcome of household production (personal hygiene, handling and preparation of food, treatment of water, etc.). From this perspective, new technologies are incorporated through absorption of knowledge by individuals. This is probably particularly important at very low levels of development (or high levels of mortality).

Second, some health technologies have a major public good component. Ideas and knowledge are extreme examples of this. Once the germ theory became accepted, for example, its main implications became publicly available to all agents. In more specific health technologies, externalities and traditional public goods are also very important (development of new medicines, water and sewerage systems, vaccination campaigns, environmental regulations, etc.). Sometimes implementation involves large fixed costs and low marginal costs, other times adoption depends on the outcome of a centralized political process. Changes are, to a great extent, outside the control of any individual agent in society and, given its political and technological nature, may be even considered exogenous to the economic conditions faced by a country.

Therefore, the diffusion of health technologies in developing countries over the last century was most likely driven by the absorption of knowledge by agents and public provision, rather than by the same factors determining diffusion of technologies associated with the production of private goods. This is particularly important for changes in mortality observed at low levels of development, when improvements can take place even with minor expenditures on health. This logic points to particular candidates as main determinants of the health improvements discussed in the Section Patterns of Health and Mortality. These are associated with diffusion of pure nonrival and nonexcludable knowledge, public or international interventions related to public-health infrastructure and to particular diseases, and family and community health programs focused on health practices.

Perhaps the clearest example of the role of technology and public good provision is the United Nations' Expanded Program on Immunization (EPI). The program started in 1974 with the objective of extending worldwide access to vaccines against measles, diphtheria, pertussis, tetanus, tuberculosis, and polio, among others. In countries covered, the EPI led to major increases in immunization rates within few years, while infection rates dropped abruptly. Among other things, the program led to virtual eradication of polio from the Americas in 1994, and raised immunization for the six target diseases from 5% of the world's newborns in 1974 to approximately 80% in 2000.

Another example of a successful intervention against particular conditions is the case of Malaria. In Sri Lanka starting in 1945, dichlorodiphenyltrichloroethane (DDT) became available, leading to the elimination of mortality differentials between endemic and nonendemic areas, and to fast declines in mortality rates. Malaria control contributed with 23% of the observed reduction in death rates up until 1960. From 1946 to 1950, malaria is estimated to have contributed with one-third of the total reduction in mortality. Similar results from other malaria control programs have been documented in countries such as Guyana, Guatemala, Mexico, Venezuela, and Mauritius.

A very important coordinated effort was the World Health Organization (WHO) campaign launched in the 1950s to eradicate malaria. The campaign counted on WHO's technical support and was partially funded by USAID and UNICEF. It was based mostly on DDT spraying, with the objective of breaking up the transmission of malaria for long enough so that the pathogen would eventually die, coupled with some medical assistance. Analyses of the experiences of Brazil, Colombia, and Mexico indicate that in all three cases the campaign was followed by large declines in malaria prevalence. In Colombia, prevalence rates fell by approximately 80%. Overall, however, for Latin America as a whole, the campaign proved ineffective in eradicating malaria, with partial resurgence observed some decades after the initial intervention. Nonetheless, even in these cases, prevalence was never again comparable to the preintervention levels.

A view sometimes presented as a competing alternative in the demographic literature postulates that focused

interventions have limited effects, and that the main driver of good health in developing countries is a set of 'appropriate' social and political conditions. This has been argued to be the case, for example, in the three famous experiences of 'breakthroughs' in mortality reduction: Kerala (India, 1956–66), Sri Lanka (1946–53), and Costa Rica (1970–80). These three cases were also exceptional in their social and political environments, and in their effectiveness in providing inputs in the areas of education, health services, and nutrition. Female autonomy, open political systems (competition), large civil society without rigid class structure, and national consensus related to policies are highlighted as factors allowing the adoption of health inputs and the absorption of new technologies. In Sri Lanka, cholera was contained in the 1870s through quarantine measures and construction of water systems, whereas neonatal tetanus was cut down by the systematic use of midwives. From 1910 on, successful campaigns against diarrhea, respiratory infections, and hookworm stressed the need for public health, sanitation, and personal hygiene. Other important events included a malaria campaign started immediately after the war (using DDT) and the popularization of penicillin and sulfa (sulphonamide) drugs. Health expenditures were never more than 1.5% of gross domestic product, despite profound improvements in public health. In Kerala, the mortality breakthrough took place between 1956 and 1966, when deaths from cholera and smallpox were drastically reduced. Extensions of public-health programs and immunization – through provision of community level services – are identified as the proximate reasons behind these mortality reductions. Costa Rica, in turn, increased expenditure on health services leading to major health improvements between 1970 and 1980. Easy access to community-level services – coupled with immunization campaigns – were also identified in this case as important factors in the reduction in infant and child mortality. The case of Jamaica (which had life expectancy greater than 75 in 2000) also fits well in the above logic: women were historically more independent, schooling developed early, and there was a tradition of discussion of political issues. In Jamaica, school teachers were trained to be health educators, coaching people on how to recognize and treat themselves against specific diseases and vectors.

The important role of easy access to primary health care and family planning, sometimes combined with other interventions, is highlighted in various studies. Data from 16 years of operation of the International Centre for Diarrheal Disease Research (Matlab Thana, Bangladesh), between 1966 and 1981, provide evidence on the effect of family planning, tetanus vaccine, and oral rehydration therapy. The data suggest that tetanus vaccine (given to pregnant women) reduced newborn 4–14 day mortality by 68%. A broad program of family planning was estimated to be responsible for a 25% reduction in death rates, with rehydration therapy accounting for another 9%.

The Brazilian Family Health Program, implemented in the 1990s and expanded during the 2000s, provides additional evidence on the role of family and community based health interventions. The program was largely based on preventive care, but evidence shows that coverage also affected breastfeeding and immunization, and improved maternal management of diarrhea and respiratory infections. It was particularly effective in improving health at early ages and reducing deaths from perinatal period conditions and infectious diseases, and it was also associated with improved subjective assessments of health status.

The extreme experience of reduction in maternal mortality in Sri Lanka is also an important example. In Sri Lanka between 1946 and 1953, there was a reduction of 70% in maternal mortality rates, from 1.8% to 0.5%. This reduction is thought to have been the consequence of changes in various health policies associated with increased access to health centers, midwives, and hospitals (and possibly also with introduction of sulfa drugs and penicillin).

The historical experience of Cuba is yet another case supporting the role of community and family based interventions. US occupation of the island between 1898 and 1902 initiated a series of sanitary reforms, culminating in the virtual elimination of yellow fever, as well as reductions in mortality from tuberculosis and other infectious and parasitic diseases. In some cases, such as tuberculosis, health improvements seem to have been due to better economic conditions and nutrition, combined with the introduction of antibiotics after the 1940s. Other infectious and parasitic diseases – such as diphtheria, malaria, diarrhea, gastritis, and enteritis – were more directly affected by specific sanitary and public-health measures and efforts to teach proper infant care (supposedly accompanied by improvements in education). Nevertheless, some researchers point out that improvements in education, urbanization and targeted health programs occurred early in the twentieth century, whereas a major fraction of the progress in life expectancy was observed only long after that. Therefore, the authors suggest that the role of easy access to primary health care should be even larger than that initially suggested.

Also in the case of Costa Rica between 1968 and 1973, access to medical care (proportion of births under medical attention) had a substantial impact on child mortality. Still, as it relates to improvements in health overtime, education, and sanitation appear as important driving forces. One study shows that the same trend of health improvement continued in Costa Rica after 1970 and suggests that factors similar to those highlighted in the previous period played a role in this later experience. For rural India, data between 1973 and 1978 show that, together with mothers' literacy, type of birth attendant and triple vaccination were closely related to regional variations in child mortality. Poverty and medical care received at birth emerged as central for neonatal mortality, whereas availability of medical facilities and immunization coverage were the main correlates for postneonatal mortality.

Public-health infrastructure, combined with education, also appears as an important determinant of health improvements in various other contexts. Sanitation and women's education were the most important factors determining child mortality differences in Guatemala between 1959 and 1973. For the case of Brazil between 1970 and 2000, education and sanitation were also the key determinants of changes in child mortality, whereas access to clean water, in addition to education and sanitation, appeared as an important determinant of life expectancy at birth.

Access to clean water, again together with women's education, appears as an important determinant of health

outcomes in several papers. This is the case in the experience of Malaysia between 1946 and 1975, where mothers' education and piped water were the factors most closely associated with child mortality (sanitation also appears as marginally relevant), as well as for Brazil. In particular, data between 1970 and 1976 have been used to track down the effects of a program that targeted the improvement of urban environmental conditions (PLANASA), showing that parents' education and access to piped water were the factors most closely related to child mortality both in 1970 and 1976 (access to piped water explained one-fifth of regional differentials in child mortality). Some evidence on the importance of water quality comes from the Argentina, where researchers have explored improvements in the quality of water provision following the privatization of local water companies in approximately 30% of Argentina's municipalities. The results show a reduction of 8% in child mortality (mostly from infectious and parasitic diseases) in areas that had their water services privatized (the reduction increases to 26% in the poorest areas).

The evidence from the historical experience of the US also lends support to the potential role of clean water technologies in developing countries. It was estimated that clean water technologies were responsible for 43% of the reductions in mortality in major American cities during the early-twentieth century. For infant mortality, this share is estimated to rise to 74%, whereas for typhoid fever, clean water is thought to have led to virtual eradication.

For some other dimensions, there is no evidence available from developing countries. In some of these cases, the historical evidence from the developed world may also be informative. Regarding the role of new drugs, for example, there is evidence on the case of the introduction and diffusion of sulfa in the US after 1937. The prevailing view from the literature is that medical innovations played a small role in US mortality declines between 1900 and 1950, but the introduction of sulfa drugs in the mid-1930s represented the development of the first effective treatment of various bacterial infections, including scarlet fever, puerperal sepsis, erysipelas, pneumonia, and meningitis. The available literature suggest that the arrival of sulfa drugs was responsible for declines of 25% in maternal mortality, 13% in mortality from pneumonia and influenza, and 52% in mortality from scarlet fever, amounting to between 40% and 75% of the total decline in mortality from these causes of death during the period. Similarly, the episodes of eradication of hookworm diseases in the American South show how powerful the use of drugs (deworming medicines) coupled with educational campaigns (on how to recognize symptoms) can be. Infection rates among children, which were approximately 40% in 1910, dropped to nearly zero after an intervention sponsored by the Rockefeller Sanitation Commission.

Discussion

The evidence on the determinants of mortality and health in developing countries from the microliterature is very diverse in nature, focus, and methodology. Still, it does reveal some repeated patterns.

First, interventions targeted at particular conditions (malaria, tetanus, diarrhea, large-scale immunizations, etc.) have shown sustained success in improving health and reducing mortality. This debunks the once common argument that narrow approaches focused on specific technologies may end up simply increasing mortality from competing causes of death, and not lead to sustained improvements. The evidence suggests just the opposite: in the case of malaria and measles eradication in Guyana, Kenya, Sri Lanka, Tanzania, and Zaire, the implementation of targeted programs led to reductions in mortality systematically larger than the direct reduction in the cause of death that constituted the initial target. Reductions in mortality from one cause of death, in reality, seem to lead through synergistic links to reductions in mortality also from other causes. This should be expected when one type of disease increases individuals' susceptibility to infections and other diseases (due to weakened immune system or reduced capacity to absorb nutrients).

Still, family health programs and other broad-based community interventions, taking into account the scope of social specificities of local populations, also seem potentially relevant. This was the case with successful programs implemented in Bangladesh and Brazil, and also with some dimensions of the Jamaican experience. Disease-specific targeted interventions and broad programs focused on health practices and the cultural context, rather than being mutually exclusive alternatives to explain health improvements in the developing world, are likely to be both relevant in explaining the diversity of experiences observed. The ideal program in each particular case seems to be a function of the incidence of endemic conditions for which specific interventions are available, as compared to the incidence of conditions that can be minimized through improvements in individual or collective health practices.

Second, in relation to the role played by specific factors, there is an overwhelming amount of suggestive evidence pointing to the importance of education as a determinant of child health. Part of this relationship reflects the effect of income on health, but studies controlling for socioeconomic status still found robust correlations between mother's education and child mortality. Irrespectively, even if taken as causal, this relationship is not yet fully understood in the literature. Some suggest that parental education leads to more use of medical care and sanitary precautions, better understanding of nutritional information, and better recognition of serious health conditions. One study, for example, shows that mothers' literacy is associated with type of medical care during birth and in the postneonatal period. Still, the effect of parental schooling may be more related to modernization and indoctrination. Schooling could be a mechanism to familiarize the population with modern values, reducing resistance to formal medical attention and medicines. A review of a vast array of evidence concludes that educated mothers are better informed about and more likely to use medical facilities and other health technologies, are more likely to have their children immunized and to have received prenatal care, and are more likely to have their deliveries attended by trained personnel. At the same time, the social aspects in the relationship between education and child mortality were also present: educated mothers marry later, tend to have fewer children, and

to invest more in each child. Overall, the following channels linking mother's education to child mortality were identified: greater cleanliness, increased utilization of health services, greater emphasis on child quality, and enhanced female empowerment.

The role attributed to public-health infrastructure can be analyzed through the results related to access to clean water and sanitation. Some microstudies emphasize one of these dimensions in detriment of the other, maybe due to the high correlation between them, and few papers have been able to identify independent effects of each. But many of the analyses discussed here find a significant correlation between either sanitation, or access to clean water, and health (in most cases, mortality). Anecdotal evidence from Cuba and Kerala, among others, also supports the potential importance of factors linked to public-health infrastructure in triggering sustained improvements in health.

From a broad perspective, the evidence does not point to one specific factor as the main determinant of health status and mortality in developing countries. There is strong evidence on the success of targeted interventions in some contexts, such as malaria control, rehydration therapy, and immunization, whereas there are also various qualitative and quantitative studies indicating that family and community health programs can be effective, by reducing the probability of infections and improving health management. Finally, there is also evidence on importance of health infrastructure, through access to clean water and sanitation. Based on the evidence currently available, it is still impossible to isolate the specific role of each of these factors, or to identify their relative importance in different contexts. These would be important goals for future research in the area.

Healthcare Safety Net in the US

PM Bernet and G Gumus, Florida Atlantic University, Boca Raton, FL, USA

Introduction

In most developed economies, universal health insurance coverage is standard and healthcare is paid for using insurance that is either mandated for those who can afford the premiums or subsidized through taxes. In the US, however, insurance purchase was not mandated through the 2000s, and almost 20% of the nonelderly had no coverage. People with no or inadequate health insurance often turn to safety net providers when they get sick.

The US does not have a formal safety net, but rather a patchwork of providers including hospitals, federally qualified health centers, local health departments, community health centers, and others. Some of these providers have an explicit mission to serve low-income, uninsured people whereas others fulfill this role as part of broader community benefit activities.

This article discusses the economic issues relating to safety net providers and the lower income population for whom they care. The most fundamental economic barrier faced by the poor is the lack of health insurance. Beyond that, however, the poor often live in rural areas, have language barriers, and often suffer from chronic conditions, making this population more difficult to treat. On the provider side, the need to remain financially viable is often at odds with charitable missions to care for the poor. The Affordable Care Act (ACA) of 2010 aims to make it easier for everyone to get health insurance, removing one of the major barriers to accessing care. Safety net providers, however, are expected to continue playing a vital role in the provision of care to the most vulnerable.

Special Needs of Lower Income Populations

Lower income populations have a number of attributes which can interfere with the efficient and effective delivery of healthcare services. First and foremost, they cannot afford adequate health insurance. They are uninsured, underinsured, or covered by Medicaid; and thus face problems with access and health outcomes. In addition to financial barriers, differences between patients and their providers can interfere with the provision of care. For lower income populations, such barriers include race, ethnicity, and language. Immigrants are especially prone to all three difficulties. Some groups with special needs are more likely to be living in poverty: children, pregnant women, and people with human immunodeficiency virus/acquired immune deficiency syndrome (HIV/AIDS). For the rural poor, geographic access barriers make it even harder to access care.

Insurance Barriers

The most effective safety net may be adequate insurance. Low income and uninsured people generally have poor access to medical care simply because they cannot afford to pay for services. There are areas that lack adequate primary care providers; however, more providers would be attracted to such areas if enough people had insurance. Unfortunately, it is hard to find affordable health insurance for those who do not work for large employers.

Health insurance coverage is associated with better access and better health outcomes. A lack of insurance often delays detection and can complicate treatment. The generosity of the insurance, measured by the physician compensation rates, may also help get patients seen in the right setting at the right time. Patients with insurance offering higher physician payments are less likely to go to hospitals for nonemergency conditions and are more likely to be seen in an ambulatory setting for conditions such as asthma and diabetes.

Even Medicaid, which generally pays providers much less than Medicare or commercial insurers, has improved its access to care for the poor. Although it would seem that expansions to Medicaid would help cover even more people, some research contends that public insurance reduces the demand for private insurance, whereby the more-expensive employer-based private options are crowded out of the market. This does not necessarily mean that the proportion covered by some form of health insurance changes; simply that the proportion covered by Medicaid increases as the proportion covered by private insurance decreases. Medicaid patients can wind up back with private insurers if the state decides to privatize care, whereby the government pays premiums to private insurers. Privatizing public insurance may not, however, save money. Some studies have observed that shifting recipients into Health Maintenance Organizations (HMOs) can result in a net increase in the overall Medicaid spending.

With the implementation of provisions of the ACA in 2010 access to insurance should improve. However, this is not projected to achieve universal coverage as some people may choose to remain uninsured because their income is too high for a subsidy but too low to afford insurance premiums. As higher take-up rates should improve system efficiencies, insurance premiums may drop as more enroll, making coverage even more affordable.

Special Medical Needs

People living in poverty frequently have special medical needs. Children are a significant portion of the poor and they require specialized care. Substance abusers and the homeless are also poor and generally require more mental healthcare. Sometimes, conditions such as pregnancy or HIV/AIDS precipitate a cash drain that leaves people unable to afford insurance in the first place. Maintaining a regiment of treatment can be difficult among lower income populations, hence further complicating care.

Even in an environment structured to meet the specific needs of the poor, the simple economic concepts of efficiency

and effectiveness are still important. Community health centers (CHCs) improve access to primary care for vulnerable populations. If it is easier for patients to get preventative and diagnostic care, then expensive complications are less likely to arise in the future. CHCs are preferred to more-expensive hospital outpatient departments, where services are more intense and it is more difficult to maintain continuity of care.

The consumers themselves are also rational economic agents. Those in need are not necessarily unsophisticated buyers and seem to have a similar propensity to use primary care *in lieu* of emergency care, where it is available. This reinforces the importance of access. Unfortunately, those in need may not always get the highest quality of care. When quality is measured by the ranking of medical training institutions, uninsured patients are treated disproportionately by physicians from lower ranked schools and residencies.

Other Barriers

Any differences between the physician and the patient – race, language, ethnicity, etc – can interfere with effective provision of care. The true nature of a patient's problems can literally be lost in translation, for example, potentially leading to missed diagnoses or delayed treatment. As many immigrants are poor and face such barriers, safety net providers must be capable of addressing a broad range of needs. As the languages supported by a private physician practice might be limited to English and Spanish, a safety net provider might have to offer Mandarin, Creole, Portuguese, etc. Economically, that raises the costs incurred by safety net providers relative to private practice.

There is much political rhetoric implying that immigrants are responsible for a significant share of uncompensated care or government-subsidized care. However, research shows that very little public tax money is spent on undocumented immigrants, who are less likely to use medical services and whose services cost less when used.

Geographic access barriers make it harder for anyone living in rural areas to get to providers. Simple transportation issues can present major logistic challenges for lower income people. Inadequate public transportation makes it hard for patients to keep appointments, increasing the difficulty and cost of executing a regiment of appropriate care. In addition to rural areas, living in an insurance dessert may also lead to bad health outcomes. Even for people who have health insurance, health service quality and access are worse in areas with higher proportions of uninsured people.

Challenges to Providers

Safety net providers face a number of challenges, both clinical and financial, in serving the needs of lower income populations. The patients often require more attention than the average patient, costing the providers more. Reimbursement, however, is often lower for these patients, compounding the financial strain on the safety net. Before going further, it is worth noting that there is no standard definition of 'safety net' providers; it varies from state to state. Many researchers classify safety net providers as those that provide a high ratio of uncompensated care. The financial challenges faced by the safety net providers start with the clinical aspects of care.

Difficult Clinical Care

In addition to problems in communication and transportation, lower income people are more likely to receive care in acute or urgent settings. As they are often uninsured or underinsured, many people living in poverty do not have a family physician. Medical problems are allowed to develop further because patients may hope the problem goes away before spending money to see a physician. Thus, by the time such patients do seek care, the condition is more complex and the severity of illness is greater. Although the poorer patients arrive sicker, safety net hospitals are still more efficient. Had the same mix of patients presented at for-profit hospitals, it may have cost the healthcare system even more.

Limited access to primary care services is not just the result of decisions by lower income patients on whether, where, or when to spend on healthcare. Managed care can indirectly make it harder for patients living in poor areas to access primary care physicians. HMO penetration is associated with limited access to primary care for poor patients. This may be the result of HMO patients crowding out poorer (possibly charity) patients, or it may be the result of HMOs not selling in primary care deserts. To the extent that the ACA reduces the proportion of the uninsured, it may mitigate complications resulting from delayed or forgone care. Once insured, a poor patient's decision to see a doctor is easier and less costly. If they see their primary care physician sooner, ailments can be addressed in a more timely manner, and thus with lower costs and better expected outcomes.

Low or No Reimbursement

In addition to having to care for patients suffering from more advanced conditions, safety net providers are generally paid less. Lower income patients are frequently uninsured or underinsured; either of which leaves the provider with the possibility of nonpayment. Or the patient might be covered by Medicaid, which normally pays less than any other payer. Providers with a disproportionate share of lower income patients will have limited ability to cross-subsidization or cost-shift to better-paying patients. Cost shifting occurs when hospitals use profits from more-generous payers to subsidize uncompensated care. As such, safety net provider cannot subsidize the more expensive care needed by poorer patients with profits from better-paying patients.

Even charitable and not-for-profit providers must obey the laws of economics; to stay in business, they have to at least break even. There is ample evidence that providers respond to financial incentives even when fulfilling their safety net missions. Safety net hospitals reduce their uncompensated care when insurer fees decrease. When Medicaid fees are cut, physician respond not only by seeing Medicaid patients less

often, but also by reducing the time spent when they do see the patient. In both cases, providers are simply responding to lower fees by offering less. Higher Medicaid fees are associated with increases in the number of services, the intensity of services, and the number of private physicians willing to care for Medicaid patients.

By making health insurance easier to obtain, one of the goals of the ACA is to move patients from self-pay to insured, removing reimbursement as a barrier to care.

Profit Motive and Access

The healthcare system in which providers operate does not give much incentive for providing care to uninsured and underinsured, exacerbating the access issues for lower income populations. Simple profit motives explain why for-profit hospitals provide significantly less uncompensated care than do public hospitals. Although for-profit hospitals are expected to provide some level of community benefit, their primary mission is to provide their investors with good returns, making charity care a lower priority. Many for-profit hospitals are affiliated to larger healthcare systems, which may further weaken the ties to one particular local community and their needs. For-profit status does not preclude a hospital from acting as a safety net provider, but it is more common in areas with less market pressure. Even when hospitals appear to be paying more attention to lower income patients, it often takes government financial incentives for charity care to illicit that reaction. Quite simply, for-profit hospitals are duty bound to provide a return for investors, and charity care cuts into profits.

Not-for-profit providers must also devise ways to survive financially. Here, too, it often involves trade-offs wherein market conditions put financial pressures on the providers to limit charity care. Hospitals provide significantly less uncompensated care in markets with higher HMO penetration. Even nonsafety net hospitals provide more uncompensated care in areas with lower levels of hospital competition, perhaps because of greater community expectations. One way that hospitals used to pay for uncompensated care was through cost shifting. However, insurer price pressures have reduced hospital revenues, leaving little surplus from private insurers to cover uncompensated care.

Disproportionate share payments provide an example of multiple financial incentives working at conflicting purposes. By improving reimbursement levels, it became easier for Medicaid patients to access better hospitals and doctors. However, this left safety net hospitals with fewer Medicaid patients, effectively increasing their relative share of uninsured and underinsured, putting them under further financial pressure. Disproportionate share payments are one possible remedy, providing relatively higher reimbursement to hospitals with a higher proportion of Medicaid patients. However, the allocation of such payments is left to state governments, resulting in multiple methods and unclear effectiveness.

The complexity of the healthcare system in the US can even result in unexpected problems associated with something as simple as a policy to expand Medicaid. On the positive side, this kind of broader access to insurance can reduce the need for safety net providers. However, some studies have found that expanding Medicaid resulted in decreased access for the uninsured because financial motives make hospitals more interested in Medicaid patients than charity patients. Furthermore, because higher reimbursements from Medicaid give poor patients access to a broader range of providers, for-profit hospitals seem to be skimming some of the more lucrative patients, such as Medicaid births. With safety net hospitals now losing Medicaid revenues that could have subsidized uncompensated care, what started as an attempt to help Medicaid patients can end up worsening the financial condition of safety net hospitals.

Taking a cue from insurer tools to avoid adverse selection, some hospitals alter their location or product mix to become less attractive to uninsured patients. By eliminating emergency rooms, AIDS units, maternity care, and substance abuse programs – all departments that attract a disproportionate share of nonpaying patients – hospitals can improve their profitability. For-profit hospitals are also located in better-insured areas, which naturally have less need for uncompensated care.

If uninsured patients still find their way to a provider, the latter can minimize losses by simply doing less. Public- and church-owned hospitals consistently provide more uncompensated care than for-profit hospitals, which may use the existence of a public hospital in the area as an excuse to provide less uncompensated care. For-profit hospitals skim profitable patients from all competitors, including safety net hospitals. This often leaves safety net hospitals under an increased financial pressure.

Precarious Future

Safety net providers are toiling under increasingly difficult financial conditions, making it impossible to provide as much care as needed. The safety net is currently inadequate and is increasingly weakening. State and local governments spending on health and hospitals is critical for providing care for the most disadvantaged populations. The recent economic recession has led to significant funding cuts, which generate serious concerns regarding the viability of the safety net systems.

Financial pressures have led many states to subcontract and privatize services. Medicaid HMOs have already been in use for years, yet have not demonstrated the ability to reduce costs. Privatization may not be the sensible financial decision because most commercial plans are not effective in targeting the special needs of the Medicaid population. Furthermore, their for-profit status gives for-profit Medicaid subcontractors conflicting incentives. For example, though it would improve the profitability of a privatized contract, insurer efforts to reduce service volumes could be extremely harmful to Medicaid recipients, many of whom suffer from chronic conditions.

The healthcare system in the US is extremely complex. Politicians, hospitals, physicians, and insurers often make decisions based on incomplete, incorrect, or misinterpreted information. One common belief is that doctors lose money on uninsured patients. In an irony borne out of the

convoluted machinations of a semimarket-based healthcare system, uninsured are likely to pay more for physician services. Virtually no insurer pays a provider's usual and customary fee, but that is what patients with no insurance are charged. Even after allowing for a share of uninsured patients who pay nothing, physicians actually make higher profits on uninsured than they do on insured patients. Put another way, physicians would have higher profits if they only accepted uninsured patients. Yet most physicians and policymakers believe the opposite to be true.

The expanded insurance availability under the ACA will bring many previously uninsured people into the traditional healthcare system, reducing the need for a safety net. Under the ACA, safety net providers are expected to continue playing a vital role as some people will still not be able to afford insurance; but they may be able to afford a reduced cost and a reduced benefit option. Some amount of insurance education will also be needed, perhaps giving safety net providers an expanded advocacy role. Many signing up for newly available insurance plans may be unfamiliar with how to get the most out of their coverage. Safety net providers are already familiar with these patients, so they may be best situated to help them navigate the healthcare system. As noted earlier, safety net providers are attuned to the specific needs of this population. Therefore, even if the ACA allows lower income populations to get care at their choice of providers, their best choice may still be a safety net provider.

Health-Insurer Market Power: Theory and Evidence

RE Santerre, University of Connecticut, Storrs, CT, USA

Introduction

The US, like the Netherlands and Switzerland, among other nations, relies primarily on private health insurance to finance and reimburse for medical care. In fact, approximately 64% of the nonelderly US population enrolled in private health insurance plans in 2011. This figure is down dramatically from its height of 76% in the mid-1970s. Some researchers point out that private insurance coverage fell over time because premium hikes have vastly outweighed raises in consumer income even though the aggregate premium elasticity of demand is slightly lower than the corresponding income elasticity. Others claim the Medicaid program crowded out some private health insurance coverage. Still others propose that occupational shifts from traditionally higher coverage manufacturing jobs to lower coverage service sector jobs in the US led to some of the reduction.

Although private health insurance enrollment has declined in the past in the US, many health policy analysts expect it to increase in the future because of the recently passed Patient Protection and Affordable Care Act of 2010. The Act mandates that most US citizens purchase private health insurance, if they are not eligible for public health coverage, or pay penalties. By 2019, nearly 8 million more nonelderly citizens are expected to purchase private insurance directly from health insurers because of the mandate. As a result, a sound understanding of the health insurance product and the current operation and performance of the health insurance industry will take on even more importance in the future.

At its most basic level, health insurance is no different than any other product sold by firms and purchased by consumers. Health insurance policies are sold indirectly to consumers in the form of employer-sponsored health insurance (ESI) or are directly purchased by consumers (DPI). Of those covered by private health insurance in 2011, approximately 88% received their coverage through employers. The ensuing transaction involving the health insurance product boils down to a potential win-win situation where both market participants stand to gain.

In particular, because of the irregularity and infrequency of health-care spending, consumers typically value health insurance because it offers financial security against unexpected losses and thereby moderates swings in their income. Additionally, consumers value health insurance because it provides them with access to expensive medical treatments which they might not otherwise be able to afford out of pocket. Hence, many consumers are willing to give up their premium dollars, even when feeling quite healthy, because that initial cost pales in comparison with the dollar benefits which they expect to receive from their health insurance companies when they unexpectedly enter into a state of sickness.

Health insurers also stand to gain from the market transaction as long as the health insurance premiums charged, at least cover the costs of providing health insurance during the policy period. Costs include the expected medical benefits to be paid out and the expense load that includes claims processing, underwriting, and marketing expenditures, taxes, and profits, less any interest income earned on invested premiums. Expected medical benefits, in turn, capture the dollar amount that health insurance companies expect to reimburse medical care providers, such as hospitals, physician clinics, and drug companies, for treating patients throughout the policy period. Thus, health insurance companies can be viewed as organizations that negotiate medical care contracts with providers; mark them up to reflect expenses, profits, and risk; and then sell those policies to employers and individuals. Within that perspective, health insurance companies are paid for negotiating health-care provider contracts, reimbursing claims, and managing the associated risks, with profits as the reward for successful performance.

It is evidenced from the preceding discussion that health insurance companies simultaneously operate on different sides of two highly intertwined markets – as buyers in the market for medical services and as sellers in the market for health insurance. It is in these important roles as buyers and sellers that health insurers potentially shape the manner in which these two markets operate and perform. As discussed in the Section 'Theoretical Aspects of Health-Insurer Market Power', economic theory generally suggests that markets operate more efficiently when structured in a competitive manner such that individual buyers and sellers act as price takers and possess no market power. But when markets are structured noncompetitively, sellers may wield market power to the detriment of buyers, or vice versa, with inefficiencies potentially arising in either case.

In the case of health insurers, some interesting market dynamics may be involved when markets are noncompetitively structured because of the simultaneous functioning on opposite sides of the medical care (input) and health insurance (product or output) marketplaces. Indeed, against the backdrop of a baseline case where both markets are reasonably competitive, a number of different scenarios can be imagined where either the medical care provider or health insurer possesses market power and the other does not, or both possess market power in the medical services input market.

With these possible market scenarios in mind, the next section of this article reviews the theoretical aspects of market power within the context of the health insurance industry. Once the basic theory is developed, Section 'Empirical Aspects of Health-Insurer Market Power' discusses the empirical aspects of testing for market power effects. Section 'Empirical

Findings Regarding Health-Insurer Market Power' reviews the empirical literature concerning market power effects in the health insurance and health-care industries. Section 'Summary and Conclusion' is the final section for this article.

Theoretical Aspects of Health-Insurer Market Power

To an economist, market power means that a single seller (buyer) can, individually or with a group of other sellers (buyers), raise (lower) the product's (input's) price without losing all of its sales (purchases). Sellers or buyers generally attain some market power when they are few in number and possess relatively large market shares. It must also be the case that some type of industry barrier prevents new sellers or buyers from entering the market because new entrants heighten competition and typically cause an offsetting price adjustment. If these market conditions hold, a few buyers or sellers will account for a dominant share of the industry purchases or sales and hence the seller side or buyer side of the market is considered to be highly concentrated.

In the limit, a single seller of a product or input is labeled as a monopoly, whereas a single buyer of a product or input is considered a monopsony. Given that health insurers simultaneously operate in the medical services input market and health insurance output market, five potential scenarios can be imagined:

1. Both medical care providers and health insurers do not possess market power (competitive case);
2. Medical care providers, as sellers, possess market power, but health insurers do not in the medical services input market (monopoly case);
3. Health insurers possess market power, but buyers (employers or individual consumers) do not in the health insurance output market (another monopoly case) (two other cases are possible (either buyers possess market power but health insurers do not or both buyers and health insurers possess market power in the output market), but their relevancy is questioned, so they are not covered in the following discussion. However, the extension of the analysis to these two cases should be evident);
4. Health insurers possess market power, as buyers, but medical care providers do not in the medical services input market (monopsony case); and
5. Both health insurers and medical care providers possess market power in the medical services input market (monopoly vs. monopsony or bilateral monopoly case).

Figure 1 provides a graphical illustration showing how the various market outcomes compare with the competitive outcome. (See Pauly (1988) and Scherer (1980) for a similar graphical model, although here the monopsonistic buyer also holds monopoly power in the product market.) Also, Table 1 provides a descriptive summary concerning how each of the scenarios compare to the competitive case in terms of price and quantity. In general terms, the positively sloped supply curve reflects that a higher price is necessary to attract increasing amounts of a particular type of medical service or more health insurance coverage into the marketplace. Also in general terms, the downward-sloping demand curve shows that the buyers' maximum willingness-to-pay declines for increasing units of an input such as medical services or output such as health insurance. If the graph represents the product market for health insurance, the demand curve captures how much additional utility consumers receive from increasing amounts of health insurance coverage. If an input market, the demand curve reflects how valuable increasing amounts of the medical services are to a health insurer, which is referred to as the value of the marginal product (VMP). The demand curve declines because of the law of diminishing marginal utility and productivity.

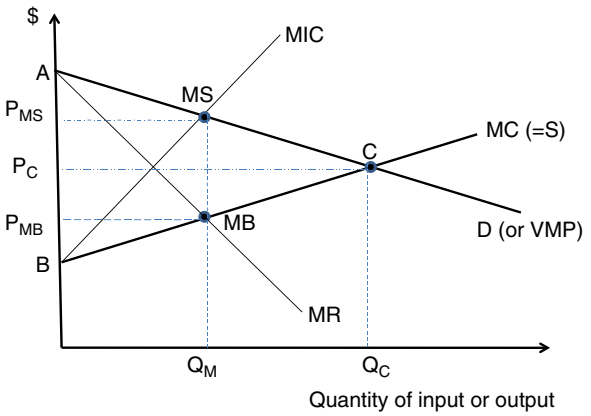

Figure 1 D (or VMP), demand for output in either type of market or demand for an input (value of the marginal product) in a competitive market; MC (=S), marginal cost or perfectly competitive supply curve; MR, marginal revenue of a monopolist in the output market or demand for an input by a monopolist (marginal revenue product); MIC, incremental cost of purchasing faced by a monopsonist; C = outcome when both the buyer and seller sides of the market are perfectly competitive in both the input and output markets; MS, outcome when the seller is a monopoly; MB, outcome when the buyer is a monopsony.

Note that the perfectly competitive equilibrium occurs at point C, where the supply and demand curves intersect. Because both individual buyers (e.g., health insurers or consumers) and sellers (e.g., medical care providers or health insurers) are assumed to be price takers in a competitive market, they each treat the good's price as a parameter – something outside their control. Thus, to maximize net returns – the difference between benefits and costs (net benefits represent profits to firms and consumer surplus to consumers) – sellers match up price to marginal cost (MC), whereas buyers match up price to demand (D) with price serving as the coordination device to equate supply and demand. In equilibrium, price and quantity equal P_C and Q_C, respectively. Buyers receive the triangular area A–P_C–C as 'consumer surplus' and sellers gain triangular area B–P_C–C as 'producer surplus.' Note the win-win aspect of the market transaction.

The two monopoly situations are scenarios (2) and (3). In these two scenarios, the sellers (either medical care providers or health insurers) possess monopoly power but the buyers (health insurers or employers/consumers) do not in the respective market. For a monopolist, theory suggests that the marginal revenue curve (MR) lies below the corresponding downward-sloping demand curve. Marginal revenue lies

Table 1 Summary of scenarios involving buyer and seller market power

Scenario	*Relevant market*	*Market power on buyer side of market*	*Market power on seller side of market*	*Label*	*Equilibrium outcome in Figure 1*	*Implication regarding price and quantity*
1	Output or input market	None	None	Perfect competition on buyer and supplier sides of the market	P_C and Q_C	Competitive price and quantity
2	Medical services input market (e.g., hospital or physician services)	None	Full	Monopoly supplier of medical services	P_{MS} and Q_M	Price of medical services higher and quantity lower than the competitive levels
3	Output market for insurance	Full	None	Monopoly supplier of insurance	P_{MS} and Q_M	Price of insurance higher and quantity lower than the competitive levels
4	Medical services input market (hospital or physician services)	None	Full	Monopsony buyer of medical services	P_{MB} and Q_M	Price and quantity of medical services lower than the competitive level
5	Medical services input market	Full	Full	Monopoly supplier and monopsony buyer	Indeterminate	Price and quantity determined by relative bargaining power

below demand because price must be continually lowered to sell additional units and the revenues from the increased volume fail to compensate for the lower revenues associated with the reduced prices on the previous units. (It is supposed that the demand curve in Figure 1 is captured by the equation $P = a - bQ$, where Q represents quantity and P stands for price. Total revenues equal P times Q or $(a - bQ)Q = aQ - bQ^2$. Taking the first derivative of this revenue function with respect to Q to get dTR/dQ gives marginal revenue equal to $a - 2bQ$. It should be noticed that MR has the same intercept as demand but twice its negative slope.)

To maximize economic profits, the monopolist-seller produces output or supplies an input up to the point where marginal profits are no longer positive (where MR equals MC) and charges the maximum price that buyers are willing to pay for that amount as indicated by the demand curve. Thus, the monopoly equilibrium occurs at MS with a price of P_{MS} and output of Q_M. Note that the monopoly outcome results in a higher price and lower quantity than those predicted by the competitive outcome, *C*. Also, note that consumer surplus shrinks to area P_{MS}–A–MS, whereas producer surplus expands to area B–P_{MS}–MS–MB. The triangular area MS–C–MB represents the competitive winnings that are lost because of the monopolistic restriction of quantity.

Scenario (3) represents a situation where a monopsonist engages in negotiations with a competitive seller side. As a single buyer, the only way a monopsonist can attract additional products or inputs into the market is by paying an increasingly higher price. As a result, if all units are similarly reimbursed when finally purchased, the actual incremental costs of purchasing a particular level of inputs will be greater than the marginal cost, which assumes a price independent of the units purchased. Thus, a monopsonist's incremental cost curve of purchasing inputs or outputs (MIC) lies above the corresponding marginal cost curve (MC) associated with a group of price-taking input buyers. (It is supposed that the supply curve in Figure 1 is captured by the equation $P = c + dQ$. Total costs equal P times Q or $(c + dQ)Q = cQ + dQ^2$. Taking the first derivative of this cost function with respect to Q to get dTC/dQ gives marginal incremental cost, which equals $c + 2dQ$. It should be noticed that MIC has the same intercept but twice the slope of the supply curve.)

To maximize economic profits, the monopsonistic health insurer continues to purchase medical services, as an input, as long as the added revenues, as reflected in *D* (or VMP), compensate for the added costs, as captured by MIC. Thus, in Figure 1, the health insurer purchases inputs up to the point where the MIC and *D* curves intersect. To attract that amount of medical services, the health insurer must pay the price indicated by point MB on the supply curve, S. Compared with the competitive case at point C, it should be noticed that the monopsonistic health insurer pays less for the medical services and purchases fewer units. Thus, in this case, the producer surplus shrinks to B–P_{MB}–MB and consumer surplus expands to P_{MB}–A–MS–MB. Once again some of the social winnings are lost, but this time because of a monopsonistic distortion.

Scenario (5), the bilateral monopoly situation, offers the most intriguing case. Here, a single buyer and a single seller haggle over the terms of the sale. The single seller prefers the MS outcome where seller profits are maximized but the single buyer prefers the MB outcome because buyer profits are maximized. However, it should be noticed that joint net benefits are maximized at the competitive outcome with a quantity of Q_C, that is, both the buyer and the seller can receive more net benefits than at their preferred outcome if they agree on the competitive output and then arrive at a mutually satisfying price to split the resulting winnings. Because neither the buyer nor the seller is able to play off the other by threatening to deal with other buyers or sellers, the resulting price depends on which party possesses a comparative advantage at bargaining or which party brings to the bargaining table something more than the other. For example, one of the

parties may be operating with greater excess capacity, so the increased volume associated with the transaction is relatively attractive and therefore that party is more willing to compromise on the deal.

The exact price that evolves from the negotiation is indeterminate without knowing more about the negotiating skills of the two parties bargaining. It is not known that the upper limit would be the price that forces the buyer's profit to zero and the lower limit would be the price that forces the seller's profit to zero because negative profits would cause one of the firms to drop out of the deal. Alternatively stated, the price must be high enough to make the seller at least as well-off with no sale and low enough to make the buyer at least as well-off with no sale. It should be noted that the alternative to bargaining is no sale because neither the monopoly nor the monopsony outcome is relevant because each entails competitive behavior on one side of the market, which is not a characteristic of bilateral monopoly.

In the real world, often markets are never perfectly competitive and a pure monopoly or monopsony situation, where only one seller or buyer exists, is also rare. A more likely scenario is when a few dominant sellers or buyers exist in some markets and thus these markets are said to be oligopolistic or oligopsonistic. Whether the few buyers or few sellers behave like the preceding models predict depends on whether each individual buyer or seller behaves independently or cooperates with others to extract more favorable prices from the other side of the market. Economic theory suggests that a host of factors influence if a group of sellers (or buyers) act independently or cooperatively. Among these factors are the exact number and relative size distribution of firms, height of any entry barriers, and the availability of close substitute products. These conditions are discussed in detail in the next section.

Empirical Aspects of Health-Insurer Market Power

Researchers have employed various methods when testing for market power effects, but here the reduced-form, structure-conduct-performance (SCP) approach is discussed. Although the SCP approach possesses several empirical shortcomings, it remains the most popular method when testing for market power effects in the health insurance industry. (Other techniques include structural modeling and stock market event analysis.) If suitable data exist, the following estimation equation would be specified to test for market power effects, where X stands for either price (P) or quantity (Q), MCS and MCB represent the market concentration of sellers and buyers, and D and C capture a vector of demand and costs factors, respectively.

$$X = f(MCS,\ MCB,\ MCS \cdot MSB;\ D, C) \qquad [1]$$

According to this monopoly theory, a direct relationship is expected between MCS and P, assuming buyer concentration is negligible and therefore has no separate impact on the market outcome. Under those same conditions, an inverse relationship is anticipated between MCS and Q. Moreover, monopsony theories predict an inverse relationship between MCB and both P and Q, based on low seller concentration. The bilateral monopoly situation, as characterized by the interaction term between the two types of concentration, $MCS \cdot MSB$, is anticipated to be directly related to Q but will have an ambiguous effect on P. Recall that the latter effect depends on the relative bargaining power of the two sides of the market. Finally, the vectors D and C simply act as control variables in eqn [1], so the independent effects of market structure on P or Q can be properly isolated. Variables in D might include buyer income and the price of substitutes and complements, whereas variables in C might include any entry barriers and the state of technology. Thus, this article is not necessarily focused on the impact of those control variables on the dependent variables.

The most basic way to estimate eqn [1] is with the ordinary least squares procedure. (The interested reader will have to consult an econometric text for specifics regarding ordinary least square estimation.) For two reasons, however, ordinary least squares estimation of eqn [1] may result in biased parameter estimates. Both of the reasons deal with some right-hand side variable, or variables, in this case market concentration, being endogenously rather than exogenously determined. First, reverse causality may hold between the dependent and market concentration variables. For instance, more firms may enter the market over time and dilute seller concentration when the market price is high. Or expectations of output, as indicated by Q, may influence seller concentration. Similar examples can be cited for how the magnitude of the dependent variables may influence buyer concentration.

The other problem is that some immeasurable and therefore omitted demand or cost factor may influence both the degree of seller or buyer concentration and the price or quantity. If so, any observed statistical correlation between market concentration and price (or quantity) may only reflect an association rather than a causal relationship because of this third-variable problem. For example, the baseline health of the population may be difficult to measure. Baseline health may influence both the number of hospitals and health insurers within an area as well as the price and quantity of medical care.

Because of the potential for reverse causality or a third-variable problem, estimation of eqn [1] typically requires a panel data set and/or an instrumental variables approach. (A social or natural experiment, which allows for a control group and random assignment of participants, is preferred but the first is expensive to design and the latter is often unavailable to the researcher. See the Appendix to Article 1 in Santerre and Neun (2013) for an elementary explanation of these two approaches.) A panel data set, which covers a number of repeating cross-sections (of individuals, household, states, etc.), allows the analyst to control for unobservable heterogeneity or any omitted variables that remain constant over time. This can be accomplished by including in the estimation equation a 0/1 binary or dummy variable to represent each of the repeating observations. If all omitted variables remain fairly constant over time, the set of dummy variables does a reasonably good job of capturing the fixed differences across observations and thereby corrects for the third-variable problem.

However, the analyst still may have to be concerned with the possibility of reverse causation and any omitted variables that do change over time. For example, the baseline health of

the population may be systematically worsening or improving because of some confounding factor that cannot be easily observed and measured. In this case, an instrumental variable approach should be employed and either implemented on a cross-sectional basis or incorporated within a fixed effects framework. A good instrumental variable is one that is highly correlated with the suspected endogenous right-hand side variable but uncorrelated with the dependent variable.

For example, suppose that the impact of health-insurer buyer concentration on the price of hospital services is empirically examined and assume that the seller side is fairly competitive in all of the hospital services markets under investigation. A good instrument, in this case, is highly correlated with health-insurer concentration but not correlated with the price of hospital services. With that in mind, some researchers have used the size distribution of employers in the market area as an instrument. The reasoning is that health insurance companies may be attracted to areas with more medium- and large-sized employers and employer size is unlikely to directly influence the price of hospital services.

This section has briefly reviewed the technique used by most researchers to test for the market power effects of health insurers as a way of providing some context to the next section that describes the empirical findings. The instrumental variables technique, although econometrically fairly powerful, is often difficult to implement in practice because suitable instruments are hard to find. This is particularly true for studies relating to health care where many variables, such as health status, health insurance coverage, and medical care utilization, are highly interrelated. The researcher must typically be ingenious with respect to uncovering an instrumental variable that influences the suspected endogenous variable but not the dependent variable in the estimation equation. It should be noticed in eqn [1] that at least three instruments may be necessary because both concentration measures as well as their interaction are likely endogenous.

Empirical Findings Regarding Health-Insurer Market Power

To estimate eqn [1], the analyst must identify the degree of market concentration in a particular market. Thus, defining the relevant market area is an important consideration. A relevant market area contains both a product and a geographical dimension. In an output market, the relevant product market considers all of the substitute products that buyers might switch to if any one product's price is raised by a nontrivial amount for a nontemporary period of time. These substitute products may satisfy similar needs or fulfill similar functions. For example, with respect to health insurance, analysts must consider if indemnity plans, health maintenance organizations (HMOs), and preferred provider organizations (PPOs) are substitutes or not. (In the past, researchers treated indemnity, HMO, and PPO plans as separate markets. More recently, the distinction between these plans have become blurred in practice, in part because most health insurers offer multiple products and buyers are willing to switch among products depending on relative prices. Also, many of these health insurance products now contain many features of the others.) In addition, for larger employer/firms, the analysts may consider if self-insured plans are reasonable substitutes for fully insured plans that are purchased from health insurance companies.

Similarly, the relevant geographical output market considers all other locations that buyers might switch to if the price of the product is increased by a significant amount for a meaningful period of time. For some products, the market may be very local in nature, but for others, the relevant geographical market may be regional, national, or even international in scope. Although many health insurers such as Aetna and Cigna operate nationally, most experts agree that the market for health insurance is local in nature because employers and consumers want access to a local network of providers. For example, consumers in Philadelphia wish access to a network of providers in that city so they likely are unwilling to purchase their insurance from a health insurer with provider network established in Boston. Consequently, the geographical market for health insurance is often defined as the metropolitan statistical area (MSA) for research and policy purposes. The important take-away for defining the relevant market area is that current purchasing patterns may not properly reflect the relevant market area because the switching of buyers to new products and locations will not take place until the change in the product's price actually occurs. Thus, one must consider potential substitute products and locations when defining the relevant market area.

Once the relevant market is identified, the degree of market concentration must be assessed. Customary measures of market concentration are the Herfindahl–Hirschman Index (HHI) of market concentration and the number of firms in the market. The HHI is computed by the squaring and adding, in percentage terms, the market shares of all firms in the industry. It ranges from 0 to 10 000 with the latter reflecting only one firm in the market.

The HHI is preferred to other measures such as the concentration ratio, which is an indicator of the percentage of output produced by the industry leaders, because it captures the relative size distribution of output among the leading firms. The value of the HHI decreases with a larger number of equally sized firms, so values closer to zero indicate a less concentrated market. The Federal Trade Commission and Department of Justice considers an HHI more than 2500 as representing a highly concentrated market or a market characterized as a tight oligopoly. In contrast, a market with an HHI more than 1500 but less than 2500 is interpreted as being mildly concentrated or a loose oligopoly. To put these numbers in some perspective, the American Medical Association (2011) reports that the health-insurer HHI is greater than 2500 in most MSAs of the US.

Theoretically, the HHI works best as a measure of market concentration when the products sold by the various firms are reasonably similar. However, when firms sell differentiated products, the HHI loses some of its appeal because niche markets may develop with some firms potentially establishing varying degrees of market power in the various niches. For example, local HMOs may not have a substantial competitive effect on those HMOs possessing a national geographic scope. In this case, the number of firms may provide a better measure

of the degree of market competition because the market takes on features similar to the economist's notion of monopolistic competition. Monopolistic competition holds when a large number of firms offering differentiated products coexist in a market and entry barriers are low or nonexistent. As a point of reference, greater than 200 health insurance companies operate in the typical US state.

Table 2 lists chronologically 17 empirical studies in the economics literature to date regarding the market power effects of health insurers on health-care provider behavior. Note in the table that information is provided for the unit of analysis and method used in each study followed by some abbreviated findings for each article. A number of caveats should be noted. First, although the author(s) may have used an

Table 2 Effect of health-insurer market concentration on provider behavior

Authors	*Unit of analysis*	*Method*	*Findings*
Feldman and Greenberg (1981)	59 BC plans in 1979	IV	Market share of BC plan does not affect hospital discount Discount directly affects market share
Adamache and Sloan (1983)	66 BC plans in 1979	IV	Greater market share directly affects hospital discount
Staten *et al.* (1987)	95 Indiana hospitals in 1983	OLS	BC market share does not affect hospital discount
Staten *et al.* (1988)	110 Indiana hospitals in 1984	OLS	Greater BC market share leads to higher hospital bid price to join PPO More hospital competition leads to greater hospital discounts
Melnick *et al.* (1992)	190 BC of California Network hospitals in 1987	IV	Greater importance of insurer lowers hospital price. Higher hospital prices are observed in more concentrated markets Greater importance of hospital raises hospital price
Foreman *et al.* (1996)	47 individual BC/BS plans during 1986–88	IV	Greater BC/BS market share lowers payments to providers
Brooks *et al.* (1997)	Random sample of more than 290 000 inpatient episodes for over 70 self-insured FFS plans during 1988–92	OLS based on bargaining model	Self-insured firms with a greater presence in a market have greater bargaining power. Greater hospital concentration leads to greater hospital bargaining power
Feldman and Wholey (2001)	Panel data set of all HMOs during 1985–97	IV hospital-FE	Greater HMO buyer power leads to lower hospital prices and greater hospital output HMO buyer power has no effect on the price or output of ambulatory services
Sorensen (2003)	31 hospitals in Connecticut from 1995–98 involving 94 payers (2010 agreements)	OLS hospital-FE based on bargaining model	Increased payer size raises hospital discount. Greater patient channeling of insurers raises discount. Hospitals with fewer rivals lower discount
Dor *et al.* (2004)	Claims data from approximately 80 large, self-insured employers in the 10 largest states of the US in 1995–96	OLS with state-FE based on bargaining model	HMO and PPOs obtain higher discounts than FFS plans for specific treatments and procedures More concentrated hospital services markets result in higher prices for specific treatments and procedures
Younis *et al.* (2005)	1967 hospitals in 1991	OLS	HMO competition has no effect on hospital costs
Bates *et al.* (2006)	306 MSAs in 1999	OLS with MSA-FE	Greater state-wide health insurer concentration leads to increased efficiency of the hospital industry
Bates and Santerre (2008)	Panel data set of 86 MSAs during 2001–4	IV with MSA-FE	Greater HMO concentration leads to more hospital inpatient care Greater PPO concentration leads to more hospital outpatient care
Schneider *et al.* (2008)	42 California counties in 2002	OLS	Health plan concentration has no effect on outpatient prices Physician organization concentration leads to higher physician prices
Dafny *et al.* (2012)	Panel data set of ESI plans enrolling more than 10 million people during 1998–2006	IV with plan-FE	Greater health-insurer concentration leads to a reduction in physician employment and relative earnings
Moriya *et al.* (2010)	National data set of 11 million insured Americans during 2001–3	OLS hospital-FE	Higher state-wide health insurance concentration leads to lower hospital prices. Hospital concentration at the health service area level did not affect hospital prices
Halsersma *et al.* (2010)	1235 unique hospital-insurer pairs during 2005–6 in the Netherlands	OLS based partly on bargaining model	Market shares and concentration of insurers (hospitals) have an inverse (a direct) impact on the hospital price-cost margin

Abbreviations: BC, Blue Cross; BS, Blue Shield; ESI, employer-sponsored insurance; FE, fixed effects; HMO, health maintenance organization; IV, instrumental variables approach; MSA, metropolitan statistical area; OLS, ordinary least squares method; PPO, preferred provider organization.

instrumental variables (IV) approach rather than ordinary least squares (OLS), the actual instrument or instruments used may have been weak in a theoretical or statistical sense. Recall that a good instrument must be correlated with the suspected endogenous independent variable but uncorrelated with the dependent variable. But in practice, some instruments are better at achieving that result than others. As a result, some statistical bias from reverse causality or a third-variable problem may still remain even though an IV procedure is employed if a weak instrument is used.

Second, notice that most of the earlier papers deal with Blue Cross (BC) plans. That early focus likely reflects that BC plans dominated many areas and data were available because most plans were organized on a nonprofit basis at the time. However, since the late 1980s, many BC plans have converted to for-profit status to gain access to equity capital so data have become more proprietary in nature. Third, only a few studies simultaneously control for both insurer and provider market concentration and none allow for an interaction term. Finally, it should be pointed out that some studies are conducted using national data for the US, whereas others are performed with data from particular states or areas.

With these caveats in mind, it appears to be the case that a majority of the relevant studies, reported in **Table 2**, find that a greater dominance of health insurers, as reflected in a higher market share or greater market concentration, results in a lower negotiated hospital price. Thus, it might appear that ample statistical evidence exists to suggest that health insurers possess and exercise market power in the hospital services market (i.e., a movement from point C to MB in **Figure 1**). However, an inverse relation between health-insurer market power and provider prices may not necessarily reflect monopsonistic exploitation, that is, instead of greater health-insurer market power resulting in a movement from point C to MB in **Figure 1**, it may actually be the case that the provider market adjusts from MS to C in response to greater health-insurer buyer pressure. If so, health insurers may actually be exercising monopoly-busting power by forcing dominant hospitals to lower price and produce more services. It follows that empirical evidence is required for both the change in price and the quantity to assess whether health insurers exercise monopsony power in provider markets.

With this perspective in mind, several articles analyze the quantity aspect of health-insurer market power effects. The first study, by Feldman and Wholey (2001), finds that greater HMO market power leads to a lower hospital price but also causes increased hospital output. Bates and Santerre (2008) extend the Feldman and Wholey study by examining the effects of both HMO and PPO market concentration on various measures of hospital output at the MSA level. They find that increased HMO and PPO market concentration leads to a more inpatient and outpatient care, respectively. Finally, Bates *et al.* (2006) find that greater health-insurer market concentration is associated with the hospital services industry using its resources in a more technically efficient manner (i.e., getting more output from the same inputs). These three papers, especially when considered together with the other studies finding lower negotiated hospital prices in response to greater health-insurer market concentration, imply fairly strongly that health insurers exercise monopoly busting rather than monopsony power in the hospital services industry.

However, some limited evidence suggests that the situation may be different in the physician services market. More specifically, although Feldman and Wholey (2001) and Schneider *et al.* (2008) find no relationship between health-insurer market power and physician pricing and output, Dafny *et al.* (2012) show that greater health-insurer market concentration is related to a reduction in both physician earnings and employment as a monopsony model suggests. The study by Dafny *et al.* (2012) comes across as being particularly persuasive because it uses a data set of 11 million people in various employer-sponsored health insurance plans across the nation over an 8-year period and specifies plan-fixed effects along with using a plausible instrumental variables approach. Dafny *et al.* (2012) findings also agree with basic intuition because physician markets are much less concentrated than hospital services markets and, unlike nurses, physicians are not unionized. Given these two conditions, health insurers may be able to exploit physicians. It will be interesting to see if future studies offer collaborative evidence.

The literature on the relationship between health-insurer market concentration and insurer behavior pales in comparison with the previous literature. It should be noted in **Table 3** that only six studies to date have focused on this particular topic and that these studies are relatively recent in comparison with the research on the previous topic. All but one study suggest that health insurers exercise market power by raising premiums and/or lowering output when the market for health insurance is more concentrated.

Dafny's (2010) study is particularly convincing because it shows that health insurers charge higher premiums to more profitable employers. Economic theory suggests that only firms with market power can practice price discrimination of that kind. In addition, Dafny *et al.* (2012) find that health insurance premiums spiked upward in areas where the health-insurer market concentration suddenly shot up because of a merger between Aetna and Prudential in 1998. Finally, Bates *et al.* (2012) show that the number of people with individually purchased health insurance (but not ESI) is lower in states where health-insurer market concentration is greater, particularly when no state rate review regulations exist. All in all, the evidence, although relatively limited, seems to suggest that health insurers are able to exercise market power in their output market. (Empirically examining the impact of mergers on premiums and profits provides another way of observing whether health insurers possess market power. Feldman *et al.* (1996) find that premiums increase in the most competitive market areas 1 year after mergers among HMOs. Hilliard *et al.* (2011) show that rivals' returns increase in response to a merger in market areas where the premerger HHI is high and the postmerger change in the HHI is large. Thus, both of these papers suggest health insurers engage in anticompetitive behavior.)

Summary and Conclusion

Whether health insurers possess and exercise market power remains an important issue for the US because the recently

Table 3 Effect of health-insurer concentration on insurer behavior

Author(s)	*Unit of analysis*	*Method*	*Findings*
Wholey *et al.* (1995)	1730 HMO market areas during 1988–91	OLS	Greater number of HMOs leads to lower HMO premiums
Foreman *et al.* (1996)	47 individual BC/BS plans during 1986–88	IV	Larger BC/BS market share leads to lower premiums
Pauly *et al.* (2002)	262 MSAs in 1994	IV	Greater competition among HMOs is associated with a lower industry profit rate
Dafny *et al.* (2012)	Panel data set of ESI plans enrolling more than 10 million people during 1998–2006	IV with plan-FE	Greater (merger-induced) health insurer concentration leads to higher employer premiums
Dafny (2010)	Panel data set of fully insured plan observations from 776 employers in 139 geographical markets during 1998–2005	IV with plan-FE	More profitable employers pay higher premiums in more concentrated markets
Bates *et al.* (2012)	Panel data set of 50 states and DC during 2001–7.	IV with state-FE	Greater health-insurer concentration leads to fewer people with individually purchased health insurance particularly in states without rate review regulations

Abbreviations: BC/BS, Blue Cross/Blue Shield; ESI, employer-sponsored insurance; FE, fixed effects; HMO, health maintenance organization; IV, instrumental variables approach; MSA, metropolitan statistical area; OLS, ordinary least squares method; PPO, preferred provider organization.

passed health insurance reform continues to rely heavily on a private health insurance industry. As discussed in this article, economic theory suggests that sellers and buyers may exploit their situation by raising prices above and lowering prices below the competitive level in the output and input markets, respectively, when the relevant market is highly concentrated. In both cases, these price distortions can lead to allocative inefficiency and large firms gaining at the expense of consumers or suppliers. The health insurance industry simultaneously plays critical roles as an important buyer of health- care provider services and as a health insurance provider to the public. Consequently, firms in the health insurance industry potentially can exercise both monopoly and monopsony power.

The empirical evidence to date suggests that health insurers may possess monopsony power in many physician services markets of the US. At least, one highly credible study finds that physicians are paid less and fewer physicians are employed when health insurers possess more market power in their area. However, studies focusing on the hospital services industry suggest the opposite. These studies find that health insurers, when they attain more market power, are able to bust the monopoly power of hospitals, thereby creating lower prices and more hospital services. Further complicating the analysis, recent research seems to have concluded that health insurers possess and exercise market power in their output market, that is, premiums are higher and fewer people are insured in areas where the health insurance industry is more highly concentrated. Consequently, it appears that health insurers, when they possess market power, are not passing along any cost savings from the hospital or physician services markets to buyers of health insurance.

Normally, reducing the market power of an industry, such as health insurance, would mean that suppliers and buyers, in this case physicians and consumer/patients, will unambiguously benefit. However, reducing market power also mean health insurers will be less able to hold the market power of hospitals in check. Given this trade-off, it is unclear how health policy authorities should craft public policies affecting the health insurance industry. For example, should public authorities level the playing field by allowing physicians to join unions so they can negotiate collectively to countervail the market power of health insurers? Or, should antitrust laws be enforced more aggressively toward health insurers or hospitals, or toward both? Or, would a profit tax on health insurers (and hospitals) be a better idea? How about a public health insurance option? According to the existing empirical literature, health policy analysts may have to confront these sorts of questions if economic efficiency is desired and a private health insurance system continues to be relied on in the US.

Heterogeneity of Hospitals

B Dormont, PSL, Université Paris Dauphine, Paris, France

Glossary

Economies of scale This is a result of increasing returns to scale: the amount of resource used per unit of output falls at higher output rates. It implies a falling unit cost as output rates increase, as long as input prices do not increase so as to offset the scale effect.

Economies of scope This enables a firm to produce several goods or services jointly more cheaply than producing them separately. The simultaneous production of hospital care and medical teaching is an example.

Exogenous source of cost variability In the context of a health care organization, a source is called exogenous if the hospital management cannot influence its level.

Legitimate source of cost variability Legitimacy is based on citizens' preferences. For instance, a particular location for a hospital, which corresponds to citizens' preferences for access to care, may be costlier than other locations.

Long-term moral hazard A time-invariant moral hazard implying that the hospital management is permanently inefficient.

Moral hazard In context with hospital payments, moral hazard refers to the fact that hospital managers can undertake more or less effort to minimize costs.

Prospective payment system A system that pays hospitals a fixed price per stay in a given diagnosis-related groups (DRG), irrespective of each hospital's actual cost. This provides a powerful incentive for managers to minimize costs.

Retrospective payment A payment representing reimbursement of the actual cost of treatment per stay.

Transitory moral hazard The effect on a hospital manager's transitory cost-reducing efforts.

Yardstick competition An industrial regulatory procedure under which the regulated price is set at the average of the estimated marginal costs of the firms in the industry. If differences in costs between hospitals are caused only by moral hazard, a yardstick competition rule of payment is to offer each hospital a lump sum payment per stay defined on the basis of average costs observed in other hospitals for stays in the same diagnosis-related groups (DRG). This system mimics competition on a free market in order to provide incentives for efficiency gains.

Introduction

Variability in hospital costs has often been used to convince citizens and policy makers of the extent of inefficiency in hospital care provision. Classification of hospital stays into diagnosis related groups (DRGs) has made it possible to place patients into groups that are supposed to be medically homogenous and to compare the cost of stays for similar cases in different hospitals. In a paper devoted to the political history of Medicare's transition to prospective payments per DRG, Mayes (2006) cited the unbelievably rapid growth rates of hospital costs in the USA: approximately 15% per year during the 1970s. However, there was still doubt about the contribution of inefficiency to such growth rates. Once DRGs were defined, policy makers finally reacted to differences in costs between hospitals for the same procedures. The introduction of prospective payments per DRG was decided on for Medicare, with the goal of forcing hospitals to increase efficiency. Similarly, in France, the debate on reforming hospital payments advanced in 1997, when the Ministry of Health decided to make public the differences in costs between French hospitals. Large differences in costs that were difficult to justify pointed to large differences in efficiency across hospitals, and showed that some of them were quite inefficient.

Nowadays, there is a general trend in all developed countries toward improving efficiency in hospital care through implementation of prospective payment systems (PPSs). Following the example of Medicare in 1983, other payers in the USA adopted PPS for inpatient care. European countries first adopted a global budget system to contain hospital costs during the 1980s, before turning to PPSs per DRG.

The Basic Inspiration of Prospective Payment Systems

The assumption at the root of a PPS is that any deviation in cost for a stay in a given DRG is because of inefficiency. Economists use the term 'moral hazard' to refer to the idea that the payer (the insurer or the regulator) cannot observe, much less monitor the efforts undertaken by hospital managers to minimize costs. Paying hospitals a fixed price per stay in a given DRG provides a powerful incentive for managers to minimize costs. Indeed, hospitals are supposed to keep the rent earned when their costs are lower than the fixed price. Conversely, they risk running operating losses if their costs are above DRG payment rates.

This payment scheme provides a perfect incentive for cost reduction because the payment is a lump sum per stay defined irrespective of a given hospital's actual cost. Yet, the regulator has an informational problem: she does not know how much care costs when the hospital is fully efficient (i.e., the 'true' minimal cost for a stay in a given DRG). The level of the lump sum defined by the regulator can lead the hospital to

Figure 1 Two hospitals in Paris. Both provide high-tech acute care. (a) *Hôpital Européen Georges Pompidou (HEPG)*, a very large hospital located in the center of Paris, has approximately 60 care units. Four older hospitals were closed and their care units grouped together at *HEPG*. Opened in 2001, this hospital was built following the latest standards of hospital architecture. It is reputed to be one of the best hospitals in Europe for cardiac surgery and cardiology. (b) *Groupe hospitalier La Pitié Salpétrière*, a very large hospital located in the center of Paris, has more than 70 care units. King Louis XIV ordered its creation. The hospital was designed by the architect Louis Le Vau, who was also in charge of the palace of Versailles. The hospital was built in the 17th century. Today, it is composed of many separate buildings, some of which date from the 17th century and some of which are modern. The old architecture of *La Pitié Salpétrière* is likely to induce higher costs because of difficulties in spatial organization. These extra costs are exogenous in the medium run. If the regulator does not pay for the consequences of this unfavorable architecture, she exposes *La Pitié Salpétrière* to operating losses, or provides incentives to reduce care quality, or to select patients, in short to cut costs in ways that run contrary to the general interest. Everybody is convinced that an old architecture induces higher costs. The question is: how much higher? It is not easy to answer this question because the extra costs are not observable: what can be observed is the impact of extra costs because of infrastructure difficulties combined with extra costs (or savings) owing to bad (or good) management.

bankruptcy or generate rents that are costly for tax payers (or the insured). This informational problem is solved by assuming that hospitals are homogeneous. In that case, differences in costs are caused only by moral hazard. Hence, an appropriate rule of payment is to offer each hospital a lump sum payment per stay defined on the basis of average costs observed in other hospitals for stays in the same DRG.

Shleifer's yardstick competition model provides the theoretical foundation for a PPS. This model is based on rather unrealistic assumptions: homogeneity of hospitals, homogeneity of patients for the same pathology, and fixed quality of care. Many studies have underscored the great diversity in hospitals' conditions of care delivery (teaching status, share of low-income patients, local wage level, etc.). Input prices can differ depending on location; care quality may vary, as may the severity of illnesses of admitted patients. These studies highlight the risks of such a PPS, namely selection of patients and a lowering of care quality. Indeed, hospitals which are subject to exogenous factors that lead to higher costs have to find ways to lower costs in order to avoid bankruptcy.

Sources of Heterogeneity in Hospital Costs

To avoid such problems, the regulator must design payments that allow for exogenous and legitimate sources of cost heterogeneity. This idea was formalized early on by Schleifer in his paper, published in 1985, one year after the beginning of Medicare's payment reform. He considered the case where the regulator can allow for the predicted impact on costs of observable characteristics that cannot be altered by the hospital. At first, Medicare adjusted its payments by a regional cost-of-labor index and gave extra payment to teaching hospitals. Currently, Medicare payments are adjusted for teaching hospitals, for a disproportionate share of indigent patients, and for local wage rates. In England, the national price per HRG (the English DRG) is adjusted for unavoidable differences in factor prices for staff, land, and building construction. More generally, in European countries, payment rates are adjusted for structural variables such as teaching, status, and region.

There is a theoretical debate on how observable causes of cost differences between hospitals should be allowed for in a PPS. Mougeot and Naegelen (2005) pointed out that most theoreticians implicitly assume that prospective payments are combined with a lump sum transfer. They show that this transfer should generally take the form of a tax paid by the hospital. Indeed, in a PPS hospitals whose costs are lower than the price per DRG receive a surplus, called a rent, which is costly to the tax payer. Social welfare will be maximized if this rent is extracted through a tax. But such a tax is not feasible in practice, given that most health care agencies do not have the power to 'fine' hospitals. If lump sum transfers are not feasible, it is possible to adjust fixed prices per DRG in order to reflect exogenous cost differences between hospitals. In this case, price adjustment should not necessarily be proportional to the extra cost; it can be optimal to discriminate against low-cost or high-cost hospitals by setting the price adjustment above or below marginal cost.

Table 1 Sources of cost variability between hospitals

Source of cost variability between hospitals	*Exogenous/endogenous*	*Are extra costs because of this factor legitimate or not?*	*Observable/ unobservable*	*Impact on costs*
Local wages, local input prices	Exogenous (for a given location)	Legitimate if the regulator wants a hospital located in the area	Observable	Can be estimated
Scale and scope economies	Exogenous or endogenous, depending on hospital's autonomy in developing supply strategies (institutional context)	Legitimate if they are because of regulations concerning the supply of care	Only rough indicators of specialization are available	Difficult to estimate (feasible for a restricted number of outputs only)
Other hospital characteristics that raise costs: poor architecture, etc.	Endogenous for private-for-profit hospitals Mostly exogenous for public hospitals	Legitimate if the regulator wants the hospital to continue to function and thinks rebuilding would be too costly	Observable	Cannot be estimated separately from other sources of cost differences
Care quality	Endogenous	Legitimate if the regulator wants to promote a quality level above the minimum	Partially observable; not all dimensions of quality are observed	Difficult to estimate
Patient characteristics	Endogenous if the hospital is allowed to select patients, exogenous otherwise	Legitimate if the regulator wants to prevent patient selection	Observable[a]	Can be estimated
Inefficiency because of moral hazard	Endogenous	Not legitimate	Unobservable	Cannot be estimated separately from other sources of cost differences

[a]It is supposed that the patient characteristics are observable for the most part, an assumption which ignores the possibility of moral hazard in reporting severity.

However, the main difficulty is that many sources of cost variability are not observable by the regulator, or the regulator cannot measure their impact on hospital costs. **Figure 1** concerns two hospitals in Paris. The *Hôpital Européen Georges Pompidou* was built recently, whereas most of *La Pitié Salpétrière* is very old and bears all the weight of its long history. Even if the regulator is convinced that *La Pitié Salpétrière* has extra costs because of the age of its buildings, the magnitude of these extra costs cannot be measured. At best, the regulator can observe the impact of additional costs because of poor infrastructure combined with extra costs (or savings) due to bad (or good) management, or combined with many other sources of cost variability: care quality, scale and scope economies, other hospital characteristics.

How can unobservable sources of cost heterogeneity be dealt with? How can we distinguish between differences in cost because of cost containment efforts and differences that cannot be reduced because they are a result of exogenous unobserved sources of hospital heterogeneity? Before turning to this question, the possible sources of cost heterogeneity are characterized by splitting them into six large categories (see **Table 1**). This classification is rather simplistic and debatable, but it may help in understanding what is at stake in the question of hospital heterogeneity.

For each source of cost variability, it is essential to know whether it is exogenous or endogenous, legitimate or illegitimate, and whether its impact on costs can be evaluated. A factor is considered to be exogenous if the hospital manager cannot influence its level. Legitimacy is based on citizens' willingness to pay (preferences). Consider for instance a hospital located in an area with limited road access. This induces higher transportation costs and possibly higher wages. Are people willing to pay an extra amount for a hospital located in this area? If the extra cost is considered illegitimate, the regulator will not adjust the DRG rate and the hospital must either reorganize or close down. Similarly, indigent patients induce higher costs because their hospital stays are generally longer. If the care system is supposed to offer similar access to care to every citizen, adjusting payments to avoid selection of patients is legitimate. The exogeneity of a cost factor may depend on hospital status: in France, patient characteristics are exogenous for public and private nonprofit hospitals, which are not allowed to select patients, whereas patient characteristics can be considered endogenous for private-for-profit hospitals.

Economies of scale are obtained when a lot of activity in one type of care service results in a lower cost per stay. Economies of scope arise when an appropriate mix of care services

results in a lower cost per stay. Very narrow specialization is generally linked to scale economies, combined with scope diseconomies. Scale and scope economies may be exogenous or endogenous, depending on the hospital's autonomy in developing supply strategies. The institutional context plays an important role: in the National Health Service of England, hospitals that are run by Foundation Trusts (FTs) have more freedom to shape their supply of care than other hospitals. In France, scale and scope economies are endogenous for private-for-profit hospitals but exogenous for public hospitals. The latter have a given capacity and their mandate obliges them to offer a broad mix of services in order to meet needs. Hence, extra costs because of diseconomies of scope for a private-for-profit hospital can be deemed illegitimate, if the hospital is not constrained by a public mandate.

The fact that a source of cost heterogeneity is observable does not imply that its impact on costs can be evaluated. As in the example of *La Pitié Salpétrière*, the regulator cannot measure extra costs associated with the age of the hospital buildings separately from other sources of extra costs. The factors considered in the table are shown in blue cells when their impacts on costs are likely to be difficult to estimate: they include moral hazard, of course, as well as some hospital characteristics, but also care quality and scale or scope economies. Indeed, quality is multidimensional and rather difficult to observe. (Concerning information on quality and the impact of competition on quality, see the contributions of Sutton and McGuire in this encyclopedia.) Scope economies are not easy to detect because currently available econometric tests are feasible only for a very small number of types of care services, which is not satisfactory, given the number of DRGs (at least several hundred) or Major Diagnosis Categories (several dozen).

How to Pay for Unobservable Heterogeneity?

Fixed payments per DRG put pressure on hospitals to compete. Because payments levels are set at average cost, hospitals which are affected by exogenous factors that induce higher than average costs risk losses. If they are already operating at full efficiency, they cannot realize further savings through efficiency gains. Hence, careless implementation of a PPS is likely to create undesirable incentives for selecting patients and lowering care quality. A regulator who aims at maximizing social welfare must design a payment system that creates virtuous incentives for enhancing hospital efficiency, without providing deleterious incentives for patient selection and quality reduction.

To address this question, many theoretical papers have tried to improve the basic model by lifting assumptions relative to patient and hospital homogeneity, and by allowing for endogenous levels in the number of procedures and quality of treatment. Using various theoretical frameworks and hypotheses, these papers show that social welfare can be improved through a mixed payment system that combines a fixed price with partial reimbursement of the actual cost of treatment per stay. To deal with unobserved sources of heterogeneity in costs, the regulator can construct a menu of contracts that combine a lump-sum transfer with partial reimbursement of actual costs. When the hospital chooses a contract, it reveals its unobserved cost component. Currently, however, such a payment scheme is not implemented in any health system. In fact, the theoretical design of the contracts often relies on unobservable variables or functions, such as, for instance, the function describing the disutility of the hospital manager's cost reduction efforts. Hence, such theoretical designs are hardly used in reality.

Another strategy is to use econometrics to evaluate unobservable sources of cost heterogeneity. The sources of hospital cost heterogeneity are summarized in **Table 1**. A hospital's activity is more or less costly, depending on its infrastructure, the existence of economies of scale or of scope, the quality of care and the cost reduction effort provided by the hospital manager (moral hazard). Moral hazard can be split into two components: long-term moral hazard and transitory moral hazard. Long-term moral hazard is supposed to be time invariant: the hospital management can be permanently inefficient. An example of permanent inefficiency would be an obsolete elevator which is very slow and subject to frequent breakdowns and which is not replaced for several years. Transitory moral hazard is linked to the manager's transitory cost reduction efforts. For instance, the manager can be more or less rigorous, each year, when negotiating prices for supplies or for services provided to the hospital by outside firms. It would be optimal for social welfare to eliminate long-term moral hazard as well as *transitory* moral hazard. However, it is very difficult to separate long-term moral hazard from other sources of cost heterogeneity which are legitimate.

The use of a three-dimensional nested database makes it possible to identify *transitory* moral hazard. It is then possible to design a payment that allows for hospital heterogeneity in costs, while still providing incentives to increase efficiency because it does not reimburse costs due to *transitory* moral hazard (see the technical appendix).

A fully PPS reimburses each stay with a fixed price regardless of the actual cost of the stay. The payment systems currently implemented in most countries take some observable sources of cost heterogeneity, such as local input prices, into account. A preferable method of payment would be to allow for observable and *some unobservable* sources of cost heterogeneity, provided they are *time invariant*. With such a payment rule, the regulator reimburses each hospital for extra costs that might correspond to undesirable long-term moral hazard, but which can as well correspond to legitimate heterogeneity. Nevertheless, this method of payment creates incentives to increase efficiency because it does not reimburse extra costs that are a result of *transitory* moral hazard.

The general idea is that the regulator has no means to disentangle legitimate and illegitimate sources of time-invariant cost heterogeneity, i.e., to separate the wheat from the chaff. In this context, it might be preferable to accept to pay for long-term moral hazard in order not to penalize hospitals which have legitimate sources of cost heterogeneity. Is this view unreasonable? The question becomes an empirical one: if transitory moral hazard has a substantial impact on cost variability, it would be possible to achieve large gains in

efficiency even while paying for permanent sources of hospital cost variability.

An empirical estimation has been carried out by Dormont and Milcent (2005) on a sample of stays for acute myocardial infarction in French public hospitals. It appears that the cost variability because of transitory moral hazard was quite sizeable. Simulations show that substantial budget savings – at least 20% – could be expected from implementation of a payment rule that takes all unobservable hospital heterogeneity into account, provided that it is time invariant. This payment rule is easy to implement if the regulator has information about costs of hospital stays. A drawback is that it gives higher reimbursements to hospitals which are costlier because of permanently inefficient management. However, it has the great advantage of reimbursing high quality care. Moreover, it can lead to substantial savings, because it provides incentives to reduce costs linked to transitory moral hazard, whose influence on cost variability can be sizeable

Technical Appendix: Designing Payments That Allow for Cost Heterogeneity between Hospitals

The use of a three-dimensional nested database, with information recorded at three levels (stays–hospitals–years), makes it possible to identify transitory moral hazard and to estimate its effect on hospital cost variability. For a given DRG, we can observe the cost $C_{i,h,t}$ of the stay i, which occurred in hospital h in year t. This cost can be decomposed as follows: $C_{i,h,t} = \tilde{C}_{i,h,t} + a + \eta_h + \varepsilon_{h,t} + u_{i,h,t}$. If stays for the same DRG always had the same cost, the cost would always be equal to the constant a. A fully PPS is based on this assumption, which implies that the other terms of the right-hand side of the equation would be equal to zero.

As stated above, there are some legitimate sources of cost variability, some of which are observable: patient characteristics, local input prices. The impact of these characteristics on costs can be estimated: we denote this cost heterogeneity as $\tilde{C}_{i,h,t}$. Given the observable characteristics, cost variability then depends on the sum of three random variables: $\eta_h + \varepsilon_{h,t} + u_{i,h,t}$. The term $u_{i,h,t}$ represents unobservable heterogeneity between patients: its average is equal to zero at the hospital level. Hence, for given observable hospital characteristics, hospital costs are affected by the terms η_h and $\varepsilon_{h,t}$. These random variables are not observed but can be estimated with a three-dimensional database.

By definition, the term η_h specifies time-constant unobservable hospital heterogeneity. It can be seen as the result of several components summarized in Table 1. In short, a hospital's activity is more or less costly, depending on several factors: its infrastructure, the existence of economies of scale or of scope, the quality of care and the cost reduction effort provided by the hospital manager (moral hazard). As a component of a time-invariant term (η_h), the moral hazard involved here is long term: the hospital management can be permanently inefficient. It would be optimal for social welfare to eliminate long-term moral hazard as well as transitory moral hazard. However, long-term moral hazard cannot be separated from the other components of η_h, which are legitimate sources of cost heterogeneity.

The term $\varepsilon_{h,t}$ is defined as the deviation, *ceteris paribus*, for a given year t, of hospital h's cost in relation to its average cost. It can be seen as the result of transitory moral hazard, measurement errors and unobserved transitory shocks affecting hospital costs. Actually, measurement errors and unobserved transitory shocks are likely to be of slight importance. Indeed, a measurement error belonging to $\varepsilon_{h,t}$ would be patient invariant by definition. In other words, it would be replicated for each stay in the same hospital during the same year, which is unlikely. As for transitory shocks, they should be observable if they are justifiable. It is true that any hospital can be affected by a shock in a given year: an electrical failure, for example. However, the regulator would be well advised to classify *a priori* these incidents as moral hazard, in order to give hospitals incentives to declare them, when the extra costs they induce are justifiable and exceptional. Hence $\varepsilon_{h,t}$ is mostly made of moral hazard: an econometric test run on French data by Dormont and Milcent (2005) gave empirical support to this conjecture. More precisely, $\varepsilon_{h,t}$ is an indicator of transitory moral hazard (indeed, all time-invariant components ofunobserved hospital heterogeneity are represented in the term η_h).

A fully PPS reimburses each stay with a fixed price $P_{i,h,t}=a$, whatever the actual cost of the stay $C_{i,h,t}$. The payment systems currently implemented in most countries take some observable sources of cost heterogeneity into account. With our notation, the reimbursement then equals: $P_{i,h,t} = \tilde{C}_{i,h,t} + a$. A preferable method of payment would be to allow for observable and some unobservable sources of cost heterogeneity, provided they are time invariant. The payment would be equal to: $P_{i,h,t} = \tilde{C}_{i,h,t} + a + \eta_h$. With such a payment rule, the regulator in effect tailors reimbursement to each hospital. Indeed, the component η_h is specific to hospital h. It might correspond to undesirable long-term moral hazard, but it can also correspond to legitimate heterogeneity. This method of payment can nevertheless create incentives to increase efficiency because it does not reimburse extra costs that are due to transitory moral hazard ($\varepsilon_{h,t}$ is not a component of payment $P_{i,h,t}$).

HIV/AIDS, Macroeconomic Effect of

M Haacker, London School of Hygiene and Tropical Medicine, London, England, UK

Introduction

Concerns about the macroeconomic consequences of the human immunodeficiency virus, and the associated acquired immunodeficiency syndrome (HIV/AIDS) have been fueled by several factors. Most obviously, the epidemic has a devastating impact on life expectancy in a number of countries. In the empirical literature on economic growth (not dealing specifically with HIV/AIDS), such a decline is associated with a steep drop in the growth of gross domestic product (GDP). More informally, there are concerns that the epidemic could affect long-term development aspects by destroying human capital and the incentives to invest in education, disrupt the social fabric of a society, and result in an increasing number of disadvantaged young people (mainly orphans).

Second, there have been concerns that the impact of the epidemic is tied up with and exacerbates the challenges of economic development. For example, the 2006 Political Declaration issued by the United Nations (UN) states "that in many parts of the world, the spread of HIV/AIDS is a cause and consequence of poverty, and that effectively combating HIV/AIDS is essential to the achievement of internationally agreed development goals and objectives."

Third, the response to HIV/AIDS in many countries has become a macroeconomic factor in its own right, not only because it partially reverses the adverse direct consequences of the epidemic but also because of the additional demand for (health) services, and the challenges of financing HIV programs.

Against this background, the article focuses on three areas. It sets out with a discussion of the state of the epidemic across countries and its correlation with the state of economic development. This is followed by a discussion of the literature and evidence on the macroeconomic impacts of HIV/AIDS. Finally, the article highlights macroeconomic aspects of the financing of HIV programs, including the role external assistance has played in this.

HIV/AIDS and the State of Economic Development

The macroeconomic implications of HIV/AIDS depend on the economic context, as well as the state of the epidemic. For example, the impact of HIV/AIDS on affected households depends on available health services and the availability of health and social insurance, companies with high value added per employee have higher stakes in investments to minimize the impact of HIV/AIDS on their staff and operations, and the government's capabilities in meeting the demand for HIV/AIDS-related services are constrained by its fiscal resources.

Moreover, the state of the epidemic is partly endogenous, and the quality of the policy response to the epidemic in turn reflects the quality of a country's institutions and its economic and public policy capacities. From the perspective of global development policy, where HIV/AIDS competes with other causes for external assistance, it is also useful to place the epidemic in an economic context.

HIV/AIDS-related deaths are concentrated in low-income countries, similar to infectious diseases more generally. According to the 'Causes of Death 2008' data published by the World Health Organisation, 41% of HIV/AIDS-related deaths and 36% of deaths from infectious diseases occurred in low-income countries in 2008 (which accounted for 12% of the global population). In terms of its association with economic development challenges, HIV/AIDS thus resembles infectious diseases in general, but it is not correlated as closely with basic economic development challenges as malaria deaths are, of which 58% occurred in low-income countries.

However, HIV/AIDS mortality has been declining, reflecting increased access to treatment. According to the data from the 2012 report on the Global AIDS Epidemic by the Joint United Nations Programme on HIV/AIDS (UNAIDS), 542,000 AIDS deaths (32% of global AIDS deaths) occurred in low-income countries in 2011.

The broad distribution of HIV deaths by income group, however, gives a misleading picture of the challenges posed by HIV/AIDS, as HIV/AIDS is distributed across countries very unevenly. Taking, for example, the global distribution of income (Gini coefficient: 0.64) as a reference point, the burden of HIV/AIDS is distributed much more unevenly (Gini coefficient: 0.74). This point is illustrated in Figure 1, which orders the global population by GDP per capita and adds a curve describing HIV prevalence in the respective countries. Indeed, HIV prevalence tends to be higher in countries with lower income. This is evident from the negative coefficient of correlation between HIV prevalence and GDP per capita (-0.09), substantial HIV prevalence in a number of low-income countries (broadly, those to the left of the 700-million population mark in Figure 1) and an absence of high HIV prevalence among high-income countries (broadly, the rightmost billion in Figure 1). The most striking feature of the distribution of people living with HIV, however, is the high concentration of HIV/AIDS in a few countries with HIV prevalence over 10% of the total population. In this regard, it also differs from malaria, which correlated more strongly with the state of economic development in general (with higher prevalence in low-income countries) but is less concentrated in specific countries.

Although the correlation between HIV prevalence and GDP per capita is not very strong, the consequences of an HIV infection differ substantially across countries. While mortality among people living with HIV typically was between 1% and 1.5% for high-income countries like France, Spain, or the US, it averaged 4.8% in 34 low-income countries in 2011, and exceeded 8% in Liberia, Nepal, and Somalia (according to estimates from the 2012 UNAIDS Report on the Global AIDS Epidemic). These estimates also illustrate the large impact of increased access to treatment – mortality among people living

 doi:10.1016/B978-0-12-375678-7.00610-6

with HIV in the 34 low-income countries has declined by almost one-half (from 8.6%) since 2005. However, very large differences in the health consequences of an HIV infection across countries with different levels of economic development appear to persist.

Within countries, the correlation between HIV/AIDS and income (or other socioeconomic characteristics) is less straightforward. One of the most important data sources are demographic and health surveys also covering HIV prevalence. Most of these surveys suggest that HIV prevalence tends to be higher for wealthier population groups, but there is no consistent pattern across countries.

In summary, as is the case with infectious diseases more generally, HIV/AIDS deaths occur predominantly in developing countries. However, HIV/AIDS is unusual as it is distributed highly uneven across countries. These observations have implications for the macroeconomic significance of the epidemic. Because the health impact of HIV/AIDS has been so disruptive in specific countries, and because this health shock has emerged as a development threat only over the last 20 odd years, it is plausible that the epidemic has economic consequences (e.g., for GDP growth), which cannot easily be detected for more common and chronic health conditions (e.g., malaria). At the same time, the impact of HIV/AIDS provides a testing ground for theories on health and economic development.

Macroeconomic Impact of HIV/AIDS

In spite of its devastating impact on health outcomes such as life expectancy in a number of countries, the impact of HIV/AIDS on economic growth is not obvious. This point is illustrated by Figures 2 and 3, which contrast trends in life expectancy in 10 countries facing the highest HIV prevalence worldwide and the recent growth experience in these countries. (As all of these countries are located in sub-Saharan Africa, the figures also provide averages for the region for comparison.)

According to Figure 2, the impact of HIV/AIDS on life expectancy has been very large, ranging from a loss of 7 years (Uganda) to a loss of 21 years (Zimbabwe) in 2000–05. Moreover, the adverse impact was so strong that life expectancy declined in absolute terms in 8 of the 9 countries, and collapsed to a level last observed in the 1950s or 1960s in Botswana, Lesotho, South Africa, Zambia, and Zimbabwe. In some countries, the negative trend was started to reverse in 2005–10, partly because the HIV epidemic had matured (and the number of AIDS cases was no longer escalating) and partly as a consequence of increased access to treatment.

As evident from Figure 3, the large decline in life expectancy has not resulted in a steep drop in GDP growth. The rate of growth of GDP per capita in 9 countries with high HIV prevalence slowed down, somewhat relative to the rest of sub-Saharan Africa since the mid-1990s. However, the timing of the slowdown precedes or is less persistent than the increase in HIV/AIDS-related mortality. By 2010, the countries with high prevalence can be divided in two groups: (1) Low-income countries like Malawi, Mozambique, Zambia, and Zimbabwe, experiencing large swings in growth rates arguably not caused by HIV/AIDS (this applies especially to the economic crisis in Zimbabwe); (2) South Africa and the enclosed or neighboring middle-income countries Botswana, Lesotho, Namibia, and Swaziland, all experiencing growth rates below the average for sub-Saharan Africa, but which also differ from most countries in sub-Saharan Africa in many regards other than the state of HIV/AIDS.

The empirical evidence is also ambiguous. Studies including HIV prevalence or AIDS-related deaths directly in regressions find no or very small impacts of HIV/AIDS on growth. In contrast, studies identifying a large impact of HIV/AIDS usually build on established findings of the empirical growth literature, notably the positive correlation of growth and life expectancy and then link the variable of interest to HIV/AIDS. In light of the strong impact of HIV/AIDS on life

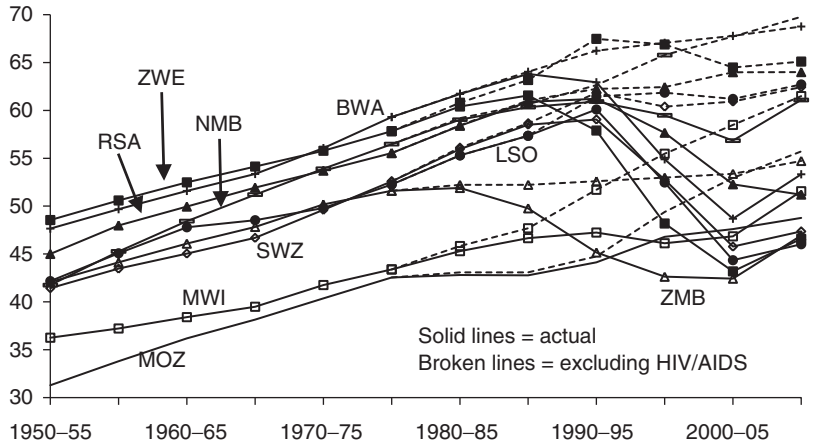

Figure 2 Life expectancy at birth, 9 countries with high HIV prevalence, 1950–2010 (years). Data sources: United Nations Population Division, world population prospects: The 2010 revision (2011). Figure covers BTW, Botswana; LSO, Lesotho; MWI, Malawi; MOZ, Mozambique; NMB, Namibia; RSA, South Africa; SWZ, Swaziland; ZMB, Zambia; and ZWE, Zimbabwe.

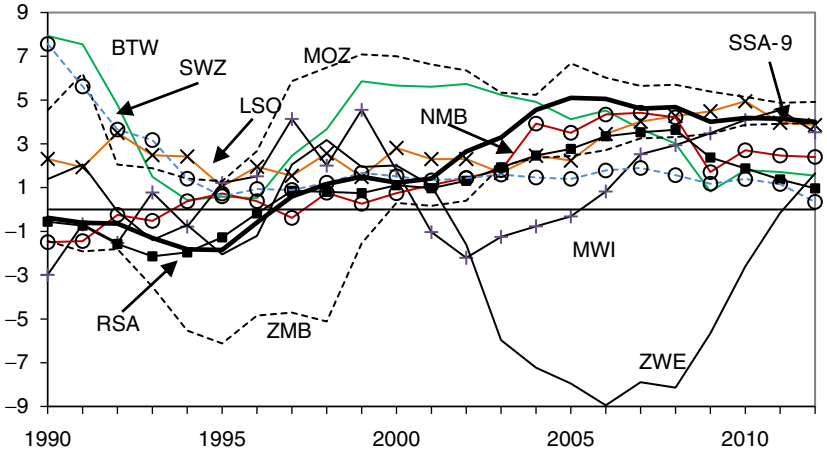

Figure 3 Growth of GDP per capita, 9 countries (average annual growth in 5-year period ending in year indicated). Data sources: International Monetary Fund, world economic outlook database, October 2012 edition (2012), and World Bank, world development indicators (2012). expectancy (or similar variables), this empirical approach returns a large negative impact of HIV/AIDS on growth but rests on two untested hypotheses: (1) The correlation of growth and life expectancy reflects a causal link between health and growth and (2) HIV/AIDS affects economic outcomes in a similar way as changes in the state of population health reflected in changes in life expectancy across countries. Both assumptions are doubtful. Some observers point to common factors like institutions affecting the functioning of health systems, governance, and growth. Also, the health impact of HIV/AIDS has a specific profile that does not simply reverse health gains achieved over the past decades, and it has occurred much more quickly than the gradual improvements in health outcomes achieved over the past decades.

If the links between health and economic outcomes are of a longer term nature, this could mean that the impacts of HIV/AIDS on economic growth have not fully materialized yet. For example, economic theory suggests that higher mortality risks reduce the returns to education. HIV/AIDS could therefore slowdown the accumulation of human capital and economic growth. As this effect would take several decades to materialize (as cohorts grow from school benches through the working-age population), it would barely show up in economic growth data at present, and there would not be a clear contemporary correlation between HIV prevalence and economic growth. Some microempirical evidence points to lower school attendance in areas highly affected by HIV/AIDS, consistent with such a hypothesis about the long-term economic consequences of HIV/AIDS.

Another possible reason why the impacts of HIV/AIDS on growth have been small so far is the fact that economic activity, within countries, is distributed unevenly. It has been observed that HIV is associated with certain economic activities like mining, and that migrant workers also play a large role in disseminating HIV. However, as value added per worker in mining is high, companies can afford to take actions

to prevent any disruptions to production from increased mortality or morbidity, at a low cost relative to turnover or value added.

The discourse regarding the macroeconomic effects of HIV/AIDS has focused on the growth impacts of the epidemic. It is important to take note of the fact that HIV/AIDS also results in a shift in the composition of spending. As governments and households shift expenditures to respond to the epidemic and address its consequences, these funds are no longer available for other purposes, i.e., private or public consumption and investment. Compared with a no-AIDS situation, HIV/AIDS-related spending therefore adds to the economic costs of the epidemic. The discussion in the Section Macroeconomic Aspects of the Response to HIV/AIDS, suggests that public HIV/AIDS spending accounts for several percent of GDP in a number of countries. Private HIV/AIDS spending and shifts in the allocation of time within households add to these economic costs.

The steep declines in life expectancy that can arise because of HIV/AIDS can also be interpreted as an economic cost. Such interpretations of the health impact of HIV/AIDS draw on estimates of the value of statistical life, which typically suggest that a loss in life expectancy of one percent is equivalent to an income loss of 3–4%. A loss in life expectancy of 23% (as in Botswana, 2005–10, compare **Figure 2**) would then translate into an economic cost exceeding one-half of GDP. Even in countries like the US, with an HIV prevalence of 0.6% and a loss in life expectancy of half an year, the costs of increased mortality, by this count, exceed 2% of GDP.

Small aggregate impacts of HIV/AIDS may mask shifts below the surface of national averages, which are relevant from a welfare perspective. For example, it is plausible that high HIV prevalence increases the risk to material living standards and – for parts of the population – of falling into poverty (even though other households may benefit, taking advantage of employment opportunities vacated by people affected by HIV/AIDS). Also, even though HIV prevalence tends to be somewhat higher among wealthier population groups, differences in access to treatment across population groups, in a country facing an HIV epidemic, can exacerbate inequalities in health prospects. Although demographic and health surveys consistently return higher rates of access to health services for wealthier population groups, little data are available regarding the benefit incidence of HIV/AIDS-related health services and the consequences of increased demand for HIV/AIDS-related health services (and a corresponding scaling-up in the supply of such services) for access to health services more generally.

Macroeconomic Aspects of the Response to HIV/AIDS

The global response to HIV/AIDS has altered the course of the epidemic. The macroeconomic impact of HIV/AIDS therefore partly reflects the consequences of policy interventions, in several dimensions: (1) HIV incidence, (2) the microeconomic consequences, (3) the growth impacts of HIV/AIDS, and (4) the costs of the response to the epidemic.

In many countries, HIV incidence has declined very considerably from its peak. In South Africa, for example, HIV incidence among the population of ages 15–49 years declined from a peak of 2.8% in 1998 to 1.3% in 2011. As a consequence, the health outlook in countries experiencing such declines is improving, and the economic consequences of HIV/AIDS become less forceful.

More immediately, the adverse economic consequences of HIV/AIDS are modified by increased access to treatment. This intuition is supported by empirical analysis on the microeconomic level, illustrating a reversal in worker's productivity following initiation of treatment. These estimates, however, are available only in settings where labor input and output are directly observable (e.g., tea pluckers) and may not translate one-to-one to other sectors and contexts, such as capital-intensive mining or services, which account for a large share in GDP.

The studies of the macroeconomic effects of HIV/AIDS also provide some pointers regarding the consequences of treatment (and the later studies frequently offer explicit estimates). In addition to mitigating productivity losses, antiretroviral treatment reduces the decline in population growth and reduces the private and public costs of care. Looking ahead, the prospect of access to treatment changes the risks associated with an HIV infection. Along with declining risk of becoming infected, it therefore increases the incentives to invest in education, therefore mitigating one of the most forceful effects through which HIV/AIDS could affect long-term growth.

Macroeconomic studies, which explicitly account for the impact of antiretroviral treatment, illustrate the extent to which increased access to treatment mitigates the economic impacts of HIV/AIDS, frequently suggesting a reversal in the growth impact of approximately one-third to one-half of the unfettered ('no treatment') impact of HIV/AIDS. This reversal is less than complete even where the rate of access to treatment is very high because treatment only mitigates and delays the adverse health consequences of HIV/AIDS, and because the costs of treatment crowd out other investments. Some observers argue that access to treatment could be financed from this 'growth dividend' (and reduced costs of other HIV/AIDS-related health services). This, however, is not necessarily the case, as the 'growth dividend' is not directly available for higher health spending (people surviving longer because of treatment need to eat).

The policy response does not merely reverse the adverse macroeconomic impacts of the epidemic. The costs of the response in many countries have attained a level that is significant from a fiscal perspective, and HIV/AIDS-related external aid may account for a substantial proportion of aid received. Globally, HIV/AIDS accounted for US$ 8.0 billion out of total disbursements of official development assistance of US$ 150 billion in 2011, and out of US$ 19.4 billion in the areas of health and population policies, according to the "creditor reporting system" database maintained by the Organisation for Economic Co-operation and Development.

The high costs of the response to HIV/AIDS in numerous countries are illustrated in **Figure 4**. The burden of funding the HIV/AIDS program, relative to GDP, is not necessarily the largest in the countries facing the highest HIV prevalence (Botswana, Lesotho, Namibia, South Africa, and Swaziland) but in a number of low-income countries facing HIV prevalence between 3% and 15%. In particular, some least-developed

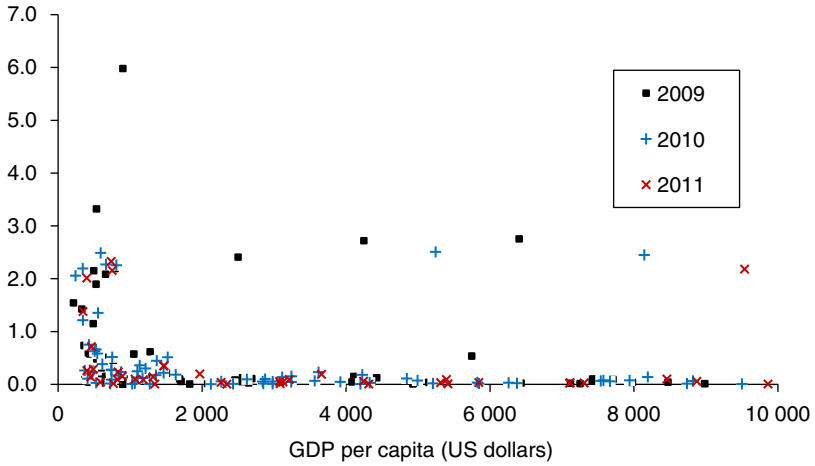

Figure 4 Total HIV/AIDS spending (percent of GDP). Data sources: International Monetary Fund, world economic outlook database, October 2012 edition (2012) and UNAIDS, AIDS spending data (2012).

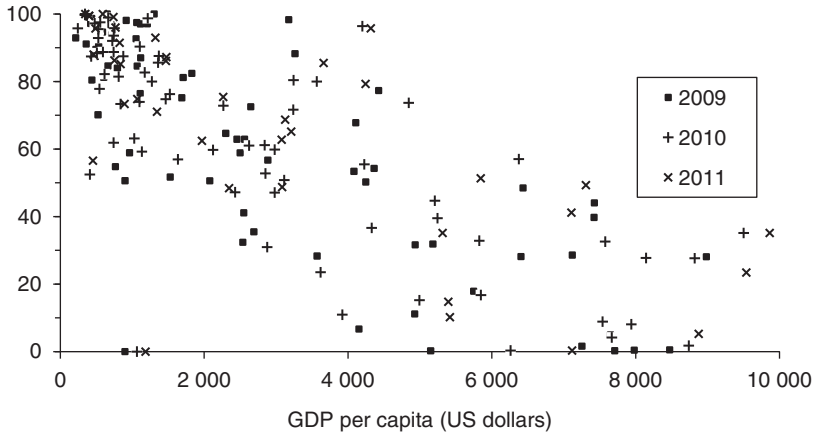

Figure 5 Externally financed HIV/AIDS spending (percent of total spending). Data sources: International Monetary Fund, world economic outlook database, October 2012 edition (2012) and UNAIDS, AIDS spending data (2012).

countries face a very large financing challenge, even though HIV prevalence is moderate. This is the case because the unit costs of HIV/AIDS interventions differ across countries much less than the level of GDP per capita.

The spending figures summarized in Figure 4 confirm that HIV/AIDS spending is significant from a fiscal perspective in many countries. In a typical low-income country (the figures are based on the median for this country group), public spending accounts for approximately 25% of GDP, of which 8% (equal to 2% of GDP) go toward health. According to Figure 4, the costs of the national response to HIV/AIDS (whether delivered through the public sector or non-governmental organisations) thus exceed total public health spending in a number of countries. These high levels of spending would be hard to envisage without high levels of external assistance.

Health is an area in which external assistance is playing a large role across developing countries in general. Owing to the uneven distribution of HIV/AIDS across countries, and the high costs of HIV/AIDS in a number of countries, the role of external assistance is even more pronounced in the area of HIV/AIDS spending, as illustrated by Figure 5. For low-income countries (broadly, those with GDP per capita of less than US$ 1000 in Figure 5), external financing usually accounts for more than 80% of the total costs of the HIV/AIDS program and in some cases close to 100%. In contrast, external assistance for public health spending rarely exceeds two-thirds of total spending. The differences in external funding between HIV/AIDS and health are even more pronounced for middle-income countries including countries which are not facing very high HIV prevalence rates.

Looking ahead, two aspects of the fiscal dimension of HIV/AIDS are worth noting. First, the costs of HIV/AIDS programs are going to remain high for a long time, even where HIV incidence is declining. This is the case because the number of people receiving treatment are still rising, and an increasing number of people who have contracted HIV in the past will require treatment. Second, there is a perception (and some early evidence) that external funding for HIV/AIDS is stagnating or even declining. This will place the funding of

HIV/AIDS programs under pressure, especially in low-income countries where HIV/AIDS spending is high relative to the government's fiscal resources.

Concluding Remarks

The impact of HIV/AIDS on economic growth has been small so far. This finding raises some questions regarding the empirical literature on health and growth (which would predict a large impact), but it could also be the case that the link from increased mortality to growth occurs so slowly and has not fully materialized yet. In many countries, HIV/AIDS programs have attained a scale that is significant from a fiscal perspective. The response to HIV/AIDS has been enabled by high rates of external assistance in the past, but the availability of funding is perceived to decline. Under these circumstances, sustaining the funding of HIV/AIDS programs will present a challenge especially for a number of low-income countries.

Glossary

Concurrency When an act of sex with one partner occurs between two acts of sex with another partner.

Disinhibition behaviors People may increase the riskiness of their behavior in response to perceived decreases in risk of acquiring or transmitting the virus.

Serodiscordance When one member in a sexual partnership is HIV positive and the other is not.

Introduction

At the end of 2011, according to Joint United Nations Program on Human immunodeficiency virus (HIV)/Acquired immunodeficiency syndrome (AIDS) (UNAIDS), an estimated 34 million people were living with HIV worldwide. The number of people dying of AIDS-related causes fell to 1.7 million in 2011, down from a peak of 2.2 million in the mid-2000s. There were 2.5 million new HIV infections in 2011, including an estimated 390 000 among children. This was 15% less than in 2001, and 21% below the number of new infections at the peak of the epidemic in 1997. Sub-Saharan Africa remains the region most heavily affected by HIV. In 2011, approximately 69% of all people living with HIV resided in sub-Saharan Africa, a region with only 12% of the global population. Sub-Saharan Africa also accounted for 70% of new HIV infections in 2010, although there was a notable decline in the regional rate of new infections. As Africa shoulders the heaviest burden, this article emphasizes evidence from this continent.

The article focuses on the economics of HIV/AIDS and therefore does not emphasize the biomedical determinants of the epidemic. However, it briefly summarizes some of the recent biomedical prevention interventions. The focus of the discussion is on behaviors, economic behaviors, and incentives in particular. For that reason, the article does not address the HIV epidemic among children, even though it constitutes a heavy burden and an important challenge. This article will mainly review the microeconomic aspects of HIV/AIDS.

The article articulates the discussion around the three themes of HIV transmission, prevention, and AIDS treatment. It starts by exploring the determinants of HIV transmission, focusing on behavioral (gender and marriage, serodiscordant couples and multiple partners, and concurrency) and socioeconomic (poverty, education, and occupation) determinants. A short Section '(Micro-) Economic Consequences of HIV/AIDS' follows. The Section 'HIV Prevention' reviews the recent advances in biomedical prevention interventions (male circumcision, treatment for prevention, and preexposure chemoprophylaxis) before discussing behavioral interventions: information and education campaigns (IECs), HIV testing and counseling (HTC), school-based interventions, and conditional cash transfers. The Section 'AIDS Treatment' reviews briefly the literature on adherence to treatment before presenting the evidence about the socioeconomic benefits of antiretroviral treatment. Before the Section 'Conclusion', the article addresses, at the intersection between AIDS treatment and HIV prevention, the issue of disinhibition behaviors.

Determinants of HIV Transmission

This article does not focus on the biological determinants of HIV transmission but rather on the behavioral and socioeconomic determinants of HIV infection.

Behavioral Determinants

Gender and marriage

An alarming demographic trend in developing countries has been the steadily increasing percentage of adolescents and women who are HIV positive. If globally, 50% of all people living with HIV are women, in sub-Saharan Africa, that proportion rises to 61% and young women (15–24 years) are 3–6 times more likely to be infected than men in the same age group. These patterns have been identified as reflecting marriage patterns and risk: women are marrying younger than men and are often initiating sexual activity earlier, but women are also biologically more vulnerable to HIV infection. Several researchers argue that early marriage by females presents an important risk factor for HIV infection that is generally not being addressed and that could be contributing to the increase in HIV among this relatively large segment of the population (almost a third of girls between the ages of 10 and 19 in developing countries marry before their 18th birthday). Using data from 22 Demographic and Health Surveys (DHS) conducted in Africa, Latin America, and the Caribbean, these researchers conclude that two main factors increase the vulnerability of young brides to HIV infection: (1) marriage dramatically increases the frequency of unprotected sex for

 doi:10.1016/B978-0-12-375678-7.00113-9

most young brides and (2) many young brides marry older men, who are more likely to be HIV positive, because of their longer sexual activity.

Another study documents the increased risk of HIV infection for young married females by comparing prevalence data among the partners of young married females and the boyfriends of unmarried females the same age who are seropositive. It reports that in Kenya 30% of male partners of young wives are HIV positive, whereas only 11.5% of partners of unmarried females the same age are seropositive.

Yet another draws the opposite conclusion. The analysis done in this study, based on DHS in Ghana, Kenya, and on cross-country comparisons, suggests that late marriage and a long interval between first sex and first marriage are risk factors for HIV infection. Other researchers use data from five DHS that include HIV testing for a nationally representative sample (Burkina Faso (2003), Cameroon (2004), Ghana (2003), Kenya (2003), and Tanzania (2003–04)) to assess the question empirically. Overall, except in Cameroon, their results do not support the hypothesis that early marriage increases the HIV risk for women. Getting married at an early age does not seem to put young married women at any greater risk of contracting HIV than women their age who do not get married. However, except in Burkina Faso, marriage does not seem to protect women against HIV either.

One study focuses on the risk associated with remarriage. Using DHS nationally representative data from 13 sub-Saharan African countries, it concludes that, in almost all of the countries examined, there are high rates of remarriage and these remarried individuals have significantly higher rates of HIV prevalence than the adult population in general and that of other married individuals. It stresses that this relationship is not necessarily causal, but that remarried individuals constitute a large segment of the population that is highly vulnerable to HIV/AIDS and has not been clearly identified as such by the existing prevention efforts. Using the same data sources, another study also investigates how reported condom use varies within and outside marriage. It reinforces and expands on previous findings that men report using condoms more frequently than women do and that unmarried respondents report that they use condoms with casual partners more frequently than married individuals report using them with their spouses. The study documents that married men from most countries report using condoms with extramarital partners about as frequently as unmarried men report using them with casual partners. Married women from most of the countries included in the study reported using condoms with extramarital partners less frequently than unmarried women reported using them with casual partners. This result is especially troubling because marriage usually ensures regular sexual intercourse, thereby providing more opportunities for a person to pass HIV infection from an extramarital partner to his or her spouse.

Serodiscordant couples

Recent research on discordant couples (couples in which only one partner is HIV positive) also shed new lights on the dynamics of HIV infection within marriage. In five countries – Burkina Faso, Cameroon, Ghana, Kenya, and Tanzania – an analysis of HIV status among discordant couples yields two findings that challenge conventional notions about HIV transmission. First, in at least two-thirds of HIV-positive couples (couples with at least one HIV-positive partner), only one partner is HIV positive. Second, in close to half of those serodiscordant couples only the woman is positive. These findings have important implications for HIV prevention policies and have been confirmed in a meta-analysis for a larger set of African countries.

A pervasive, if unstated, belief is that males are by and large responsible for spreading the infection among married and cohabiting couples. The results from the analysis of discordant couples suggest, however, that HIV prevention policies should take into account the fact that women are almost as likely to be the infected partner.

Multiple partners and concurrency

In terms of behaviors, strong emphasis has been put on the hypothesis that concurrent sexual partnerships have been and remain an important driver of the HIV epidemic, especially in southern and eastern Africa. Concurrency is defined when an act of sex with one partner occurs between two acts of sex with another partner. In a network where people engage in concurrent sexual partnerships, if one person is living with HIV, the virus can spread much more rapidly among the other partners, as at any point in time a larger number of individuals is connected through the sexual network and is susceptible of becoming infected and then transmitting the infection. This network effect is further reinforced by the fact that immediately after becoming infected with HIV, HIV-positive individuals are more infectious and at higher risk of transmitting HIV within their network. Although concurrent sexual partnerships occur everywhere in the world, they might be more prevalent or last longer in southern or eastern Africa, which might be one of the key factors explaining the higher HIV prevalence in those regions. However, the hypothesis that concurrency is one of the main drivers of the HIV epidemic is difficult to establish empirically and there is a debate as to whether the evidence is strong enough to support it. The debate focuses on the measurement of concurrency (recent surveys using improved questionnaire design show reported concurrency to be between 0.8% and 7.6% in sub-Saharan Africa), the assumptions used in mathematical models of concurrency, and on whether a correlation between HIV and concurrency can be established.

Socioeconomic Determinants

Poverty

To what extent is poverty to be blamed for the AIDS epidemic? Globally, the countries hardest hit by the AIDS epidemic are poor; within sub-Saharan Africa, however, the hardest hit countries are relatively richer. The macroeconomic evidence is discussed in more detail in another article in this Encyclopedia.

Despite the lack of evidence, poverty is still believed to be a driver of the epidemic. A number of compelling arguments have been made that would support the notion that poverty causes AIDS. A naive reason underpinning this view is that health and disease exposure are usually positively correlated with poverty: richer people live longer, are in better health, and are less exposed to the deadliest diseases in low-income

countries (diarrheal diseases, malaria, and so forth). This argument does not work in the case of HIV/AIDS, because the HIV virus is contracted very differently from other contagious diseases. Indeed, it is associated with behaviors and characteristics that are often associated with higher income, such as more concurrent partners, geographic mobility, and urbanization. One study characterizes these traits as those that are a direct function of wealth (e.g., increased demand for partners) and those that are correlated with wealth (such as residence and population density).

Another study examines empirically if higher household incomes are associated with less risky behaviors for individuals (particularly females) in Cape Town, South Africa. Females in poorer households are more likely to be sexually active and experience earlier sexual debut. They are more likely to reduce condom use when they experience economic shocks, but are less likely to have multiple partners. Males are more likely to have multiple partners when confronted with a negative economic shock. However, overall, the study does not find systematic difference in condom use at last sex by income level or the experience of economic shocks.

Education

There have been different conclusions reached about the association between HIV infection and education. There are various reasons why the association may be different, including the specific context and ways of analyzing the data but the factor that seems to have the biggest influence is the time the data was recorded relative to the stage of the HIV/AIDS epidemic in the country.

Several researchers completed two systematic reviews of studies relating to the association between educational attainment and risk of HIV infection in sub-Saharan Africa. The first review concluded that there was either no association between educational attainment and HIV infection (16 studies) or that there was a positive association between education and HIV infection (15 studies), with the exception of one case of negative association in Uganda where the response to the epidemic was the most developed.

An updated version of the review combined additional data published between 2001 and 2006 with the previous data. Overall, 44 studies did not show any statistically significant association between HIV infection and education, 20 studies showed a positive association, and in only 8 studies was there a negative association. In this updated version, there is evidence that the HIV epidemic is changing as shown by the fact that a larger proportion of studies conducted from 1996 onwards identified a lower risk of infection associated with the most educated than studies from before 1996; 7 studies showed a negative association with post-1996 data compared with only one study showing a negative association with the pre-1996 data. In addition, studies from after 1996 (5/40 studies) were less likely to show a positive association between HIV infection and the highest level of education than studies from before 1996 (15/32 studies). In studies from 1996 onwards that showed changes over time, there seemed to be a shift from strong positive associations toward weaker or negative associations between the highest levels of educational attainment and HIV infection. Additionally, HIV prevalence seemed to fall more consistently among the higher educated groups. Another study also noted a shift toward a more negative association between HIV and education between 1995 and 2003 based on the analysis, controlling for wealth, of data from serial population-based surveys in both urban and rural Zambia.

Referring to the two systematic reviews above, some researchers highlight the theory that the nature of the relationship between education and HIV infection is changing over time, whereby the early positive association between education and HIV is weakening as the epidemic matures in a particular country, though they also say that there is no hard evidence that these shifting associations can be attributed to a causal effect of education on HIV infection rates.

It was also found that there is a negative association between HIV and education among young women in an analysis of an individual-level longitudinal dataset in rural Uganda. It explores the evolution of this association over a period of 12 years and finds it changes over time. The study found no robust association between HIV/AIDS and education in 1990 but then found a negative association for young females in 2000.

Occupation

Occupation can also contribute to the risk of HIV infection and transmission. Commercial sex workers have been identified as a particularly vulnerable group. One study uses a panel set of 192 self-reported daily diaries compiled by commercial sex workers in Kenya to analyze decisions to engage in unprotected sex with clients. It finds that women who engage in transactional sex substantially increase their supply of risky, better compensated sex to cope with unexpected health shocks, particularly the illness of another household member. Women are 3.1% more likely to see a client, 21.2% more likely to have anal sex, and 19.1% more likely to engage in unprotected sex on days in which another household member (typically a child) falls ill. Similar responses are observed on days just after a woman recovers from the symptoms of a sexually transmitted infection (STI), which arguably might be seen as an exogenous shock to her ability to supply sex, or from other health problems. Women do this in order to capture the roughly 42 Kenyan shilling (US$0.60) premium for unprotected sex and the 77 shilling (US$1.10) premium for anal sex. Other studies, in very different settings, Calcutta and Mexico respectively, confirms the existence of a compensating differential and that female sex workers not using condoms obtain higher prices.

Truck drivers, migrants, and miners are also often perceived as occupations at risk. Two researchers investigate the role that mines and migration played in southern Africa. They start from the observation that Swaziland and Lesotho are the countries with the highest HIV prevalence in the world. They have in common another distinguishing feature: during the past century they sent massive numbers of migrant workers into South African mines. A job in the mines implies spending a long period away from the household of origin surrounded by an active sex industry. This creates potential incentives for multiple concurrent partnerships. Using DHS, their analysis shows that migrant miners aged 30–44 years are 15% points more likely to be HIV positive and having a migrant miner as a partner increases the probability of infection for women by

8% points. The study also shows that miners are less likely to abstain and to use condoms and that female partners of miners are more likely to engage in extramarital sex. The fact that mobility might be one of the key factors of HIV transmission is also highlighted by another study that shows a positive relationship between HIV prevalence and the volume of exportations. However, a recent study examining the effects of the early twenty-first century copper boom on risky sexual behavior in Zambian copper mining cities found that the copper boom substantially reduced rates of transactional sex and multiple partnerships in copper mining cities. Copper boom induced in-migration to mining cities appears to have contributed to these reductions.

(Micro-) Economic Consequences of HIV/AIDS

From a microeconomic point of view, the costs of the epidemic are numerous. The negative impact on labor markets has been documented. For example, using firm-level data from South Africa and Botswana, one study calculates that the value of an incident HIV infection was between 0.5 and 3.6 times the annual salary of the worker. It estimated that costs varied widely between firms and among job levels within the firm. Another studied the productivity and attendance of 54 tea workers who died or were medically retired because of AIDS between 1997 and 2002 compared with other workers. After adjusting for age and environmental factors, cases were absent from work 31 days or more often (an increase of 87%); spend 22 days more on light duty (an increase of 66%); produce an average of 7.1 kg less tea leaf per plucking day (a decrease of 17%), when compared with the control group.

One of the most devastating consequences of the HIV/AIDS epidemic is the large increase in the number of orphans. In 2008, more than 14.1 million children in sub-Saharan Africa were estimated to have lost one or both parents to AIDS. There is a large literature on the consequences of orphanhood. Summarizing it has been done elsewhere and would be beyond the scope of this article. In brief, though the results from cross-sectional studies point to a large heterogeneity in the orphan/nonorphan differential across countries, longitudinal studies who can contrast the situation of the child before and after the death of the adult generally conclude that orphans are disadvantaged in terms of schooling outcomes, even if it is not always in terms of enrollment.

Beyond orphanhood, the HIV epidemic could reduce the incentives to invest in education and affect fertility behaviors. By looking at the DHS data from 15 countries in sub-Saharan Africa, one study examines the relationship between HIV prevalence and changes in human capital investment over time and finds that areas with higher HIV prevalence experienced relatively larger declines in schooling. One of the suggested mechanisms is that a lower life expectancy reduces the incentives to invest in human capital. Another also finds that short life-spans might be one of the reasons why, even when confronted with high HIV prevalence numbers, the extent of behavior change has been limited in most African settings.

Yet another study shows evidence for the fact that HIV has had little impact on fertility, both overall and in a sample of HIV-negative women; however, it was estimated that the presence of HIV reduces the average number of births a woman gives during her lifecycle by 0.15.

HIV Prevention

Although this article focuses on the economic and behavioral aspects of the HIV/AIDS epidemic, it is worth noting that currently the field of HIV prevention is dominated by recent advances in biomedical interventions for HIV prevention. This section starts by reviewing some of these advances, with some emphasis on the behavioral responses to these advances. The discussion moves next to behavioral interventions for HIV prevention.

Biomedical Interventions

The first biomedical approach to be rigorously tested for HIV was the treatment of other STIs. As summarized in one particular study, the earliest study of the efficacy of treating other STIs on HIV incidence conducted in Tanzania suggested that when STIs are treated, HIV infection declined by almost 40% over a 2 year period. Following this result, STI treatment was included in the catalog of HIV prevention measures endorsed by the World Health Organization (WHO) and UNAIDS. However, another randomized control trial in Uganda showed contradictory results and other studies have not replicated the level of efficacy found in the initial study.

However, male circumcision has been shown to be protective and more recently, new biomedical approaches have been more successful. In particular, 'treatment for prevention' or 'test-and-treat,' and preexposure chemoprophylaxis for HIV prevention have shown promising results.

Male circumcision

The evidence showing the protective effect of male circumcision from three randomized control trials is strong. Unlike other HIV prevention strategies, male circumcision is a one-time procedure with lifelong benefits and thus potentially highly cost effective. However, till date, there is no rigorous impact evaluation of male circumcision at scale. Those would be important studies to carry not only to confirm the external validity of the randomized control trials but also to learn what are the most effective delivery mechanisms for scaling up male circumcision or to assess whether behavioral responses such as disinhibition might differ in an environment where the benefits of male circumcision have been largely publicized and where a large number of men have been recently circumcised.

Treatment for prevention

The 'treatment for prevention' approach proposes to test regularly a large fraction of the population and treat immediately those who have tested positive with antiretroviral therapies, without waiting for the AIDS symptoms to develop. By treating HIV positives immediately after they have tested, the objective is to reduce the viral load of HIV positives and therefore their infectiousness. While earlier studies advocating this approach were based on modeling, recent results from the HPTN 052 study indicate that treatment for prevention is efficacious.

Preexposure chemoprophylaxis for HIV prevention

One study also reports on recent trials evaluating preexposure chemoprophylaxis for HIV prevention. In the Center for the AIDS Programme of Research in South Africa (CAPRISA) study in South Africa, high-risk women used an applicator that delivered 1% tenofovir gel into the vaginal vault up to 12 h before, and within 12 h after intercourse. Investigators reported a 39% reduction in overall acquisition of HIV, and the maximum reduction was 54% among the most adherent women. In the Iniciativa Profilaxis Pre Exposicion or Prexposure Prophylaxis Initiative (iPrEx) study in 2010, HIV-negative men who have sex with men were given daily an antiretroviral combination, emtricitabine and tenofovir disoproxil fumarate (TDF plus FTC) for up to 2.8 years. The study recorded a 44% reduction in HIV acquisition and, as with the CAPRISA study, efficacy was strongly associated with concentrations of antiretroviral drugs, a direct marker of adherence. By contrast, the Preexposure Prophylaxis Trial for HIV Prevention among African Women (FEM-PrEP) trial of TDF plus FTC offered to high-risk women was discontinued because an equal number of infections occurred in both the placebo and treatment groups.

As with treatment for prevention, the efficacy and efficiency of preexposure chemoprophylaxis for HIV patients needs to be further established and confirmed, but if they are confirmed it would open very promising perspectives for the prevention of sexual transmission. Compared with treatment as prevention, preexposure chemoprophylaxis offers two advantages. First, there is no need for frequent and widespread testing in order to identify HIV-positive individuals. This is logistically challenging in most settings in sub-Saharan Africa, especially if one of the objectives is to detect individuals with recent HIV infections that are more infectious, but more difficult to detect with accuracy. Second, preexposure chemoprophylaxis for HIV prevention can be self-targeted by individuals who feel they are most at risk. However, both approaches require a high level of adherence in the absence of symptoms and are operationally challenging to implement considering that it has proved difficult so far to fully scale up HIV testing in the general population and access to antiretroviral treatment for all AIDS patients.

Behavioral Interventions

One study reviews 37 randomized controlled trials of HIV prevention interventions and finds only six demonstrating effects in reducing HIV incidence. Those six were all evaluating biomedical interventions (male circumcision trials, STI treatment, and care). None of the behavioral interventions reviewed demonstrated impact in reducing HIV incidence. The review suggests that lack of statistical power, poor adherence, and diluted versions of the intervention in comparison groups may have been important issues in some of the trials that did not show any results.

Information and education campaigns

IECs have been among the first behavioral interventions for HIV prevention. One researcher reviews the much touted abstain, be faithful, use condoms (ABC) campaigns in Uganda. The study concludes that the effects of such a national mass media campaign on behavior are difficult to estimate as a control group is not available. The ABC initiative in Uganda, combined with a high level of political commitment to HIV prevention, seemed to have been successful in significantly reducing the prevalence of HIV. However in mass efforts such as this, it is difficult to ascribe success to individual components (there is a debate about the relative importance of condoms in the ABC strategy), but they do provide suggestive evidence that broad-based and well supported efforts at behavior change can be effective prevention strategies. Overall, IECs by itself have not been shown to have more than a minor impact on patterns of HIV transmission and the trajectory of the epidemic. Numerous studies have shown that information alone is typically insufficient to change risk behavior. The impact of mass media campaigns tends to be short in the absence of an ongoing effort, and these campaigns can be aided by condom distribution and by more targeted education programs aimed at youth in and out of school.

HIV testing and counseling

HTC is recognized as the necessary gateway for HIV/AIDS treatment. However, the prevention benefits of individual HTC remain under discussion. One study estimates the behavioral responses by individuals to a public HIV testing program. It posits that only individuals who are surprised by the test results, i.e., low-risk individuals testing HIV positive or high-risk individuals testing negative, will change their behaviors. For those individuals HTC can lead to unexpected behaviors that might not reinforce prevention. It finds that although the aggregate effect of the testing program is quite small, the effects disaggregated by private beliefs about own risks are consistent with information elastic behavior for the average individual. It concludes that the subgroups of the population affected by HTC may have roughly offsetting behavioral responses, which may lead to little effect or possibly even perverse outcomes with regard to an objective of lowering disease transmission.

Another study finds that beliefs are an important determinant of risky behavior, with downward revisions in the belief of being HIV positive increasing risky behavior and upward revisions decreasing it. Yet another tests the hypothesis that only individuals who are surprised by the test results will change their behaviors, using STIs as objectively measured proxies for unsafe sexual behavior. On the one hand, individuals who believed they were at low risk for HIV before testing, are nine times more likely to contract an STI following an HIV-positive test, indicating riskier sexual behavior. On the other hand, individuals who believed they were at high risk for HIV have an 84% decrease in their likelihood of contracting an STI following an HIV-negative test, indicating safer sexual behavior. When HIV tests agree with a person's belief of HIV infection, there is no statistically significant change in contracting an STI. Using the randomly assigned incentives and distance from results centers as instruments for the knowledge of HIV status, one researcher finds that sexually active HIV-positive individuals who learned their results are 3 times more likely to purchase condoms 2 months later than sexually active HIV-positive individuals who did not learn

their results. However, there is no significant effect of learning HIV-negative status on the purchase of condoms.

Meta-analyses of the prevention benefits of HTC conclude that HIV counseling and testing appears to provide an effective means of secondary prevention for HIV-positive individuals but is not an effective primary prevention strategy for uninfected participants and that, overall, there is only moderate evidence in support of HTC as an effective prevention strategy.

Joint couple or partner testing appears to have stronger prevention benefits, especially in the case of serodiscordant couples. However, despite the importance of couple testing for treatment and prevention, there are few successful experiences of HTC programs reaching couples. Recent evidence on the effectiveness of ART for the prevention of HIV transmission among couples makes this a key intervention of prevention programs in generalized epidemic countries. Recent evidence from Rwanda suggests that pay-for-performance schemes at the health facility level can be an effective intervention to target discordant couples for HTC.

School-based interventions

The school environment offers a useful platform to deliver HIV information and prevention messages to individuals just before or as they start their sexual life.

Several researchers analyzed results from a randomized evaluation comparing two different HIV prevention interventions and one economic intervention, and their impact on the students in certain behaviors considered to be risk factors for HIV infection. They tested three different types of school-based interventions in rural Kenya. One intervention involved training teachers in the national HIV/AIDS curriculum for them to present to their students. The second intervention consisted of students being encouraged to debate the benefits of using condoms and write essays on ways to protect themselves against HIV. The third intervention involved lowering the cost of schooling by providing school uniforms to students attending school as a way to get students to stay in school longer. To measure effectiveness, the researchers primarily evaluated teenage childbearing as a proxy for unprotected sex, the main risk factor for HIV/AIDS in Africa. They also collected information on knowledge, attitudes, and behavior regarding HIV/AIDS. The teacher training was found to have little impact on teen childbearing, students' knowledge, and self-reported sexual activity and condom use. The debate and essay intervention increased self-reported condom use, but not self-reported sexual activity. Paying for uniforms reduced dropout rates by 15%, resulted in an almost 10% decrease in teen childbearing, girls were 12% less likely to be married, and boys were 40% less likely to be married.

The UK Department for International Development (DFID) trial (2004) in rural Tanzania evaluated the impact of an intervention aimed at changing the knowledge and sexual behavior of adolescents on HIV rates, other STIs, unintended pregnancy and adolescents' knowledge, and reported attitudes and behaviors. The intervention included an in-school teacher-led, peer-assisted sexual and reproductive health education component, training for health workers to make reproductive health services at the clinics more youth-friendly, community-based condom promotion, and periodic community activities promoting sexual health. Comparing the communities that received the interventions with the control communities showed that the intervention communities had statistically significant improvement in knowledge and reported sexual attitudes for both males and females. Males also reported delayed sexual debut, fewer sexual partners, and more condom use at last sex. However, there was no evidence of a consistent impact of the intervention on biological outcomes including HIV incidence, other STIs, and unintended pregnancies.

A review of 11 quasiexperimental designs that measured the impact of a variety of school-based HIV prevention interventions in sub-Saharan Africa reinforce the finding from the DFID trial that behavior is more difficult to change than knowledge.

Although general HIV knowledge may not often result in behavior change, another study shows that specific information that distinguishes the levels of HIV risk may be more useful in changing behavior. The study rigorously tests an information campaign telling teenagers about the relative risks of different types of partners, based on their HIV infection rates. The objective of the campaign was to make teenagers aware of the relative risks of partners of different ages in the hope that they will take these different levels of risk into account when choosing a partner. As a result of the campaign, the incidence of cross-generational pregnancies among the treatment group decreased by 61% while intragenerational pregnancies remained stable. This information on the relative risks of different partners resulted in a sizable decrease in unprotected sex between older men and teenage girls but without an increase in unprotected sex between teenage boys and girls. In contrast, another program that only gave general information about HIV risk had no impact on the incidence of unprotected sex as measured by pregnancy rates.

Conditional cash transfers

Conditional cash transfer programs have become an increasingly popular approach for incentivizing socially desirable behavioral change. The principle of conditionality – making payments contingent, for example, on a minimal level of schooling attendance or preventative care use – distinguishes conditional cash transfer programs from more traditional means-tested social programs. The evaluation of conditional cash transfer programs have shown that they can be effective at raising consumption, education, and preventative health care, as well as actual health outcomes. Similarly, 'contingency management' approaches have shown important substance abuse reductions by conditioning rewards on negative tests for drug or alcohol. The evidence on the efficacy of conditional cash transfers for STI or HIV prevention is still unfolding and remains limited. In Malawi, small financial incentives have been shown to increase the uptake of HTC. Another study in Malawi, conducted a conditional cash transfer program for adolescents in which the cash transfer was conditional on school attendance but which, in addition to increased enrollment and attendance also caused a reduction in HIV and herpes simplex virus type 2 (HSV-2) incidence. HIV prevalence among program beneficiaries was 60% lower than the control group (1.2% vs. 3%). Similarly, the prevalence of HSV-2 (which is the common cause of genital herpes) was more than 75% lower in the combined treatment group (0.7% vs. 3%). No significant differences were detected between those offered

conditional and unconditional payments. In addition, cash payments offered to the girls who had already dropped out of school at the beginning of the trial made no difference on their risk of HIV or HSV-2 infection. The same program also led to a modification of self-reported sexual behaviors with adolescent girls having younger partners.

Till date, two studies evaluated conditional cash transfers in which the conditionality is attached to negative test results for STIs. In Malawi, one study tested an intervention promising a single cash reward in 1 year's time for individuals who remained HIV negative. This design had no measurable effect on HIV status, but the number of seroconversions in the sample was very small and statistical power was therefore low. The Rewarding STI Prevention and Control in Tanzania (RESPECT) study evaluated a randomized intervention that used economic incentives to reduce risky sexual behavior among young people aged 18–30 years and their spouses in rural Tanzania. The goal was to prevent HIV and other STIs by linking cash rewards to negative STI test results assessed every 4 months. The study tested the hypothesis that a system of rapid feedback and positive reinforcement using cash as a primary incentive to reduce risky sexual behavior could be used to promote safer sexual activity among young people who are at high risk of HIV infection. Results of the randomized controlled trial after 1 year showed a significant reduction in STI incidence in the group that was eligible for the US$20 quarterly payments, but no such reduction was found for the group receiving the US$10 quarterly payments. Further, though the impact of the Conditional Cash Transfers (CCTs) did not differ between males and females, the impact was larger among poorer households and in rural areas. Although the results from those studies are important in showing that the idea of using financial incentives can be a useful tool for preventing HIV/STI transmission, this approach would need to be replicated elsewhere and implemented on a larger scale before it could be concluded that such conditional cash transfer programs, for which administrative and laboratory capacity requirements are significant, offer an efficient, scalable, and sustainable HIV prevention strategy.

AIDS Treatment

Antiretroviral therapy (ART) has dramatically reduced morbidity and mortality for people living with HIV/AIDS. By the end of 2010, an estimated 6.6 million people in low- and middle-income countries received ART. In sub-Saharan Africa, approximately 47% of the 14.2 million eligible people living with HIV were on ART. This is an extraordinary achievement, considering that as recently as 2003, relatively few people living with HIV/AIDS had access to ART in Africa. A total of 2.5 million deaths have been averted in low- and middle-income countries since 1995 due to the ART being introduced, according to new calculations by UNAIDS.

Adherence to Treatment

Medical research has established that a minimum level of adherence to antiretroviral drug (ARV) treatment of 95% is necessary to achieve significantly better health outcomes as assessed by the viral load, immune system, and occurrence of opportunistic infections. Nonadherence predicts disease progressions and survival rates, and increases the risk of transmission of drug-resistant viruses. Failure to achieve proper adherence to treatment is thus both an individual and collective risk.

Determinants of adherence depends on several factors such as the treatment regimen (which can be quite complex and include food restrictions, specific schedules, etc.), disease characteristics, the quality of the patient–provider relationship, or the clinical setting. Sociodemographic factors do not consistently predict adherence behavior. The meta-analysis on socioeconomic status as a determinant of adherence finds that while the relationship is weak, there is generally a positive association between income, education, or employment status and adherence. It is worth noting that adherence is not found to be consistently lower in developing countries, and largely depends on access to treatment and financial barriers. When therapy is fully subsidized in developing countries, it can be at least as good as in developed countries.

Even when treatment per se is free, transportation costs to the health facility to get a prescription refilled are found to be a powerful barrier to adherence. Moreover, patients have to make 'impossible choices' between competing claims: transport costs and good nutrition of the patients compete with schooling fees or medical costs for children, food for the rest of the family, etc. As already mentioned, malnutrition can be an obstacle to adherence.

Several interventions aiming to improve adherence have been evaluated. For example, weekly Short Message Service (SMS) reminders have been shown to increase the percentage of participants achieving 90% adherence to ART by approximately 13–16% compared with no reminder and were also effective at reducing the frequency of treatment interruptions.

The Economic Benefits of Antiretroviral Treatment

The most immediate benefit of the scaling up of antiretroviral treatment is a reduction in mortality and morbidity. A second-order set of benefits is related to the increase of labor supply and productivity of AIDS patients and their family members as well as related changes in income, time allocation, and school participation of children.

A study from Botswana provides evidence on the link between a worker's health status (measured by his/her cluster of differentiation 4 (CD4) count) and absenteeism in a given month, using measurements of the CD4 count at 0, 6, and 12 months after treatment initiation. The estimates provide robust evidence of an inverse V-shaped pattern in worker absenteeism around the time of ARV treatment inception. In the 1–5 years before the start of treatment, there is no difference in the rate of worker absenteeism before the start of treatment. At 12–15 months before the start of treatment, there is a sharp increase in absenteeism to approximately 20 days in the year before the start of treatment and a peak of 5 days in the month of treatment initiation (absence rate of 22%). Recovery is quick within the first year. At 1–4 years after treatment starts, treated workers have low rates of absenteeism similar to

nontreated workers. In Tamil Nadu, India, at 6 months after initiation of ART, AIDS patients were 10% points more likely to be economically active and worked 5.5 additional hours per week.

On the basis of data from rural Kenya, several researchers compare the change in the extensive and intensive margins of labor supply of patients on ARV and their household members. They document a 20% increase in the likelihood of patient participating in labor force and a 35% increase (7.9 h) in weekly hours worked within 6 months of treatment. Young boys in treated patients' households work significantly less after treatment initiation, whereas girls and adult household members do not change their labor supply. In the same setting in Kenya, with ARV treatment, females increase time for water and firewood collection, but decrease time on medical care translating into a lower burden on children with less time spent on housework and chores. Finally, based on the same longitudinal survey data from Kenya, weekly hours of school attendance of children, particularly for girls, in the patient's household increased by more than 20% within 6 months after ARV treatment was initiated for the adult patient. In Kenya, there is weaker evidence that the short-term nutritional status of young children also improves. However, in a recent study in Zambia, the researcher finds that adult access to ART resulted in increased weight-for-age and decreased incidence of stunting among children younger than 60 months of age.

At the Intersection of Prevention and Treatment: Disinhibition Behaviors

Part of the economics literature on HIV/AIDS has investigated disinhibition – or risk compensation – behaviors. The main proposition of this literature is that people may alter their behavior in response to perceived changes in risk. In the specific case of HIV/AIDS, the focus has been mainly related to the increased access to antiretroviral treatment. The concern is that increased access to ART may lead to a decrease in the perceived risk and costs of contracting HIV and, as a consequence, may lead to an increase of risky sexual behaviors. Such disinhibition behaviors, if large enough, may (at least partially) offset the benefits of scaling up access to ART. This conjecture is supported by several studies in the US and Europe, which have identified an upward trend in risky sexual behaviors since the introduction of ART in 1996. More specifically, an association has been identified between decreased concern about HIV due to ART availability and unprotected sex, and in particular among men who have sex with men.

Investigations of disinhibition behaviors in sub-Saharan Africa are limited. Studies exploring directly the behaviors of ART patients have generally concluded that there was no evidence of increase in risky behaviors after the ART initiation, even if sexual activity increased. One of the earliest studies looked at change in the use of condom by sex workers in Nairobi, Kenya. This analysis provided at least some suggestive evidence that condom use by sex workers decreased when 'fake' cures of AIDS were announced. Such a pattern is consistent with disinhibition behaviors, although the result may not be generalizable to the general population as it uses a much selected segment of the population. Another study used population-based surveys to test risk compensation behavior in the general population in a sub-Saharan African context. The researchers observed that in Kisumu (Kenya), ART-related risk compensation and the belief that ART cures HIV were associated with an increased HIV seroprevalence in men but not women. Others study the effect of increased access to ART on self-reported risky sexual behavior, using the data collected in Mozambique in 2007 and 2008. Controlling for unobserved individual characteristics, the findings support the hypothesis of disinhibition behaviors. In particular, risky behaviors are more positively associated with efficacious ART for family members of HIV-positive persons and for individuals from neighboring households, whereas disinhibition behaviors are not found among AIDS patients themselves.

Although disinhibition might more directly be a consequence of the availability of ART, disinhibition behaviors could also be present as a consequence of HIV prevention interventions. For example, one study advances that HTC might be effective in persuading HIV-positive individuals to reduce their risky behaviors and the risk of transmission of HIV to their partners, but potentially leads to disinhibition among those who receive an HIV-negative test result. Disinhibition should be considered and investigated in the case of male circumcision, treatment for prevention, and preexposure prophylaxis. In the case of male circumcision, it is possible that as a consequence of male circumcision – which is protective, but only to a certain extent – male individuals and their partners opt for less safe sexual practices and, for example, become less likely to use condoms or more likely to engage in concurrent partnerships. Another study discusses compensating behaviors related to male circumcision. The assessment is that the current empirical evidence does suggest that disinhibition is unlikely to substantially reduce the effectiveness of medical male circumcision. This assessment is based on the evidence from self-reported sexual behaviors of study participants in the randomized control trials that have established the efficacy of medical male circumcision. It would be important to assess the possibility of disinhibition from male circumcision interventions at scale.

Overall, it is fair to conclude that the evidence on disinhibition behaviors is limited and inconclusive. Several studies have provided a comprehensive review, with studies finding evidence of disinhibition and others not. The evidence is even more limited in sub-Saharan Africa but the potential risks associated with disinhibition on a large scale are important enough to be taken into consideration in further studies.

Conclusion

After reviewing the behavioral and socioeconomic determinants of HIV transmission, this article has focused on HIV prevention intervention and AIDS treatment. There is a tendency to present prevention and treatment as alternatives competing for scarce (donor) resources. However, HIV prevention remains crucial. Only by sustaining recent reductions in mortality and bringing down the number of new infections will the total number of people with HIV finally decline and will an AIDS transition be attainable.

It has been stressed that behavioral responses are very important mediators of HIV transmission and of the efficacy of HIV prevention and AIDS treatment. Currently, the field of HIV prevention is dominated by recent advances in biomedical interventions for HIV prevention such as male circumcision, treatment for prevention, and preexposure chemoprophylaxis. Though these interventions represent important breakthroughs, it is important to keep in mind potential behavioral responses, such as disinhibition to these interventions as well as the role that incentives can play. Further, it will be important to evaluate those interventions at scale. Such impact evaluations would not only confirm the external validity of the randomized control trials but also would allow learning what are the most effective delivery mechanisms for scaling up those interventions.

Home Health Services, Economics of

G David and D Polsky, University of Pennsylvania, Philadelphia, PA, USA

Introduction

Throughout the nineteenth century in the western world, home health care (HHC) existed to care for new mothers and those with infectious diseases. In the mid-twentieth century, HHC began to transform, as the proportion of older people in the general population steadily increased and with it the need for care for chronic degenerative diseases. The emergence of new medical innovation allowed the shift from facilities to the patient's residence and demographic trends such as a decrease in the size of families and a decline in families' colocation changed the social attitudes toward formal care. Finally, rising hospital costs led government to favor lower cost settings.

Although the trends described above are shared by most developed countries, the size of the home health sector as well as the way in which it is delivered, financed, and regulated varies across countries. Spending on home care accounts for a large proportion of resources spent on long-term care. According to 2009 data published by the Organization for Economic Co-operation and Development (OECD), spending on long-term care as a percent of gross domestic product (GDP) was as high as 2.72% in Denmark and as low as 0.84% in Spain. The US spends 0.98% of GDP on long-term nursing care, and approximately 40% of that on HHC.

Home health services are provided by agencies that are primarily engaged in providing skilled nursing or medical care in the home, under the supervision of a physician. The services provided can range from assisting with basic 'activities of daily living' (bathing, dressing, getting out of bed, and feeding oneself) to providing complex care. Skilled care can include audiology and speech pathology, dietary and nutritional services, drug services, home health aide, laboratory, medical social services, nursing, occupational therapy, and physical therapy.

Unlike the US, where a mix of public and private home health agencies (HHAs) provides both skilled nursing as well as home aide services, the organization of home health services is different in Europe. In some countries there is a divide, where skilled services are provided by the health care sector, whereas home aide services are provided by social services (e.g., Norway, Finland, and Sweden). In other countries, both skilled and nonskilled care are provided by either municipalities (e.g., UK, France, Italy, and Spain) or covered under social insurance and provided by a mix of governmental and private agencies (e.g., Germany and the Netherlands).

This article will both discuss the salient features of the home health industry, with a focus on the institutional structure in the US. The authors emphasize how these features pose challenges for economic analysis of competition, regulation, and integration. The typical way economists analyze hospital or nursing home markets to not always apply for HHC markets. In particular, the location in which services are rendered – the patient residence – changes the nature of competition, the ability to engage in effective monitoring, and the benefits of organizing services along the health care continuum.

Home Health Care Industry

Freestanding home care services of all types accounted for US$68.3 billion in annual expenditures in 2009, approximately 3% of all personal health care spending. The largest payer of HHC services is Medicare, accounting for 41%. The total coverage from all government sources is 80% because Medicaid covers 24% and other government sources cover 15%. Private insurance accounts for only 8% and most of the remainder is paid from out-of-pocket expenditure.

The Bureau of Labor Statistics estimated that 1 071 960 persons were employed in home health service sector in 2012. The central figure within home care agencies is the registered nurse. The RNs comprise approximately 15% of total home care employment and receive an annual median salary of US$63 850. Approximately 59% of jobs in this segment are in low-income service occupations, mostly home health aides and personal and home care aides. Home health aides, comprising the largest fraction of employees at 35%, receive an annual median salary of $20 560. Nursing and therapist jobs also account for substantial shares of employment in this segment. It should be noted that formal home health is just a fraction of home caregiving; more than one in three US households (an estimated 48.9 million caregivers more than age 18) are informal caregivers for a person older than age 18, with an additional 16.8 million caring for children or both children and adults, for a total of 65.7 million individual caregivers.

From an organizational perspective, there are 10 422 Medicare-certified HHAs. Approximately 85% of them are freestanding; the remainder are predominantly affiliated with hospitals. Approximately 70% of the freestanding HHAs were classified as proprietary or for-profit and the remaining freestanding HHAs were nonprofit agencies, including Visiting Nursing Associations, government or voluntary agencies, public agencies (typically run by the state or local government) and private nonprofits. There are HHAs that do not certify with Medicare but data on these facilities are sparse. HHC agencies are distinct from other home care organizations such as hospices where the focus is on care of terminally ill patients and their families, home care aide agencies where the focus is on assistance with activities of daily living, and home care equipment providers. Home-hospice, home infusion therapy, and home dialysis are outside the scope of this article. HHC agencies are also a distinct from other organized settings for postacute care. These other settings include skilled nursing facilities (SNFs), long-term care hospitals, and inpatient rehabilitation facilities.

The service lines of these HHAs are separated into personal care services (care provided by home health aids or personal

care for the elderly such as bathing, dressing when there is no concurrent need for skilled care, and homemaking), which are more likely to be covered by Medicaid and services to treat an illness or injury to regain independence which are covered by Medicare. Medicare home health services consist of skilled nursing care by a registered nurse or licensed practical nurse with supporting services by home health aides; therapy services including physical therapy, occupational therapy, and speech–language therapy; medical social services; and medical supplies. Home health visits typically last approximately 45 min. A typical clinical episode of care may be approximately a month, but payment is fixed as long as the clinical episode does not exceed 60 days. If the clinical episode needs to be extended beyond 60 days, there can be sequential 60-day payment episodes through recertification. Although there is great variation, there are approximately 12 visits on average during a typical clinical episode. Most of this article focuses on the Medicare service line, which is the largest segment of HHC services. However, Medicaid's role in home health has been growing rapidly as long-term nursing care is moving away from institutional settings and into community-based settings.

The Value Proposition for Home Health Services

Given that care in the home is less expensive to Medicare than care in a hospital or a SNF – in 2009, the average Medicare charges on a per day basis for hospital came to US$6 200, SNF was US$622, and home health Medicare charges averaged US$135/day – there are great opportunities for value in home health. Value is derived when home health can cost-effectively substitute for these more intensive locations of care or when home health services can play an important role in avoiding rehospitalizations during postacute care or hospitalizations for chronically ill patients. However, because standards for what constitutes appropriate or necessary care do not exist, the value of what gets delivered in home health on the margin is often questioned.

Empirically, value in home health is typically shown for select conditions where the evidence for home health is strongest (i.e., diabetes, chronic obstructive pulmonary disease, and congestive heart failure patients). Measured in 1995, savings accrued when home health was successfully substituted for more intensive sites of care in cases of pediatric AIDS (US$2263 per hospital per day vs. US$531 at home per day), respiratory care (US$188 909 per year at hospital vs. US$109 836 per year at home), and hip-fracture (savings of US$2300 per incident if home health used in conjunction with hospital care). For the majority of conditions, however, there are few studies that even attempt to demonstrate value. As a result, great geographic variations exist in home health.

Holding HHAs accountable for outcomes may be an avenue to improve both the quality of home health services and patient outcomes in general, but the measurement and assessment of outcomes in home health is a challenge. Although outcomes can be measured from the Outcome and Assessment Information Set (OASIS), there is no consensus regarding the outcomes that capture the effectiveness of home health. And more importantly, because outcomes are typically measured within HHC, home health outcomes are not compared to the alternative of reduced access to home care. This makes it difficult to assess whether improvements in staffing or increasing the number or coverage of agencies would, in fact, spillover to other services, for example, through reduced hospitalization rates.

Reimbursement under Medicare

Reimbursement Mechanism

To be eligible for Medicare's home health benefit, beneficiaries must need part-time (fewer than 8 h per day) or intermittent (temporary but not indefinite) skilled care to treat their illnesses or injuries and must be unable to leave their homes without considerable effort. Medicare does not require beneficiaries to pay copayments or a deductible for home health services. In the Balanced Budget Amendment of 1997, Medicare changed from paying a fee per home health visit to a Prospective Payment System (PPS). Under the PPS system, which began in 2000 after a 3-year interim system, Medicare pays a fixed amount for HHC in 60-day episodes. These Medicare payment episodes begin when patients are admitted to HHC. Patients who complete their course of care before 60 days have passed are discharged. If they do not complete their care within 60 days, another episode starts and Medicare makes another episode payment. As long as they meet the eligibility standards for the benefit, beneficiaries may receive an unlimited number of consecutive home health episodes. Medicare adjusts the payment based on several factors including measures of patients' clinical and functional severity and the use of therapy during the home health episode. This case-mix adjusted payment rate is similar to the Medicare SNF and inpatient hospital PPS's. However, a major difference among the systems is the unit of payment. SNFs are paid by the day, whereas the home health PPS pays by the 60-day episode. In 2009, the Medicare payment per user of home health was US$5748. This was up from US$3803 in 2002.

Yet the system will continue to be changed as savings are sought within Medicare. One reason for this is that HHAs continued to be paid by Medicare significantly above cost, with margins of 16.6% in 2007 though there have been recent changes that include a payment-rate update that represents a 5% decrease and caps on outlier payments. Several changes were part of health care reform that have expanded the role of the physician so that a physician face-to-face encounter is now a requirement for certification of eligibility for home health services, the final rule provided that the encounter must occur with the 90 days before start of care, or within the 30 days after. This is a means of increasing physician accountability and providing an additional check on beneficiaries' eligibility for home health benefits.

Incentives Created by Reimbursement Mechanism

The shift from per-visit payment to prospective payment shifted incentives from rewarding the number of visits, which can lead to a more intensive pattern of visits, to rewarding a limited number of visits within an episode, but encouraging expansion through the number of episodes. Care patterns

appear to be very sensitive to the payment system. For example, during the interim period (Interim Payment System (IPS)) between the end of per-visit payment and the beginning of PPS, there was an annual reduction of 1.3 million HHC episodes with a 30% decline in the number of Medicare-certified HHAs. However, PPS did not have the same disincentive for visits as the IPS as the PPS scheme includes lower payments if 5 visits are not achieved and enhanced payments when therapy visits exceed 10 visits. As a result the transition from IPS to PPS has resulted in an increase in both episodes and agencies.

Various changes to reimbursement design illustrate the influence of incentives in determining where Medicare beneficiaries receive postacute care. The results of switching from fee-for-service (FFS) to PPS were profound, suggesting highly elastic patterns based on reimbursement design. When the Balanced Budget Act (BBA) was passed and the IPS was implemented after years of FFS, the industry changed rapidly. In addition to heavily cutting reimbursement rates, the IPS ended a period in which providers had no little incentive to control the amount of service per user. After the IPS's enactment, a trend emerged in which patients were shifted from HHAs and SNFs to having no formal care. Also, because reimbursement was not case-mix adjusted, the IPS created backward incentives for HHAs to cut service to high-cost patients. HHAs that did not use strategic admission of low-cost patients suffered the risk of insolvency. Furthermore, the scale of the industry responded quickly and intensely: The number of active agencies decreased by 20% after IPS. Between 1996 and 1999, the number of new agencies declined by a drastic 86%, and the number of terminated agencies increased by 523%. In 1996, the ratio of terminated HHAs to new HHAs was less than 1, but 1997 after the IPS, terminated HHA's outnumbered new HHA's 9 to 1. The industry is highly reactive to reimbursement changes, and the roughly 30% of the decline in HHAs between 1997 and 2001 has been attributed to changes in Medicare home health coverage and reimbursement enacted as part of the BBA.

The PPS, introduced in October 2000, continued prospective payment but adjusted for case-mix when determining reimbursement payments. By replacing the IPS with the PPS's risk-adjusted episode system, Medicare alleviated HHAs' financial risk of treating patients. The PPS reversed some of the IPS's impacts: From 1999 to 2002, the number of new HHAs increased 78% and the number of HHA termination fell by 88%. By 2002, the PPS had stopped the contraction of HHAs providers, and more agencies were added than terminated. However, throughout both the IPS and PPS, proprietary and freestanding HHAs experienced greater volatility. Not until 2009, with 10 581 agencies, did the number of HHAs surpass that of 1997. With respect to quality, the Office of Inspector General found that the change in the reimbursement system did not lead to increased use of hospital and ER services. Recently MedPAC has responded to the HHC industry's high margins (16.6% in 2007), which it feels undermine the efficiency goals of a PPS. Consequently, it has recommended cuts in reimbursement rates.

Even before the BBA there was strong evidence of drastic industry responses to incentive changes. A 1987 court case, Duggen versus Bowen, resulted in changes in reimbursement and incentive changes. Before 1986, Medicare suffered from excessive administrative complexity and unreliable reimbursements. The lawsuit's success contributed to increased annual Medicare home health outlays and a doubling of the number of Medicare-Certified HHAs between 1989 and 1996. Additionally, growth of the HHC services industry was 18%, whereas it was 7.2% for the total US health care services.

Managed Care in Home Health

After the passage of the Medicare Modernization Act, Medicare Advantage enrollment has increased rapidly. As of February 2010, 25.2% of Medicare beneficiaries were enrolled in Medicare Advantage.

Incentivized by the increasingly competitive nature of the health care industry, HHAs have entered into managed care provider networks. However, the extent to which HHAs participate in managed care is largely unstudied. An early study by Center for Medicare and Medicaid Services (CMS's) predecessor, Health Care Financing Administration, found that managed care patients used less home health resources but also had worse outcomes when compared with FFS patients. Further research is needed on the effect of managed care plans on outcomes in HHC.

The Nature of Competition

The most salient distinctive feature of HHC is the site of care. With services delivered in the home rather than in a centralized facility, the nature of competition is different. For hospitals and physician offices, location provides a degree of market power that does not exist for HHAs because the consumers do not face travel costs when receiving home health services. Travel costs, in both emergencies and nonemergencies, lead most consumers to prefer a closer provider and similarly for admitting and referring physicians. Without location as a natural barrier to competition, home health markets are expected to be highly competitive.

Quality of care in home health may be more important for agency choice because consumers do not need to tradeoff quality off against distance, as is the case for hospitals, nursing homes, ambulatory surgery centers, and other facilities. Studies of hospitals and other health care facilities have shown distance to be an important factor in the choice of health care provider. For example, the effect of distance to provider for mental health institutions was found to overshadow other incentives to initiate treatment. Similarly, patients often prefer to receive care at a near hospital, even if it has higher mortality rates and less experience with certain procedures. Distance to nearest hospital was shown to significantly impact utilization of preventative care, psychiatric, geriatric, and elective surgery and had a much stronger effect on the probability of hospital choice than waiting time. Moreover, physicians typically mention in surveys that the hospital's location strongly influences their decision on where to admit patients. Geographic proximity was found to be a strong predictor of whether or not a physician utilizes a hospital.

In classic spatial models of competition each firm chooses a location such that it attracts the profit maximizing amount of consumers. In markets for services such as HHC or home repair the site of exchange is the consumer's home and although proximity to consumers remains the source of market power, it is the firms who engages in travel. Under fixed prospective payments, the firm bears the costs of travel. When firms choose a price schedule, discriminatory pricing occurs if the firm bears the transportation cost. More importantly, the notion of a marginal consumer (a consumer that is indifferent between traveling to the closest firm to her right and the closest firm to her left), is different than the one in Salop (1979). Here the marginal consumer is the one that makes the firm indifferent between serving her or not, and as such does not directly defines the boundaries of the demand for the firm (unless the firm is a local monopoly). Therefore, multiple firms may compete for the same consumers in equilibrium.

Because provision of care takes place in patients' homes, service delivery in this industry is both labor-intensive and decentralized. These two features have a potentially important effect on the nature of competition in HHC markets. The fact that there are few capital requirements lowers the barriers to entry. In the next section the authors discuss the fact that states have imposed an artificial barrier to competition by restricting the creation of new HHAs through Certificate of Need (CON) regulation. The decentralized nature of service delivery has two important effects: First, because patients are 'matched' to a home aide, nurse, or therapist by agencies, switching costs within and across agencies may be similar. Secondly, monitoring quality of care is difficult for both agencies and regulatory bodies.

Nature, Roles, and Impacts of Regulation

Entry Regulation through Certificate-of-Need Laws

Although states universally adopted CON for hospitals in the 1970s, 38 states also applied CON regulation to the HHC sector. When the federal mandate was repealed in 1987, only 18 states continued active CON regulations for HHC. Interestingly, the lessons from hospitals will not necessarily apply to home health. Unlike hospitals, SNFs, or physician offices, where location provides a degree of market power, HHAs deliver services at the patient residence. Without location as a natural barrier to competition, one might expect home health markets to be a highly competitive. Similarly, unlike hospitals and other facilities that require major capital investments in order to become operational, HHC is labor intensive and is expected to be highly competitive absent of entry regulation.

CON for hospitals, nursing homes, and rehabilitation centers were designed to give state governments the authority to restrict the construction of new and expansions to existing facilities, as well as the purchase of expensive technology. These restrictions were designed to prevent overutilization and duplication of services and ensure quality by centralizing medical services to high-volume facilities. Although acquisition or expansion of hospitals requires large capital investments, home health is a labor intensive industry with little capital investment and no evidence of a volume-outcome relationship. Therefore, there is no reason to expect an effect of CON on expenditures, costs, procedure volume, or mortality. Moreover, CON for home health, operates as a mechanism for restricting entry of new agencies. Most states with CON regulations follow specific policies and guidelines for the approval of additional HHAs in a given market, but in practice new agencies are rarely approved, leaving markets in CON-regulated states uncontested by potential entrants. CON laws serve as an artificial barrier on the number of competitors in a given market. Unlike in the case of hospitals, it is nearly impossible for a potential entrant to demonstrate 'need,' as incumbent agencies are not constrained by capacity and have no hurdles when it comes to expansion of services. Not surprisingly, CON states have almost half the number of Medicare-certified agencies compared to non-CON states although Medicare expenditures are similar in CON and non-CON states.

An alternative rationale for CON programs in home health is that they can improve quality of care through enhanced ability to monitor agencies. With fewer agencies, state regulators may be more effective at having a positive influence on the quality of care delivered by the HHAs in their state. However, although HHC in CON states was found to be less intensive (lower frequency of visits and lower skill mix), to date there is no evidence to suggest CON in HHC is quality enhancing. This may not be surprising, as the number of evidence-based standards of care in home health on which effective quality regulation can be based is limited.

Price Regulation

As discussed in Section Reimbursement under Medicare, the price of a 60-day home health episode is fixed and set at admission according to the severity of the patient's condition. Because prices are regulated, providers can no longer compete for patients based on price of services and instead compete for patients on the quality of their services. Economic theory suggests that market competition in the presence of regulated prices can drive up quality. Indeed, most empirical studies of the relationship between competition and quality under regulated prices in the case of dialysis centers and hospitals found more competition to result in higher quality (as measured by lower mortality).

Although the effect of market concentration on quality has been studied extensively in the hospital sector, this relationship has received little attention in the HHC industry. Some studies focused on the effect that Medicare PPS for home health services had on market concentration. One study has found that reimbursement cuts under IPS and PPS led to massive closure of HHAs, which found it difficult to remain fiscally viable. Moreover, states with higher barriers to entry through CON laws showed relatively lower rates of agency termination.

The Role of Integration

Vertical integration of acute care sites (i.e., hospitals) into postacute care (e.g., SNFs, rehabilitation centers, and HHAs) is

common and has the potential to influence the nature of health interventions. Vertical integration increased dramatically during the 1990s, with three-quarters of hospitals integrated with postacute care in 2001. Although patient care is produced along a care continuum, which includes both acute and postacute care entities, reimbursement for entities along the same continuum does not incorporate the fact that patient outcomes depend on the entire patient experience, including the transition between facilities. Vertical integration has the potential to correct such distortions, and is a key feature of the Accountable Care Organization concept.

Environmental changes in health care in the form of PPS's, managed care, and aging of the population have resulted in greater interdependence among acute and postacute providers. Although postacute care has been described as highly fragmented and with much redundancy, the increase in the level of interdependence among contracting parties increases the costs of external market exchange and favors integration. From an efficiency perspective, vertical integration in the health care sector can reduce transaction costs, and raise quality of care due to greater coordination and continuity of care.

Another study looked at vertical integration of hospitals and SNFs before and after the introduction of PPS for hospitals. PPS produced strong incentives to reduce costs per admission by shortening the average length of patient stays, which in turn created a new dependency of hospitals on nursing homes. The price paid to the nursing home to accept a hospital patient is established unilaterally by Medicare and therefore cannot be negotiated between the hospital and the nursing home. Hence, vertical integration becomes the only feasible route to affect the implicit transfer prices governing patient flows between the hospital and its own nursing home division. Hospitals with larger fractions of their patients covered by Medicare were significantly more likely to integrate vertically into nursing home services than were hospitals with proportionately fewer Medicare patients. A similar argument was put forth in another study, which concludes that financial pressure was the key driver leading to vertical integration of hospitals and HHAs in the mid-80s. As environmental pressures increase, hospitals benefited from tighter linkages with home health providers. Furthermore, an even earlier study compared the medical process at two hospitals, one with and one without a home nursing department. Regression analysis showed that home nursing care significantly reduced both the length of hospital stays and the number of follow-up visits to outpatient clinics. After accounting for the cost of the home nursing program, however, the program did not significantly reduce overall hospital expenditures.

Consistent with these findings, in a recent paper the authors introduce a theoretical framework, in which vertical integration allows hospitals to shift patient recovery tasks downstream to lower cost delivery entities (e.g., SNFs or HHAs) by discharging patients earlier. Because integrated hospitals fully control the postacute tier, they can ensure that patients discharged earlier and in poorer health receive greater posthospitalization service intensity. Although integration facilitates a change in the timing of hospital discharge, health outcomes are no worse when patients receive care from an integrated provider. It is shown that vertically integrated hospitals tend to discharge patients to their own HHAs sooner, with poorer health at the time of transition out of the hospital, yet with similar overall health outcomes. The authors used rehospitalization rate within 60 days of hospital discharge as the outcome variable. According to a recent report to Congress, "Hospital readmissions are sometimes indicators of poor care or missed opportunities to better coordinate care. Research shows that specific hospital-based initiatives to improve communication with beneficiaries and their other caregivers, coordinate care after discharge, and improve the quality of care during the initial admission can avert many readmissions." The Hospital Readmissions Reduction Program is a new Medicare program that establishes a financial incentive for hospitals to lower readmission rates. Under the program, Medicare's base operating diagnosis-related group payment amounts will be reduced for hospitals with excess readmissions.

The Use of Technology in Home Health Care

Telemedicine is a term used to cover a broad category of services, defined by the Institute of Medicine as "the use of electronic information and communications technologies to provide and support health care when distance separates the participants." The term is also applied more narrowly to medical care that uses interactive video, generally for consultations with specialists. However, telemedicine (or more generally, telehealth) is also comprised of the transmission of still images, e-health including patient portals, remote monitoring, medical education, and nursing call centers.

In the 1960s, the first uses of electronic telemedicine were to support neurologic and psychiatric services in Nebraska. With the exception of teleradiology, its adoption by physicians since then has been slow. Some of the main difficulties are licensing providers across state lines, liability concerns, reimbursement concerns, and physician awareness. From the 1960s through the 1990s, telemedicine consisted mostly of specialty consultations though videoconference technology. The millennium, however, saw more attention focused on noninteractive data storage and transmission. The thawing of Medicare's and other insurers' collective reluctance to cover telemedicine helped contribute to the 2000s' expansion. Both interactive and noninteractive technologies are increasingly used for remote monitoring of health status in homes.

Remote patient monitoring (RPM), or 'home telehealth,' is a subset of telemedicine that includes technology in a patient's home that records biometric data and transmits it to a central monitoring facility for interpretation. Consequently, patients can receive monitoring that might otherwise require physical nurse visits or trips to outpatient or inpatient facilities. Currently, Medicare spending on telemedicine is tracked as a whole, but not by class. Teleradiology has the largest expenditures, but the total amount is not documented, nor is it for RPM. Medicare reimburses for remote cardiac monitoring technologies and remote screening. Videoconference technology for rural patients has seen rapid growth, but it is still underutilized with less than US$1 million in expected reimbursements for 2011. Home telemedicine (and delivery for it) is paid for under the prospective payment reimbursement system.

An early and successful application of RPM was in heart monitoring, which culminated in greater safety for at-risk, rural-dwelling patients. RPM has rendered home health more likely to be substitutable for medical treatment in a more intensive location. By lifting the burden of face-to-face contact between providers and patients, telemedicine in theory should be access expanding, cost-effective, and quality improving. There is evidence that access has improved as technology enabled rural patients now receive care that was once too costly and impractical to provide, but there are no well-controlled studies that demonstrate cost-effectiveness or quality improvement with these technologies.

RPM is characterized by large, up-front costs to acquire the capital, the need for highly trained labor to operate it, and the integration of care with response teams and specialists. An important potential limitation of delivering RPM in a cost-effective system is related to the way care is reimbursed in Medicare. If home health providers cannot recover the added capital expense of RPM, they may underinvest. But if home health providers are reimbursed for RPM at a higher rate there may not be sufficient controls to only use this technology in those patients who would gain the most from it. The challenge is for hospitals to work more effectively with providers and technology developers. When determining reimbursement for RPM, it is important to consider the true costs of the alternative form of care and to align incentives such that those making decisions about the course of treatment are not penalized for selecting treatment patterns that may save the system money. The ideas behind Accountable Care Organizations where savings to Medicare are shared among providers may create the environment for a more cost-effective use of telehealth.

The Nature, Role, and Impact of Quality Initiatives in Home Health Care

Quality in health care is significant because it greatly impacts an individual's well-being and is more influential on well-being than quality of most other goods and services. Prompted by consumers, providers, and the growing body of evidence about the poor quality of health care, policymakers developed a strong interest in designing and implementing system-wide, market-based reforms to promote quality in health care. CMS implemented quality reporting in HHC in 2003 and has a demonstration project testing pay for performance in home health.

Public Reporting in Home Health: Home Health Compare

The public reporting initiative in home health started in October of 2003 when CMS launched a website called Home Health Compare. This website posts quality performance information for HHAs that serve a particular zip code. The quality measures generally measure how well the patients of an HHA regain or maintain their ability to function. There are 10 quality measures posted on HHC which come from a subset of larger set of 41 OASIS outcome measures that are well known to the HHAs, including improvements in ambulation, bathing, transferring, management of oral medication, pain interfering with activity, dyspnea (shortness of breath), and urinary incontinence, as well as measures of acute care hospitalization, emergent care, and discharge to community. The emphasis of this initiative was to give consumers information regarding the quality of care provided by HHAs. Other similar initiatives, such as Hospital and Nursing Home Quality Initiatives, suggest that measured quality improves in response with these two initiatives.

In HHC, there are two pathways for which quality to be improved. The first is 'selection,' which is that knowledge about performance leads patients, their payers, and agents engaged in referrals to be more likely to select higher quality providers. This will raise average quality in a market because a greater share of patients receives care from high performers. The second pathway is 'change' which is that more information in the hands of stakeholders creates motivation for organizations and their providers to improve quality and that more feedback about performance within an organization can also lead to positive change.

There is limited research on the environments in which HHC will be most effective. Although competition's effect on quality has been studied extensively in the hospital sector, it has not yet been in home health. HHC should be studied separately because with services delivered in the home rather than in the facility of the provider – the nature of competition is different. Theoretically, patients in more competitive markets will have higher quality based on conduct measures (visits per admission) and performance measures (improved functional outcomes and fewer adverse events). Furthermore, HHC should result in quality improvement, and competitive markets should have greater quality improvement in outcomes. The only evidence currently available comes from the initial demonstration project for HHC which did show some improvement in quality.

Pay-for-Performance

In 2003, MedPAC recommended that Medicare reward providers who provide 'high-quality care or improve the quality of care for their patients.' Pay-for-performance ties a direct financial payment to performance on selected quality measures and creates incentives for individual providers to improve the quality of care. The program aims to reward quality where it is possible to measure. In home health, the measures based on currently mandatory patient evaluations met the proposed criteria. MedPAC seeks to make sure that measure sets are not fixed and that they progress to integrate new measures and to eliminate any obsolete or ineffective measures.

Readmissions reduction payments have been considered as well. With respect to lowering readmissions, hospitals are the most obvious focus, but in a 2007 report, MedPAC focused on aligning incentives across all with influence on outcomes. However, there is disagreement over the best way to reward reductions in hospital readmissions. It can be done by directly penalizing or rewarding hospitals or secondary means of reduction, such as RPM and HHC improvements.

In 2007, a P4P pilot was implemented in seven states been 2008 and 2009. The 'incentive pool' used to fund the program

was generated from savings due to less utilization of costly Medicare services. The payout structure was setup such that 75% of the pool went to agencies in the top 20% of the highest level of patient care and 25% of the pool went to the top 20% of those making the biggest improvements in patient care. If there were no savings, there would be no compensation. Results: for 2008, aggregate Medicare savings were US$15.4 million for three of four regions, with the Midwest region not achieving any savings. The demonstration is still under evaluation.

Acknowledgements

The authors are grateful to Richard Chesney, Bruce Kinosian, and Rachel Werner for their feedback during the development of the ideas in this article. Special Thanks to Robert Sanders who provided exceptional skilled research assistance to the writing of this article. This work is supported by NIH/NHLBI grant #R01 HL088586-01.

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is arranged as a series of articles in alphabetical order.

There are four features to help you easily find the topic you're interested in: an alphabetical contents list, cross-references to other relevant articles within each article, and a full subject index.

1 Alphabetical Contents List

The alphabetical contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

2 Cross-References

Most of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an entry as a See also list, serve four different functions:

i. To draw the reader's attention to related material in other entries.
ii. To indicate material that broadens and extends the scope of the article.
iii. To indicate material that covers a topic in more depth.
iv. To direct readers to other articles by the same author(s).

Example

The following list of cross-references appears at the end of the entry Abortion.

> *See also*: Education and Health in Developing Economies. Fertility and Population in Developing Countries. Global Public Goods and Health. Infectious Disease Externalities. Nutrition, Health, and Economic Performance. Water Supply and Sanitation

3 Index

The index includes page numbers for quick reference to the information you're looking for. The index entries differentiate between references to a whole entry, a part of an entry, and a table or figure.

4 Contributors

At the start of each volume there is list of the authors who contributed to that volume.

SUBJECT CLASSIFICATION

Demand for Health and Health Care

Collective Purchasing of Health Care
Demand Cross Elasticities and 'Offset Effects'
Demand for Insurance That Nudges Demand
Education and Health: Disentangling Causal Relationships from Associations
Health Care Demand, Empirical Determinants of
Medical Decision Making and Demand
Peer Effects, Social Networks, and Healthcare Demand
Physician-Induced Demand

PREFACE

What Do Health Economists Do?

This encyclopedia gives the reader ample opportunity to read about what it is that health economists do and the ways in which they set about doing it. One may suppose that health economics consist of no more than the application of the discipline of economics (that is, economic theory and economic ways of doing empirical work) to the two topics of health and healthcare. However, although that would usefully uncouple 'economics' from an exclusive association with 'the (monetized) economy,' markets, and prices, it would miss out a great deal of what it is that health economists actually do, irrespective of whether they are being descriptive, theoretical, or applied. One distinctive characteristic of health economics is the way in which there has been a process of absorption into it (and, undoubtedly, from it too); in particular, the absorption of ideas and ways of working from biostatistics, clinical subjects, cognitive psychology, decision theory, demography, epidemiology, ethics, political science, public administration, and other disciplines already associated with 'health services research' (HSR) and, although more narrowly, 'health technology assessment' (HTA). But to identify health economics with HSR or HTA would also miss much else that health economists do.

… And How Do They Do It?

As for the ways in which they do it, in practice, the overwhelming majority of health economists use the familiar theoretical tools of neoclassical economics, although by no means all (possibly not even a majority) are committed to the welfarist (specifically the Paretian) approach usually adopted by mainstream economists when addressing normative issues, which actually turns out to have been a territory in which some of the most innovative ideas of health economics have been generated. Health economists are also more guarded than most other economists in their use of the postulates of soi-disant 'rationality' and in their beliefs about what unregulated markets can achieve. To study healthcare markets is emphatically not, of course, necessarily to advocate their use.

A Schematic of Health Economics

To think of health economics merely in these various restricted ways would be indeed to miss a great deal. The broader span of subject matter may be seen from the plumbing diagram, in which I have attempted to illustrate the entire range of topics in health economics. A version of the current schematic first appeared in Williams (1997, p. 46). The content of the encyclopedia follows, broadly, this same structure. The arrows in the diagram indicate a natural logical and empirical order, beginning with **Box A** (Health and its value) (**Figure 1**).

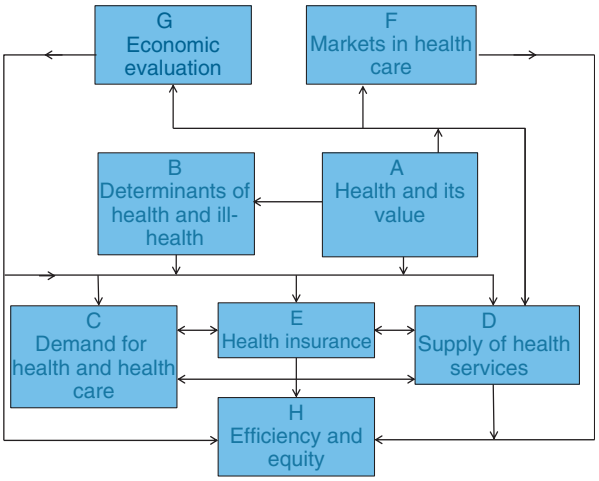

Figure 1 A schematic of health economics.

Box A, in the center-right of the schematic, contains fundamental concepts and measures of population health and health outcomes, along with the normative methods of welfarism and extra-welfarism; measures of utility and health outcomes, including their uses and limitations; and methods of health outcome valuation, such as willingness to pay and experimental methods for revealing such values, and their uses and limitations. It includes macro health economic topics like the global burden of disease, international trade, public and private healthcare expenditures, Gross Domestic Product (GDP) and healthcare expenditure, technological change, and economic growth. Some of the material here is common to epidemiology and bioethics.

Box A Health and its value

Concepts and measures of population health and health outcomes.
Ethical approaches (e.g., welfarism and extrawelfarism).
Measures of utility and the principal health outcome measures, their uses, and limitations.
Health outcome valuation methods, willingness to pay, their uses, and limitations.
Macro health economics: global burdens of disease, international trade, healthcare expenditures, GDP, technological change, and economic growth.

Box B (Determinants of health and ill health) builds on these basics in various 'big-picture' topics, such as the population health perspective for analysis and the determinants of lifetime health, such as genetics, early parenting, and schooling; it embraces occupational health and safety, addiction (especially tobacco, alcohol, and drugs), inequality as a determinant of ill health, poverty and the global burden of disease in low- and middle-income countries, epidemics, prevention, and public health technologies. Here too, much is

Box B Determinants of health and ill health

The population health perspective.
Early determinants of lifetime health (e.g., genetics, parenting, and schooling).
Occupational health and safety.
Addiction: tobacco, alcohol, and drugs.
Inequality as a determinant of ill health.
Poverty and global health (in LMICs).
Epidemics.
Prevention.
Public health technologies.

shared, both empirically and conceptually, with other disciplines.

From this it is a relatively short step into **Box C** (Demand for health and healthcare): here we are concerned with the difference between demand and need; the demand for health as 'human capital'; the demand for healthcare (as compared with health) and its mediation by 'agents' like doctors on behalf of 'principals'; income and price elasticities; information asymmetries (as in the different types of knowledge and understandings by patients and healthcare professionals, respectively) and agency relationships (when one, such as a health professional, acts on behalf of another, such as a patient); externalities or spillovers (when one person's health or behavior directly affects that of another) and publicness (the quality which means that goods or services provided for one are also necessarily provided for others, like proximity to a hospital); and supplier-induced demand (as when a professional recommends and supplies care driven by other interests than the patient's).

Box C Demand for health and healthcare

Demand and need.
The demand for health as human capital.
The demand for healthcare.
Agency relationships in healthcare.
Income and price elasticities.
Information asymmetries and agency relationships.
Externalities and publicness.
Supplier-induced demand.

Then comes **Box D** (Supply of healthcare) covering human resources; the remuneration and behavior of professionals; investment and training of professionals in healthcare; monopoly and competition in healthcare supply; for-profit and nonprofit models of healthcare institutions like hospitals and clinics; health production functions; healthcare cost and production functions that explore the links between 'what goes in' and 'what comes out;' economies of scale and scope; quality of care and service; and the safety of interventions and modes of delivery. It includes the estimation of cost functions and the economics of the pharmaceutical and medical equipment industries. A distinctive difference in this territory from many other areas of application is the need to drop the assumption

Box D Supply of health services

Human resources, remuneration, and the behavior of professionals.
Investment and training of professionals in healthcare.
Monopoly and competition in healthcare supply.
Models of healthcare institutions (for-profit and nonprofit).
Health production functions.
Healthcare cost and production functions.
Economies of scale and scope.
Quality and safety.
The pharmaceutical and medical equipment industries.

of profit-maximizing as a common approach to institutional behavior and to incorporate the idea of 'professionalism' when explaining or predicting the responses of healthcare professionals to changes in their environment.

Supply and demand are mediated (at least in the high-income world) by insurance: the major topic of **Box E** and a large part of health economics as practiced in the US. This covers the demand for insurance; the supply of insurance services and the motivations and regulations of insurance as an industry; moral hazard (the effect of insurance on utilization); adverse selection (the effect of insurance on who is insured); equity and health insurance; private and public systems of insurance; the welfare effects of soi-disant 'excess' insurance; effects of insurance on healthcare providers; and various specific issues in coverage, such as services to be covered in an insured bundle and individual eligibility to receive care. Although the health insurance industry occupies a smaller place in most countries outside the US, the issues invariably crop up in a different guise and require different regulatory and other responses.

Box E Health insurance

The demand for insurance.
The supply of insurance services.
Moral hazard.
Adverse selection.
Equity and health insurance.
Private and public systems.
Welfare effects of 'excess' insurance.
Effects of insurance on healthcare providers.
Issues in coverage: services covered and individual eligibility.
Coverage in LMICs.

Then, in **Box F**, comes a major area of applied health economics: markets in healthcare and the balance between private and public provision, the roles of regulation and subsidy, and the mostly highly politicized topics in health policy. This box includes information and how its absence or distortion corrupts markets; other forms of market failure due to externalities; monopolies and a catalog of practical difficulties both for the market and for more centrally planned systems; labor markets in healthcare (physicians, nurses, managers, and allied professions), internal markets (as when the public sector of healthcare is divided into agencies that commission care on behalf of populations and those that

Box F Markets in healthcare

Information and markets and market failure.
Labor markets in healthcare: physicians, nurses, managers, and allied professions.
Internal markets in the healthcare sector.
Rationing and prioritization.
Welfare economics and system evaluation.
Comparative systems.
Waiting times and lists.
Discrimination.
Public goods and externalities.
Regulation and subsidy.

provide it); rationing and the various forms it can take; welfare economics and system evaluation; waiting times and lists; and discrimination. It is here that many of the features that make healthcare 'different' from other goods and services become prominent.

Box G is about evaluation and healthcare investment, a field in which the applied literature is huge. It includes cost-benefit analysis, cost-utility analysis, cost-effectiveness analysis, and cost-consequences analysis; their application in rich and poor countries; the use of economics in medical decision making (such as the creation of clinical guidelines); discounting and interest rates; sensitivity analysis as a means of testing how dependent one's results are on assumptions; the use of evidence, efficacy, and effectiveness; HTA, study design, and decision process design in agencies with formulary-type decisions to make; the treatment of risk and uncertainty; modeling made necessary by the absence of data generated in trials; and systematic reviews and meta-analyses of existing literature. This territory has burgeoned especially, thanks to the rise of 'evidence-based' decision making and the demand from regulators for decision rules in determining the composition of insured bundles and the setting of pharmaceutical prices.

Box G Economic evaluation

Decision rules in healthcare investment.
Techniques of cost-benefit analysis in health and healthcare.
Techniques of cost-utility analysis and cost-effectiveness analysis in health and healthcare in rich and poor countries.
Techniques of cost-consequences analysis.
Decision theoretical approaches.
Outcome measures and their interpretation.
Discounting.
Sensitivity analysis.
Evidence, efficacy, and effectiveness.
Economics and health technology assessment.
Study design.
Risk and uncertainty.
Modeling.
Systematic reviews and meta-analyses.

The final Box, H, draws on all the preceding theoretical and empirical work: concepts of efficiency, equity, and possible conflicts between them; inequality and the socioeconomic 'gradient;' techniques for measuring equity and inequity; evaluating efficiency at the system level; evaluating equity at system level: financing arrangements; evaluating equity at system level: service access and delivery; institutional arrangements for efficiency and equity; policies against global poverty and for health; universality and comprehensiveness as global objectives of healthcare; and healthcare financing and delivery systems in low- and middle-income countries (LMICs). This is the most overtly 'political' and policy-oriented territory.

Box H Efficiency and equity

Concepts of efficiency, equity, and possible conflicts.
Inequality and the socioeconomic 'gradient.'
Evaluating efficiency: international comparisons.
Techniques for measuring equity and inequity.
Evaluating equity at system level: financing arrangements.
Evaluating equity at system level: service access and delivery.
Institutional arrangements for efficiency and equity.
Global poverty and health.
Universality and comprehensiveness.
Healthcare financing and delivery systems in LMICs.

A Word on Textbooks

The scope of a subject is often revealed by the contents of its textbooks. There are now many textbooks in health economics, having various degrees of sophistication, breadth of coverage, balance of description, theory and application, and political sympathies. They are not reviewed here but I have tried to make the (English language) list in the Further Reading as complete as possible. Because the assumptions that textbook writers make about the preexisting experience of readers and about their professional backgrounds vary, not every text listed here will suit every potential reader. Moreover, a few have the breadth of coverage indicated in the schematic here. Those interested in learning more about the subject to supplement what is to be gleaned from the pages of this encyclopedia are, therefore, urged to sample what is on offer before purchase.

Acknowledgments

My debts of gratitude are owed to many people. I must particularly thank Richard Berryman (Senior Project Manager), at Elsevier, who oversaw the inception of the project, and Gemma Taft (Project Manager) and Joanne Williams (Associate Project Manager), who gave me the most marvelous advice and support throughout. The editorial heavy lifting was done by Billy Jack and Karen Grépin (Global Health); Aki Tsuchiya and John Wildman (Efficiency and Equity); John Cawley and Kosali Simon (Determinants of Health and Ill health); Richard Cookson and Mark Suhrcke (Public Health); Erik Nord (Health and its Value); Richard Smith (Health and the

Macroeconomy); John Mullahy and Anirban Basu (Health Econometrics); Tom McGuire (Demand for Health and Healthcare); John Nyman (Health Insurance); Jim Burgess (Supply of Health Services); Martin Gaynor and Sean Nicholson (Human Resources); Patricia Danzon (Pharmaceutical and Medical Equipment Industries); Pau Olivella and Pedro Pita Barros (Markets in Healthcare); and John Brazier, Mark Sculpher, and Anirban Basu (Economic Evaluation). Finally, my thanks to the Advisory Board: Ron Akehurst, Andy Briggs, Martin Buxton, May Cheng, Mike Drummond, Tom Getzen, Jane Hall, Andrew Jones, Bengt Jonsson, Di McIntyre, David Madden, Jo Mauskopf, Alan Maynard, Anne Mills, the late Gavin Mooney, Jo Newhouse, Carol Propper, Ravindra Rannan-Eliya, Jeff Richardson, Lise Rochaix, Louise Russell, Peter Smith, Adrian Towse, Wynand Van de Ven, Bobbi Wolfe, and Peter Zweifel. Although the Board was not called on for frequent help, their strategic advice and willingness to be available when I needed them was a great comfort.

Illegal Drug Use, Health Effects of

JC van Ours, Tilburg University, Tilburg, The Netherlands and University of Melbourne, Melbourne, VIC, Australia
J Williams, University of Melbourne, Melbourne, VIC, Australia

Introduction

The potential health risks associated with using illicit drugs remain the key argument for maintaining their criminal status. And although many studies find that drug users are in worse health than nonusers, the proper interpretation of this evidence is contentious. This is because, in order to conclude that it is in fact their drug use that causes them poor health, two alternative explanations for the association must be eliminated. This issue is not new. Determining the true nature of the relationship between drug use and health has a long history. An early example of a discussion of the issues can be found in the 1894 Indian Hemp Commission Report (Kendell, 2003). The first alternative explanation is referred to as reverse causality. Under reverse causality, the observed relationship between drug use and poor health runs in the reverse direction – from poor health to drug use. This may occur if, for example, people use illegal drugs to treat symptoms of their illness. The second alternative explanation is referred to as spurious correlation. This is an issue if there exists an unobserved factor, for example, childhood abuse, which causes both drug use and poor health. If this is the case, then the resulting correlation between drug use and poor health is spurious because drug use is simply capturing the unmeasured effect of the confounding factor, childhood abuse, on health. Untangling these competing and more than likely coexisting mechanisms generating the observed relationship between drug use and health is not merely of academic importance. The economic cost of maintaining criminal sanctions for illicit drug use is large. This cost is typically justified on the grounds that criminalizing drug use prevents health-related harms associated with drug use. For this reason, it is important to know whether and to what extent drug use causes ill health. This article reviews the evidence on this issue.

To begin, section The Extent of Illegal Drug Use introduces facts and figures regarding the extent of illicit drug use. To do so, the authors present data on the prevalence and intensity of use for the major illicit drugs: heroin, cocaine, amphetamines, ecstasy, and cannabis. These data illustrate the dominance of cannabis among illegal drugs. Although the prevalence of drug use provides an overview of the extent of drug use in a population, it is not necessarily informative about the type of drug use that may give rise to health-related problems. For example, the prevalence of use is unable to distinguish between those who have experimented once or twice (in the given time frame) and the more policy-relevant group who become long-term heavy users. Second, there is mounting evidence that uptake of drugs in the teenage years carries significantly more risks than uptake at later ages. Therefore, it is not simply the prevalence of use, but the age of first use and the duration of use that is informative in terms of risk of potential health-related harms. To provide information on these dimensions, the authors describe the dynamics of drug use. They do so for cannabis as this is by far the most popular illegal drug.

In Section Health Effects of Illegal Drug Use, the authors present and discuss a number of recent studies on the direct and indirect health effects of cannabis use. They distinguish between epidemiological and econometric studies. Section Discussion and Conclusion concludes that although consumers of illegal drugs are assumed to face substantial health risks, the evidence base regarding the nature and extent of these risks is, by and large, yet to be well established. For the most popular illegal drug, cannabis, there do not seem to be serious harmful effects with moderate use. There may be negative harmful effects for heavy users who are susceptible to mental health problems.

The Extent of Illegal Drug Use

Annual Prevalence of Illegal Drug Use

Table 1 provides information on the annual prevalence of use for the most important illegal drugs: amphetamines, ecstasy, cannabis, cocaine, and heroin. The annual prevalence refers to the percentage of the population aged 15–64 years who report any use of the substance in the year before being surveyed. The age range varies slightly for some countries. This information is reported for 10 developed countries and the authors refer the interested reader to United Nations (2011) for information on additional countries.

As shown in Table 1, with the exception of cannabis, the annual prevalence rate of use for any of these illegal drugs is not more than a few percentages of the population. The annual prevalence of amphetamine use ranges from a low of 0.2% of the population in France to a high of 2.7% of the population in Australia, and the annual prevalence of ecstasy use ranges from 0.1% of the population in Sweden to 4.2% in Australia. The range for the annual prevalence of cocaine use is similar, with a low of 0.5% of the population in Sweden to a high of 2.6% of the population in Spain. The annual prevalence rate of heroin use is low in all countries, ranging from 0.1% of the population in Spain to 0.8% of the population in England and Wales. For cannabis, the annual prevalence rate of use is substantially higher, ranging from 1.2% of the population in Sweden to a 14.6% of the population in Italy. The information in Table 1 makes it clear that cannabis is the most popular illegal drug by a wide margin. This is not an artifact of the countries that has been reported on. Globally, cannabis is the most commonly used illegal drug. In 2009, between 2.8 and 4.5% of the world's population aged 15–64 years, corresponding to between 125 and 203 million people, had used cannabis at least once in the past year (United Nations, 2011).

Table 1 Annual prevalence of illegal drugs; various countries (percentages)

Country	*Year*	*Age*	*Amph.*	*Ecstasy*	*Cannabis*	*Cocaine*	*Heroin*
Australia	2007	15–64	2.7	4.2	10.6	1.9	0.4
Denmark	2008	16–64	1.2	0.4	5.5	1.4	0.6
England	2010	16–59	1.0	1.6	6.6	2.5	0.8
France	2005	15–64	0.2	0.5	8.6	0.6	0.5
Germany	2009	18–64	0.7	0.4	4.8	0.9	0.2
Italy	2008	15–64	0.6	0.7	14.6	2.2	0.6
The Netherlands	2005	15–64	0.3	1.2	5.4	0.6	0.3
Spain	2010	15–64	0.6	0.8	10.6	2.6	0.1
Sweden	2008	15–64	0.8	0.1	1.2	0.5	0.2
United States	2009	15–64	1.5	1.4	13.7	2.4	0.6

Note: England includes Wales; Amph., amphetamines; heroin includes opium and except for the United States, it also includes other opioids such as morphine, methadone, etc. The information for heroin always refers to the population aged 15–64 years; the information is for the following years: Denmark and the Netherlands (2005), Germany and Italy (2008), United States (2009), all other countries (2007).

Intensity of Cannabis Use

Table 2 reports more detailed information on cannabis use for the same set of countries contained in Table 1. Specifically, Table 2 distinguishes between lifetime use, use in the last year, and use in the last month. There is substantial variation in these measures of use both across countries and within countries. The variation across countries is demonstrated by comparing Sweden, where just 21% of the population aged 15–64 years has used cannabis in their lifetime, with the US where 42% of those aged 12 years or older have used cannabis at some point in their lifetime. Similarly, just 1% of those aged 15–64 years in Sweden has used cannabis in the past year compared with 14% of those in Italy. Equally striking is the variation between lifetime and past year use within each country. In the Netherlands, for example, 26% of the population aged 15–64 years has used cannabis in their lifetime but only 7% have done so in the last year. Apparently, cannabis use is not very addictive for a substantial proportion of users (see van Ours, 2005 for details).

The proportion of the population who has used cannabis in the past month gives an indication of the extent of current use. However, as shown in Table 3, there remain substantial differences across countries in the frequency with which past month users consume cannabis. In Denmark, for example, almost 60% of past month users consumed cannabis no more than 1–3 days in the past 30 days whereas just 16% used at least 20 days out of the past 30. Even in Spain, where almost 9% of the population aged 15–64 years has used cannabis in the last 30 days, less than 3% of the population (or one-third of current users) has used cannabis on 20 or more days out of the last 30. In Germany, Italy, and the Netherlands, less than 1% of the population aged 15–64 years used cannabis on at least 20 days out of the past 30, and in France just 1.5% has done so. This demonstrates that, although cannabis is by far the most widely used among the illegal drugs, the prevalence of heavy use in the population is still low among the countries reported in Table 3.

Dynamics in Cannabis Use

Although a significant proportion of the population will have tried cannabis at some point in their life, many will simply experiment once or twice without suffering harmful consequences. To assess the degree of risk of harmful consequences, one needs to understand the profile of the duration of cannabis use. In addition, a growing literature provides evidence that early onset of cannabis use has especially harmful effects on health and life outcomes. Therefore, in this section, information on the dynamics of cannabis use, including age at first use and the duration of use, is provided.

Figure 1 shows typical patterns in the dynamics of cannabis use derived from a sample of Amsterdam residents (van Ours, 2005). Figure 1(a) provides information on the uptake

Table 3 Frequency of cannabis use in the past 30 days

Country	Year	Days in the past 30 days (%)				Total (%)	Last month prevalence (%)	
		1–3	4–9	10–19	20+		Total	20+ days
Denmark	2005	58	19	7	16	100	2.6	0.4
France	2005	36	17	15	32	100	4.8	1.5
Germany	2003	47	16	14	23	100	3.4	0.8
Italy	2005	47	25	10	18	100	5.8	1.0
The Netherlands	2005	38	12	27	23	100	3.3	0.8
Spain	2005/06	32	23	15	31	100	8.7	2.7

Note: Population aged 15–64 years.
Source: Reproduced from European Monitoring Center for Drugs and Drug Addiction.

of cannabis and Figure 1(b) provides information on quitting behavior as a function of the duration of cannabis use. The first graph in Figure 1(a) shows the hazard rate for starting cannabis use, defined as the probability of starting cannabis use at each age conditional on having not used up until that age. As can be seen from the graph, uptake typically occurs between the ages of 15 and 25 years, with clear spikes in the rate of uptake at ages 16, 18, and 20 years. The starting rate for ages greater than 25 years is small. This means that, if a person has not started cannabis use by the age of 25 years, they are unlikely to do so at a later age. The second graph in Figure 1(a) shows the cumulative starting probability. This is defined as the proportion of individuals at each age who have started cannabis use. The cumulative starting probability shows that 10% of 15-year olds have ever used cannabis. This proportion rises to 50% by the age of 25 years. The slowing in the rate of uptake after the age of 25 years is reflected in the flattening of the cumulative starting probability, which increases from 52% to 55% over the ages of 25–30 years.

Figure 1(b) shows the quit rate, defined as the probability of quitting cannabis use at each duration of use (measured in years) conditional on not previously quitting, and the cumulative quit probability, defined as the proportion of those who have ever used cannabis quitting at each duration of use. The graph of the quit rate shows that approximately 20% of cannabis users stop using within a year of starting use. The graph of the cumulative quit probability shows that although many cannabis users quit use after a couple of years, a significant proportion do not. For example, 20 years after first using cannabis, between 30% and 40% are still using. Based on these dynamics three groups of individuals can be distinguished; those who never use (abstainers), those who use but only for a short time (experimenters), and persistent users some of whom are recreational users whereas others are addicts. It is important to note that although these graphs were constructed using data on residents of Amsterdam, the patterns in Figure 1 are typical of the dynamics found in other countries.

In addition, the characteristics found in the dynamics of cannabis use are similar to those found for other illegal drugs, although the magnitude of use and the timing over the lifecycle may differ slightly from drug to drug. For example, for the sample of Amsterdam inhabitants on which Figure 1 is based, van Ours (2005) reports that the mean age of first use is 20 years for cannabis, 23 for amphetamines, 24 for heroin, 25 for cocaine, and 26 for ecstasy. In comparison, the mean age of first use for alcohol and tobacco is 17.5 years. He also finds drug-specific critical ages, such that if individuals have not started using by the critical age, then they are not very likely to do so at a later age. As seen above, the critical age is 25 years for cannabis. For cocaine it is 30 years, whereas for tobacco the critical age is approximately 20 years.

It is often found that the age of onset influences user quit rates. The earlier the individuals start using a particular drug, the less likely they are to stop using that drug. Although the general pattern in user dynamics is very much the same across the various drugs, there are also differences between drugs. Cannabis and cocaine use are characterized by relatively low starting rates that begin in the mid-teen years and by high quit rates especially in the first year after starting use. Tobacco use is characterized by high starting rates at a young age and by low quit rates. Once individuals start using cigarettes, they are very unlikely to stop using. Apparently, among the users of cannabis and cocaine there are many experimenters, that is, individuals who use the drug for a very short time but then decide very quickly to stop using.

From the dynamics in illegal drug use it is clear that there are differences between drugs in terms of the duration of use. These differences are related to the variation in the degree of psychic dependence of illegal drugs. As shown in column (1) of Table 4 the degree of psychic dependence is strongest for heroin, tobacco and alcohol, and weakest for cannabis. Nutt *et al.* (2010) present an attempt to score drugs according to 16 criteria of harm ranging from the intrinsic harms of the drug to social and health-care costs. Based on the criteria they distinguish between harm to users and harm to others. Drugs are scored on a scale of 0–100, with 100 assigned to the most harmful drug and 0 indicating no harm. The points were assigned in consultation with expert groups. The outcome is replicated in the second to fourth column of Table 4. In the second column harm to individual users is represented. The most harmful drugs to users are heroin and alcohol, whereas cannabis and ecstasy are least harmful to the users. The third column presents harm to others and here alcohol is the most harmful followed by heroin; ecstasy is the least harmful. The overall harm score is presented in the fourth column. Overall, alcohol is the most harmful drug and ecstasy the least harmful.

Of course such rankings of harm are not uncontroversial. Caulkins *et al.* (2011), for example, argue that the harmfulness of a drug cannot be indicated using one number as the harm is more than the harm to the user and spillover effects in terms of harm to others. Furthermore, harms related to drug-related

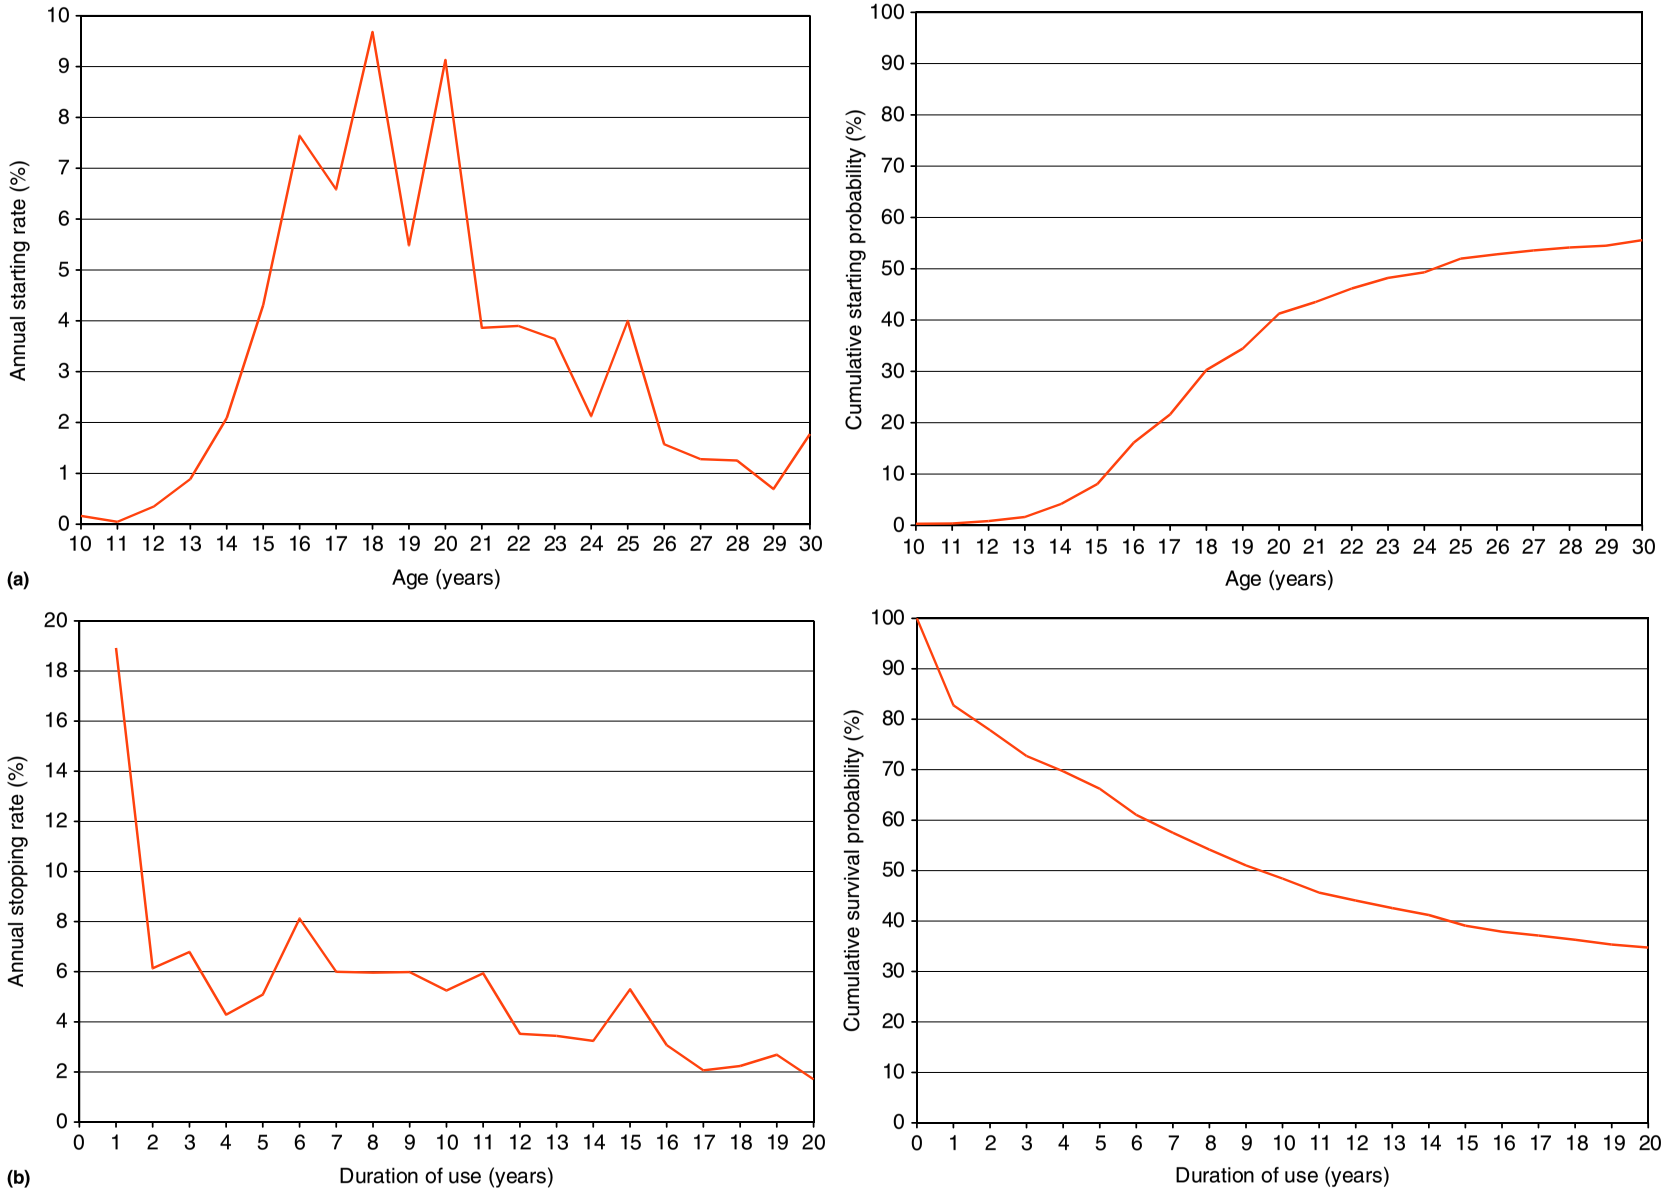

Figure 1 Dynamics in cannabis use in Amsterdam. (a) Starting rates (left) and cumulative starting probability (right) by age. Table 4 Illegal drugs and legal drugs; addictiveness, degree of psychic dependence, and danger ratio

	Degree of psychic dependence	*Harm score*			*Danger ratio (%)*
	(1)	*Users (2)*	*Others (3)*	*Total (4)*	*(5)*
Illegal drugs					
Amphetamines	Middling	19	4	23	10.0
Ecstasy	–	8	1	9	6.3
Cannabis	Weak	12	8	20	<0.1
Cocaine	Strong, intermittent	19	8	27	6.7
Heroin	Very strong	34	21	55	16.7
Legal drugs					
Alcohol	Very strong	26	46	72	10.0
Tobacco	Very strong	19	9	26	<0.1

Note: Danger ratio = normal dose as a percentage of lethal dose.

Source: Column (1): Room, R., Fischer, B., Hall, W., Lenton, S. and Reuter P. (2010) *Cannabis policy: Moving beyond stalemate.* Oxford, England: Oxford University Press; columns (2–4): Nutt, D., King, L. and Phillips, L. (2010). Drug harms in the UK: A multi-criteria decision analysis. *Lancet* **376**, 1558–1565, column (5): Gable, R. (2004). Comparison of acute lethal toxicity of commonly abused psychoactive substances. *Addiction*, **99**, 686–696; except tobacco which is assumed to be similar to cannabis.

crime, environmental damage, and the cost of police and prisons depend on the legal status of the drug. Finally, the fifth column of Table 4 provides information about the acute lethal toxicity of illegal drugs, i.e., the 'danger ratio,' defined as the usual effective dose as a percentage of usual lethal dose (see Gable, 2004). Heroin is the most dangerous drug as the usual effective dose is almost 17% of the usual lethal dose. Heroin is followed by amphetamines and alcohol with a danger ratio of 10%. Cannabis (and tobacco) do not present an immediate danger of a lethal dose.

Health Effects of Illegal Drug Use

The literature that seeks to determine the impact of drug use on health is reviewed. As cannabis is the most widely used illegal drug, the focus is on the relationship between cannabis use and health. Much of the research in this area is contributed from epidemiology and is focused on the mental health effects of drug use. There is a smaller and more recent literature contributed by economics. A distinguishing feature of this literature is the utilization of methodologies designed to identify causal effects of drug use. In addition to studying the direct effects of drug use on health, the economics literature also considers the impact of drug use on labor market outcomes. Because a significant cost of poor health resulting from drug use is considered to be reduced labor market success, understanding the evidence regarding the indirect health effects of drug use is of significant interest. The indirect health effects of illegal drug use which originate, from effects on crime, violence, traffic accidents, etc., are not discussed. The relative contribution of illegal drug use to the economics costs of risky behavior more generally is discussed by Cawley and Ruhm (2011). They find that illegal drug use makes a modest contribution to these costs.

Medical and Epidemiological Literature

The earliest attempt to identify the causal impact of cannabis use on mental illness is by Andreasson *et al.* (1988) who study a cohort of more than 50 000 18- to 20-year-old Swedish conscripts. The authors find that the postconscription risk of developing schizophrenia is increasing in the number of times cannabis is used before conscription. This was a controversial finding and prompted a raft of epidemiological studies on the relationship between cannabis use and mental health more generally. This literature is so large that there is now a large number of studies dedicated to reviewing it.

In their 2003 review, Degenhardt *et al.* (2003) conclude that there is a modest but significant association between early-onset regular or problematic cannabis use and depression later in life, although there is little evidence of an association between depression and infrequent cannabis use. The authors go on to conclude that even if the association between cannabis use and depression is assumed to be causal, regular cannabis use can only explain a small proportion of depression in the population. Macleod *et al.* (2004) review more than 200 studies based on longitudinal data that seek to determine the psychosocial impact of cannabis use. They conclude that although there is evidence of associations between cannabis use and various measures of psychosocial harm, the extent of the associations and the strength of the evidence is not always large. Furthermore, the authors conclude that the causal nature of the associations is far from clear.

Many of the overview studies have focused on the relationship between cannabis use and psychosis. Arseneault *et al.* (2004) conclude on the basis of their review of previous research that cannabis use is likely to have a causal role in the development of psychosis but the magnitude of its impact is unclear. Kalant (2004) concludes from his review of previous studies that there is more evidence for a causal relationship running from cannabis use to psychiatric problems than there is for reverse causality, i.e., psychiatric problems leading to cannabis use. Henquet *et al.* (2005) review seven studies and conclude that cannabis use has a causal effect on later psychosis. They note, however, that the effect is not very large and the mechanism underlying the causality is unclear. Semple *et al.* (2005) provide an overview of 17 case–control studies that examined the association between cannabis use and schizophrenia or schizophrenia-like psychosis. They also

conclude that cannabis is a risk factor for psychosis but indicate that it is not clear whether cannabis is a precipitating or a causative factor in the development of schizophrenia. Hall (2006) argues on the basis of his review of studies that there is a strong association between cannabis use and psychosis, but it remains controversial whether the association is causal. Moore *et al.* (2007) present an overview of 11 studies on psychosis based on data from seven cohort studies. Although they find that there is an association between cannabis use and psychosis, they are unable to rule out spurious correlation resulting from unobserved confounding factors as the underlying explanation for this association.

In their recent review, Hall and Degenhardt (2009) argue that previous research on the relationship between mental health and illegal substance use has produced mixed findings, with some papers reporting a positive association between cannabis use and mental health problems and others reporting no association. McLaren *et al.* (2010) review the methodological strengths and limitations of major cohort studies that have sought to determine the causal nature of the relationship between cannabis use and psychosis. The authors conclude that, on the basis of the current studies, no inference can be made about a potential causal relationship from cannabis use to psychosis. Discussing a variety of papers Werb *et al.* (2010) conclude that the research to date is insufficient to conclusively claim that the association between cannabis use and psychosis is causal in nature. The fact that population-level rates of psychotic disorders do not appear to correlate with population-level rates of cannabis use suggests that these two phenomena may not be causally related.

Econometric Studies – Direct Health Measures

In examining the relationship between mental health and cannabis use, the literature from epidemiology cited above has attempted to identify the causal effect of cannabis use by controlling for observed factors that may be a source of confounding. However, as noted by Pudney (2010), the potential for unobserved common confounding factors makes inference regarding the causal impact of cannabis use difficult. In contrast, economic research routinely makes use of statistical techniques designed to account for unobserved confounding factors in studying the impact of one outcome on another. Despite the potential to provide strategies for addressing the issue of unobserved confounders, and thus better assess the health risks faced by drug users, there are very few contributions from the economics literature on this issue. As detailed below, the economic studies that do attempt to tease out causal effects suggest that there may be risks to both mental and physical health from using cannabis.

Williams and Skeels (2006) and van Ours and Williams (2011) use Australian data to study the impact of cannabis use on physical and mental health, respectively. Williams and Skeels (2006) find the probability of reporting very good or excellent self-assessed health to be 8% lower among those who consumed cannabis in the past year compared with those who had not, and 18% lower for those who reported weekly use. Along similar lines, van Ours and Williams (2011) find that cannabis use increases the likelihood of mental health problems, with the probability of experiencing mental distress increasing with the frequency of past year use. Although each of these studies considers a single dimension of health, there is significant evidence that poor mental health is correlated with poor physical health. van Ours and Williams (2012) investigate the impact of cannabis use on health in a framework that accounts for the potential for shared frailties in the domains of physical and psychological well-being, as well as selection into cannabis use. Their analysis of Amsterdam data suggests that cannabis use reduces the mental well-being of men and women and the physical well-being of men. Although statistically significant, the magnitude of the effect of using cannabis on mental and physical health is found to be small.

van Ours *et al.* (2013) is the only study to address both the potential for common unobserved confounders and reverse causality in studying the health impact of cannabis use. Their analysis of the relationship between suicidal ideation and cannabis use is based on a 30-year longitudinal study of a birth cohort. They find that intensive cannabis use – at least several times per week – leads to a higher transition rate into suicidal ideation for susceptible males. There is no evidence that suicidal ideation leads to regular cannabis use for either males or females.

Econometric Studies – Indirect Health Measures

In addition to their stock of human capital, a person's labor market productivity is determined by their health capital stock (Grossman and Benham, 1974). Drug use is conjectured to reduce labor market productivity through its deleterious effects on an individual's stock of health. Although intuitively appealing, empirically assessing the validity of this conjecture is complicated by the fact that individuals choose, or self-select into, drug use. Specifically, there may be important unobserved determinants of wages or employment that also influence the decision to use drugs. An example of an omitted variable particularly relevant in this context is an individual's discount rate. Individuals who discount the future heavily are more likely to use drugs because they place little weight on the future negative health consequences of their drug use (Becker and Murphy, 1988). They are also more likely to choose jobs with little investment in on-the-job training, and that consequently pay relatively high current wages but relatively low future wages. This may give rise to a positive correlation between drug use and wages even if drug use is negatively causally related to wages. Similarly, individuals with strong preferences for leisure may also be more likely to use drugs if drug use and leisure are complements in the production of euphoria. Such a relationship would produce a negative correlation between drug use and labor supply even in the absence of a causal effect of drug use on labor supply.

The empirical strategy pursued by the first-wave studies for estimating the causal impact of drug use on wages and employment is instrumental variables. Three of these studies draw on data on 18- to 27-years old from the 1984 cross section of the National Longitudinal Survey of Youth (NLSY) and all three studies found evidence that, rather than reduce wages, drug use increases wages. Kaestner (1991) finds that for

males, drug use measured as past 30-day use of cannabis, lifetime use of cannabis, past 30-day use of cocaine, or lifetime use of cocaine, raises hourly wages. Similarly, male wages are found to be increasing in the frequency of cannabis use in the past 30 days by Register and Williams (1992). Gill and Michaels (1992) report that the use of any drugs in the past year or any hard drugs (cocaine, heroin, inhalants, psychedelics, other drugs, other narcotics) in the past year increases the hourly wage rate received in a combined sample of males and females. The estimated magnitudes of the wage effects are quite large. For example, Kaestner (1991) estimates that males who have tried cannabis earn 18% more than otherwise similar males who have not tried cannabis, Register and Williams (1992) estimate that using cannabis on one more occasion per month increases hourly wages by 5%, and Gill and Michaels (1992) find that drug users earn approximately 4% more per hour than nonusers, and that hard drug users earn approximately 10% more per hour than nonhard drug users. Moreover, both Kaestner (1991) and Gill and Michaels (1992) report that the premiums for drug use are attributable to unobserved differences between the users and nonusers and not differences in returns to human capital and other characteristics.

Kaestner (1994a,b) uses the 1984 and 1988 waves of the NLSY to compare cross-sectional and longitudinal estimates of the impact of cocaine and cannabis use on labor supply and wages, respectively. He finds that the results based on the 1984 data, which show that cannabis and cocaine use increases wages and cannabis use decreases hours spent working in the sample of males, cannot be replicated using the 1988 data. Moreover, when unobserved differences that affect drug use and labor market outcomes are controlled for through a fixed-effect estimator, drug use is found to have a negative but insignificant impact on wages for males (Kaestner, 1994b), and mixed, although generally insignificant, effects on hours worked (Kaestner, 1994a). The overall conclusion reached by Kaestner is that drug use does not have a systematic impact on labor supply or wages.

The counterintuitive and inconsistent findings of the above studies motivated a second wave of economic research into the impact of drug use on wages and labor supply. Taken at face value, most of the second-wave studies tend to find evidence that nonproblematic use of drugs (light to moderate use, or the use of soft drugs) has no impact on labor supply, measured by employment or hours worked, but that problematic use (heavy use, or the use of hard drugs) does, although Burgess and Propper (1998); DeSimone (2002); Zarkin *et al.* (1998) and van Ours (2006) provide counterexamples. Similarly, most of the second-wave studies find that infrequent or nonproblematic drug use has no impact on wages, whereas problematic use does have negative wage effects. Once again, there are also exceptions to this generalization, such as MacDonald and Pudney (2000). It is noteworthy that many of these studies (especially those based on US data) tend to treat drug use as exogenous to labor market outcomes.

Focusing on the studies that are more rigorous in their efforts to address the potential endogeneity of drug use, the results are mixed. For example, although van Ours (2007) finds that using cannabis at least 25 times in one's lifetime reduces the wage of prime-age males, the use of cocaine is found to have no effect, and MacDonald and Pudney (2000) are unable to detect any impact of either hard or soft drug use on their proxy for wages, that is, occupational attainment. Similarly, with respect to the employment of males, DeSimone (2002) finds that both past year cannabis and cocaine use reduces the probability of employment, whereas, MacDonald and Pudney (2000) find no employment impact of soft drug use (which includes cannabis) and van Ours (2006) finds no impact of cannabis or cocaine use on employment. Finally Conti (2010) introduces cognitive ability as additional variable in a wage equation with cannabis use as explanatory variable, showing that this causes the effect of cannabis use to become insignificantly different from zero.

Given the conflicting nature of the empirical findings, it is simply uncertain as to whether there are negative labor market consequences of drug use in general, and cannabis use in particular. Furthermore, it is unclear as to whether this literature should be interpreted as reflecting a lack of robust evidence of a negative health effect of drug use, or as reflecting the presence of a productivity improving effect of drug use that is confounding the negative health effects.

Discussion and Conclusion

The use of illegal drugs is limited to a small part of the population. Not many people consume amphetamines, ecstasy, cocaine, or heroin. The most popular illegal drug by far is cannabis. However, even for the most popular illegal drug, heavy use is quite rare. And whereas a substantial proportion of the population has used cannabis in their lifetime, for many their use was a short-lived experiment. Even among individuals who persist in cannabis use, many do so on a recreational basis. Despite a large number of epidemiological studies and a handful of econometric studies little is known with any degree of certainty about the health effects of illegal drug use. Researchers agree that drug use is associated with worse health. The issue is whether this association is causal, with drug use causing poor health, or whether spurious correlation or reverse causality underlies this association. The main impediment to determining the nature of the relationship between illegal drug use and health is that the optimal setup for addressing this issue is a randomized control trial in which individuals are randomly allocated to the treatment group (who are administered illegal drugs) or to the control group (who receive a placebo). However, this type of experiment is not possible for at least two reasons. First and foremost, individuals will always know whether they are in the treatment group receiving illegal drugs, or in the control group receiving the placebo. Second, long-term exposure to illegal drugs would be necessary in order to determine the health effects, and this would be rather unethical should the outcome be that there are serious health problems related to illegal drug use. The so-called 'natural experiments,' in which a policy change that affects drugs use is exploited as if it were an experiment, are rare simply because drug policies have the tendency not to change.

The lack of econometric research that seeks to identify causal effects of drug use on health is surprising but likely to

be related to lack of good data as a basis for the research. Drug use is not a static phenomenon. On the contrary, dynamics in use are very important. Within the population some individuals may start using a drug but others will abstain. Among those who have started using a drug there are individuals who will stop using and other individuals who will persist in drug use. By and large, in the population there are never-users, experimental users, and persistent users. Even within the group of persistent users there may be transitions from high intensity of use to low intensity of use and vice versa. To understand the dynamics of illegal drug use, information is needed from the time when individuals are first confronted with the choice of whether to use a particular drug. Ideally, this information should capture how relevant circumstances change over time. Information that could be relevant includes: family situation, experiences at school, changing drug supply conditions, and drug prices. Unfortunately, this type of information is not typically available. Another issue which makes it hard to research in this area is the fact that it is hard to quantify drug use. Whereas standard quantity measures are available for tobacco (cigarettes per day) and for alcohol (standard units of alcohol per day), there are no obvious standard quantity measures for the use of illegal drugs.

Despite the absence of experimental research it is still possible to draw some conclusions from previous research on the direct and indirect health effects of illegal drug use. Intensive use of illegal drugs over a long period of time generates negative health effects for its users whereby the magnitude depends on the nature of the drug involved. Whether short-term use or long-term, recreational use is harmful is not clear. For cannabis, the evidence finds that use is neither necessary nor sufficient for mental health problems to occur. It could be that individuals who are susceptible to mental health problems are vulnerable for cannabis use, but as yet this is unclear. Most likely, experimenters will not suffer serious health effects, whereas the same holds for persistent but recreational users. The group of persistent heavy users is at risk of negative health effects. However, the size of this group is limited to 1% or 2% of the adult population. In this sense, from an aggregate point of view, the magnitude of the health effects of illegal drug use is limited. Nevertheless, for individuals the negative health effects may be severe. How severe it may be is yet to be established.

Given the limited circumstances for which cannabis use may pose a threat of harm, there is growing interest in possible medical applications of cannabis, the so-called 'medical marijuana' most notably as a treatment for the symptoms of muscle spasm and tremors in multiple sclerosis patients and the symptoms of vomiting and nausea in cancer patients undergoing chemotherapy (Hall *et al.*, 2001). Cannabinoids may allay pain, improve sleep, and possibly inhibit degenerative processes (McCarberg, 2007). Caulkins *et al.* (2012) refer to a summary of 12 double-blind clinical trials where 57% report positive outcome of cannabis use, 33% found no effect and 10% found adverse outcomes. Research on the therapeutic use of cannabis and cannabinoid drugs is hampered by 'Catch 22' situation that as long as cannabis is illegal the medical benefits cannot be established in a way that it would be accepted as a treatment and cannabis remains illegal if the medical benefits of cannabis use cannot be established. Nevertheless, 18 US states and the District of Columbia allow patients who have a recommendation from a doctor to use cannabis for medical purposes without the risk of being prosecuted.

When assessing the health effects of illegal drug use some caveats are important to keep in mind. First, all health effects are established under one type of policy regime, prohibition. Although there is variation in the way prohibition is implemented, there is no country or jurisdiction that has legalized selling, buying, or using any illegal drug. In the USA, Colorado and Washington states have recently passed referendums to legalize cannabis but at the time of writing, the framework for implementing legalization was yet to be established. However, the legal status of a drug may affect the relationship between drug use and health. Furthermore, because it is an illegal activity, it is not easy to collect reliable data on drug use. A second caveat is that the health consequences of using an illegal drug are likely to depend on the manner in which it is consumed. Smoking heroin, for example, is less dangerous than injecting heroin and inhaling cannabis that has been vaporized is less dangerous than smoking cannabis. A third caveat to keep in mind is that the health risks posed by specific illegal drugs may have changed over time. For example, in recent years, the proportion of Δ^9-tetrahydrocannabinol present in cannabis is thought to have risen, whereas the proportion of cannabidiol is thought to have decreased. Δ^9-tetrahydrocannabinol is believed to exaggerate the psychotic effects of cannabis, whereas cannabidiol is thought to moderate the psychotic effects. However, due to paucity of information on the composition of cannabis, the health effects of any changes are unknown.

It is concluded that adverse health effects of cannabis use are clearly present but their magnitude seems rather limited. Nevertheless, using illicit drugs is not good for one's health. Even cannabis, which is considered to be a soft drug in some countries because of its limited health effects, has a negative health effect. Whether one should worry about this is another matter. In the grand scheme of things cannabis use – and even hard drug use – has a limited health effect compared with other risky behavior. Heavy cannabis use and early onset of cannabis use, which often but not always coincide, have the largest negative health effects. Preventing youngsters from starting to use cannabis or least preventing them from doing this early on in life could be sufficient to prevent serious health effects.

As to the health effects of other illegal drugs the weight of evidence supports the finding that the harms associated with cannabis use are much less serious than those associated with 'hard' drugs such as cocaine or heroin and may even be smaller than those associated with alcohol and cigarettes. And although it is generally acknowledged that there are risks associated with long-term heavy use of cannabis such as respiratory diseases, cancer, and perhaps psychotic disorders, only a small fraction of those who ever use cannabis actually become long-term heavy users.

Impact of Income Inequality on Health

J Wildman and J Shen, Newcastle University, Newcastle Upon Tyne, UK

Introduction: What Are Health Inequalities?

Health inequalities are observed in all societies. Although some inequalities may be considered unavoidable, resulting from sociodemographic characteristics such as age, gender, and genes, many of these health inequalities are associated with socioeconomic characteristics that are potentially amenable to policy interventions and could be considered as avoidable. In Europe, measuring and understanding these differences have been the major part of the literature on 'health inequalities.' In the US, these types of analyses are often referred to as 'health disparities.' For the purpose of this section the term 'health inequalities' will be used. It will also be assumed that it is clear what is meant by 'health.' Health, in this section could refer to a range of outcomes such as coronary heart disease, remaining expected quality-adjusted life-years (QALYs), length of life lived, mortality, morbidity, etc.

Avoidable health inequalities are commonly defined as unfair systematic differences in health outcomes, although whether such inequalities are unfair may depend on the equity criterion applied. Inequalities are not generally considered unjust in cases where genes or the human body's natural capacity are largely at play, for example, women tend to live longer than men, or 20-year olds in general have better health than 60-year olds. However, the marked differences evident in the populations of some countries in mortality rates (and other health measures) between occupational classes, between regions, between races, and between the rich and the poor are all considered to be examples of avoidable and unfair health inequalities. Researchers across the disciplines of economics, sociology, epidemiology, and psychology have suggested various theories that could explain health inequalities, and among these, theories regarding the influence of material factors – especially income – have been fundamental to the research into health inequalities.

The Link between Income and Health

The association between levels of income and health is well documented, with research suggesting that income levels and health outcomes are positively correlated. At the individual level (and controlling for other factors such as age, gender, and socioeconomic characteristics), income is often found to be a significant predictor of health. However, the direction of causality is difficult to identify: Does higher (lower) income lead to better (worse) health, or does health affect income? Further, the causality may be direct, or indirect, with income and health affecting each other via mediating factors. It is also possible, although not likely, that there may be a third factor affecting both health and income, giving the impression of a relationship but without any causal link between them.

At the aggregate level, cross-country comparisons have shown that higher average income (gross domestic product (GDP) per capita) correlates with higher average health (in this case, measured as life expectancy). This is often known as the absolute income hypothesis (AIH). This evidence can be found for both cross-sectional and longitudinal studies. The way average health has improved along with average income is clearly demonstrated here: http://www.youtube.com/watch?v=jbkSRLYSojo

These data give a clear animated illustration of Preston curves that demonstrate a concave relationship between life expectancy and average income (measured as GDP per capita). This means that as average income increases, life expectancy increases at a decreasing rate, or still more simply, a proportionate increase in average income is associated with larger health gains at lower initial levels of average income than at higher initial levels of income.

However, this aggregate-level result does not seem to hold when GDP per capita reaches a certain level. In developed countries that have passed through the 'epidemiological transition,' where the main causes of death are chronic conditions rather than contagious diseases, there is little evidence of a relationship between income and health (countries are on the flatter part of the Preston curve). It is worth noting that the flatter part of the Preston curve only implies that there is no difference in average health by average income across societies, but there can still be variations in average health across income groups within societies. Based on this evidence, it has been proposed that absolute income is not the main determinant of health in developed countries.

Relative Income Hypothesis

In developing countries, individual absolute income seems to be the main determinant of individual health. If income or material factors are important for health, then continuing growth in income should result in increasing health. Thus, for example, if mortality risk (or any other health outcome) at the individual level is convex (as shown in Figure 1) so that the risk of death decreases at a decreasing rate as income increases, then health inequalities should decrease as countries became richer – for example, 'as they progress toward becoming developed countries. As income grows, those at the top end of the distribution see their health improve but at a slower rate than that of individuals at the lower end of the distribution (because of the steeper gradient for these individuals). So over time, health inequalities will disappear if all individuals see the benefits of income growth: if the relationship at the individual level becomes completely flat, then even if the income of the most wealthy grows at a faster rate than that of the least wealthy, health inequalities will diminish as long as the least wealthy experience some income growth.

 doi:10.1016/B978-0-12-375678-7.00209-1

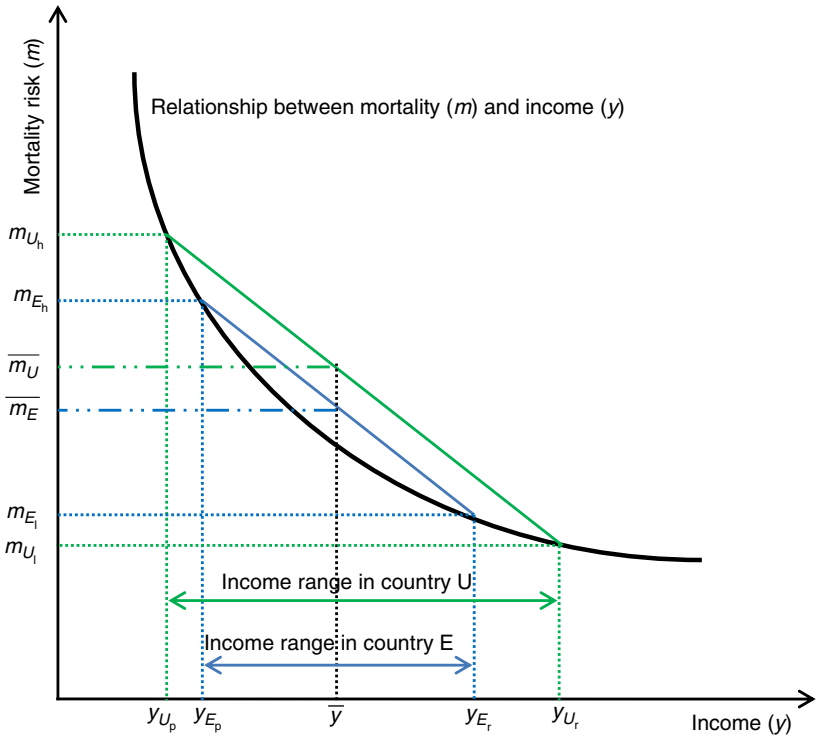

Figure 1 Effect of increased inequality of income on population mortality.

However, this is not what is observed: health inequalities persist in developed countries and are even increasing in some instances. Although this may be explicable by the AIH due to those in the lower socioeconomic groups not benefiting from income growth, it may be that an alternative explanation is more likely. The most influential alternative theory to date is the relative income hypothesis (RIH), which has been developed most notably by Richard Wilkinson. In his groundbreaking work, Wilkinson (1996) identifies the possibility that it is the distribution of income within a country or region rather than the absolute level of income that causes inequalities in health. The essence of the theory is that income inequality negatively affects individual health. In its strongest form, this means that all individuals, even the richest, experience worse health when there is high income inequality. Weaker forms involve only those individuals who are at the lower end of the socioeconomic spectrum experiencing worse health.

There is a large body of empirical evidence supporting the RIH using aggregate-level data. Measures of income inequality – the Gini coefficient is the most widely used – have been shown to have a significant negative association with health (measured either by life expectancy or by infant mortality): the larger a country's Gini coefficient, the higher the income inequality and the worse its health outcomes (Box 1).

Studies investigating the relationship between average health and the share of income (by quintiles or percentiles of the study population) or the percentage of the population in relative poverty, all seem to confirm that the wider a country's income distribution, the worse the average level of health in that country appears to be.

Box 1 What is the Gini coefficient?

The Gini coefficient is derived from the Lorenz curve. To derive a Lorenz curve, the population is ranked by income and the cumulative proportion of income is plotted against the cumulative proportion of the population. If income is equally distributed, this plots a 45° line (the line of perfect equality). If income is unequally distributed, it plots a line below the 45° line. The Gini coefficient measures the area between the Lorenz curve and the line of perfect equality.

Theories Behind the Relative Income Hypothesis

The RIH has its theoretical basis in, and is supported by, evidence from sociology and epidemiology. From a sociological perspective, social cohesion and social capital (such as trust, participation, and social inclusion) are the bases for the RIH, with income inequality acting as a proxy for either a lack of social cohesion or a lack of social capital. Countries with a wide distribution of income are assumed to have fewer social support mechanisms, thereby leading to higher crime rates and a diminished quality of social environment. As a result, the health of every individual in these unequal societies will be affected directly via disease development or hindered recovery, and indirectly through health-damaging behaviors (such as smoking or substance abuse) when individuals at the lower end of the social scale react to their adverse circumstances. The psychosocial effects of living in an unequal society could also support the RIH, as inequality may cause stress

or anger due to either a lack of social support networks or an inability to maintain a socially acceptable standard of living.

Epidemiology provides a large body of evidence of the impact of social status on health. Much of this work is summarized by Marmot in his book, Status Syndrome (2004). Studies suggest that health inequalities reach up the social scale because hierarchy and social regimentation are harmful to health: people at every level of the 'pecking order' suffer worse health than those above them. Income or income inequality acts as a proxy for the control in one's life. In wider hierarchies, those at the bottom suffer more than those at the top. Such a premise is partly based on the flight or fight syndrome – where the body produces a reaction in times of stress of whether to fight or take flight. With the body under stress, there are detrimental impacts on individual health.

Neither of these approaches is without problems. The sociological psychosocial approach looks only at psychological effects and appears to disregard the material, behavioral, or biological factors that may cause ill health. The epidemiological evidence is criticized because it often does not control for income as being part of the study. Without controlling for individual income, it is always possible that this confounds the relationship between health and income inequality.

Box 2 Health production function

The individual health production function is analogous to a firm's production function. As firms use combinations of capital and labor to produce the output, the individual uses combinations of goods to produce health. In its simplest for it can be considered that the only input to health is income. For a general relationship that gives:

$$H_i = f(Y_i)$$

This reads as individual health (H_i) being some unspecified function of individual income (Y_i). This would represent the AIH.

If health is measured as mortality risk and the function is decreasing, then the first derivative of the health production function would be negative (demonstrating that mortality risk falls as income increases). And if the function is nonlinear (convex), the second derivative would be negative (mortality risk falls at a decreasing rate – so the extra unit of income causes the mortality risk to fall, but by a smaller amount than that of the previous unit of income).

For the RIH, at the individual level, it is possible to specify a health production function of the form:

$$H_i = f(Y_i G)$$

This shows individual health (H_i) as being a function of both individual income (Y_i) and income inequality (G), measured at an appropriate level.

Aggregate-Level Data Problems

Much of the data used to investigate the relationship between income inequality and health are at the aggregate level, and although these 'aggregate-level data studies have provided considerable evidence in favor of the RIH, it is important to recognize their limitations. The key limitation of aggregate-level studies is the aggregation problem, which occurs when the existence of a nonlinear relationship between health (e.g. mortality risk) and income at the individual level leads to spurious results at the aggregate level.

The aggregation problem is best explained by using an example: Assume that absolute income is the only factor affecting individual health (AIH) and the relationship is nonlinear, so the relationship between mortality risk and income is convex – as income increases the risk of death decreases at a decreasing rate. This situation was described earlier and it is illustrated in Figure 1. The framework can be considered as a health production function (*see* Box 2). In this situation, income inequality has no impact on individual health – it is absolute income and not relative income that matters.

Now imagine that there are two countries (these are illustrated in Figure 1 as Evenland (E) and Unevenland (U)). In each country, there are only two groups: the rich (y_r) and the poor (y_p). The average level of income is the same in both countries ($\bar{y}$), but in Evenland, the difference between the incomes of the rich and the poor is smaller than in Unevenland.

The relationship between income and mortality risk (the graphical version of our convex health production function) is the same for both countries, which is the convex curve in Figure 1. Aggregating individuals and comparing average health in each country, shows that the average risk of mortality is lower in Evenland ($\overline{m_E}$) than it is in Unevenland ($\overline{m_U}$). From this aggregate-level evidence, it may be concluded that the distribution of income has a negative impact on health at the individual level; nevertheless, in fact, this would be a spurious conclusion because at the individual level, it has been assumed that there is no relationship between income distribution and health – it is only absolute income that matters.

In this example, the result $\overline{m_E} < \overline{m_U}$ can be explained solely by the AIH with no reference to the RIH. This occurs simply because of the nonlinear relationship between health and income at the individual level: the poor individuals in Unevenland are on a steeper part of the production function than those in Evenland. Conversely, the rich individuals in Unevenland are on a flatter portion of the production function than those in Evenland. The aggregation problem is demonstrated in its mathematical form by Gravelle *et al.* (2002).

Despite the aggregation problem, this example does show that more even distributions of income have better health on average than more unequal distributions. Again consider Figure 1. This time instead of thinking of two countries being compared consider the same country at two different time points – time E and time U. There are still two groups, the poor (p) and the rich (r), and between times E and U, there is a redistribution of income from the poor to the rich that leaves average income unchanged (at $\bar{y}$), but the income gap between the rich and the poor widens. Following the redistribution, the income of the poor falls from y_{E_p} to y_{U_p}, whereas the income of the rich increases from y_{E_r} to y_{U_r}. This leads to the mortality risk of the poor increasing from m_{E_h} to m_{U_h}, and the mortality risk of the rich decreasing from m_{E_l} to m_{U_l}. The increase in mortality risk for the poor outweighs the fall in risk for the rich, so $\overline{m_E} < \overline{m_U}$ and overall mortality risk increases. This result stems purely from the impact of individual income on

individual health (as predicted by the AIH) but clearly demonstrates why the distribution of income is important.

The aggregation problem highlights the need for individual-level studies to explore the RIH. Individual-level studies allow the exploration of the link between income inequality and health without having to deal with the aggregation problem. Lynch *et al.* (2004) have conducted a systematic review of the literature, investigating income inequality and health, and Jones and Wildman (2008) have considered the literature investigating relative deprivation and health. Although many of the results have been mixed – perhaps due to difficulties in a number of methodological and empirical issues, to be discussed in the next section – a recent meta-analysis does suggest a significant, if not causal, relationship between income inequality and health (Kondo *et al.*, 2009). It is likely that income inequality and health are related at the individual level; however, there are many unresolved issues before reaching a more definitive conclusion.

Unresolved Issues

The RIH presents a number of unresolved issues. Firstly, studies often use cross-sectional data that assume a contemporaneous relationship between income, income inequality, and health. This assumption raises an identification problem, which has not been dealt with adequately. When considering the mechanisms by which income inequality may affect health, such as stress generated by being of low social status, lack of social cohesion, or an inability to purchase status goods to 'keep up with the Joneses,' then the contemporaneous specification may not be detecting the true nature of the influence of income inequality on health. The impact of all these mechanisms on health takes time to develop; for example, being of low status may have a cumulative detrimental impact over time, so *ceteris paribus* the impact on health will be greater for older individuals. Longitudinal data are needed to examine the impact of income inequality over an individual's life course and whether the impact increases in severity over time.

Secondly, health can be measured across many different dimensions (e.g. expected lifetime QALYs, self-assessed health, long-standing limiting illness), but not all of these are sensitive to the effects of income inequality. If the psychosocial theory is correct, one would expect income inequality to have a greater effect on mental health measures than on measures of general health such as self-assessed health or physical health such as mortality or certain chronic illnesses. In addition, one may also expect a link between mental health and physical health, but the transitional effect from mental health to physical health may take time to develop. Furthermore, even though the observation of individuals over time provides the ability to control for unobservable heterogeneity, there are rarely data available that allow for the examination of the impact of inequality over the life course. So, if income inequality affects mental health, it may take even longer for the impacts to be revealed in more general health measures such as chronic illness or self-assessed health that are commonly collected in population surveys. To detect the psychosocial impact of income inequality on health, there is a need for longitudinal data with good measures of mental health.

Thirdly, investigating the RIH requires the construction of a relative income measure, namely, how an individual compares his or her income in society against a particular reference group; therefore, it is inevitable that investigations into the RIH are affected by the choice of a reference group against which individuals compare their income. There is no consensus in the literature on the reference group and there is no empirical solution to the problem – it is not possible to determine reference groups by observing behaviors because the choice of the reference group can itself be endogenous. Individuals may choose to compare their own income either with the average income of the country (region/town) they live in, or with the income of their peers, neighbors, people in the same age group, or any other plausible reference groups. Many of these reference group definitions have been used for research in this area.

A further issue for researchers is the measure of income inequality. The way in which this variable is constructed is yet another key element in understanding how income inequality affects health. The choice of measure can determine how income inequality appears to affect health. As noted above, the Gini coefficient is a commonly used measure of income inequality. Because this measure is an aggregate-level measure, there is only one Gini coefficient for any specific population wherein its use assumes that all individuals in that population are affected by income inequality in the same way. For example, in cross-national studies, each country has one Gini coefficient for any given year, and this means that there is no differential impact of income inequality for individuals within that country. Other methods have tried to create measures of income inequality that vary across individuals, and these measures are often considered to be measuring relative deprivation. Such measures compare an individual's income to a reference point, which may be the median or the highest income in an area. Such an approach acknowledges that income inequality may affect some individuals more than others as the relative income deprivation measure of someone being further away from, for example, the median income, is larger than that of someone being closer to it. This does raise an issue about the asymmetry of the inequality effect – individuals are negatively affected by having people above them in the income distribution, but they are unaffected by having people below them. It may be possible that individuals gain satisfaction from looking down on people in the income distribution, but this position has not been widely considered in the literature, partly because it is difficult to disentangle the positive effects of being above people from the negative effects of being below them for any given individual in a distribution (except the one at the very bottom end and the one at the top end of the income distribution).

Finally, there are theoretical or modeling issues that may be fundamental to examining the RIH. The measures of income inequality are often functions of individual income, which may cause multicollinearity in a regression while controlling for the effect of income. The income inequality measures may directly enter into the health production function or utility function, or enter indirectly through third factors, or both, and this may require a whole new theoretical framework for constructing the relationship between income inequality and

health. It could also be that as relative concerns allow such a broad range of behavior, their inclusion in choice models that theoretically consider individual behaviors may give them little or no predictive power. For these reasons, it is important to research and develop a proper theory underpinning the study of the RIH.

Conclusion

There is a substantial body of evidence linking inequalities in health with material factors, with income being considered as the most important factor. Recently, the RIH has been identified as an alternative explanation of health inequalities in developed nations. Initially, strong support for the RIH was provided by aggregate data studies, but these have been criticized because of the aggregation problem. Individual-level studies that overcome problems of aggregation have reported mixed results.

In recent years, research on income inequalities has widened its focus. Wilkinson and Pickett (2009) have considered the relationship between income inequality and a whole range of outcomes, including health and health behaviors (such as drug and alcohol addiction), social mobility, crime, well-being, and educational performances. This consideration of the relationship between income inequality and a wider range of outcomes suggests the importance of understanding the causal pathways at play.

Among both supporters and critics of the RIH, there appears to be a consensus calling for more research to model the effects of relative income on health from a broader perspective. Individuals live in societies and their behaviors need to be modeled and placed within a macro context in order to fully understand the relationship between income inequality and health; this would include individual-level characteristics and macro-level social factors such as social capital, social support mechanisms, and societal structures that cause inequalities. Developing a model to account for all these factors is the challenge for future research.

Income Gap across Physician Specialties in the USA

G David and H Bergquist, University of Pennsylvania, Philadelphia, PA, USA
S Nicholson, Cornell University, Ithaca, NY, USA

Glossary

Relative value unit A value assigned to each service that a physician performs that reflects the time, intensity of effort, malpractice costs, and practice costs associated with the service.

Introduction

Despite their common medical school training and their shared title of 'physician,' there are many differences between physicians who enter different fields of medical practice. The most obvious difference is the variation in knowledge set and patient population that comes with each specialty. For example, pediatricians take care of children, whereas geriatricians take care of the elderly, and the types of conditions and diseases treated by these two types of physicians are completely disparate. Even among doctors who treat patients of the same age, there can be vast differences, as seen, for example, between psychiatrists (who often use counseling to treat unseen diseases of the mind, emotion, and personality) and radiation oncologists (who, with a requisite knowledge of physics, use radiation therapy to treat cancerous tumors).

However, the differences across medical fields go beyond scope of practice. With different areas of specialization come a range of patient interactions; whereas gynecologists almost always have face-to-face interactions with their patients, anesthesiologists most frequently see unconscious patients, and pathologists and radiologists rarely (if ever) see their patients at all. Similarly, the practice settings where physicians in different specialties work are quite variable: a family practitioner typically works out of an office, a hospitalist works in hospital medical/surgical units, an intensivist works amidst the machinery of a critical care unit, and a surgeon works in the operating room. Along with these different settings and patients come different schedules and work hours. Although a dermatologist may have typical office hours (Monday through Friday, 9 a.m. to 5 p.m.), a surgeon will typically start much earlier (5 or 6 a.m.) and frequently run late into the evening, and emergency medicine physicians have to work nights and weekends to staff the emergency room 24 h a day, 365 days a year. Another difference across medical fields is the degree of specialization. Whereas a family doctor will treat patients of all ages and genders, and thus must be expected to recognize (and treat) a vast range of conditions and diseases, a neonatologist, cardiac electrophysiologist, or gastroenterologist who specializes in colonoscopy will focus on a relatively specific subset of patients and conditions. Along with varying degrees of specialization come different lengths of training programs. A general internal medicine physician can practice after 3 years of residency training, whereas a pediatric neurosurgeon requires a 7-year neurosurgery residency, followed by a pediatric neurosurgery fellowship of at least 1 year.

Another significant difference between medical specialties, and the focus of this article, is average income. For example, in the US, physicians who practice in the primary care specialties (e.g., general internal medicine, family practice, and pediatrics) earn substantially less than physicians in non-primary care specialties (e.g., dermatology, radiology, and orthopedic surgery), with some higher-income specialty physicians earning more than three times as much as their primary care contemporaries. These income differences also exist in other developed countries. For example, orthopedic surgeons earn twice as much per year as primary care physicians in Australia and the UK, and more than 50% more in Canada, France, and Germany.

To provide a glimpse of the variety in physician specialty income in the US, data from several waves of the annual Physician Compensation and Production Survey between 1995 and 2010 have been used in this article. The survey was conducted by the Medical Group Management Association (MGMA), spanning more than 2300 medical organizations and multiple specialties. Specialty classifications have been used based on Modern Healthcare salary surveys and Sigsbee (2011).

Figure 1 reports physicians' median compensation in 1995 versus 2010 across 18 medical specialties. The dotted line represents the case where the 2010 compensation level equals the inflation-adjusted 1995 compensation level (using the consumer price index). Points below this line represent specialties for which median salary grew at a slower pace relative to inflation. For example, median compensation between 1995 and 2010 for Obstetrics and Gynecology grew 31.4% whereas inflation was 41.6%. Figure 1 highlights both the dispersion in compensation level within period as well as the widening of the gap over time. Even in 1995, the median compensation for anesthesiology, cardiology, radiology, and orthopedic surgery was nearly double the median compensation for family practice, internal medicine, pediatrics, and psychiatry. By 2010, these differences were more pronounced with orthopedic surgeons earning close to three times more than family practitioners. It is interesting to note that some specialties experienced greater growth than others. For example, the fastest growth in median compensation occurred for dermatology and gastroenterology.

Figure 2 tracks average annual compensation for 10 specialties, for which data were available between 1995 and 2009. The income is plotted for five high-compensation specialties (radiology, anesthesiology, cardiology, urology, and oncology) and five low-compensation specialties (hospitalist (added to

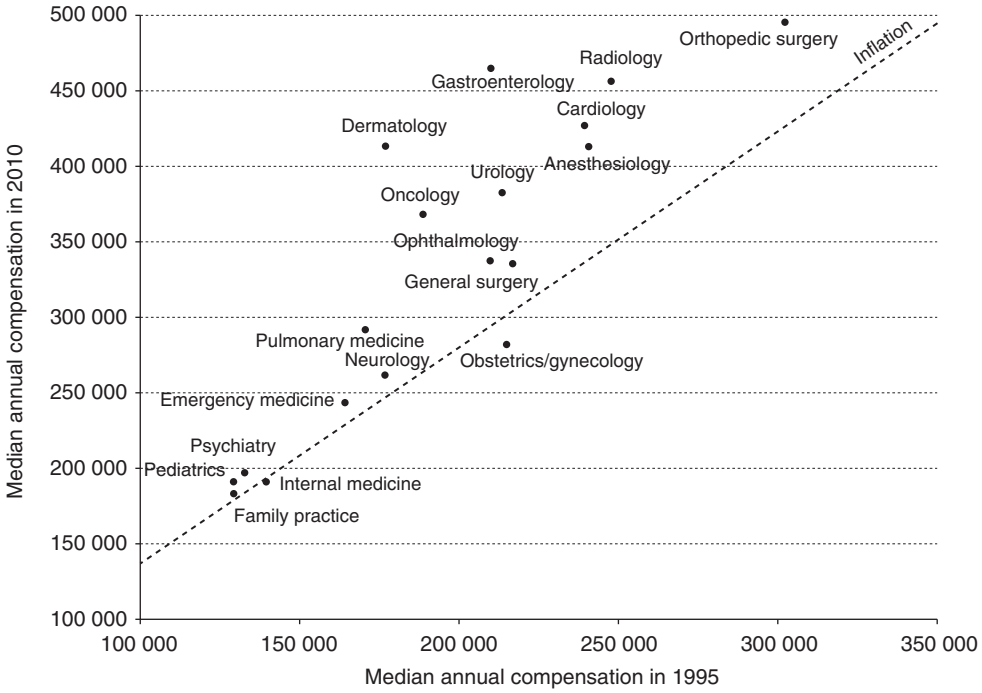

Figure 1 Median physician compensation in 1995 versus 2010 by specialty. Based on data from the 1995 and 2010 MGMA Physician Compensation and Production Surveys.

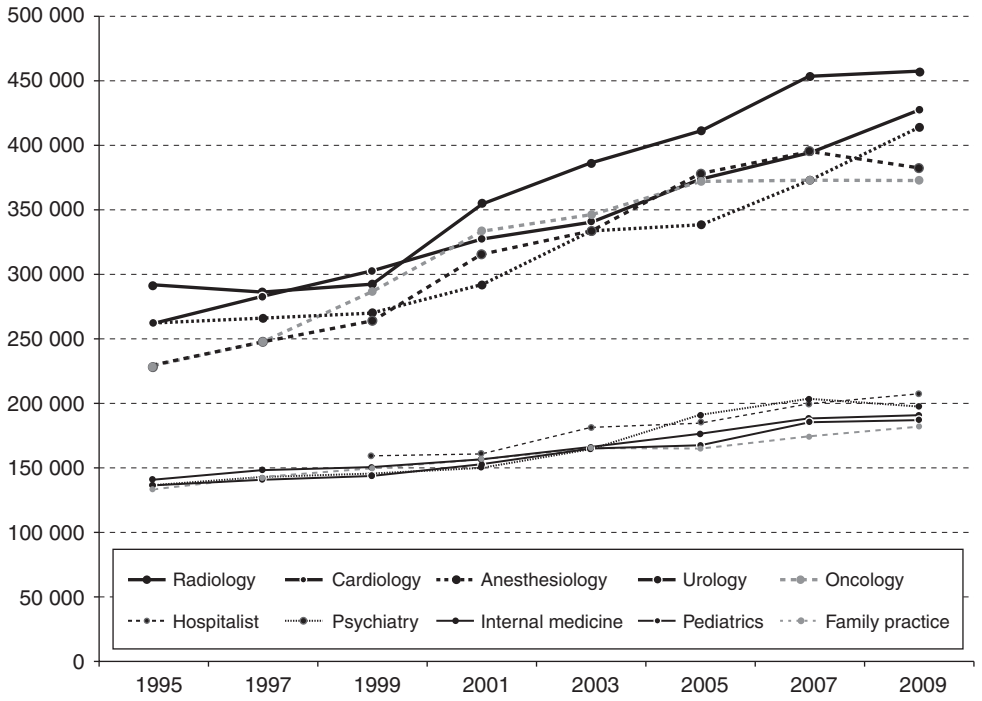

Figure 2 Trends in average annual compensation for selected specialties (1995–2009). Based on data from the 1995, 1997, 1999, 2001, 2003, 2005, 2007, and 2009 MGMA Physician Compensation and Production Surveys.

the survey in 1999), psychiatry, internal medicine, pediatrics, and family practice). Similar to Figure 1, both the difference at baseline (1995) and the difference in growth rates across high- and low-compensation specialties are apparent.

Specialists in most other developed countries receive much higher income than their primary care counterparts, although there are a few exceptions. In 2004, specialists earned at least 50% more than primary care physicians in Canada, Austria,

France, Luxembourg, and the Netherlands (in the US in that year, specialists earned 62% more than primary care physicians, on average) (Fujisawa and Lafortune, 2008). Primary care physicians in Japan earn more than specialists. This is probably because specialists are employed by hospitals, whereas primary care physicians tend to own their own practices, and physicians in Japan can provide a small number of hospital beds in their practice.

Aside from the potential discontent that this income gap may breed among different physicians, from a social or government policy perspective, this difference in expected income may have undesirable consequences. Research has shown that the US and Canadian medical students in general, when selecting their career specialty, are responsive to income differences. However, research has also shown that increased specialization leads to higher medical expenditures, without necessarily improving quality, mortality, satisfaction, or other important metrics of medical care. Thus, if specialists continue to have higher expected incomes than generalists or primary care physicians, the country's healthcare system may continue down a path of higher cost, lower value care, and a shortage of generalist physicians.

Although the ongoing existence of this salary disparity is undisputed, the reasons for its existence are subject to continued investigation and debate. For many in the medical community, the explanation for this income gap is simple: the major government and private payers of medical services (e.g., National Health Service in the UK, Medicare in Canada, US Medicare, US Medicaid, and private health insurers) have decided to reimburse specialists at higher rates than primary care doctors. In 1992, Medicare adopted the resource-based relative value scale system for the US, which is designed to set reimbursement rates according to the relative value of and resource requirements of different services, and most major insurers have followed suit. This payment system generally reimburses specialists at much higher rates, even for patient visits of comparable duration (Bodenheimber *et al.*, 2007). The relative value units used by the Centers for Medicare and Medicaid Services in the US to label each type of physician visit and procedure are updated periodically, under the recommendation of the Relative Value Scale Update Committee, which is dominated by specialty (i.e., nonprimary care) physicians, who make up 85% of its voting members.

Although it may be true that reimbursement rates for physicians are set exogenously by payers, it is not clear how such price setting would establish a persistent income gap across physician specialties. As mentioned two paragraphs above, studies have shown that expected income has a strong influence on specialty physician labor supply. If this is true and if there were no major differences between medical specialties aside from their expected income, one would expect all medical students to choose specialties with higher expected incomes (e.g., radiology, orthopedic surgery, anesthesiology, and cardiology), leading to a massive shortage of physicians in specialties with lower expected incomes (e.g., general internal medicine, family practice, psychiatry, and pediatrics). A large enough shortage would increase the demand for physicians in primary care and other low-paying specialties, which would eventually lead health insurers to offer increased income to attract medical students to these specialties, ultimately equalizing the expected incomes of different physician specialties. However, in reality, although there is a perceived shortage of primary care physicians, there is an enduring disparity in physician incomes across specialties, indicating that there are underlying causes or forces preventing the equilibration of expected income for physicians.

Two potentially different phenomena are required for this physician income gap to emerge and persist. First, there must be factors that cause medical students to sort into different medical fields, despite the difference in expected income. Second, there must be a reason (or reasons) that the income gap across specialties is allowed to continue and expand. That is, there must be some factors preventing prices from clearing the physician labor market. This article considers these two elements as different possible explanations and their supporting evidence for the observed income gap are evaluated.

Potential Explanations for the Income Gap

As evident from Figure 1, the income gap between different physician specialties has been persistent and has widened over time. However, the reason that this gap exists and persists is less obvious and is subject to continued debate and research. In reviewing the different hypotheses that attempt to explain the persistent income gap, this article will consider both mechanisms by which physicians sort themselves into different specialties independent of income (i.e., the reason the income gap is established) and also mechanisms that limit physicians' ability to concentrate in the highest paying specialties (i.e., the reason the income gap is maintained). The conclusion is that although individual preferences can help explain why incomes differ across specialties to begin with, the most important reason why these differences persist and have grown over time is that barriers prevent medical students from entering high-income specialties. Because physicians who are already in a specialty largely control the number of students who are allowed to enter that specialty, this raises the possibility that certain specialties are behaving as a cartel.

Preferences and Compensating Differentials

Aside from expected income, there are many other differences across medical specialties, including scope of practice, level of patient interaction, and regularity of working hours. Given this variety across medical fields, one might expect that a student's choice of medical specialty will be multifactorial and will depend on more than just expected income. The idea that job features and amenities may compensate for lower income may provide a possible explanation behind the physician salary gap and its persistence. If preferences for specialty choice are motivated by nonincome-related factors because individuals place less importance on expected income and more importance on, for example, the scientific content of their field, then some physicians will knowingly and purposefully choose lower-paying specialties, all in accordance with their individual valuation of other nonmonetary dimensions of the specialty.

In support of this hypothesis, many researchers have examined the influence of personality and personal preference on medical students' choice of career specialty. Many studies have found associations between different personality types and specific medical fields. As an example, research has shown that the traits of 'rule-consciousness' and 'tough-mindedness' predicted differences between physicians in general surgery and family practitioners (Borges, 2001). Furthermore, other studies have found that predictability of working hours and lifestyle are key factors driving medical students' choice of career specialty. For example, although pediatricians are paid less than trauma surgeons on average, it is often the difference in schedule structure (where general pediatricians work standard business hours that may extend into the evening as patient visits run over, whereas trauma surgeons work nights and weekends, but only in shifts with a well-defined beginning and end) that motivates students' selection of one specialty over the other. Similarly, one might expect that a student who is passionate about treating children would choose to be a pediatrician, even though (as the student knows) most pediatric specialists are paid notably less than adult specialists covering the same area of expertise (e.g., cardiology, neurology, intensive care, etc.).

Other factors that vary across specialties and individual preferences include specialties' level of intellectual content, number of challenging diagnostic problems, availability of research opportunities, likelihood (and severity) of malpractice litigation, and prestige relative to other specialties. Indeed, research has shown each of these different factors can play important roles in shaping medical students' choice of career specialty. It is important to note that not only is it possible for students to have different preferences for any given career attribute (e.g., one student may prefer a field that is diagnostically challenging, whereas another student may prefer a field that is diagnostically simpler) but it is also likely that students assign different degrees of importance to different attributes (e.g., predictable working hours is very important to some students, whereas other students' top priority is working in a specialty with more research opportunities). When considering all these different factors and how they might influence physician specialty selection, it is not surprising that differences in specialty income may be allowed to exist and persist. Certain specialties must have nonmonetary attributes that appeal to a large percentage of medical students, and this appeal has persisted (and perhaps grown) over time.

Ability Differences

In addition to preferences, another individual characteristic that varies between people and might explain the income disparity is ability, although it does not appear to play a strong role in explaining income differences for physicians. Although the admission process for medical school is rigorous and extremely selective, medical students still vary in ability. Here, ability may refer to IQ, memory (e.g., learning speed, and capacity), physical skills (e.g., dexterity and endurance), or personality type or temperament. Realizing the diversity that exists across medical specialties, one might hypothesize that some specialties require abilities that are relatively rare among medical students whereas other specialties require more common abilities. This article will assume that specialties that require greater ability (or more uncommon ability) are intrinsically more difficult or challenging, as it is not clear otherwise why they would demand greater skill or talent. As in many other professions, workers with the highest abilities have rare attributes, skills, or talents, which would demand a salary premium over other workers, so the difficult or challenging specialties will offer higher salaries to attract high-ability workers.

Another type of ability to consider is a physician's capacity for dealing with risk. Owing to their patient population and scope of practice, some specialties require physicians to act in higher risk situations. For example, most would agree that the likelihood and severity of patient harm from a physician mistake is greater in the fields of neurosurgery, anesthesiology, or interventional cardiology than in family practice or sports medicine. Moreover, specialists often accept more responsibility and thus risk compared to generalists. For example, it is commonplace for a family practitioner or general pediatrician to refer the patient to a specialist or an expert. The specialist, on the contrary, often represents the 'end of the line,' so the ultimate task of diagnosing and treating the patient often falls on the specialist. In this position, the specialist accepts more responsibility and risk (if the diagnosis or treatment is incorrect), so one might expect this additional responsibility to justify a salary premium.

As with the case of personal preferences, differences in individual ability can potentially explain both why students sort themselves into different medical specialties and why the income gap between specialties is able to endure. If the more challenging specialties (that require greater ability) pay more and all medical students prefer greater income, all students will prefer to work in the more difficult fields. However, if entrance into a specialty, which is typically dictated by acceptance to a residency program, is determined according to ability, then only the highly skilled or talented students will be able to work in the more difficult specialties. Given the demanding application and interview process that is required for admission to residency programs, which consider test scores, clinical evaluations, and letters of recommendation, there is clearly a process that prevents low-ability students from achieving positions in high-ability specialties, thus allowing persistence of the income disparity.

In the literature, theoretical economic work has supported this hypothesis that large income differences may reflect even relatively small differences in ability. Furthermore, research has shown that some medical specialists score higher than others in terms of, among other traits, intelligence and self-sufficiency. However, other works have found little evidence that differences in ability are responsible for the large gap in physician income (Bhattacharya, 2005).

The National Resident Matching Program and the Association of American Medical Colleges collect data on the medical students who match into different residency programs in the US, and these data indicate differences in ability between the students entering different specialties (NRMP and AAMC, 2009). For example, there are significant differences in scores on Step 1 of the US Medical Licensing Examination between

some higher-paying specialties (plastic surgery, neurosurgery, dermatology, and radiology) and lower-paying specialties (family practice, pediatrics, psychiatry, and physical medicine). Of course, these data do not indicate a causal relationship, but nevertheless the association between higher-paying specialties and students with higher test scores (a measure of ability) is noteworthy.

This being said, it is not clear whether or not the specialties with higher incomes are actually more challenging or demanding of greater physician ability than specialties with lower incomes. For example, is ophthalmology or dermatology more challenging than emergency medicine or neurology? Without any evidence of this, it is not clear that differences in medical students' or physicians' abilities are the reason that different specialties have different expected incomes. As long as students all want to maximize income and all residency programs want to attract students with the highest level of ability, residency programs for high-paying specialties will be able to select the most skilled and talented students, regardless of the reason(s) that different specialties have different expected incomes.

Workload and Effort

A straightforward explanation for why physicians in some specialties have higher salaries is that their specialties may require greater labor input. Taking this logic to the extreme, it may be that all physicians are paid approximately the same hourly wage, but those who work longer hours accumulate a greater total income. Furthermore, the effect of hours worked on income might be even greater if the marginal value of time increases as the number of hours worked increases. That is, comparing a physician who works 60 h per week to a physician who works 40 h per week, one might expect that the wage for the marginal hour should be higher for the former, because leisure time is more valuable to someone who spends more time working. This hypothesis of increased income with increased workload, if true, would provide a mechanism for both physician sorting into different specialties and the maintenance of the income gap, based on individual preferences for income and leisure. Given equivalent hourly rates, those physicians who choose to work longer hours (i.e., choose specialties that demand more time) are knowingly sacrificing leisure to receive higher pay, whereas those who place a higher value on leisure will willingly forego higher income.

Although this concept is intuitively plausible, it is not supported by evidence. In fact, it would be more likely that labor input is responsive to the hourly wage than vice versa. Put differently, exogenous variation in hourly wage across specialties would induce physicians with identical labor-versus-leisure preferences to vary in their labor supply. Thus, without the ability to verify the authors' assumptions of physician preferences, it cannot be determined if the income disparity results from variation in the value that different physicians place on their leisure (even with similar hourly wages), or from variation in hourly rates, which translates mechanically into an income gap even when physicians exhibit similar labor-versus-leisure preferences. To this end, research has shown that the number of physicians choosing a specialty is more responsive to changes in the number of relative hours worked than to changes in relative income earned. However, regardless of the assumptions, studies have found that only a small fraction of the income gap can be attributed to differences in the number of hours worked, indicating that hourly rates are almost certainly not equivalent across specialties (Bhattacharya, 2005).

Length of Training

Another hypothesis commonly believed to explain the income disparity across physician specialties is the difference in required training. The reasoning behind this belief is frequently offered as an explanation for why physicians, on average, compared to other professionals are among the best-paid members of most societies. Looking within medicine and comparing different types of physicians, specialists undergo more training than generalists, and additional years in residency and fellowship create potentially important opportunity costs for specialists (in terms of lost time and wages). Thus, the hypothesis states that specialists are paid more to compensate for the additional costs of their extended training. Without this increase in expected income, physicians would not be willing to incur the additional costs of training required for specialization. Therefore, if medical students have different time preferences for income, with some unwilling to take on short-term costs of training for the long-term gain of increased future income, they will sort themselves into specialties with different expected incomes.

In support of this hypothesis, research has indicated that medical students tend to prefer specialties with shorter residency training programs. However, other studies have shown that a relatively small portion of the income gap between different physician specialties can be explained by differences in training time; that is, students' choice of specialty is mostly unresponsive to expected length of training (Bhattacharya, 2005). Furthermore, although some specialties (e.g., gastroenterology) provide a favorable return to specialization, other specialties (e.g., rheumatology) actually provide an unfavorable return to specialization (e.g., compared to staying in general internal medicine). As another example, the postgraduate training requirements for geriatricians and dermatologists are typically equivalent, but the expected income of geriatricians is often less than half that of dermatologists.

Aside from direct costs of longer training, other short-term financial considerations may motivate students to choose a specialty with a shorter training requirement, even if it means lower expected long-term income. The majority of graduating medical students has extensive debt, mostly from accumulated loans for undergraduate and graduate education, and although such loans can be deferred while students are in school, when the students graduate and enter residency programs, they must begin repaying these loans. Given the amount of debt that some students have (more than US$200 000), the size of loan repayments can be substantial, causing significant financial stress during residency. Other than educational loans, some students might expect other

large financial burdens during residency, for example, supporting a new or growing family. Furthermore, although facing mounting financial demands, young physicians may have decreased access to private financial markets, as they are no longer eligible for educational loans. Any combination of these reasons can make residency training a particularly stressful financial time for young doctors, and this predicted stress may motivate students to choose specialties that minimize the length of residency, allowing them to become a practicing physician sooner. (Even the lowest paying jobs for practicing doctors pay at least three to four times more than a resident's salary.) However, most of the specialties with shorter residency programs have lower lifetime expected incomes than the specialties with longer residency training, so students who choose shorter residencies are typically choosing lower long-term expected salaries. Thus, differences in specialty length of training combined with debt and short-term financial considerations may explain why some students choose lower-income specialties and why the physician specialty income gap continues to exist. Furthermore, other work has shown that not only just the amount of student debt but also the type of debt (e.g., subsidized vs. unsubsidized loans) is a significant variable in students' choice of specialty.

Even for those medical students who are not carrying student debt or expecting increased financial stress during residency, there may be other motivations to choose a specialty with shorter residency training. For example, students might have very different future discount rates. Whether for financial reasons or otherwise, one could imagine students placing greater importance or value on the upcoming 5–10 years than on the more distant future; that is, a student might drastically discount all considerations that are more than 5–10 years away. In this time horizon, a medical specialty with a shorter residency program might appear more ideal than other specialties. For example, over the first 10 years of postgraduation, a student who enters family practice (3 years of residency) can expect to earn more than a student who pursues a career in surgery (more than 7 years of residency) because the income of the family practitioner will be much higher than that of a surgery resident. Thus, heterogeneity in time preferences and subjective discount rates may help explain why income-maximizing students choose specialties with very different lifetime expected incomes.

Although most of the literature has explored variation in the length of formal training across specialties as a potential explanation for the income gap, no attention has been given to aspects of on-the-job training across specialties. Surgical and procedural specialists have to keep up with changing equipment, technology, and procedures and are required to invest considerable amount of time in order to do so. Therefore, an argument could be made that physicians in more dynamic fields require a premium for keeping up with the latest technologies and procedures. Nevertheless, it could be argued that generalists and nonprocedural specialists have just as many journals to read and new guidelines to keep up with. Moreover, most states necessitate continuing medical education (CME), but do not make distinctions across specialties; hence, specialists do not have to perform more CME than generalists.

Variation in Training Focus across Medical Schools

Despite the theories and supporting studies that connect student debt to medical specialty choice, other researchers have shown that medical students entering primary care fields do not have significantly more (or less) debt than students entering nonprimary care fields. A medical student's choice of career specialty is a complicated, multifactorial decision. Not only is that decision influenced by the interplay of personal preferences and specialty characteristics but also the type of environment in which medical students are educated may also shape their choice of specialty. Medical schools can be viewed as producers of medical students, and although there is some standardization across medical schools, there can be substantial variation in the inputs that schools supply to this production process. Inputs in the medical student education process for any given medical specialty include, among other factors, preclinical curriculum, clinical rotation requirements, availability of mentors, and the presence of a residency training program. Through the variable use of these different inputs, some schools will produce more students who choose to pursue careers in primary care or other specialties. For example, the percentage of US graduating students who enter family practice varies (over a 10 year mean) from 1.7% to 34.9% depending on their medical school. Although the income gap across medical specialties may be established for exogenous reasons, the role played by medical schools may help explain how the income disparity is maintained. When students first enter medical school, they are less likely to exhibit strong preferences toward a given medical specialty, because they may have limited understanding of the different fields and little awareness of income differentials across fields. Therefore, students are likely to select their medical school regardless of the specialty mix it typically produces, and hence to be sorted into specialties with different income profiles.

Research has verified that medical schools do influence students' choices of career specialties. For example, the differential production of generalists versus specialists has been examined by studies that characterize the population of students who choose to enter family medicine residences. Supporting the hypothesis that medical schools may have different 'production functions' for medical students, research has shown that students from publicly funded schools are more likely to choose family medicine than students from privately funded medical schools. In some years, although some medical schools (including Johns Hopkins University, New York University, and Washington University in St. Louis) had no graduates who pursued careers in family medicine, at other schools (including University of Arkansas, the Medical College of Georgia, and University of Minnesota) greater than 22% of graduates entered family medicine residencies.

Institutional Barriers to Entry

Bhattacharya (2005) examined the role of different factors in explaining the disparity in physician income across specialties, and finds that only approximately half of the increase in expected income from specialization can be attributed to differences in hours of work, length of training, and skill or ability. Although individual preferences and their implications

for career path selection may explain some of the income disparity, barriers that prevent medical students from entering higher-income specialties offer another plausible explanation.

The Accreditation Council for Graduate Medical Education (ACGME) is the organization responsible for accrediting residency programs in the US, and thus it determines how many residency positions are available for training new physicians. Regulation of medical education and training is common in most developed countries. For example, the Medical Council of India, the Korean Institute of Medical Education, the General Medical Council (UK), the Netherlands–Flemish Accreditation Organization, and the Japan University Accreditation Organization approve curricula and accredit medical schools in their respective countries.

Broadly speaking, the restricted number of residency positions is a substantial factor (if not the most important factor) limiting the number of physicians who can enter professional practice, but it also plays a role in determining the number of physicians in different specialties. The ACGME oversees and sets policies for Residency Review Committees (RRCs), which are specialty specific and tasked with reviewing and accrediting hospital residency programs in their target specialties. In this position, an RRC essentially has complete control over the flow of physicians into a specialty because medical students who attend programs that are not certified by the ACGME are not eligible to take the licensing exam, and thus not able to practice in the US (Nicholson, 2003). Therefore, incumbents in a specialty determine how many new physicians may be trained in that specialty, which in turn will influence future earnings in that specialty.

Thus, regardless of the reasons why expected incomes vary across medical fields, the constrained number of available residency positions for each specialty prevents all medical students from entering higher-paying specialties, thus allowing the income gap to be sustained. High-income specialties in the US tend to have more residents who are trying to enter than there are positions available. For example, between 1991 and 2009, the ratio of the number of medical students who were trying to enter a specialty to the available number of first-year residency positions exceeded 1.40 in orthopedic surgery in all but 1 year, and between 1997 and 2009 the ratio exceeded 1.60 in dermatology in all but 1 year. Barriers to entry exist in other countries as well. Medical school graduates in Greece often wait several years for a nonprimary care residency position opening.

Concluding Remarks

In developed countries, specialists, or nonprimary care physicians, earn considerably more than primary care physicians, and these income differences have persisted over time. This article reviews and assesses the support for different hypotheses regarding nonmonetary reasons why physicians may sort themselves into different specialties (i.e., the reason an income gap is established), and also hypotheses that help explain why the income gap persists.

Specialists can earn more than primary care physicians if the former medical fields require scarce abilities, have unattractive nonmonetary attributes (e.g., undesirable working environment), and require relatively long training. This will be particularly true if medical students have different time preferences and debt levels. If these factors persist over time, such as medical students' preferences for the nonmonetary attributes of primary care, then the higher income of specialists relative to primary care physicians can also persist. The empirical support is strongest for the hypothesis that occupational attributes other than expected income do matter when medical students choose a specialty, and therefore do help explain income differences across specialties.

However, Bhattacharya (2005) finds that student preferences explain approximately one-half of the specialty premium, with entry barriers to high-income specialties possibly explaining the balance. Thus, regardless of the reasons why expected incomes vary across medical fields to begin with, constraints on the number of available residency positions in high-income specialties prevent medical students from entering high-income specialties and driving down specialist income, and thus allow the income gap to persist. Because physicians who are already practicing in a specialty largely control the flow of new physicians into that specialty, this raises the question of whether certain high-income specialties are behaving as cartels. Making it easier for medical students to enter high-income specialties would reduce income differences across specialties.

Incorporating Health Inequality Impacts into Cost-Effectiveness Analysis

M Asaria, R Cookson, and S Griffin, University of York, York, UK

Introduction

Health sector programs often have important policy objectives relating to the reduction of unfair health inequality, as well as the improvement of total population health. Health inequality reduction objectives are particularly common in public health decision-making, for example, in relation to screening and vaccination programs, and are sometimes also relevant to decisions regarding the introduction and delivery of new medicines, surgical procedures, and other health technologies.

Standard economic evaluation methods, however, focus solely on identifying cost-effective interventions to maximize health. The distributional cost-effectiveness analysis (DCEA) framework described in this article builds on standard cost-effectiveness methods by extending them to incorporate distributional impacts on health. Like the standard cost-effectiveness analysis (CEA) framework, this framework focuses exclusively on health benefits and opportunity costs falling on the health sector budget. It focuses on the health impacts of health sector programs, assuming that there are no important impacts on the distribution of income, education, or other determinants of health outside the health sector. It is therefore not suitable for evaluating cross-government public health program with important nonhealth benefits and opportunity costs falling outside the health sector budget.

The key steps in the DCEA framework outlined below are: estimating the baseline health distribution in the general population; modeling changes to this baseline distribution due to the health interventions being compared, and using this to estimate the mean change in health due to each intervention; adjusting the resulting modeled distributions for alternative social value judgments regarding fair and unfair sources of health variation; using these adjusted distributions to estimate the change in the level of unfair inequality due to each intervention; and finally combining the mean level of health and level of unfair inequality associated with each intervention by using an appropriately specified social welfare function to rank interventions, and decide as to which best fulfills the dual objectives of maximizing health and minimizing unfair health inequality.

Estimating the Baseline Health Distribution

The first step in DCEA is describing the baseline distribution of health in the general population, taking into account variation in both quantity and quality of life among different subgroups in the population as defined by relevant population characteristics. A natural health metric to use in this context is quality adjusted life expectancy (QALE) at birth, though other suitable health metrics can be used – such as disability adjusted life expectancy at birth or age-specific QALE – so long as they are on an interpersonally comparable ratio scale suitable for use within CEA. Mortality rates and morbidity adjustments differentiated by relevant population characteristics are required to estimate this distribution. Figure 1 shows the estimated baseline population health distribution in the UK in the year 2010 as measured in QALE at birth, taking into account differential mortality and morbidity by age, gender, and area level deprivation.

Estimating the Distribution of Health Changes Due to the Intervention

The next step in DCEA is to estimate the net impact of one or more interventions on the baseline distribution of health within the general population. This requires not only 'effectiveness' information on the direct health benefits of the health intervention on individuals receiving the intervention, but also information on the indirect health impacts of the intervention – in particular, the health opportunity costs due to displaced expenditure within the health sector budget – on both recipients and nonrecipients of the intervention. There are a number of factors that may vary by relevant population subgroup characteristics, which must be incorporated into the model to estimate correctly the impact of a health intervention on the population health distribution, including:

- Prevalence and incidence of the health condition, which will also help to analyze the differing maximum potential impact that the intervention could have on each population subgroup.
- Uptake of the intervention, which for more complex interventions may include differential uptake by subgroup at multiple stages of the patient pathway.
- Effectiveness of the intervention.
- Mortality and morbidity due to condition and comorbidities.
- Opportunity cost.

Under the assumption of a fixed overall health budget, any additional costs associated with the intervention will result in some displacement of activity. The distribution of the health

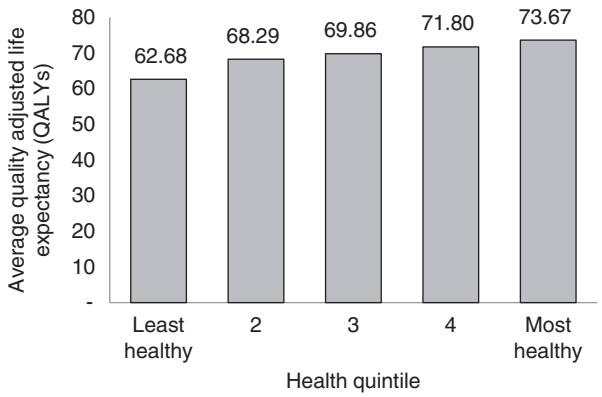

Figure 1 Baseline health distribution.

 doi:10.1016/B978-0-12-375678-7.01415-2

opportunity costs due to this displacement on both recipients and nonrecipients of the intervention in the population needs to be characterized by subgroup to give the overall distribution of health losses due to the intervention. A simple and convenient assumption is that the distribution is neutral – i.e., all subgroups share equally in the health opportunity cost of displaced health sector activity. However, this assumption may not be accurate, and ideally, one would want evidence on the likely distribution of health opportunity cost.

Once the distribution of health gains and health opportunity costs of an intervention for each population subgroup have been estimated, these distributions can be combined to produce a distribution of net health changes by subgroup and applied to the baseline health distribution to give an estimate of the impact of the intervention on the overall health distribution.

Measuring the Level of Inequality in the Estimated Health Distributions

The overall health distributions associated with each intervention can be assessed in terms of the level of health inequality they comprise. There are a number of commonly used indices for measuring inequality in the distribution of income, which can also be applied to health when measured on a ratio scale such as quality adjusted life expectancy. These indices are based on a common set of fundamental principles:

- Principle of transfers: The most universally recognized concept of what is meant by inequality in a distribution is the weak principle of transfers, also known as the Pigou–Dalton transfer principle. It broadly states that the transfer of health from a more healthy to a less healthy person reduces inequality so long as the amount of health transferred is less than the difference in health between them. It is of course not possible directly to transfer current health from one person to another (except in rare cases such as organ transplant); but one can think of indirect transfers in terms of gains or losses in people's expected future lifetime experience of health. This concept of inequality is useful for comparing alternative distributions of a fixed total pot of health. The next two concepts discuss how inequality measures react to a change in the size of the pot.
- Scale independence: Scale independence focuses attention on concern for relative inequality between individuals – their 'fair shares' of the total pot – rather than the size or scale of absolute differences between individuals. It states that any equal proportional change in each individual's level of health should not change the measure of health inequality. Although this is relatively uncontroversial when applied to changes in the scale used to measure health, it is harder to justify when looking at real differences in health. A commonly used tool to describe relative inequality in a distribution is the Lorenz curve, this plots the cumulative proportion of individuals ordered by their health on the x axis against their cumulative share of total health on the y axis. The difference between the Lorenz curve and the 45° line of equality represents the level of relative inequality in the distribution. Common relative inequality measures such as the Gini coefficient are based on measuring this difference. There are also relative inequality measures such as the Atkinson index that allow for the specification of a level of inequality aversion to adjust the sensitivity of the measure to inequalities in different parts of the distribution, and which also allow explicit formulation of tradeoffs with sum total health within a social welfare function framework.
- Translation independence: Translation independence focuses on concern for absolute inequality between individuals. It states that any equal absolute change in each individual's level of health should not change the measure of health inequality. Simple measures such as absolute gaps and slope indices are widely used to quantify absolute inequality. There are also absolute inequality measures such as the Kolm index – an absolute inequality equivalent to the Atkinson index – which allow the specification of an absolute inequality aversion parameter and the modeling of explicit tradeoffs with sum total health.

Although all reasonable inequality measures satisfy the principle of transfers, a measure cannot fully satisfy both scale independence and translation independence. For example, if everyone in a health distribution gains 25 years in life span the absolute gap between any two individuals remains the same, a relative gap between two individuals living 60 and 50 years respectively of 20%, however, declines into a relative gap of only 13%, with these individuals living 85 and 75 years after the gain in life span. When selecting inequality indices to rank distributions, it is important to recognize these distinctions and identify those that most closely represent the concept of inequality of relevance in the context of the decision being evaluated.

Adjusting for Social Value Judgments Regarding Fair and Unfair Sources of Inequality

The purpose of DCEA is to identify the health intervention that results in the best improvement in both average health and unfair health inequality in the population. The distributions of health estimated thus far represent all variation in health in the population. However, some variation in health may be deemed 'fair' or, at least 'not unfair,' perhaps because it is due to individual choice or unavoidable bad luck. The health distributions should therefore be adjusted to include only any health variation that is deemed 'unfair' before measuring the level of inequality. The DCEA framework allows multiple sources of unfair health inequality – for example, by income, education, ethnicity, geography, and other factors – to be analyzed in the same model. If decisionmakers are interested in one particular source of unfair health inequality, this can also be analyzed separately, or by decomposing the influence of this factor on overall unfair inequality. To make these adjustments for unfair sources of health variation, the association between relevant population characteristics and the estimated health distributions must be modeled. Social value judgments then need to be made regarding whether or not health variation associated with each of the population

characteristics is deemed fair. The modeled associations combined with these social value judgments are used to isolate unfair variation in the distribution, using either the methods of direct or indirect standardization. Inequality measures can then be used to assess the level of unfair inequality in the estimated health distributions associated with each health intervention and hence to rank health interventions by their impact on minimizing this inequality.

Social Welfare Functions and Distributional Dominance

Once both the mean level of health and the fairness adjusted distribution of health associated with each of the interventions have been estimated, social welfare functions (SWF) can be used to compare interventions. Several properties are considered useful when constructing a SWF. In describing these properties, one can use the terminology h_{iA} to represent the health of individual i in health distribution A, U_i to represent an individual utility function for individual i, and W to represent social welfare:

- Individualistic: This means the SWF is a function of the individual utilities, i.e., the SWF has the form: $W=W(U_1, U_2..., U_n)$.
- Nondecreasing: This states that if every individual has at least as good health in distribution A as in distribution B, then overall distribution A is at least as good as distribution B.
- Additive: This means that the social welfare function can be written as a sum of the individual utility functions, i.e., the SWF has the form: $W(h_1, h_2,..., h_n)=U_1(h_1)+U_2(h_2)+...+U_n(h_n)$.
- Symmetric: This means that the SWF treats individual utilities anonymously, i.e., the SWF has the form: $W=W(U_1, U_2,..., U_n)=W(U_2, U_1,..., U_n)=...=W(U_n, U_2,..., U_1)$.
- Concave: This means that when evaluating changes to social welfare lower weight is applied to increases in health to those with higher health than to those with lower health, where the welfare weight is defined as: $U'(h_i)=dU(h_i)/dh_i$.

These properties can be used to derive rules to help determine which of two health distributions are preferable. By using these dominance rules, the exact nature of the SWF need not be specified but can instead be described by broad characteristics that encompass whole classes of SWFs, under any of which the welfare rankings of particular interventions would be the same. The following rules are listed in order from least restrictive to most restrictive that allow a partial ordering of health distributions:

- Rule 1 – Pareto Dominance: For any individualistic, increasing and additive SWF, if $h_{iA} \geq h_{iB}$ for all i and $h_{iA} > h_{iB}$ for at least one i, then distribution A is preferred to distribution B, where subscript i represents the same individual in each distribution.
- Rule 2 – Reranked Pareto Dominance: If additionally, the SWF is also symmetric, then the same condition applies, only that now subscript i represents the individual with equivalent health ranking in each distribution rather than necessarily the same individual in both distributions.
- Rule 3a – Atkinson's Theorem: If additionally, the SWF is strictly concave and distributions A and B have equal mean health, then distribution A is preferred to distribution B if, and only if, the Lorenz curve for distribution A lies wholly inside the Lorenz curve for distribution B.
- Rule 3b – Shorrocks' Theorem: if Lorenz curves cross and the mean health in distribution A is greater than that in distribution B, then distribution A is preferred to distribution B if, and only if, the generalized Lorenz curve for distribution A lies wholly inside the generalized Lorenz curve for distribution B, where the generalized Lorenz curve is derived by multiplying the Lorenz curve for the distribution by the mean of the distribution.

These dominance rules may be used to rank the estimated distributions associated with the health interventions being compared and hence to rank the interventions in terms of social welfare. These rules do not, however, allow for trading off between health inequality and overall health and hence will only provide a partial ranking of interventions when rankings on these two objectives do not coincide.

Social Welfare Indices

Where interventions cannot be ranked based on distributional dominance rules, the SWF needs to be fully specified by defining the nature of the inequality aversion that it will embody to create social welfare indices. The principle underlying the interpretation of these indices is that if health is distributed unequally then, given an aversion to inequality, more overall health would be required to produce the same level of social welfare than if health were distributed equally. Social welfare is represented in these measures using the concept of 'equally distributed equivalent' health: the common level of health in a hypothetical equal distribution of health that results in the same level of social welfare as the actual unequal distribution of health. Two common alternatives specifications for the nature of inequality aversion expressed in social welfare indices are constant relative and constant absolute levels of inequality aversion, yielding the Atkinson and Kolm indices of social welfare respectively:

- Constant relative inequality aversion: This means that a constant proportionate change in health results in a constant proportionate change in welfare weight, i.e., function U(.) takes the form:

$$U(h_i) = \frac{{h_i}^{1-\varepsilon}}{1-\varepsilon}, \varepsilon \neq 1$$

$$U(h_i) = \ln h_i, \varepsilon = 1$$

Summing across this population gives the Atkinson index of social welfare:

$$h_{ede} = \left[\frac{1}{n}\sum_{i=1}^{n}[h_i]^{1-\varepsilon}\right]^{\frac{1}{1-\varepsilon}}$$

where the parameter ε, which can take any value from zero to infinity, specifies the level of societal inequality aversion.

The higher the ε, the further the index tilts toward concern for health improvement among less healthy individuals rather than more healthy individuals. A value of zero represents a classic 'utilitarian' view that all that matters is sum total health and not inequality in the distribution of health. Although as the value approaches infinity, the index comes to represent the 'maximin' view that all that matters is the health of the least healthy individual, irrespective of the health of all other individuals. The proportion of mean health that can be sacrificed to achieve equality will increase as the level of inequality aversion rises.

- Constant absolute inequality aversion: This means that a constant absolute change in health results in a constant proportionate change in welfare weight, i.e., function U(.) takes the form:

$$U(h_i) = -\frac{1}{\alpha}e^{-\alpha h_i}$$

Summing across the population, this gives the Kolm leftist index of social welfare:

$$h_{ede} = -\left(\frac{1}{\alpha}\right)\log\left(\frac{1}{n}\sum_{i=1}^{n} e^{-\alpha h_i}\right)$$

where the parameter α specifies the level of societal inequality aversion, with higher α values making the index more sensitive to changes at the lower end of the health distribution. The value of this index represents the absolute amount by which average health could be reduced to achieve equal health for all. As with the Atkinson index, the amount of mean health that could be sacrificed to achieve an equal distribution rises with the level of inequality aversion.

The ranking of health distributions using social welfare indices will always be consistent with that produced by the distributional dominance rules where these apply. Where distributional dominance does not apply, rankings may be sensitive to the type and level of inequality aversion embodied by the SWF and these should be chosen with care.

Comparing and Ranking Interventions

Having fully specified the SWF, all interventions can be compared and ranked on the combined objectives of maximizing health and minimizing unfair health inequalities in the population. Conclusions on which intervention is best may be sensitive to alternative social value judgments made both in the fairness adjustment process and in the specification of the type and level of inequality aversion. These social value judgments should ideally be made by the appropriate stakeholders through a deliberative decision-making process, and the robustness of conclusions to alternative plausible social value judgments should be explored.

Conclusion

DCEA is a framework for incorporating equity concerns into the standard methods of CEA. A number of social value judgments regarding which inequalities are deemed to be unfair and the nature and strength of inequality aversion need to be made when using the framework to evaluate and rank alternative health interventions. The framework makes these social value judgements explicit and transparent, and lends itself well to checking the sensitivity of conclusions drawn to alternative plausible social value judgments.

There are a number of alternative methods proposed in the literature for including health inequality concerns in economic evaluation. These typically involve either weighting health gains differently for different groups in the population or weighting overall health gains directly against overall changes in heath inequality. Both these types of method can be replicated using the DCEA framework by imposing the relevant restrictions on the fairness adjustment process and on the form and parameters of the social welfare function.

An important emerging source of empirical literature on incorporating health inequality impacts into economic evaluation in low and middle income countries is the 'extended cost-effectiveness analysis' work being developed by Dean Jamieson, Ramanan Laxminarayan, and colleagues as part of the Disease Control Priorities 3 project (www.dcp-3.org). Their approach to distributional analysis is similar in spirit to the approach outlined in this article, although simplifying the analysis by (1) focusing on a single distributional variable (wealth quintile group) rather than analyzing multiple distributional variables, (2) setting aside the issue of opportunity costs falling on the health budget by assuming that the intervention is funded by the tax system, and (3) presenting results as a disaggregated 'dashboard' of costs and consequences by social group rather than using inequality indices and social welfare functions to analyze tradeoffs between improving health and reducing unfair health inequality explicitly. However, their approach takes a broader perspective than standard CEA by incorporating financial risk protection benefits as well as health benefits. It therefore points the way toward the next great methodological challenge in this area: developing methods of 'distributional cost-consequence analysis' and 'distributional cost-benefit analysis' for incorporating health inequality impacts into economic evaluation of cross-government interventions with important nonhealth benefits and opportunity costs.

Incorporation of Concerns for Fairness in Economic Evaluation of Health Programs: Overview

R Cookson and S Griffin, University of York, York, UK
E Nord, Norwegian Institute of Public Health and the University of Oslo, Norway

Glossary

Cost-value analysis A variant of cost-effectiveness analysis in which *Quality-Adjusted Life-Years* are replaced by social values of a topically relevant kind that take explicit account of the severity of the condition for which the intervention is intended.

Discrete choice analysis A procedure used in experimental economics in which subjects choose real or simulated discrete (i.e., 'on' or 'off') options and thereby reveal (or 'state') their preferences over, for example, states of health.

Economic evaluation A general term for the economic evaluation of options.

Equity Equity is not necessarily to be identified with equality or egalitarianism, but relates in general to ethical judgments about the fairness of the distribution of such things as income and wealth, cost and benefit, access to health services, exposure to health-threatening hazards and so on. Although not the same as 'equality', for some people, equity frequently involves the equality of something (such as opportunity, health, access).

Equity weights The relative importance or value attached to different elements in a decision about what is fair. They may be numerical. In matters of vertical equity, the weights would make the desired adjustment to cost or outcome according to the differentiating features of individuals, such as their age or the severity of their illness.

Fair innings The name given to the idea that benefits to individuals who have not yet had a 'fair innings' (in terms of length of life in reasonable health) should receive a higher weight in cost-effectiveness analyses than those to people who have.

Fairness The ethical consideration of differences between people in terms of their health, access to health care, wealth, opportunities and so on. Fairness does not necessarily require equality since some differences may be regarded as fair ones as, for example, when they are deserved.

Horizontal equity Treating equally those who are equal in some morally relevant sense. Commonly met horizontal equity principles include 'equal treatment for equal need' and 'equal treatment for equal deservingness.'

Multi-criteria decision analysis A technique (often abbreviated as MCDA), akin to cost-effectiveness analysis (CEA), for helping decision makers to take decisions. It differs from CEA by explicitly helping decision makers to consider factors beyond standard welfare or health maximization.

Opportunity cost The value of a resource in its most highly valued alternative use. In a world of competitive markets, in which all goods are traded and where there are no market imperfections, opportunity cost is revealed by the prices of resources: The alternative uses forgone cannot be valued higher than these prices or the resources would have gone to such uses.

Person trade-off A method of assigning utilities to health states that works as follows: Subjects are asked a question of the following kind: 'If x people have health state A (described) and y have health B, and if you can only help (cure) one group, which group would you choose?' One of the numbers x or y is then varied until the subject finds the two groups equally deserving of their vote. The ratio x/y gives the 'utility' of state B relative to A.

Public health Similar to population health, drawing on social epidemiology to embrace the widest range of determinants of health in a society; a broader range of technologies for addressing them than is usually encompassed in public health medicine, such as population vaccination, safety at work, health education, and water purification. The wider range includes determinants such as better parenting for childhood development, better housing, even greater equality of income and wealth; and the broader range of institutional pathways and vectors of influence implied by the forgoing, such as schooling and schools, working and workplace.

Social welfare function A function that maps from the levels of utility attained by members of society to the overall level of welfare for society.

Vertical equity Treating unequally those who are unequal in some morally relevant sense. Commonly met vertical equity principles include 'higher contributions from those with greater ability to pay', 'more resource for those with greater need'.

Introduction

This article is a review of methods for incorporating concerns for fairness or equity in economic evaluation of health care and public health programs. By way of background, the next two sections review the role of equity concerns relative to concerns for efficiency and cost-effectiveness in actual health policy on the one hand and in health economics on the other hand. Section Concerns for Equity: Overview gives an overview of a number of different kinds of concerns for equity and highlights the most salient ones. In section Methods for Incorporating Concerns for Fairness into Economic Evaluation, the various methods for incorporation of equity concerns in economic evaluation are explained.

Equity in Health Policy

Health care decision makers are interested in equity in the finance and delivery of health care, and public health decision makers are interested in equity and inequality in health more broadly. The nature and importance of these equity objectives varies between countries, reflecting variation in concerns for fairness between different societies and over time. For example, in the US policy concerns for fairness in health care focus on offering all citizens a decent minimum of health care but, beyond that, tolerating substantial inequalities of access to health care and substantial risks of catastrophic household expenditure on health care. Although in most other high-income countries policy concerns about fairness in health care focus on minimizing catastrophic household expenditure on health care, minimizing socioeconomic inequality in health care, giving priority to the worse off, and securing equal access to people with equal need. Despite this heterogeneity between different societies, important concerns for fairness exist in all societies, which health sector decision makers need to reflect in their decision making.

Fairness concerns sometimes clash with efficiency concerns. For example, health care decision makers routinely face clashes between the efficiency concern to do as much good as possible with scarce resources and the fairness concern to give priority to the most severely ill patients. Such clashes are seen, for example, in relation to dialysis machines, intensive care for preterm babies, and new drugs for end-of-life cancer patients. In each case, these forms of care are often not cost effective by conventional standards, implying that health decision makers could do more good by diverting scarce resources to other more cost effective forms of care. Yet decision makers often choose to fund these cost ineffective forms of care, reflecting important concerns for fairness that lie outside the conventional calculusof economic evaluation. Clashes of this kind are likely to become more frequent and more intense over time, even in high-income countries, as cost-increasing medical innovation increasingly drives a wedge between what is technologically possible and what publicly funded health systems can afford.

Similarly, public health decision makers in all countries routinely face clashes between improving population health and reducing socioeconomic inequality in health. For example, smoking cessation programs, physical activity programs, and other public health programs that seek to change lifestyle behavior are typically more effective in higher socioeconomic groups – and hence tend to increase socioeconomic health inequalities. Decision makers may therefore seek to redesign such programs to encourage participation among lower socioeconomic groups. In doing so, however, they may incur additional costs and limit the scope for improving health among socioeconomically advantaged populations, thus potentially reducing the sum total gain in population health. Clashes of this kind are fundamental and perennial issues in public health. The nature, size, and persistence of health inequalities are well-known. Yet policy makers still do not know how to reduce them. For example, despite a series of concerted attempts by the UK government in the 2000s to tackle health inequality, the 2010 Marmot Report found a gap of 14 years in disability-free life expectancy between the most and least deprived twentieths of small areas of England. Equity concerns of this kind are likely to become sharper over time, as global economic growth continues to be driven by technological innovation and other factors favoring high-skill workers. Applied economic evaluation evidence is needed about the costs and benefits of alternative programs for tackling health inequalities, to identify what works and to measure not only effects on average health outcomes but also effects on the socioeconomic distribution of health outcomes.

Figure 1 presents a simple stylized example of the two kinds of trade-off described above. Program 1 maximizes total health – it yields a gain of 2 health units for both groups – whereas program 2 results in a more equal distribution of health – it yields a gain of 3 health units for the worse off group B, but nothing for the better off group A. If group B is a severely ill group and the health units represent quality of life on a 0–100 scale, then this is a trade-off between total health and priority to the most severely ill patient group. If group B is a socioeconomically disadvantaged group and health units are life-years, then this is a trade-off between total health and socioeconomic inequality in life expectancy.

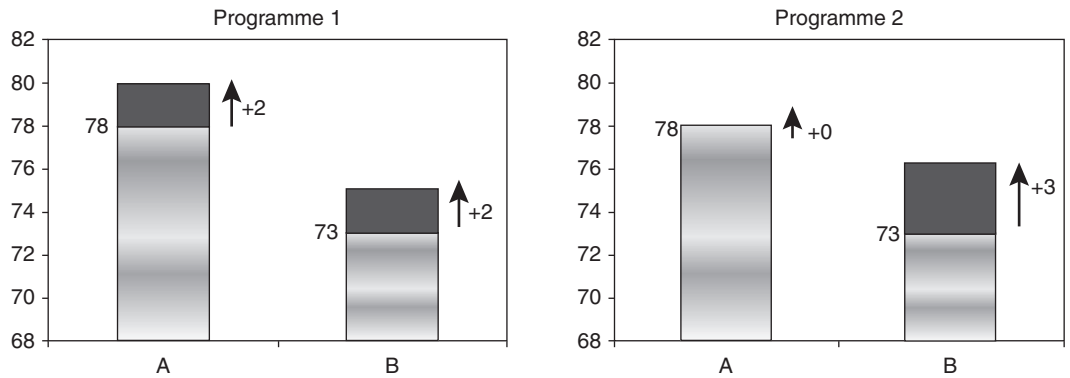

Figure 1 Trade-offs between total health and equal distribution of health. Imagine you are asked to choose between two programs, which will increase health in a population consisting of two groups. The programs cost the same. The areas in black represent increases in health. Program 1 delivers a larger total health benefit than program 2, whereas program 2 gives priority to the worse off group B and results in more equal levels of health. Which would you choose? Worse off group B might be a more socioeconomically disadvantaged group with lower life expectancy. Alternatively, it might be a more severely ill group with lower quality of life.

Equity in Health Economics

Health economists have made progress in the economic evaluation of health programs in recent decades. In the 1970s, the very idea of 'cost-effectiveness' was controversial among the medical community, methods were developmental, and applied economic evaluations were rarely used to inform real health care resource allocation decisions. Since then, health economists have developed sophisticated methods of economic evaluation that are now routinely used around the world to inform decisions about the funding of new health care technologies for particular groups of patients.

However, progress has focused on addressing concerns for efficiency, or cost-effectiveness, defined in terms of maximizing population health within a fixed health budget. Less attention has been devoted to addressing concerns for equity or fairness. Considerable methodological research has been done, and a variety of different theories and methods have been proposed for incorporating concerns for fairness into the economic evaluation of health programs. However, most of these methods remain developmental and even the most finished ones are still almost never used in the applied economic evaluations used to inform real resource allocation decisions.

The specific methods that have been proposed are reviewed in section Methods for Incorporating Concerns for Fairness into Economic Evaluation. Before that, it is useful to summarize the most frequently mentioned concerns for equity.

Concerns for Equity: Overview

In health care, concerns for equity often relate to the general principle that health care should be distributed in relation to need. This general principle can be divided into a vertical equity principle of greater treatment for greater need and a horizontal equity principle of equal treatment for equal need. Box 1 lists some potential concerns for fairness in health care that are often raised in relation to economic evaluations of new health care technologies. The first set of concerns, about prioritized patient subgroups, raises issues about which patients are in most 'need' – i.e., concerns for 'vertical equity'. The second category is about wishes not to discriminate between patients with the same degree of 'need' – i.e., concerns for 'horizontal equity'. The third set of concerns, about nonpatient benefits and nonhealth benefits, raise issues about how far 'need' relates to the needs of carers and dependents, as well as the needs of the patient, and how far 'need' relates to nonhealth needs as well as health needs. The fourth set of concerns, about industrial factors, raises issues about how far wider social policy objectives can be traded off against the equity principle of distribution according to need. The latter two categories can be thought of as concerns for efficiency, broadly construed to incorporate nonhealth benefits as well as health benefits, as opposed to concerns for fairness. However, they are important issues of social value judgment in health care resource allocation that go beyond concern for efficiency narrowly construed in the sense of health maximization.

In public health, as opposed to health care, concerns for equity often focus on reducing inequalities in population health – such as differences in life expectancy between socioeconomic groups. However, distinguishing between 'fair' and 'unfair' health inequality is problematic. Political and economic theorists have proposed numerous rival theories of what counts as 'fair'. Key dilemmas include how far decision makers should be concerned with:

- health inequality versus priority to improving the health of the worst off;
- inequality of income and other social determinants of health versus inequality in health;

Box 1 Potential societal concerns for fairness in health technology assessment

Prioritized patient subgroups
- The least healthy (e.g., severity of illness, poor current health, and poor prognosis)
- The socially disadvantaged (e.g., income, race/ethnicity, and vulnerable minority groups)
- Children and adolescents
- Life saving (i.e., permanently restored to normal life expectancy)
- Life extension near end of life (i.e., temporary relief from terminal illness)
- Type of illness and 'dread' (e.g., cancer)
- Health service responsibility (e.g., hospital infection)
- Unavailability of alternative treatment

Nondiscrimination
- Equal treatment of patients with different age; disability; gender reassignment; marriage and civil partnership; pregnancy and maternity; race; religion or belief; sex, and sexual orientation
- Equal treatment of patients with different potentials for health benefit
- Equal treatment of patients with different costs of treatment

Nonpatient and nonhealth benefits
- Impact on carers' health and wellbeing
- Impact on dependents' wellbeing
- Impact on productivity
- Impact on responsiveness and patient experience

Industrial factors
- Innovation and dynamic efficiency
- Promoting domestic industry
- Orphan drugs (i.e., prohibitive development cost due to rarity of condition)

- absolute inequality (e.g., gaps) versus relative inequality (e.g., ratios);
- inequality between groups versus inequality within groups (e.g., between individuals);
- univariate health inequality (i.e., the 'pure' distribution of health) versus bivariate health inequality (i.e., the joint distribution between health and one unfair determinant of health, such as income) versus multivariate health inequality (i.e., the joint distribution between health and multiple unfair determinants of health);
- avoidable versus unavoidable health inequality;
- compensable versus incompensable health inequality; and
- inequality of achieved health versus inequality of opportunity for health.

Each dilemma raises difficult value-laden issues of definition and measurement (see separate entries on 'Techniques for measuring equity in health and health care', and 'Field of inequality of opportunity in health').

Methods for Incorporating Concerns for Fairness into Economic Evaluation

The most ambitious approaches to incorporating concerns for fairness into applied economic evaluations are formal numerical value functions that take both efficiency and equity into account. The authors first review these. Less ambitious approaches include systematic characterization of relevant health equity concerns, multicriteria decision analysis, and estimation of the opportunity costs of equity. The authors return to these later on.

Formal Numerical Value Functions

In formal numerical value functions, trade-offs between efficiency and equity are expressed at a cardinal level of measurement, allowing for the overall value of an intervention or program to be estimated at that same level of measurement and thus made directly comparable with intervention or program costs. Formal value functions can in principle be applied in a fairly 'algorithmic' fashion, in the sense of requiring decision makers to use a single all-purpose set of social value judgments about equity, which leaves little room for deliberation and consultation with stakeholders about the appropriate set of value judgments to apply in each particular case. With suitable sensitivity analysis, however, formal value functions can also in principle be used in a more 'deliberative' fashion, in the sense of helping decision makers and stakeholders to deliberate their way toward a suitable set of value judgments. In this more 'deliberative' role, formal numerical value functions can help answer the questions: what are the implications of different value judgments for decision making in this case, and what implications might such value judgments have for other decisions in other contexts?

The social welfare function

One approach is to value health programs as a mathematical function of the distribution of health among individuals or groups in the relevant population. The standard theoretical framework that economists have used is a social welfare function, which takes as its arguments individual health or group average health, which might be measured, for example, using expected lifetime quality-adjusted life-years (QALYs). The social welfare function is typically increasing in health, reflecting concern for efficiency in the sense of health maximization. However, the social welfare function need not be a simple linear sum of individual or group average health. Instead, it may give more weight to improvements in health for some individuals or groups than others, depending on societal concerns for fairness.

One social welfare function is the isoelastic or Cobb-Douglas function, first proposed in a health context by Adam Wagstaff and subsequently used by Paul Dolan and Aki Tsychyia and others to empirically estimate 'equity weights' based on surveys of public views. In the simplest case of two individuals (or groups), this function takes the following form:

$$W = [\alpha h_1^{-r} + (1-\alpha)h_2^{-r}]^{-1/r}$$
$$h_1, h_2 \geq 0, \quad 0 \leq \alpha \leq 1, \quad r \geq -1, \quad r \neq 0$$

where h_1 and h_2 are respectively the health of person 1 and person 2 (or the average health of group 1 and group 2). This function can be visualized as a set of social indifference curves that pick out a socially preferred point on the health possibility frontier, see Figure 2. Points to the southeast of the maximin point are 'Pareto efficient', in the sense that the health of one person cannot be improved without reducing the health of another person. The social indifference curves pick out the best or fairest of these multiple 'Pareto efficient' points along the health frontier. Two parameters determine the shape of the social indifference curves. First, a general inequality aversion parameter, r, reflecting general aversion to health inequality between all individuals or groups. The magnitude of this parameter reflects the degree of curvature of the social indifference curves. Zero inequality aversion implies straight line 'utilitarian' style indifference curves, with $r = -1$, as illustrated by the blue-dashed lines, which pick out the health maximizing point in Figure 2. Complete inequality aversion implies L-shaped 'Leontief' or 'Rawlsian' style indifference curves, as r approaches infinity, as illustrated by the green-dashed lines, which pick out the maximin point in Figure 2. Second, a special priority parameter, α, reflecting priority to individuals or groups with a special equity-relevant characteristic (e.g., low socioeconomic status). This parameter would pivot the social indifference curves about the 45 degree line of equality. When additional individuals or groups are added into the analysis, additional special priority parameters can be added to allow for additional equity-relevant characteristics (e.g., ethnicity, disability, responsibility etc.), whereas the general inequality aversion parameter will apply to all individuals or groups in the analysis.

Another type of formal approach consists of weighting QALYs achieved by an intervention or program by the characteristics of the people who get the health gains, or possibly by the characteristics of the program, rather than by the resulting distribution of health. Different programs may then be compared with respect to value in terms of 'equity-weighted QALYs'.

One approach of this kind was proposed by Alan Williams in the so-called 'extended fair innings argument'. According to

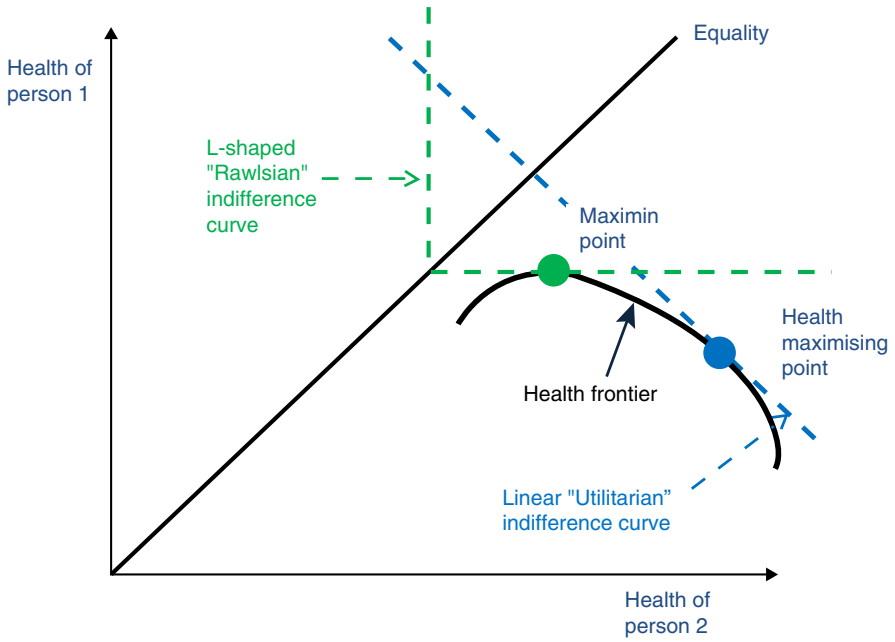

Figure 2 Health possibility frontier with social indifference curves.

Williams, all individuals are entitled to a normal 'fair share' of quality-adjusted life expectancy (the 'fair innings'). This implies that health gains to individuals below the fair innings norm – for example, the poor and disabled – should receive greater weight than health gains to individuals above the norm. In Williams' approach, this is achieved by multiplying QALY gains by separate fair innings weights. A similar model was proposed by Han Bleichrodt and colleagues, whose 'rank-dependent utility' theory weights individuals according to their rank in the distribution of expected lifetime health. Other approaches focusing on equality in life time health have been proposed by Magnus Johannesson and Ole Frithjof Norheim (*see* Further Reading).

A problem with models that focus on equality in life time health is the implication that health gains to older individuals who have already enjoyed a long and healthy life should receive lower weight than health gains to younger individuals expected to have a shorter or less healthy life. This could, for instance, mean that pain relief in an elderly person would receive lower priority than pain relief in a young person with a life expectancy below that of the elderly person, assuming the pain relief in both cases has the same cost per QALY gained.

Another approach to equity weighting of QALYs is so-called 'cost-value analysis' (CVA, mentioned below). In this approach, health gains in terms of QALYs are valued more the more severe the condition of the target group is. The approach furthermore discriminates less strongly than the conventional QALY maximization approach does between gains for people with equal severity of illness with different capacities to benefit from treatment – for example, due to differences in disease, age, or comorbidity. Erik Nord and colleagues showed in 1999 that these two features may – as with concerns for fair innings – be achieved by application of separate equity weights. However, the main approach in CVA is to replace conventional utilities by 'societal values' that – in a coordinate diagram with utilities on the x-axis and societal values on the y-axis – form a curve that is convex toward the y-axis and compresses moderate and mild problems toward the upper end of the 0–1 scale (mentioned above).

In the Netherlands, a government guideline from 2009 indicates that willingness to spend public money in order to gain a QALY will range from 10 000 euros for conditions of little severity to 80 000 euros for conditions of great severity. This 'graded willingness to pay' is effectively the same as assigning severity weights to QALYs. In the Dutch context, severity is measured in terms of 'proportional shortfall', which builds on 'absolute shortfall'. Absolute shortfall is the difference between a patient's expected remaining QALYs and the number of remaining QALYs in average individuals of the same gender and age. Proportional shortfall is absolute shortfall relative to the number of remaining QALYs in average individuals of the same gender and age.

Preference data

All the above models require data on societal preferences regarding trade-offs between efficiency and equity. Only on the basis of such data can the models be of practical use.

Preferences for such trade-offs are normally elicited from samples of the general population. They can be elicited in various ways.

In estimating parameters in a social welfare function, one possible approach is to ask subjects to compare different possible health scenarios for a set of social groups. The scenarios might vary, for example, with respect to average health in terms of quality-adjusted life expectancy (QALE) and the distribution of QALE between groups. Subjects may be asked to compare scenarios pairwise, and their willingness within each pair to trade-off equality for gains in average health (and vice versa) may be observed. Through statistical techniques the central tendency of such trade-offs may then be used to

estimate parameters in the social welfare function. This approach has not been widely applied, but was used by Paul Dolan and Aki Tsuchyia in 2009 in a small-scale methodological study.

Another approach is the person trade-off technique as described by Nord in 1995. This is commonly used to obtain equity weights for QALYs. The basic format is that subjects are asked to compare health gains for different groups of people that differ on some variable that is considered relevant for equity reasons. For instance, subjects are asked to consider a group A of 10 people who can obtain an improvement from 0.6 to 0.8 on a 0–1 utility scale. Another group B of *N* people can obtain an improvement from 0.8 to 1.0. All else equal, the health gain in terms of QALYs is equally large for each individual in the two groups. But people in group A are worse off. QALYs to them may therefore be valued more highly than the same number of QALYs to people in group B. To measure the strength of preference for the more severely ill group, subjects are asked how many people there would have to be in group B for that program to be considered equally worthy of funding as the program for group A. If the mean response is 20 B ~ 10 A, the implication is that the improvement from 0.6 to 0.8 is valued twice as highly as the improvement from 0.8 to 1.0. Weights for age and duration of benefits can be obtained in a similar fashion. In the last three decades, results from a number of person trade-off studies in different countries have been published. In principle, the results may be used as guidance in construction of models of equity-weighted QALYs. In practice, however, little use has hitherto been made of these data, partly because of uneasiness about their accuracy. An exception is Norway, where the Norwegian Medicine Agency since 2000 has recommended that conventional cost-utility analyses in terms of QALYs be supplemented by analyses using person trade-off-based health state values.

A third measurement approach was introduced by Paul Dolan in 1998. He asked subjects to compare a health gain from utility level 0.2 to 0.4 for a person A with a gain from level 0.4 to level X for a different person B. What would X have to be for subjects to consider the two health gains equally worthy of funding? On average, subjects answered 0.8, which suggests that they thought person A deserved a 'severity weight' of 2 compared to person B.

Finally, a fourth approach is to use pairwise choices between different groups with different health gains. This is similar to the person trade-off approach, except that individual subjects do not directly state their strength of preference but instead this is indirectly inferred from between-subject and/or within-subject patterns of pairwise choices using statistical modeling methods. This 'stated preference' or 'discrete choice experiment' approach has for instance been used in the UK by Rachel Baker and colleagues.

Other Approaches to Incorporating Concerns for Equity

Systematic characterization of relevant health equity concerns

This approach merely aims to foster a more systematic approach to identifying and characterizing the equity considerations at stake and to presenting relevant qualitative and quantitative background information that decision makers may find helpful. It might be useful, for instance, to develop a 'checklist' of potentially relevant equity concerns, based on precedent from past decisions and deliberation among stakeholder groups. Where a particular concern on the checklist is deemed relevant to the decision in hand, it would then be useful to present background information about the importance of this concern to the decision in hand. This might include qualitative information about stakeholder views and prior decision precedents; it might also include quantitative information, which puts the relevant equity concern into perspective – for instance, about how large and important the decision-relevant health inequality is compared with other health inequalities.

Multicriteria decision analysis

Multicriteria decision analysis aims not only to provide a qualitative 'checklist' of equity concerns but also to give each concern a numerical score and weight so as to arrive at an overall ranking of decision options. This approach has been advocated by Rob Baltussen and Louis Niessen in the context of both local and national health care planning in low and middle income countries, and has from time to time been used in health care priority setting exercises conducted in high-income countries. An advantage of this approach over an informal 'checklist' is that the scoring and weighting process can facilitate stakeholder engagement, transparency, and consistency. However, this approach does not integrate fairness concerns within economic evaluation – rather it takes the results of economic evaluation as one of many parameter inputs into a broader quantitative assessment. Furthermore, methods for the scoring and weighting of criteria currently lack the analytical rigor and evidential basis of methods for economic evaluation: much of the scoring and all of the weighting is typically done using decision maker or stakeholder opinion.

Health opportunity cost of equity

A third approach aims to estimate the health opportunity cost of a particular equity concern – for example, in terms of QALYs forgone by pursuing a more 'equitable' option compared with the QALY maximizing option. Every departure from health maximization on grounds of equity has an opportunity cost in terms of sum total health forgone. The size of that opportunity cost is a test of how important that equity concern is deemed to be.

This approach can be implemented using the standard methods of cost-effectiveness analysis, using the cost per QALY threshold to represent the health opportunity costs of unknown displaced programs. Or, if displaced programs can be identified and evaluated, mathematical programming can be used based on data rather than assumptions about the opportunity costs and equity characteristics of displaced program. Either way, one can compute the opportunity cost of equity by computing the difference in total net QALY benefit between 'more efficient' and 'more equitable' programs. When the equity concern relates to health inequality, this approach can be extended by calculating a health opportunity cost per unit reduction in health inequality. One could even imagine establishing a 'cost-equality threshold'

in terms of a benchmark cost per unit reduction in health inequality from previously evaluated programs.

An advantage of the opportunity cost approach is that it can be used to address any kind of equity consideration and not just concerns about health inequality. For example, during the 1990s, the UK Standing Medical Advisory Committee advised local health authorities against adopting a racially selective policy on screening for sickle cell anemia – which is more prevalent in certain ethnic minority groups – even though this may have been the most cost-effective strategy. Franco Sassi and colleagues showed in 2001 that imposing the equity constraint of nondiscrimination imposed a health sacrifice in terms of cost-effectiveness.

A limitation of the opportunity cost approach, however, is that it only looks at the cost of the equity concern, not the benefit. It measures the equity–efficiency trade-off implied by a particular decision (a factual matter) but does not value the trade-off that policy makers ought to make (a moral matter). That is, it does not help the decision maker decide how large a sum total sacrifice (in terms of health and/or nonhealth benefits) is worth making in order to pursue a particular equity consideration. This runs the risk of lack of transparency and inconsistency across decisions, because decision makers are then free to make implicit judgments about how much health sacrifice is worth making in pursuit of a particular equity principle – and to vary those judgments from one decision to another without giving any explicit justification.

Conclusion

Health economists have developed a substantial and growing body of theoretical tools and empirical methods for incorporating concerns for fairness into economic evaluation. However, these methods have not yet been taken up and applied in routine economic evaluations used to inform resource allocation decisions. There are two main barriers to this. First, concerns for fairness are contested and context specific. Second, research requirements for measuring population preferences for fairness are often greater than those for measuring health and valuations of health. Data on preferences for fairness are therefore much more limited than valuation data used in estimating efficiency.

These barriers to progress are not insurmountable. As the authors have shown, there are ways of specifying equity objectives in such a way they can be quantified in economic evaluation. As pressures for transparency and accountability in public life increase, and as clashes between equity and efficiency concerns in health care and public health become ever more apparent and insistent, policy makers may be persuadable to articulate more specific health equity goals. To the extent that these equity goals are context specific, it may be possible to harness deliberative approaches to facilitate stakeholder 'buy-in' to particular equity goals and analytical approaches in particular decision-making contexts. Furthermore, data sources are increasingly rich as are the methods available for analyzing them. Person trade-off data already yield some useful information for equity weighting of QALYs. Methods of evidence synthesis are available for combining patient level data from a network of randomized control trials along with observational data sources. These methods could be exploited to generate information on the distribution of health effects between equity-relevant patient groups. Econometric methods are available for identifying causal effects and subgroup heterogeneity in causal effects, by exploiting observational data from surveys, administrative databases and trials – including record-linkage studies that link together all three types of data. A key challenge for the next generation of health economists is to harness these data and methods in ways that fit the contours of societal concerns for fairness and deliver analytical insights that health sector decision makers find convincing and useful.

Infectious Disease Externalities

M Gersovitz, Johns Hopkins University, Baltimore, MD, USA

Glossary

Endogeneity An economic variable is said to be endogenous if it is a function of other parameters or variables in a model.

Equity Equity is not necessarily to be identified with equality or egalitarianism, but relates in general to ethical judgments about the fairness of the distribution of such things as income and wealth, cost and benefit, access to health services, exposure to health-threatening hazards, and so on. Although not the same as 'equality', for some people, equity frequently involves the equality of something (such as opportunity, health, and access).

Externality An externality is a consequence of an action by one individual or group for others. There may be external costs and external benefits. Some are pecuniary, affecting only the value of other resources (as when a new innovation makes a previously valuable resource obsolete); some are technological, physically affecting other people (communicable disease is a classic example of this type of negative externality); and some are utility effects that impinge on the subjective values of others (as when, e.g., one person feels distress at the sickness of another, or relief at their recovery).

Herd immunity The effective stoppage of the spread of a disease when a particular percentage of a population is vaccinated. This critical percentage varies according to the disease, the interactions between members of the population and the vaccine, but 90% is not uncommon.

Market imperfections Markets in health care are notable for 'failing' on a number of grounds, including asymmetry of information between producers (medical professionals of all kinds) and consumers (patients actual and potential); distorted agency relationships, failure of patients to behave in accordance with the axioms of rational choice theory; incomplete markets, especially those for risk; monopoly; and externalities and the presence of public goods.

Public good The technical meaning of a 'public good' in economics is a good or service that it is not possible to exclude people from consuming once any is produced. Street lighting and national defense are classic examples. Public goods are nonrival in the sense that providing more for one person does not entail another having any less of it. Some externalities have the character of publicness, such as the comfort one may have when others are protected from ill-health.

Rationality Technically, in economics, rationality means behaviour in conformity with axioms such as: completeness (either A is preferred to B, or B to A or an individual is indifferent between them – where the As and Bs are objects of choice); transitivity (if A is preferred or indifferent to B and B is preferred or indifferent to C, then A is preferred or indifferent to C); continuity (there is an indifference curve such that all points to its north-east are preferred to all points to its south-west); convexity (the marginal rate of substitution is negative); and nonsatiation (more is always preferred).

Utility Variously defined in the history of economics. Two dominant interpretations are hedonistic utility, which equates utility with pleasure, desire-fulfilment, or satisfaction; and preference-based utility, which defines utility as a real-valued function that represents a person's preference ordering.

Introduction

Infectious diseases are caused by pathogenic microorganisms, such as viruses, bacteria, parasites, or fungi. For almost any infectious human disease, what one person does about it affects the probability that other people get infected. Some infectious diseases spread from person to person through direct physical contact as in the case of sexually transmitted infections. People can also shed an infectious agent into the air, water, onto food, or other surfaces where other people come into contact with it and become infected, as with respiratory or diarrheal infections. Some infectious agents have life cycles that involve stages in both the human host and in a vector organism such as a mosquito. Thus in the case of malaria, an infected mosquito transfers the malaria parasite to an uninfected person through feeding, but an uninfected mosquito can likewise become infected by an infected person, making it possible for the mosquito to infect someone else. Infected people do not always play this role in infecting other people because humans may be dead-end hosts. For example, people infected by roundworms with trichinosis pose no risk to others as long as the larvae in their flesh are not eaten by suitable host animals that are subsequently eaten by other people.

To this point, one person puts another at risk because the first person is infected. Although operative for most infectious diseases, this mechanism is not the only one that affects the risks of infection faced by others. People may put others at risk of infection without being infected themselves. People who do not spray their own houses with insecticide to kill mosquitoes and other disease vector organisms put their neighbors at risk regardless of whether they themselves are or become infected or not.

In all these situations, people face choices. At an abstract level people are making choices about prevention including immunization and about therapy. For any actual disease, these choices are about a wide variety of day-to-day actions.

Of course, epidemiologists and other researchers on human health are well aware how infections spread and, in particular, that the actions of people affect the risks that others face. Epidemiologists use terms such as herd immunity

and community or mass effects to denote the ways that a lessening of the infection risk for some people lessens the risk for others. For the most part, it is from these disciplines that economists and others learn about the pathways of infection and what can be done to prevent infections or to mitigate them once they have occurred. Mathematical epidemiology provides algebraic models of the dynamics of infectious diseases, the starting point for an economic theory of infectious diseases and their control. Even without endogenous behavior by utility-maximizing individuals, these models are nonlinear and dynamic, capable of exhibiting complicated even chaotic behavior.

Basic Nature of the Externality

Unlike epidemiologists, economists predict behavior and devise policy using the hypothesis of rational decision making by self-interested individuals who pursue objectives subject to constraints. To the extent that people are selfish, they ignore the consequences to others put at risk by their actions or failure to act. It is the discrepancy between the choices made by this type of individual and the choices that are desirable for society as a whole taking into account all the consequences of an individual's actions that defines the externality and gives precision to this central concept in the economics of infectious disease control.

If individuals do too little of something from society's perspective, the classic solution to the problem of such an externality is to subsidize the activity – and in the reverse situation to tax the activity. With more than one activity going on simultaneously, it is desirable to think in terms of a package of interventions. For instance, if there is a preventive activity and a therapeutic one, the government should intervene to influence both and it is natural to ask how these interventions should be coordinated. If an infection is transmitted from one person to another, and if a person once infected recovers to be again susceptible, then the optimal package is to subsidize prevention and therapy at equal rates. The externality arises because people spend too much time in the state of being infected and it is socially just as desirable to give them incentives to stay out of this state as to get out of it once they are in it. This finding underlines that both prevention and therapy are associated with externalities. For other diseases from which people do not recover but rather die, or from which they recover to be immune, the package has different qualitative properties. In the case of vectors there may be many different types of prevention in terms of their roles in the model, with consequently different rates of subsidy.

Not all formulations of dynamic models of infectious disease lead to externalities or at least ones that justify government interventions. For instance, consider a simple model in which immunization always confers complete immunity, people if infected stay that way forever and never die, there are no newly born susceptibles, and all individuals have the same preferences (including attitudes toward risk and time) and susceptibility to infection. In this model, everyone gets immunized at the same time. This time is determined by the overall infection rate which determines the risk of infection and therefore the benefit of immunization. Once everyone is immunized, there is no one left to benefit from other people protecting themselves against being infected and therefore, no reason to move the time at which everyone who has remained susceptible gets immunized. Consequently there is no justification for government intervention to offset an externality. But this example is not very general and its importance is in emphasizing that it is being infected, rather than being susceptible and potentially infectible, that generates the externality. In general, even in models for which the only choice is to be immunized or not, there will be a justification for an optimal subsidy to immunization because one or other of the assumptions stated above do not obtain.

There is even the possibility of positive externalities if individuals increase activity that puts them at risk of infection. An example of this result occurs when there is more than one (homogeneous) group in which the groups mix together. First, consider a high-activity (and therefore high-risk) group mixing randomly only with its own members. The infection rate will be high. Now consider a second, low-activity group that increases its level of random contacts from none to one, some of which are with the high-activity group. Any member of the low-activity group who becomes infected does not infect anyone else because they have no more contacts. But by diverting high-activity people from having contact with other high-activity people, the prevalence of infection overall may fall and if the effect is strong enough, the infection may even disappear. The example illustrates not just the possibility of positive externalities but also the danger of thinking in terms of average activity levels without regard for the variability in activity levels in the face of a highly nonlinear process.

Policies to Offset Externalities

The general expectation, however, is that people do too little from a social perspective to avoid being infected, either by making too little effort to avoid becoming infected or to recover once infected. In principle, these problems could be fixed by subsidies, but in practice subsidies may be infeasible so that the first best as seen by society is unattainable. To internalize the externalities associated with infectious diseases optimally, subsidies have to be targeted at outcomes such as the probabilities of becoming infected or recovering from infection. If each probability depended only on inputs that could be subsidized then these inputs could be targeted. But in practice such probabilities depend on many inputs, both marketed goods and services such as insecticides, bed nets, medicines, or the services of health professionals, and nonmarketed inputs such as time and effort by the person involved who may also suffer side effects in the case of therapies. All these inputs may be brought together in activities that may be spread over time and space and expensive to monitor, and therefore hard or impossible to subsidize. Some health-related activities are even private and intimate. Consequently, policy may not be able to achieve targeting at the probabilities but rather only at some of the inputs not all of which are necessarily used exclusively to affect the probabilities, hence situations of the second best.

Examples of imperfect targeting abound. For instance, one can subsidize hand soap but not the outcome of sanitized

hands. Soap may be used for other purposes than health-related hand washing such as clothes washing that are then subsidized as well with a loss of economic efficiency. If people find washing hands disagreeable but its social benefits are large enough, it may be necessary in theory to pay them to wash their hands but it may be impossible in practice to do more than give soap away free. Paying people to take soap is not the same thing as getting them to use it to wash their hands. In the case of freely provided bed nets for protection against malaria, it has been claimed that they have been diverted for other uses such as fishing, but a recent review has found almost no such evidence. In the case of sexually transmitted infections, it is safe sex acts that should be subsidized, but typically what has been done is subsidizing or giving away condoms, which is not the same thing as ensuring their use. In the case of tuberculosis, programs of directly observed therapy short course (DOTS) pay for patients to be supervised to make it more likely that they take their medicines. People who do not comply and do not recover continue to infect others, and may even develop drug-resistant infections through incomplete adherence to the therapeutic protocol and then infect other people who in turn are more difficult to cure even if they comply. In principle, people could be paid to maintain their uninfected status as regards human immunodeficiency virus (HIV) or other infectious diseases if it is possible and cheap to test infection status. But it will often be much more difficult to implement subsidies to correct the externalities of infectious diseases than to deal with other types of externality such as vehicular pollution or congestion, which themselves pose difficult enough challenges to the implementation of the first best even under ideal conditions.

A failure of the government to intervene, either completely or partially, has implications for the effect on welfare of changes in the parameters of the system. The outcome can be immiserization, a perverse transformation of a seemingly beneficial change into an actual decrease in welfare. For instance, there is the question of how welfare responds to a lowering in the cost to individuals of being infected because of a more effective treatment. If the externality has been internalized by first-best government interventions, welfare is always increased by such a change even though the infection rate likely rises. But if the externality is not internalized, the direct effect of the reduction in the cost of infection (corresponding to the only effect if the externality were internalized) may be overwhelmed by a worsening of the externality. The reason immiserization may occur is that people make choices about prevention and therapy that are socially suboptimal because they disregard their effect on the welfare of others. A decrease in the private cost of infection could worsen this discrepancy between the socially desirable choices and privately rational choices about prevention and therapy, and on balance welfare declines even though the direct effect of the decrease in the cost of infection is to increase welfare.

Instead of, or in addition to subsidies, governments use methods of coercive physical control such as quarantine of people who may be incubating an infection, isolation of people known to be infected, and culling of domestic animals that may play a role in the infection of people. Thailand has successfully used administrative measures such as tracing clients who attend clinics for sexually transmitted infections back to brothels where condoms are not used and then pressuring brothel owners to ensure that condoms are used under threat of closure. DOTS has aspects of a subsidy and physical control depending on how one interprets the way it promotes compliance with the drug protocol. It does not mandate compliance subject to coercive sanctions but its supervision could either be thought to facilitate compliance by lowering its cost, for instance by providing a reminder, or to raise the cost of not complying by hectoring and nagging. In either case, it influences people one-on-one, rather than through a general subsidy of something people purchase.

People subject to policies of physical restriction are usually not fully compensated for the costs to themselves and so the policies are often resisted and dodged. In the case of isolation, people may have access to therapy so there is that benefit to them which promotes compliance. During the severe acute respiratory syndrome (SARS) epidemic in Taiwan, quarantined people were brought food and had odd jobs done for them to lessen their costs of compliance. In other cases, compensation may help induce compliance although it is important to ensure that it does not result in perverse effects such as the needless slaughter of animals by making such activity profitable.

Need for Persistent Policies

In addition to specifying how to target subsidies, program design has to address whether interventions need to be permanent or temporary. If it is optimal for the infection to remain endemic at some level, then subsidies will have to be permanent because there will be an ongoing discrepancy between the socially and privately desirable levels of prevention and therapy. Beginning from an infection rate that is different from the final one, the discrepancy between the social and private incentives to undertake prevention and therapy will be changing over time and consequently so will the optimal levels of subsidies as the infection rate settles toward its long-run endemic level. If, however, the infectious disease can be eradicated, then by definition further subsidies will not be necessary and programs can be ended. Indeed, it is this hope combined with the end to all the costs borne by individuals that makes eradication for all its difficulties such an attractive goal.

In the absence of scientific breakthroughs of an almost magical sort, however, eradication is not likely in the near future for most infectious diseases. One reason it may nonetheless be possible to lessen expenditures over time is if part of the reason for subsidies is to pay for the dissemination of information about the infection and how to respond to it. Information dissemination may be implicit, as when someone learns about the benefits of prevention or therapy by trying them out. Information dissemination may also have an externality component if people learn from others and without compensating the people from whom they learn for their own costs of acquiring and providing this information. There is also an externality associated with information if a lack of information leaves people acting against their own interest in ways that also have costs to others. Once the message is out, however, it may need little subsequent repetition so that it

may indeed be possible to wind down expenditure on information. Information dissemination by itself does not, however, deal with the ongoing hard core of discrepancy between the private and social benefits of prevention and therapy.

Sometimes noneconomists argue that people will take 'ownership' of measures to control the spread of infections and thenceforth subsidies can be lowered or ended altogether. If by ownership one means that once people are informed about the existence of a disease, its modes of transmission and the possibilities of prevention and therapy, they will do things differently, then such a view is partially consistent with an externality-based argument. If not, however, it is hard to understand what the argument means other than a somewhat naive faith in the power of habit formation as once subsidies are removed, behavior will likely revert to its original self-interested and socially suboptimal form.

Span of the Externality

In the case of infectious disease, people do not generate risks and external costs (and possibly benefits) equally for everyone in the whole world. It makes sense to think of the span of the externality, i.e., the range of people who may suffer costs external to someone else's choices. People who are directly exposed to risk by someone are more likely to be close to the person putting them at risk. This closeness may be because the people put at risk have important social relationships with the people who are infected, such as family, sexual partners and friends, or because they are in close geographical proximity such as people who live, work or shop in the same neighborhoods, or commute on the same routes. Of course, someone's failure to avoid infection can have worldwide implications through a chain of infection, as in the case of emerging infections like HIV, SARS, or avian influenza.

Naturally, what it means to be geographically close depends on the mode of transmission of the disease and intervention, something that needs documentation on a case-by-case basis. For instance, insecticide-treated bed nets protect people who sleep under them from malaria by providing a barrier. But they also kill mosquitoes (and other disease-transmitting insects) that make contact with the nets. In effect, the people sleeping under them serve as bait. The consequence is that these insects do not have the chance to bite other people who are not under nets, effects that seem to prevail up to 300 m from the people using the nets, a clear external benefit to the non-users.

Close relationships such as family or sexual partners raise several issues. At the simplest, people in this type of relationship may know about each other's infection status through observing symptoms or medication, or through knowing who could have infected them as in the case of a sexually transmitted infection. Information of this sort in turn raises questions of strategy, in which susceptible people take actions with regard to specific people. There may be conflict over the use of condoms or testing. Families may dissolve over the infection of some of its members and the threat they pose to others. This potential for conflict raises the question of altruism versus self-interest. To what extent does someone act to avoid infecting others? If people are entirely altruistic, caring about the well-being of everyone who is affected by their decisions, then there are no externalities. In other situations they may be forced to take account of the risks they pose to others. Here one sees very starkly, possibly as a matter of life or death, the many possible considerations that arise in families.

Tuberculosis provides a good example of these family issues. It is often fatal and casually transmitted – a terrifying combination. As a result, relatives do indeed force infected members to leave the household. Understanding the motivations within the household is especially important in the case of DOTS. One focus of debate among DOTS professionals is who should be the supervisor that ensures that the infected person complies. Cost is an issue because specialized personnel – especially medical personnel – are expensive and either they or the patient have to travel for compliance to be observed and the protocol extends over many months with daily medication. Another alternative is supervision by a family member. Here it is important to identify motivated supervisors who will get the job done. There can be several motivations: Altruistic concern for the infected family member, fear of contraction of infection, or self interest in having the infected family member return to contributing to the family by earning income or doing chores. But by the very nature of the fact that not all costs external to the infected individual occur within the family, it is unlikely that family members will always be sufficiently motivated to serve the broader social interest.

The span of the externality is important not just in determining who infects whom. It also helps think about what level of government should be dealing with the internalization of the externality. The government should encompass the people who generate and experience the external costs, otherwise the government itself will lack the motivation to internalize the externality. It is a simple principle but one that is difficult to apply when the infection spreads globally. At a global level there is no supranational government that can compel action on health and even international organizations such as the World Health Organization (WHO) depend on the cooperation of their member countries and have no independent authority. National governments may not want to share information or admit WHO or other foreign teams to investigate outbreaks and, in general, they have made no commitment to do so. This type of issue has arisen in the surveillance of avian influenza in some Asian countries during the 2000s. Conflict between different national interests also arises. For example, rich countries may decide to ban dichlorodiphenyltrichloroethane (DDT) for environmental reasons even though DDT if used for antimalarial spraying of dwellings in poor countries can be highly beneficial and without significant environmental costs if it is not diverted to agricultural use.

Conclusion

Taken together, what is known suggests a robust role for the externality in understanding the dynamics of infectious diseases and how to control them. But it is only one set of economic considerations in the design of policies. Insurance markets are notorious for posing their own set of market

imperfections and are highly relevant to health where the risks are large and people are fearful. Issues involving equity also deserve important attention.

Infectious Disease Modeling

RJ Pitman, Oxford Outcomes Ltd, Oxford, UK

Glossary

Basic reproductive number (R_0) The number of secondary infectious hosts arising from one average primary infectious host in an entirely susceptible population.

Communicable disease Illness due to a specific infectious agent or its toxic products that arises through transmission of that agent or its products from an infected person, animal, or reservoir to a susceptible host, either directly or indirectly through an intermediate plant or animal host, vector, or the inanimate environment.

Incidence of infection The number of new infections arising in a defined period of time, typically expressed as a rate per 100 000 population per year.

Prevalence of infection The proportion of the population infected at one point in time.

Introduction

The first recorded mathematical model describing a communicable disease was constructed by the Swiss mathematician Daniel Bernoulli and read at the Royal Academy of Sciences in Paris in 1760. His model aimed to evaluate the impact on human life expectancy at birth if smallpox were to be eliminated as a cause of death through the use of variolation: the practice of deliberately infecting individuals with a mild form of smallpox in order to induce immunity to the disease. Bernoulli's work was used to inform the sale of annuities and so had an immediate economic impact.

The model constructed by Bernoulli assumed that the instantaneous probability of infection, or force of infection, remained constant over time and so was, what is now termed, a static model. This approach to infectious disease modeling, using a static force of infection, remained the norm in modeling for cost-effectiveness analysis until the turn of the twenty-first century.

Dynamic epidemiological modeling of communicable disease transmission started in 1906, when William Hamer, working on childhood infections including measles, postulated that the course of an epidemic depends on the rate of contact between susceptible and infectious individuals, defining the so-called 'mass action' principle of transmission for directly transmitted viral and bacterial infections. In doing so, he removed the assumption of a static force of infection and laid the foundations of modern transmission modeling.

In 1908, Hamer's initial discrete-time model was translated into a continuous time framework by Ronald Ross, who received the Nobel Prize in 1902 for identifying mosquitoes as the vector transmitting malaria. His work was further developed by Kermack and McKendrick, who, in 1927, recognized that a threshold population density was required before an epidemic could take place. The critical elements were now in place for the development of the models used today.

The first landmark textbook on mathematical modeling of epidemiological systems was published by Norman T. Bailey in 1975 and led to the recognition of the importance of epidemiological modeling in public health decision making.

There were, however, still two separate disciplines informing public health policymaking: health economics and epidemiology. Policymakers inevitably have to make decisions about fair and efficient allocation of limited resources and, as such, economic modeling, and cost-effectiveness models in particular, are of critical importance. Unfortunately, when analyzing interventions that targeted communicable diseases, most cost-effectiveness models were static in nature and ignored the developments in dynamic modeling that flowed from the foundations outlined above. At the same time, dynamic transmission models largely ignored the economic aspects of disease control.

The first model to bring these two schools together was published in 1994 by Rowley and Anderson and sought to model the impact and cost-effectiveness of HIV prevention efforts.

Over the past 20 years the fields of dynamic communicable disease modeling and cost-effectiveness modeling have developed rapidly and, when combined, are an indispensable tool used to inform health technology assessments and the formulation of public health policy to control these diseases.

This article is aimed at health economists, who would like an introduction to dynamic infectious disease modeling.

Communicable diseases are each caused by a pathogen, transmitted from one individual to another in whom they may or may not cause clinical symptoms. Such pathogens are typically bacteria (*Salmonella*), viruses (influenza), fungi (*Aspergillus*), protozoa (malaria), or prions (bovine spongiform encephalopathy) and exhibit a wide range of natural histories.

The specific details of the biological interaction between a pathogen and its host are fundamental to its epidemiology at the population level. The site of infection may influence the route of transmission, examples being direct airborne transmission between individuals, contaminative transmission via the fecal–oral route, or sexual transmission.

The site of infection also influences the host's ability to mount an effective immune response. Replication within sites that are not easily reached by the immune system is one way that pathogens, such as the herpes viruses responsible for cold sores, genital herpes, chicken pox, and shingles, can remain latent for decades. Such 'immunologically privileged' sites include cells of the nervous system and to a lesser degree the external mucosal surfaces in the nose. The latter are exploited

 doi:10.1016/B978-0-12-375678-7.01402-4

by the numerous rhinoviruses that collectively cause the common cold.

So what are the key features that set communicable diseases apart from noncommunicable conditions such as heart disease and why do they need special consideration in economic analyses? To illustrate some of these features, the rest of this article will focus on directly transmitted airborne infections.

Direct Airborne Transmission

With directly transmitted airborne pathogens, the hosts typically experience a period of immunological naïvety before they first become infected (Figure 1). This naïve period is typically measured in years. Such susceptible individuals may then become infected, after which there is a delay before becoming infectious, while the pathogen replicates to sufficiently high levels. These exposed, but as yet not infectious, individuals are said to be latently infected and may remain so for days (influenza) to years (tuberculosis), depending on the pathogen. A distinction should be noted between this latent period and an incubation period, the latter being the time from infection to the development of clinical symptoms. An individual may remain infectious for days (rhinovirus) to years (tuberculosis). A proportion of those infected may die; those that survive either remain infected or recover, often with the development of pathogen specific immunity that typically lasts for decades.

The rate at which individuals transition from one state to another dictates the dynamic pattern of temporal change in the prevalence and incidence of infection in a population.

Pathogen transmission is dependent on both biological factors, as described in the Section Introduction, and on the behavior of the host. Host behavior will influence the probability of a susceptible and an infectious individual coming into contact, whereas pathogen and host biology dictate the probability of such a contact resulting in the successful transmission of the pathogen.

The probability of meeting an infectious individual is in part dependent on the number of infectious individuals in the community, a number that is likely to change over time as susceptible individuals are infected and in turn become infectious, recover, or die. This feedback in the risk of infection is a key characteristic of communicable diseases and one of the principal features that distinguishes them from noncommunicable diseases. Feedback produces nonlinear interactions allowing the possibility for small interventions to have large, possibly counterintuitive outcomes and for different pathogens to exhibit a rich diversity of dynamic patterns of infection.

The basic reproductive number (R_0) is a pivotal concept in infectious disease epidemiology, and is defined as the number of secondary infectious cases arising from an average primary infectious case, in a totally susceptible population. In other words, if you start with a population in which no one is immune to a particular infection and a single infectious individual is introduced, how many people will they infect who themselves go on to become infectious.

Processes that drive the transmission dynamics of infectious diseases can be broadly divided into those factors which allow a disease to invade a population and those that enable it to persist there.

When an infection is introduced into an entirely susceptible population the occurrence, or not, of an epidemic depends on the basic reproductive number (R_0). If R_0 is greater than 1 then the number of infections can increase and an epidemic may ensue. If it is less than 1, then the infection is destined to die out.

Directly transmitted infections that induce long-lasting immunity in those that recover are responsible for many of the classic epidemics, characterized by a wave of cases. The chance of any one individual becoming infected will change over the

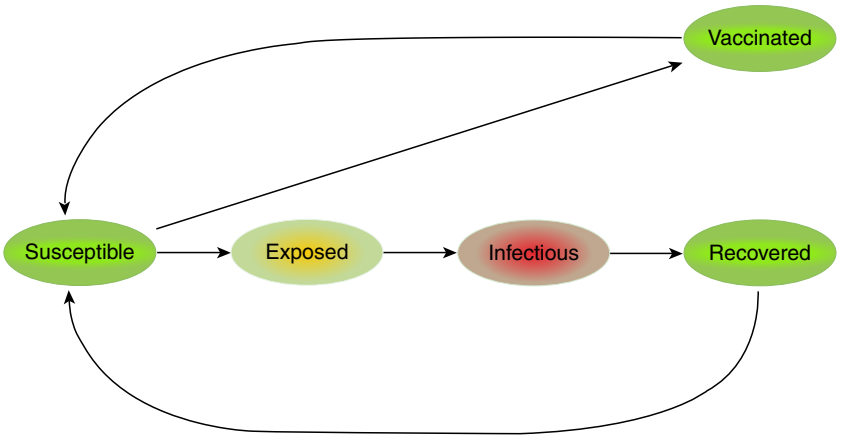

Figure 1 States of host infection and immunity for a typical directly transmitted airborne pathogen. The period of immunological naïvety typically last years to the point of first infection. Once infected, the exposed host may take days to years to become infectious, depending on the pathogen. An individual may then be infectious for days to years during which time a proportion may die; those that survive either remain infected or recover, often with the development of pathogen specific immunity that typically lasts for decades. Reproduced from Figure 2 in Pitman, R., White, L. and Sculpher, M. (2012). Estimating the clinical impact of introducing paediatric influenza vaccination in England and Wales. *Vaccine* **30**, 1208–1224.

course of such an epidemic wave. At the start, with an entirely susceptible population, any encounter with a newly arrived infectious case has the potential to result in transmission of the infection. The spread of the infection is therefore initially dependent on there being sufficient encounters which, on average, result in transmission, such that R_0 is greater than 1. This is easier to achieve in large, dense populations.

As the wave of infection sweeps through the population, infected individuals recover and are immune to further infection. As the proportion of immune individuals in a population increases, a diminishing percentage of people encountered by infectious cases will be susceptible to infection. As the epidemic wave reaches its peak, the average number of secondary infections per infectious individual falls to 1. As the population is no longer fully susceptible, this measure is known as the effective reproductive number (R). Ongoing transmission continues to deplete the susceptible pool, such that R falls below 1 and the number of infectious hosts starts to decline (Figure 2). If the number of infectious individuals is not to continue to decline, the pool of susceptibles must be replenished sufficiently quickly to maintain R at or above 1. This may be via the birth of new individuals, immigration, and the waning of acquired immunity over time. Persistence of an infection (endemicity) is therefore more likely in populations with high birth rates. Conversely, many common infections are absent from small isolated communities as birth rates are too low to supply new susceptibles sufficiently quickly for these infections to remain endemic.

Provided there is sufficient replenishment of susceptibles and all external factors remain constant, the number of infections will settle to a stable endemic state at a constant prevalence that corresponds to an effective reproductive number equal to 1. A consequence of this is that the proportion of the population that is naturally immune will also settle to a constant value that crucially is less than 100%. This is sometimes referred to as the critical proportion immune. Should the number of infections rise for any reason then infectious cases will be generated at a faster rate resulting in an increase in the proportion immune and a decline in the number of susceptibles, which will in turn downregulate the rate of infection, bringing the prevalence of infections back down to its equilibrium state. The converse is true should the number of infections fall.

Vaccination

The aim of vaccination is firstly to protect the vaccinee against infection; however, given sufficiently high uptake, vaccination also benefits the wider, unvaccinated population. This is a consequence of immunized individuals blocking chains of transmission sufficiently often to reduce the number of new infectious individuals produced by each infectious case. Vaccination, therefore, reduces the probability of encountering an infectious individual, thereby helping to protect the whole population. This population-wide protection is known as herd immunity and is the reason an infection may be eliminated from a population without having to vaccinate everyone.

Vaccination that immunizes a proportion of the population may also affect the temporal dynamics of an infection. This may be observed when a program that utilizes a new vaccine is first introduced into a population (Figure 3). Before the introduction of vaccination, immunity is naturally acquired by infection. When a vaccination program is introduced, vaccine-derived immunity supplements this preexisting naturally acquired immunity; the proportion immune now exceeds the equilibrium critical proportion leading to a fall in the incidence of infection and a decline in prevalence. With fewer infectious individuals to transmit the pathogen, the proportion of the population with naturally acquired immunity falls, reducing the overall proportion protected back down to below the critical proportion. This reduction in the proportion immune allows the rate of infection to increase again, leading to a partial rebound in the numbers infected and restoration of the critical

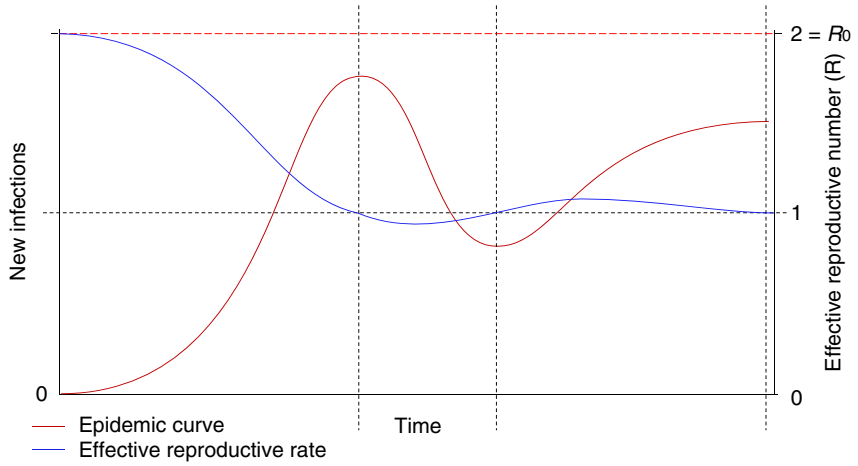

Figure 2 Schematic representation of the relationship between the incidence of infection and the effective reproductive number (R), see text for definitions. If an infectious case arrives in a totally susceptible population, provided R_0 is above 1, the infection will start to spread. As the proportion of the population susceptible starts to fall, R falls to 1, at which point incidence levels off. Continuing transmission further decreases the proportion susceptible, supressing R below 1 and reducing the incidence rate to below the rate at which new susceptible are generated, allowing the proportion susceptible to increase again. As a result, R increases to exceed 1 allowing the incidence rate to recover. If all else remains constant, R will eventually equilibrate to 1 and incidence will settle to a constant rate, equal to the rate of replenishment of susceptibles.

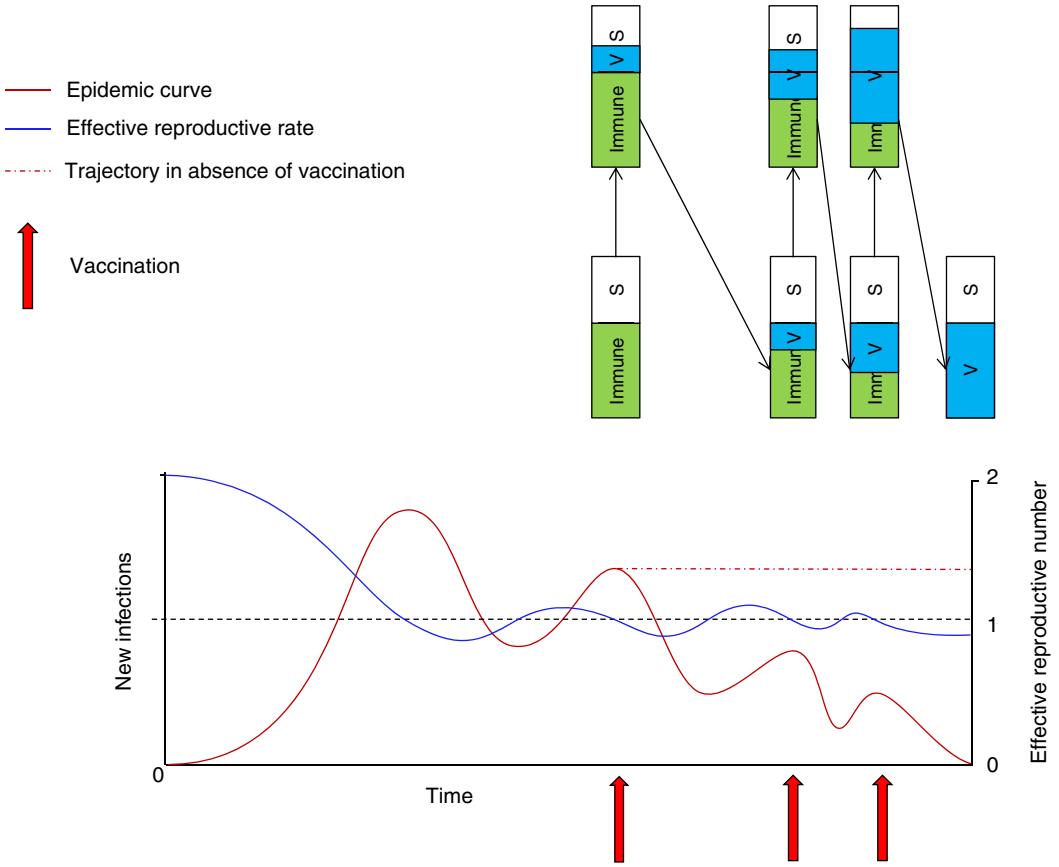

Figure 3 The effect of vaccination on a hypothetical directly transmitted infection. Rectangles represent the total population, green area is the proportion with naturally acquired immunity, blue have vaccine acquired immunity, white are susceptible. Rectangles align with the relevant point on the time axis. When in a stable endemic state, in an unvaccinated population, a constant proportion of the population is immune following a natural infection. Vaccination supplements this equilibrium proportion immune, reducing incidence and with it the proportion acquiring immunity through natural infection, until the equilibrium proportion immune is restored. The effective immunization of a proportion equal to the equilibrium proportion immune leads to local elimination.

proportion immune. The resulting transient low prevalence following program initiation is a well recognized phenomenon known as the honeymoon period.

Should a sufficiently large proportion of the population be vaccinated to account for the entire critical proportion, then local elimination of a pathogen may be achieved. Consequently, the critical proportion immune is also known as the critical proportion to vaccinate (V_c). In a randomly mixing (homogeneous) population, this is defined as $V_c = 1 - 1/R_0$.

Endemic persistence of an infection within a population is therefore dependent on the balance between the generation of immunity, resulting either from pathogen spread or from vaccination, and replenishment of susceptibles as a result of the loss of effective immunity, births, and immigration (Figure 4).

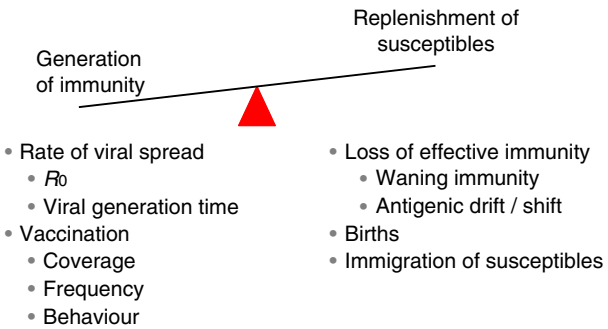

Figure 4 Endemic persistence of an infection is dependent on there being a balance between the rate at which immunity is generated and the rate of replenishment of susceptibles.

An Example Transmission Model

One way to simulate the flow of individuals between each of the stages of infection and immunity outlined above is to compartmentalize the population into corresponding subgroups (susceptible, exposed, infectious, recovered, and vaccinated). Movement between these compartments, including the dynamics of viral transmission, progression, and recovery, may then be described by the following set of linked

differential equations, for $a=0, 1, 2, \ldots, 100$ years of age:

$$\frac{dS_a}{dt} = \Lambda_a + \omega_v V_a(t) + \omega_i R_a(t) - S_a(t)[\mu_a + \psi_a + \lambda_a(t)]$$

$$\frac{dE_a}{dt} = \lambda_a(t) S_a(t) - E_a(t)[\mu_a + \gamma]$$

$$\frac{dI_a}{dt} = \gamma E_a(t) - I_a(t)[\mu_a + \rho]$$

$$\frac{dR_a}{dt} = \rho I_a(t) - R_a(t)[\mu_a + \omega_i]$$

$$\frac{dV_a}{dt} = \psi_a S_a(t) - V_a(t)[\mu_a + \omega_v]$$

where ω_v and ω_i are the rate of loss of vaccine induced and naturally acquired immunity, respectively. The natural death rate is given by μ_a, the average latent period by $1/\gamma$, and the mean duration of infectiousness as $1/\rho$. The age-dependent vaccination rate is signified by ψ_a and $\lambda_a(t)$ represents the age-dependent force of infection in the model:

$$\lambda_a(t) = \sum_{a'} \beta_{a,a'} I_{a'}(t)$$

where $\beta_{a,a'}$ is the transmission coefficient describing the rate of contact and per contact probability of transmission from individuals of age a' to those of age a and

$$\Lambda_a = \begin{cases} \text{birth rate}, & a = 0 \\ 0, & a > 0 \end{cases}$$

To arrive at an expression for R_0, first note that the incidence of infection at age a ($\zeta_a(t)$) is a function of both the force of infection and prevalence of susceptible hosts of age a:

$$\zeta_a(t) = \lambda_a(t) S_a(t)$$

This may be written in the form

$$\zeta_a(t) = \left(\sum\nolimits_{a'} \beta_{a,a'} I_{a'}(t)\right) S_a(t)$$

Now consider the simplified situation where age is ignored and the population assumed to mix homogeneously. Recalling the definition of R_0 as the number of secondary infectious hosts arising from one primary infectious host, in an entirely susceptible population:

$$S = N$$

$$I = 1$$

where N is the total population size. The basic reproductive number may now be expressed in the following form:

$$R_0 = \beta N D q$$

where D is the duration of infectiousness and q is the proportion of infections that become infectious. Note that for the model outlined above

$$D = \frac{1}{(\mu + \rho)}$$

$$q\Big| = \frac{\gamma}{(\mu + \gamma)}$$

This expression of R_0 may be adapted to give the number of infectious hosts of a particular age, arising from infectious individuals of the same or a different age and is usually expressed in matrix form, using the same notation $R_{a,a'}$ as for $\beta_{a,a'}$ above:

$$\begin{pmatrix} R_{0,0} & \cdots & R_{0,100} \\ & \ddots & \\ R_{100,0} & \cdots & R_{100,100} \end{pmatrix}$$

$$= \begin{pmatrix} \beta_{0,0} N_0 D_0 q_0 & \cdots & \beta_{0,100} N_0 D_{100} q_0 \\ & \ddots & \\ \beta_{100,0} N_{100} D_0 q_{100} & \cdots & \beta_{100,100} N_{100} D_{100} q_{100} \end{pmatrix}$$

This matrix is known as the 'next generation matrix,' $\mathbf{M}$, in which

$$D_{a'} = \frac{1}{(\mu_{a'} + \rho)}$$

$$q_a = \frac{\gamma}{(\mu_a + \gamma)}$$

The basic reproductive number for an age structured population may be calculated as the dominant eigenvalue of the next generation matrix, that is to say it is equal to the largest value of R_0 that satisfies the following equation:

$$\det|\mathbf{M} - R_0 \mathbf{I}| = 0$$

where $\mathbf{I}$ is the identity matrix.

Toward Further Realism

All models are, to a greater or lesser degree, caricatures of the real world. To be useful, such caricatures need to capture the essential details of the system being modeled. Models should therefore only be as complex as is required to address the question being asked. Unnecessary complexity reduces the transparency of a model and increases the number of parameters that must be estimated, each of which bringing with it its own uncertainty. The unnecessary proliferation of parameters also makes it harder to decide which model best fits any observed data that may be available. A model should therefore also only be as complex as can be supported by the available data.

Additional complexity may be justified, for example, where certain subgroups of the population need to be accounted for, such as the important risk groups that have a strong influence on the transmission dynamics of a pathogen or where certain types of behavior are similarly important. An example of the latter is the willingness of different subgroups to be vaccinated.

In temperate climates, certain directly transmitted infections, such as influenza, show a strong seasonal variation in incidence, tending to circulate more easily during the winter months. Although the precise reasons for this remain unclear, low temperatures that extend the time exhaled droplets take to evaporate and increased periods of time spent in poorly ventilated congregate settings have both been implicated.

One way to capture such phenomena is to utilize a periodic function such as a sine wave to emulate the seasonal fluctuation in the force of infection. Using the same notation as employed in the example model above, the force of infection may now be expressed in the following way:

$$\lambda_a(t) = z(t)\sum_{a'}\beta_{a,a'}I_{a'}(t)$$

where $z(t)$ is the sine wave function;

$$z(t) = 1 + h.\sin\left(\frac{2\pi(t-f)}{365}\right)$$

t being the number of days since the start of the simulation, whereas h controls the amplitude, and f the phase of the wave.

Choice of Model

The population-based approach to modeling communicable diseases, outlined above, is the method of choice when dealing with common infections, transmitted in large populations. In these circumstances it is a set of population averages that are being modeled and numbers are sufficiently large that they are not significantly affected by chance variations at the individual level. However, where populations are small or an infection is rare, such as at the very start or end of an epidemic, these chance, or stochastic, variations may have a profound effect on the course of events. Epidemics may fail to take off or may simply burn out due to chance. In these circumstances, individual-based models should be used.

Individual or agent-based models simulate each person in a population, recording for each of them their current state with regards to age, infection, immunity etc. Such models are well suited for simulating stochastic events and can capture a greater level of population heterogeneity than can population models; however, this flexibility comes at a cost. When used to simulate even moderately large populations, they have a high computational overhead necessitating the use of high-performance computers with memory capacity measured in terabytes. Consequently, it is often not possible for such models to simulate transmission over more than a single year, which has implications for the time horizon of an analysis.

Burden of Disease

Once an individual is infected, numerous factors may influence whether or not they develop disease, such as their age, physical fitness, and the presence of any comorbidities. The relationship between age and morbidity is of particular importance, as any change in the probability of infection can have an impact on the average age at which individuals first become infected. Widespread vaccination can reduce the prevalence of infection in a population and with it, the probability of encountering an infectious individual, leading to an increase in the average age of first infection. Very young babies may benefit from such a shift, as they are often at an increased risk of more serious disease; however, more perverse outcomes are also possible. If the average age of infection moves into the childbearing ages, this can have disastrous consequences with pathogens such as rubella, where the pathogen poses a significant risk if contracted during pregnancy. In such cases, high levels of vaccine coverage in the wider population must be maintained to produce a net reduction in the risk of morbidity in vulnerable age groups. Alternatively, vulnerable age groups can be targeted for vaccination.

To move from a model of infection incidence to one that captures disease burden, the age stratified probabilities of developing disease, given infection, need to be estimated by dividing the incidence of disease outcome by the incidence of infection, over a defined period of time. Disease outcomes of interest may include primary care consultations, outpatient visits, hospitalizations and death.

Cost-Effectiveness Analysis

Once the dynamic aspects of transmission have been accounted for, the cost-effectiveness analysis of interventions that target communicable diseases is conducted in much the same way as for any other intervention. There are, however, a few areas in which special consideration is required, particularly with regard to the time horizon of the analysis and the implementation of discounting.

Economic analyses recognize the fact that individuals prefer to receive the benefits of an intervention immediately and to defer the costs incurred till later. Such 'time preference' is the reason for discounting future costs and benefits, but can raise difficult questions when applied to public health interventions such as vaccination program that target communicable diseases. Such programs typically incur large upfront costs but accrue benefits over a much longer time scale.

As an example, certain strains of human papillomavirus (HPV) can cause genital warts relatively soon after infection, whereas other strains can induce cervical cancer typically decades later. Applying a standard discounting approach to the cost-effectiveness analysis of HPV vaccination, where costs and benefits receive equal discounting, would only account for the benefits of preventing genital warts, a condition that is relatively easily treated. The lifesaving benefits of preventing cervical cancer would be largely discounted away. Such considerations have led to a widespread debate over the most appropriate approach to discounting, a debate that is as yet unresolved. The reason for this indecision lies more in the lack of information on social attitudes to the value of public health interventions of this nature than in the technical challenges of constructing an appropriate model formulation.

A related challenge concerns the choice of time horizon: how far into the future should costs and benefits be counted in a cost-effectiveness analysis. Again, the upfront costs and deferred benefits of vaccination raise an issue. With an

ongoing vaccination program, any choice of time horizon will result in those individuals being vaccinated toward the end of the simulation accruing all of the costs associated with vaccination, but none of the benefits.

One solution is to extend the time horizon to the point where discounting renders further increases in costs and benefits insignificant. However, this approach is still problematic in circumstances such as those described above for HPV vaccination, where benefits accrue decades after vaccination. The uncertainty in projecting transmission dynamics so far into the future is also a potential hindrance to this approach.

Despite these challenges, numerous successful cost-effectiveness analyses have been conducted on interventions targeting communicable diseases, including vaccines to prevent influenza, pneumococcal disease, HPV, meningococcal group C (MenC), and varicella-zoster.

Growing interest in this field has also led to the publication of guidelines covering various aspects of communicable disease modeling (see Further Reading).

Inference for Health Econometrics: Inference, Model Tests, Diagnostics, Multiple Tests, and Bootstrap

AC Cameron, University of California – Davis, Davis, CA, USA

Glossary

False discovery proportion (FDP) The proportion of incorrectly rejected hypotheses.

False discovery rate (FDR) The expectation of the proportion of incorrectly rejected hypotheses.

Family-wise error rate (FWER) The probability of finding statistical significance in at least one test.

This article presents inference for many commonly used estimators – least squares, generalized linear models, generalized method of moments (GMM), and generalized estimating equations – that are asymptotically normally distributed. Section Inference focuses on Wald confidence intervals and hypothesis tests based on estimator variance matrix estimates that are heteroskedastic-robust and, if relevant, cluster-robust. Section Model Tests and Diagnostics summarizes tests of model adequacy and model diagnostics. Section Multiple Tests presents family-wise error rates and false discovery rates (FDRs) that control for multiple testing such as subgroup analysis. Section Bootstrap and Other Resampling Methods presents bootstrap and other resampling methods that are most often used to estimate the variance of an estimator. Bootstraps with asymptotic refinement are also presented.

Inference

Most estimators in health applications are m-estimators that solve estimating equations of the form

$$\sum_{i=1}^{N} g_i(\hat{\theta}) = 0 \qquad [1]$$

where θ is a $q \times 1$ parameter vector, i denotes the ith of N observations, $g_i(\cdot)$ is a $q \times 1$ vector, and often $g_i(\theta) = g_i(y_i, x_i, \theta)$ where y denotes a scalar-dependent variable and x denotes the regressors or covariates. For ordinary least squares, for example, $g_i(\beta) = (y_i - x_i'\beta)x_i$. Nonlinear least squares, maximum likelihood (ML), quantile regression, and just-identified instrumental variables estimators are m-estimators. So too are generalized linear model estimators, extensively used in biostatistics, that are quasi-ML estimators based on exponential family distributions, notably Bernoulli (logit and probit), binomial, gamma, normal, and Poisson.

The estimator $\hat{\theta}$ is generally consistent if $E[g_i(\theta) = 0]$. Statistical inference is based on the result that $\hat{\theta}$ is asymptotically normal with mean θ and variance matrix $V[\hat{\theta}]$ that is estimated by

$$\hat{V}[\hat{\theta}] = \hat{A}^{-1}\hat{B}\hat{A}^{-1'} \qquad [2]$$

where $N^{-1}\hat{A}$ and $N^{-1}\hat{B}$ are consistent estimates of $A = E\left[N^{-1}\sum_i H_i(\theta)\right]$, where $H_i(\theta) = \partial g_i(\theta)/\partial\theta'$ and $B = E[N^{-1}\sum_i\sum_j g_i(\theta)g_j(\theta)']$. The variance is said to be of 'sandwich form,' because $\hat{B}$ is sandwiched between $\hat{A}^{-1}$ and $\hat{A}^{-1'}$. The estimate $\hat{A}$ is the observed Hessian $\sum_i H_i(\hat{\theta})$, or in some cases the expected Hessian $E\left[\sum_i H_i(\theta)\right]\big|_{\hat{\theta}}$. By contrast, the estimate $\hat{B}$, and hence $\hat{V}[\hat{\theta}]$ in eqn [2], can vary greatly with the type of data being analyzed and the associated appropriate distributional assumptions.

Default estimates of $V[\hat{\theta}]$ are based on strong distributional assumptions, and are typically not used in practice. For ML estimation with density assumed to be correctly specified $B = -A$, so the sandwich estimate simplifies to $\hat{V}[\hat{\theta}] = -\hat{A}^{-1}$. Qualitatively similar simplification occurs for least squares and instrumental variables estimators when model errors are independent and homoskedastic.

More generally, for data independent over i, $\hat{B} = \frac{N}{N-q}\sum_i g_i(\hat{\theta})g_i(\hat{\theta})'$, where the multiple $N/(N-q)$ is a commonly used finite sample adjustment. Then the variance matrix estimate in eqn [2] is called the Huber, White, or robust estimate – a limited form of robustness as independence of observations is assumed. For OLS, for example, this estimate is valid even if independent errors are heteroskedastic, whereas the default requires errors to be homoskedastic.

Often data are clustered, with observations correlated within a cluster but independent across clusters. For example, individuals may be clustered within villages or hospitals, or students clustered within class or within school. Let c denote the typical cluster, and sum $g_i(\theta)$ for observations i in cluster c to form $g_c(\theta)$. Then $\hat{B} = \frac{C}{C-1}\sum_{c=1}^{C} g_c(\hat{\theta})g_c(\hat{\theta})'$, where C is the number of clusters, and the variance matrix estimate in eqn [2] is called a cluster-robust estimate. The number of clusters should be large as the asymptotic theory requires $C \to \infty$, rather than $N \to \infty$. The clustered case also covers short panels with few time periods and data correlated over time for a given individual but independent across individuals. Then the clustering sums over time periods for a given individual. Wooldridge (2003) and Cameron and Miller (2011) survey inference with clustered data.

Survey design can lead to clustering. Applied biostatisticians often use survey estimation methods that explicitly control for the three complex survey complications of weighting, stratification, and clustering. Econometricians instead usually assume correct model specification conditional on regressors (or instruments), so that there is no need to weight; ignore the potential reduction in standard error estimates that can occur with stratification; and conservatively

 doi:10.1016/B978-0-12-375678-7.00706-9

control for clustering by computing standard errors that cluster at a level such as a state (region) that is usually higher than the primary sampling unit.

For time series data, observations may be correlated over time. Then the heteroskedastic and autocorrelation consistent (HAC) variance matrix estimate is used; see Newey and West (1987). A similar estimate can be used when data are spatially correlated, with correlation depending on the distance and with independence once observations are more than a given distance apart. This leads to the spatial HAC estimate; see Conley (1999).

Note that in settings where robust variance matrix estimates are used, additional assumptions may enable more efficient estimation of θ such as feasible generalized least squares and generalized estimating equations, especially if data are clustered.

Given $\hat{\theta}$ asymptotic normal with variance matrix estimated using eqn [2], the Wald method can be used to form confidence intervals and perform hypothesis tests.

Let θ be a scalar component of the parameter vector θ. Since $\hat{\theta} \overset{a}{\sim} N[\theta, \hat{\mathrm{V}}[\hat{\theta}]]$, we have $\hat{\theta} \overset{a}{\sim} N[\theta, s^2_{\hat{\theta}}]$, where the standard error $s_{\hat{\theta}}$ is the square root of the relevant diagonal entry in $\hat{V}[\hat{\theta}]$. It follows that $(\hat{\theta} - \theta)/s_{\hat{\theta}} \overset{a}{\sim} N[0,1]$. This justifies the use of the standard normal distribution in constructing confidence intervals and hypothesis tests for sample size $N \to \infty$. A commonly used finite-sample adjustment uses $(\hat{\theta} - \theta)/s_{\hat{\theta}} \overset{a}{\sim} T(N - q)$, where $T(N-q)$ is the students T distribution with $(N-q)$ degrees of freedom, N is the sample size, and K parameters are estimated.

A 95% confidence interval for θ gives a range of values that 95% of the time will include the unknown true value of θ . The Wald 95% confidence interval is $\hat{\theta} \pm c_{.025} \times s_{\hat{\theta}}$, where the critical value $c_{.025}$ is either $z_{[.025]} = 1.96$, the .025 quantile of the standard normal distribution, or $t_{[.025]}$ the .025 quantile of the $T(N-q)$ distribution. For example, $c_{.025} = 2.042$ if $N - q = 30$.

For two-sided tests of $H_0{:}\theta = \theta^*$ against $H_a{:}\theta \neq \theta^*$, the Wald test is based on how far $|\hat{\theta} - \theta^*|$ is from zero. On normalizing by the standard error, the Wald statistic $w = (\hat{\theta} - \theta^*)/s_{\hat{\theta}}$ is asymptotically standard normal under H_0, though again a common finite sample correction is to use the $T(N-q)$ distribution. H_0 at the 5% significance level is rejected if $|w| > c_{.025}$. Often $\theta^* = 0$, in which case w is called the t-statistic and the test is called a test of statistical significance. Greater information is conveyed by reporting the p-value, the probability of observing a value of w as large or larger in absolute value under the null hypothesis. Then $p = \Pr[|W| > |w|]$, where W is standard normal or $T(N-q)$ distributed. $H_0{:}\theta = \theta^*$ is rejected against $H_0{:}\theta \neq \theta^*$ at level 0.05 if $p < .05$.

More generally, it may be interesting to perform joint inference on more than one parameter, such as a joint test of statistical significance of several parameters, or on functions(s) of the parameters. Let $\mathrm{h}(\theta)$ be an $h \times 1$ vector function of θ, possibly nonlinear, where $h \leq q$. A Taylor series approximation yields $\mathrm{h}(\hat{\theta}) \simeq \mathrm{h}(\theta) + \hat{\mathrm{R}}(\hat{\theta} - \theta)$, where $\hat{\mathrm{R}} = \partial \mathrm{h}(\theta)/\partial \theta'|_{\hat{\theta}}$ is assumed to be of full rank h (the nonlinear analog of linear dependence of restrictions). Given $\hat{\theta} - \theta \overset{a}{\sim} N[0, \hat{v}[\hat{\theta}]]$, this yields $\mathrm{h}(\hat{\theta}) \overset{a}{\sim} N[\mathrm{h}(\theta), \hat{\mathrm{R}}\hat{\mathrm{V}}[\hat{\theta}]\hat{\mathrm{R}}']$. The term delta method is used as a first derivative and is taken in approximating $\mathrm{h}(\hat{\theta})$.

Confidence intervals can be formed in the case that $h(\cdot)$ is a scalar. Then $h(\hat{\theta}) \pm c_{.025} \times [\hat{R}\hat{V}[\hat{\theta}]\hat{R}']^{1/2}$ is used. A leading example is a confidence interval for a marginal effect in a nonlinear model. For example, for $E[y|x] = \exp(x'\theta)$ the marginal effect for the jth regressor is $\partial \mathrm{E}[y|\mathrm{x}]/\partial x_j = \exp(\mathrm{x}'\theta)\theta_j$. When evaluated at $\mathrm{x} = \mathrm{x}^*$ this equals $\exp(\mathrm{x}^{*\prime}\hat{\theta})\hat{\theta}_j$ which is a scalar function $h(\hat{\theta})$ of $\hat{\theta}$; the corresponding average marginal effect is $\sum_i \exp(\mathrm{x}_i'\hat{\theta})\hat{\theta}_j$.

A Wald test of $H_0{:}\mathrm{h}(\theta) = 0$ against $H_a{:}\mathrm{h}(\theta) \neq 0$ is based on the closeness of $\mathrm{h}(\hat{\theta})$ to zero, using

$$w = \mathrm{h}(\hat{\theta})'[\hat{\mathrm{R}}\hat{\mathrm{V}}[\hat{\theta}]\hat{\mathrm{R}}']^{-1}\mathrm{h}(\hat{\theta}) \overset{a}{\sim} \chi^2(h) \qquad [3]$$

under H_0. H_0 at level 0.05 is rejected if $w > \chi^2_{.95}(h)$. An F version of this test is $F = w/h$, and is rejected at level 0.05 if $w > F_{.95}(h, N-q)$. This is a small sample variation, analogous to using the $T(N-q)$ rather than the standard normal.

For ML estimation the Wald method is one of the three testing methods that may be used. Consider testing the hypothesis that $\mathrm{h}(\theta) = 0$. Let $\tilde{\theta}$ denote the ML estimator obtained by imposing this restriction, whereas $\hat{\theta}$ does not impose the restriction. The Wald test uses only $\hat{\theta}$ and tests the closeness of $h(\hat{\theta})$ to zero. The log-likelihood ratio test is based on the closeness of $L(\hat{\theta})$ to $L(\tilde{\theta})$, where $L(\theta)$ denotes the log-likelihood function. The score test uses only $\tilde{\theta}$ and is based on the closeness to zero of $\partial L(\theta)/\partial \theta|_{\tilde{\theta}}$, where $L(\theta)$ here is the log-likelihood function for the unrestricted model.

If the likelihood function is correctly specified, a necessary assumption, these three tests are asymptotically equivalent. So the choice between them is one of convenience. The Wald test is most often used, as in most cases $\hat{\theta}$ is easily obtained. The score test is used in situations in which estimation is much easier when the restriction is imposed. For example, in a test of no spatial dependence versus spatial dependence, it may be much easier to estimate θ under the null hypothesis of no spatial dependence. The Wald and score tests can be robustified. If one is willing to make the strong assumption that the likelihood function is correctly specified, then the likelihood ratio test is preferred due to the Neyman–Pearson lemma and because, unlike the Wald test, it is invariant to reparameterization.

GMM estimators are based on a moment condition of the form $\mathrm{E}[\mathrm{g}_i(\theta)] = 0$. If there are as many components of $\mathrm{g}(\cdot)$ as of θ the model is said to be just identified and the estimate $\hat{\theta}$ solves $\sum_i \mathrm{g}_i(\hat{\theta}) = 0$, which is eqn [1]. Leading examples in the biostatistics literature are generalized linear model estimators and generalized estimating equations estimators. If instead there are more moment conditions than parameters there is no solution to eqn [1]. Instead make $\sum_i \mathrm{g}_i(\hat{\theta})$ as close to zero as possible using a quadratic norm. The method of moments estimator minimizes

$$Q(\theta) = \left(\sum_{i=1}^{N} g_i(\theta)\right)' \mathrm{W} \left(\sum_{i=1}^{N} \mathrm{g}_i(\theta)\right)$$

where W is a symmetric positive definite weighting matrix and the best choice of W is the inverse of a consistent estimate of the variance of $\sum_i \mathrm{g}_i(\theta)$.

The leading example of this is two-stage least-squares (2SLS) estimation for instrumental variables estimation in overidentified models. Then $\mathrm{g}_i(\beta) = z_i(y_i - \mathrm{x}_i'\beta)$, and it can be shown that the 2SLS estimator is obtained if $\mathrm{W} = (\mathrm{Z}'\mathrm{Z})^{-1}$. The estimated variance matrix is again of sandwich form eqn [2], though the expressions for $\hat{\mathrm{A}}$ and $\hat{\mathrm{B}}$ are more complicated. For

instrumental variables estimators with instruments weakly correlated with regressors an alternative asymptotic theory may be warranted. Bound *et al.* (1995) outline the issues and Andrews *et al.* (2007) compare several different test procedures.

Model Tests and Diagnostics

The most common specification tests imbed the model under consideration into a larger model and use hypothesis tests (Wald, likelihood ratio, or score) to test the restrictions that the larger model collapses to the model under consideration. A leading example is test of statistical significance of a potential regressor.

A broad class of tests of model adequacy can be constructed by testing the validity of moment conditions that are imposed by a model but have not already been used in constructing the estimator. Suppose a model implies the population moment condition

$$H_0 : \mathrm{E}[\mathrm{m}_i(\mathrm{w}_i, \theta)] = 0 \qquad [4]$$

where w is a vector of observables, usually the dependent variable y, regressors x, and, possibly, additional variables z. An m-test, in the spirit of a Wald test, is a test of whether the corresponding sample moment

$$\hat{\mathrm{m}}(\hat{\theta}) = \frac{1}{N}\sum_{i=1}^{N} \mathrm{m}_i(\mathrm{w}_i, \hat{\theta}) \qquad [5]$$

is close to zero. Under suitable assumptions, $\hat{\mathrm{m}}(\hat{\theta})$ is asymptotically normal. This leads to the chi-squared test statistic

$$M = \hat{\mathrm{m}}(\hat{\theta})'\hat{\mathrm{V}}_{\mathrm{m}}^{-1}\hat{\mathrm{m}}(\hat{\theta}) \overset{a}{\sim} \chi^2(rank(V_{\mathrm{m}})) \qquad [6]$$

if the moment conditions eqn [4] are correct, where $\hat{\mathrm{V}}_{\mathrm{m}}$ is a consistent estimate of the asymptotic variance of $\hat{\mathrm{m}}(\hat{\theta})$. The challenge is in obtaining $\hat{\mathrm{V}}_{\mathrm{m}}$. In some leading examples an auxiliary regression can be used, or a bootstrap can be applied.

Especially for fully parametric models there are many candidates for $\mathrm{m}_i(\cdot)$. Examples of this approach are White's information matrix test to test correct specification of the likelihood function; a regression version of the chi-squared goodness of fit test; Hausman tests such as that for regressor endogeneity; and tests of overidentifying restrictions in a model with endogenous regressors and an excess of instruments. Such tests are not as widely used as they might be for two reasons. First, there is usually no explicit alternative hypothesis so rejection of H_0 may not provide much guidance as to how to improve the model. Second, in very large samples with actual data any test at a fixed significance level such as 0.05 is likely to reject the null hypothesis, so inevitably any model will be rejected.

Regression model diagnostics need not involve formal hypothesis tests. A range of residual diagnostic plots can provide information on model nonlinearity and observations that are outliers and have high leverage. In the linear model, a small sample correction divides the residual $y_i - x_i'\hat{\beta}$ by $\sqrt{1-h_{ii}}$, where h_{ii} is the ith diagonal entry in the hat matrix $\mathrm{H}=\mathrm{X}(\mathrm{X}'\mathrm{X})^{-1}\mathrm{X}$. As H has rank K, the number of regressors, the average value of h_{ii} is K/n and values of h_{ii} in excess of $2K/N$ are viewed as having high leverage. This result extends to generalized linear models where a range of residuals have been proposed; McCullagh and Nelder (1989) provide a summary. Econometricians place less emphasis on residual analysis, compared with biostatisticians. If datasets are small then there is concern that residual analysis may lead to overfitting of the model. Besides if the dataset is large then there is a belief that residual analysis may be unnecessary as a single observation will have little impact on the analysis. Even then diagnostics may help detect data miscoding and unaccounted model nonlinearities.

For linear models, R^2 is a well understood measure of goodness of fit. For nonlinear models a range of pseudo-R^2 measures have been proposed. One that is easily interpreted is the squared correlation between y and $\hat{y}$, though in nonlinear models this is not guaranteed to increase as regressors are added.

Model testing and diagnostics may lead to more than one candidate model. Standard hypothesis tests can be implemented for models that are nested. For nonnested models that are likelihood based, one can use a generalization of the likelihood ratio test due to Vuong (1989), or use information criteria such as Akaike's information criteria based on fitted log-likelihood with a penalty for the number of model parameters. For nonnested models that are not likelihood based one possibility is artificial nesting that nests two candidate models in a larger model, though this approach can lead to neither model being favored.

Multiple Tests

Standard theory assumes that hypothesis tests are done once only and in isolation, whereas in practice final reported results may follow much pretesting. Ideally reported p values should control for this pretesting.

In biostatistics, it is common to include as control variables in a regression only those regressors that have $p<.05$. By contrast, in economics it is common to have a preselected candidate set of control regressors, such as key socioeconomic variables, and include them even if they are statistically insignificant. This avoids pretesting, at the expense of estimating larger models.

A more major related issue is that of multiple testing or multiple comparisons. Examples include testing the statistical significance of a key regressor in several subgroups of the sample (subgroup analysis); testing the statistical significance of a key regressor in regressions on a range of outcomes (such as use of a range of health services); testing the statistical significance of a key regressor interacted with various controls (interaction effects); and testing the significance of a wide range of variables on a single outcome (such as various genes on a particular form of cancer). With many such tests at standard significance levels one is clearly likely to find spurious statistical significance.

In such cases one should view the entire battery of tests as a unit. If m such tests are performed, each at statistical significance level α^*, and the tests are statistically independent, then the probability of finding no statistical significance in all m

tests is $(1-\alpha^*)^m$. It follows that the probability of finding statistical significance in at least one test, called the family-wise error rate (FWER), equals $\alpha=1-(1-\alpha^*)^m$. To test at FWER α, each individual test should be at level $\alpha^*=1-(1-\alpha)^m$, called the Sidak correction. For example, if $m=5$ tests are conducted with FWER of $\alpha=0.05$, each test should be conducted at level $\alpha^*=0.01021$. The simpler Bonferroni correction sets $\alpha^*=\alpha/m$. The Holm correction uses a stepdown version of Bonferroni, with tests ordered by p-value from smallest to largest, so $p_{(1)}<p_{(2)}<<p_{(m)}$, and the jth test rejects if $p_{(j)}<\alpha_j^*=\alpha/(m-j+1)$. A stepdown version of the Sidak correction uses $\alpha_j^*=1-(1-\alpha)^{m-j+1}$. These corrections are quite conservative in practice, as the multiple tests are likely to be correlated rather than independent.

Benjamini and Hochberg (1995) proposed an alternative approach to multiple testing. Recall that test size is the probability of a type I error, i.e., the probability of incorrectly rejecting the null hypothesis. For multiple tests it is natural to consider the proportion of incorrectly rejected hypotheses, the false discovery proportion (FDP), and its expectation E[FDP] called the FDR. Benjamini and Hochberg (1995) argue that it is more natural to control FDR than FEWR. They propose doing so by ordering tests by p-value from smallest to largest, so $p_{(1)}<p_{(2)}<\cdots<p_{(m)}$, and rejecting the corresponding hypotheses $H_{(1)},\ldots,H_{(k)}$, where k is the largest j for which $p(j)\leq\alpha j/m$, where α is the prespecified FDR for the multiple tests. If the multiple tests are independent then the FDR equals α.

In practice tests are not independent. Farcomeni (2008) provides an extensive guide to the multiple testing literature. A recent article on estimating the FDR when tests are correlated is Schwartzman and Lin (2011). Duflo *et al.* (2008) provide a good discussion of practical issues that arise with multiple testing and consider the FEWR but not the FDR. White (2001) presents simulation-based methods for the related problem of testing whether the best model encountered in a specification search has a better predictive power than a benchmark model.

Bootstrap and Other Resampling Methods

Statistical inference controls for the uncertainty that the observed sample of size N is just one possible realization of a set of N possible draws from the population. This typically relies on asymptotic theory that leads to limit normal and chi-squared distributions. Alternative methods based on Monte Carlo simulation are detailed in this section.

Bootstrap

Bootstraps can be applied to a wide range of statistics. The most common use of the bootstrap is considered here, to estimate the standard error of an estimator when this is difficult to do using conventional methods.

Suppose 400 random samples from the population were available. Then 400 different estimates of $\hat{\theta}$ can be obtained and the standard error of $\hat{\theta}$ is simply the standard deviation of these 400 estimates. In practice, however, only one sample from the population is available. The bootstrap provides a way to generate 400 samples by resampling from the current sample. Essentially, the observed sample is viewed as the population and the bootstrap provides multiple samples from this population.

Let $\hat{\theta}^*_{(1)},\ldots,\hat{\theta}^*_{(B)}$ denote B estimates where, for example, $B=400$. Then in the scalar case the bootstrap estimate of the variance of $\hat{\theta}$ is

$$\hat{V}_{\text{Boot}}\left[\hat{\theta}\right]=\frac{1}{B-1}\sum_{b=1}^{B}(\hat{\theta}^*_{(b)}-\overline{\hat{\theta}^*})^2 \qquad [7]$$

where $\overline{\hat{\theta}^*}=\frac{1}{B}\sum_{b=1}^{B}\hat{\theta}^*_{(b)}$ is the average of the B bootstrap estimates. The square root of $\hat{V}_{\text{Boot}}[\hat{\theta}]$, denoted $\text{se}_{\text{Boot}}[\hat{\theta}]$, is called the bootstrap estimate of the standard error of $\hat{\theta}$. In the case of several parameters

$$\hat{V}_{\text{Boot}}\left[\hat{\theta}\right]=\frac{1}{B-1}\sum_{b=1}^{B}(\hat{\theta}^*_{(b)}-\overline{\hat{\theta}^*})(\hat{\theta}^*_{(b)}-\overline{\hat{\theta}^*})'$$

and even more generally the bootstrap may be used to estimate the variance of functions $h(\hat{\theta})$, such as marginal effects, not just $\hat{\theta}$ itself.

There are several different ways that the resamples can be obtained. A key consideration is that the quantity being resampled should be independent and identically distributed (i.i.d).

The most common bootstrap for data (y_i,x_i) that are i.i.d. is a paired bootstrap or nonparametric bootstrap. This draws with replacement from $(y_1,x_1),\ldots,(y_N,x_N)$ to obtain a resample $(y_1^*,x_1^*),\ldots,(y_N^*,x_N^*)$ for which some observations will appear more than once, whereas others will not appear at all. Estimation using the resample yields estimate $\hat{\theta}^*$. Using B similarly generated resamples yields $\hat{\theta}^*_{(1)},\ldots,\hat{\theta}^*_{(B)}$. This bootstrap variance estimate is asymptotically equivalent to the White or Huber robust sandwich estimate.

If data are instead clustered with C clusters, a clustered bootstrap draws with replacement from the entire clusters, yielding a resample $(y_1^*,X_1^*),\ldots,(y_C^*,X_C^*)$. This bootstrap variance estimate is asymptotically equivalent to the cluster-robust sandwich estimate.

Other bootstraps place more structure on the model. A residual or design bootstrap in the linear regression model fixes the regressors and only resamples the residuals. For models with i.i.d. errors the residual bootstrap samples with replacement from $\hat{u}_1,\ldots,\hat{u}_N$ to yield residual resample $\hat{u}_1^*,\ldots,\hat{u}_N^*$. Then the typical data resample is $(y_1^*,x_1),\ldots,(y_N^*,x_N)$ where $y_i^*=x_i'\hat{\beta}+\hat{u}_i^*$. If errors are heteroskedastic one should instead use a wild bootstrap; the simplest example is $\hat{u}_i^*=\hat{u}_i$ with probability .5 and $\hat{u}_i^*=-\hat{u}_i$ with probability .5.

For a fully parameterized model one can generate new values of the dependent variable from the fitted conditional distribution. The typical data resample is $(y_1^*,x_1),\ldots,(y_N^*,x_N)$ where y_i^* is a draw from $F(y|x_i,\hat{\theta})$.

Whenever a bootstrap is used in applied work the seed, the initial value of the random number generator used in determining random draws, should be set to ensure replicability of results. For standard error estimation $B=400$ should be more than adequate.

The bootstrap can also be used for statistical inference. A Wald 95% confidence interval for scalar θ is $\hat{\theta}\pm1.96\times\text{se}_{\text{Boot}}[\hat{\theta}]$. An asymptotically equivalent alternative

interval is the percentile interval $(\hat{\theta}^*_{[.025]}, \hat{\theta}^*_{[.975]})$, where $\hat{\theta}^*_{[\alpha]}$ is the αth quantile of $\hat{\theta}^*_{(1)}, \ldots, \hat{\theta}^*_{(B)}$. Similarly, in testing $H_0{:}\theta = 0$ against $H_a{:}\theta \neq 0$ the null hypothesis may be rejected if $|w| = |\hat{\theta}/\text{se}_{\text{Boot}}[\hat{\theta}]| > 1.96$, or if $\hat{\theta} < \hat{\theta}^*_{[.025]}$ or $\hat{\theta} > \hat{\theta}^*_{[.975]}$.

Care is needed in using the bootstrap in nonstandard situations as, for example, $\text{V}[\hat{\theta}]$ may not exist, even asymptotically; yet it is always possible to (erroneously) compute a bootstrap estimate of $\text{V}[\hat{\theta}]$. The bootstrap can be applied if $\hat{\theta}$ is root-N consistent and asymptotically normal, and there is sufficient smoothness in the cumulative distribution functions of the data-generating process and of the statistic being bootstrapped.

Bootstrap with Asymptotic Refinement

The preceding bootstraps are asymptotically equivalent to the conventional methods of section Inference. Bootstraps with asymptotic refinement, by contrast, provide a more refined asymptotic approximation that may lead to better performance (truer test size and confidence interval coverage) in finite samples. Such bootstraps are emphasized in theory papers, but are less often implemented in applied studies.

These gains are possible if the statistic bootstrapped is asymptotically pivotal, meaning its asymptotic distribution does not depend on unknown parameters. An estimator $\hat{\theta}$ that is asymptotically normal is not usually asymptotically pivotal as its distribution depends on an unknown variance parameter. However, the studentized statistic $t = (\hat{\theta} - \theta_0)/s_{\hat{\theta}}$ is asymptotically $N[0,1]$ under $H_0{:}\theta = \theta_0$, so is asymptotically pivotal. Therefore compute $t^* = (\hat{\theta}^* - \hat{\theta})/s_{\hat{\theta}^*}$ for each bootstrap resample and use quantiles of $t^*_{(1)}, \ldots, t^*_{(B)}$ to compute critical values and p-values. Note that t^* is centered around $\hat{\theta}$ because the bootstrap views the sample as the population, so $\hat{\theta}$ is the population value.

A 95% percentile t-confidence interval for scalar θ is $(\hat{\theta} + t^*_{[.025]}s_{\hat{\theta}}, \hat{\theta} + t^*_{[.975]}s_{\hat{\theta}})$, where $t^*_{[\alpha]}$ is the αth quantile of $t^*_{(1)}, \ldots, t^*_{(B)}$. A percentile-t Wald test rejects $H_0{:}\theta = \theta_0$ against $H_a{:}\theta \neq \theta_0$ at level 0.05 if $t = (\hat{\theta} - \theta_0)/s_{\hat{\theta}}$ falls outside the interval $(t^*_{[.025]}, t^*_{[.975]})$.

Two commonly used alternative methods to obtain confidence intervals with asymptotic refinement are the following. The bias-corrected method is a modification of the percentile method that incorporates a bootstrap estimate of the finite-sample bias in $\hat{\theta}$. For example, if the estimator is upward biased, as measured by estimated median bias, then the confidence interval is moved to the left. The bias-corrected accelerated confidence interval is an adjustment to the bias-corrected method that adds an acceleration component that permits the asymptotic variance of $\hat{\theta}$ to vary with θ.

Theory shows that bootstrap methods with asymptotic refinement outperform conventional asymptotic methods as $N \to \infty$. For example, a nominal 95% confidence interval with asymptotic refinement has a coverage rate of $0.95 + O(N^{-1})$ rather than $0.95 + O(N^{-1/2})$. This does not guarantee better performance in typical sized finite samples, but Monte Carlo studies generally confirm this to be the case. Bootstraps with refinement require a larger number of bootstraps than recommended in the previous subsection, as the critical values lie in the tails of the distribution. A common choice is $B = 999$, with B chosen so that $B + 1$ is divisible by the significance level 100α.

Jackknife

The jackknife is an alternative resampling scheme used for bias correction and variance estimation that predates the bootstrap.

Let $\hat{\theta}$ be the original sample estimate of θ, let $\hat{\theta}_{(-i)}$ denote the parameter estimate from the sample with the ith observation deleted, $i = 1, \ldots, N$, and let $\bar{\hat{\theta}} = N^{-1}\sum_{i=1}^{N}\hat{\theta}_{(-i)}$ denote the average of the N jackknife estimates. The bias-corrected jackknife estimate of θ equals $N\hat{\theta} - (N-1)\bar{\hat{\theta}}$, the sum of the N pseudovalues $\hat{\theta}^*_{(-i)} = N\hat{\theta} - (N-1)\hat{\theta}_{(-i)}$ that provide measures of the importance or influence of the ith observation estimating $\hat{\theta}$.

The variance of these N pseudovalues can be used to estimate $\text{V}[\hat{\theta}]$, yielding the leave-one-out jackknife estimate of variance:

$$\hat{\text{V}}_{\text{Jack}}\left[\hat{\theta}\right] = \left[\frac{1}{N(N-1)}\sum_{i=1}^{N}(\hat{\theta}^*_{(-i)} - \bar{\hat{\theta}})(\hat{\theta}^*_{(-i)} - \bar{\hat{\theta}})'\right]$$

A variation replaces $\bar{\hat{\theta}}$ with $\hat{\theta}$.

The jackknife requires N resamples, requiring more computation than the bootstrap if N is large. The jackknife does not depend on random draws, unlike the bootstrap, so is often used to compute standard errors for published official statistics.

Permutation Tests

Permutation tests derive the distribution of a test statistic by obtaining all possible values of the test statistic under appropriate rearrangement of the data under the null hypothesis.

Consider scalar regression, so $y_i = \beta_1 + \beta_2 x_i + u_i$, $i = 1, \ldots, N$, and Wald test of $H_0{:}\beta_2 = 0$ based on $t = \hat{\beta}_2/s_{\hat{\beta}_2}$. Regress each of the $N!$ unique permutations of $(y_1, \ldots, y_N)$ on the regressors $(x_1, \ldots, x_N)$ and in each case calculate the t-statistic for $H_0{:}\beta_2 = 0$. Then the p-value for the original test statistic is obtained directly from the ordered distribution of the $N!$ t-statistics.

Permutation tests are most often used to test whether two samples come from the same distribution, using the difference in means test. This is a special case of the previous example, where x_i is an indicator variable equal to one for observations coming from the second sample.

Permutation methods are seldom used in multiple regression, though several different ways to extend this method have been proposed. Anderson and Robinson (2001) review these methods and argue that it is best to permute residuals obtained from estimating the model under H_0, a method proposed by Freedman and Lane (1983).

Conclusion

This survey is restricted to classical inference methods for parametric models. It does not consider Bayesian inference, inference following nonparametric and semiparametric

estimation, or time series complications such as models with unit roots and cointegration.

The graduate-level econometrics texts by Cameron and Trivedi (2005), Greene (2012) and Wooldridge (2010) cover especially sections Inference and Model Tests and Diagnostics; see also Jones (2000) for a survey of health econometrics models and relevant chapters in this volume. The biostatistics literature for nonlinear models emphasizes estimators for generalized linear models; the classic reference is McCullagh and Nelder (1989). For the resampling methods in section Bootstrap and Other Resampling Methods, Efron and Tibsharani (1993) is a standard accessible reference; see also Davison and Hinkley (1997) and, for implementation, Cameron and Trivedi (2010).

Information Analysis, Value of

K Claxton, University of York, York, North Yorkshire, UK

Policy Relevance

The general issue of balancing the value of evidence about the performance of a technology and the value of providing patients with access to a technology can be seen as central to a number of policy questions in many different types of health-care systems (HCS). For example, decisions about approval or reimbursement of new drugs are increasingly being made close to their launch when the evidence base to support their use is least mature and when there may be substantial uncertainty surrounding their cost effectiveness. In these circumstances, further evidence maybe particularly valuable as it will lead to better decisions about the use of the technology, which would improve patient outcomes and/or reduce resource costs. Therefore, it is useful to establish the key principles of what assessments are needed to decide whether there is sufficient evidence to support reimbursement or recommending the use of a new drug, whether it should be approved but additional evidence sort or whether its widespread use should be restricted until the additional evidence is available. Such assessments can help to inform the questions posed by coverage with evidence development and managed entry in many health-care systems including restricting approval to 'only in research' which is part of the UK National Institute for Heath and Clinical Excellence (NICE) statutes.

If there are constraints on the growth of health-care expenditure, then approving a more costly technology will displace other activities that would have otherwise generated improvements in health for other patients, as well as other socially valuable activities outside health care. If the objective of a HCS is to improve health outcomes across the population it serves then, even if a technology is expected to be more effective, the health gained must be compared to the health expected to be forgone elsewhere as a consequence of additional costs, i.e., whether the technology is expected to be cost effective and offer positive net health benefits (NHB) (other effects, e.g., on consumption, can also be expressed as their health equivalent). An assessment of expected cost effectiveness or NHB relies on evidence about effectiveness, impact on long-term overall health and potential harms, as well as additional health-care costs together with some assessment of what health is likely to be forgone as a consequence (the cost-effectiveness threshold).

Such assessments are inevitably uncertain and, without sufficient and good quality evidence, decisions about the use of technologies will also be uncertain. There will be a chance that the resources committed by the approval of a new technology may be wasted if the expected positive net health effects are not realized. Equally, rejecting a new technology will risk failing to provide access to a valuable intervention if the net health effects prove to be greater than expected. Therefore, if the social objective is to improve overall health for both current and future patients then the need for and the value of additional evidence is an important consideration when making decisions about the use of technologies. This is even more critical once it is recognized that the approval of a technology for widespread use might reduce the prospects of conducting the type of research that would provide the evidence needed. In these circumstances there will be a trade-off between the net health effects for current patients from early access to a cost-effective technology and the health benefits for future patients from withholding approval until valuable research has been conducted.

Research also consumes valuable resources which could have been devoted to patient care, or other more valuable research priorities. Also uncertain events in the near or distant future may change the value of the technology and the need for evidence (e.g., prices of existing technologies, the entry of new technologies and other evidence about the performance of technologies as well as the natural history of disease). In addition, implementing a decision to approve a new technology may commit resources which cannot subsequently be recovered if a decision to approve or reimburse might change in the future (e.g., due to research reporting). Therefore, appropriate research and coverage decisions will depend on whether the expected benefits of research are likely to exceed the costs and whether any benefits of early approval or reimbursement are greater than withholding approval until additional research is conducted or other sources of uncertainty are resolved. Methods of analysis which provide a quantitative assessment of the potential benefits of acquiring further evidence allow research and reimbursement decisions to be addressed explicitly and accountably.

The Value of Additional Evidence

The principles of value of information analysis have a firm foundation in statistical decision theory with closely related concepts and methods in mathematics and financial economics with diverse applications in business decisions, engineering, environmental risk analysis, and financial and environmental economics. There are now many applications in health, some commissioned to directly inform policy and others published in specialist as well as general medical and health policy journals. Most commonly these methods of analysis have been applied in the context of probabilistic decision analytic models used to estimate expected cost effectiveness of alternative interventions. However, the same type of analysis can also be used to extend standard methods of systematic review and meta-analysis. Indeed the principles or value of information analysis can also be used as a conceptual framework for qualitative assessment of how important uncertainty might be and the relative priority of alternative research topics and proposals.

Additional evidence is valuable because it can improve patient outcomes by resolving existing uncertainty about the cost effectiveness of the interventions available, thereby

informing treatment choice for subsequent patients. For example, the balance of existing evidence might suggest that a particular intervention is expected to be cost effective and offer the greatest NHB, but there will be a chance that others are in fact more cost effective, offering higher NHB to the HCS. If treatment choice is based on existing evidence then there will be a chance that other interventions would have improved overall health outcomes to a greater extent, i.e., there are adverse net health consequences associated with uncertainty. The scale of uncertainty can be indicated by the results of probabilistic analysis of a decision analytic model and/or based on the results of a meta-analysis of the evidence relevant to the choice between interventions. The expected consequences of this uncertainty can be expressed in terms of NHB or the equivalent HCS resources that would be required to generate the same net health effects. These expected consequences can be interpreted as an estimate of the NHB that could potentially be gained per patient if the uncertainty surrounding their treatment choice could be resolved, i.e., it indicates an upper bound on the expected NHB of further research.

Expected Value of Perfect Information

More formally, if there are alternative interventions (j), where the NHB of each depends on uncertain parameters that may take a range of possible values (θ), the best decision based on the information currently available would be to choose the intervention that is expected to offer the maximum net benefit (i.e., $max_j\ E_\theta\ NHB(j, \theta)$). If the uncertainty could be fully resolved (with perfect information), the decision maker would know which value θ would take before choosing between the alternative interventions. They would be able to select the intervention that provides the maximum NHB for each particular value of θ (i.e., $max_j\ NHB(j, \theta)$). However, when a decision about whether further research should be undertaken is made, the results (the true values of θ) are necessarily unknown. Therefore, the expected NHB of a decision taken when uncertainties are fully resolved (with perfect information) is then found by averaging these maximum net benefits over all the possible results of research that would provide perfect information (over the joint distribution of θ); $E_\theta\ max_j\ NB(j, \theta)$. The expected value of perfect information (EVPI) for an individual patient is simply the difference between the expected value of the decision made with perfect information about the uncertain parameters θ, and the decision made on the basis of existing evidence ($EVPI = E_\theta\ max_j\ NB(j, \theta) - max_j\ E_\theta\ NHB(j, \theta)$).

Once the results of research are available they can be used to inform treatment choice for all subsequent patients. Therefore, the potential expected benefit of research (EVPI) needs to be expressed for the population of patients that can benefit from it. The population EVPI will increase with the size of the patient population whose treatment choice can be informed by additional evidence and the time over which evidence about the cost effectiveness of these interventions is expected to be useful, but will tend to decline with the time that research is likely to take to be commissioned, conducted and report.

Time Horizons for Research Decisions

The information generated by research will not be valuable indefinitely, because other changes occur over time, which will have an impact on the future value of the information generated by research that can be commissioned today. For example, over time the prices of the alternative technologies are likely to change (e.g., patent expiry of branded drugs and the entry of generics versions) and new and more effective interventions become available which will eventually make current comparators obsolete, so information about their effectiveness will no longer be relevant to future clinical practice. Other information may also become available in the future which will also impact on the value of the evidence generated by research that can be commissioned today. For example, other evaluative research might be (or may already have been) commissioned by other bodies or HCS, that may resolve much of the uncertainty anyway. Also, this research or other more basic science may fundamentally change our understanding of disease processes and effective mechanisms. Finally, as more information about individual effects is acquired through greater understanding of the reasons for variability in patient outcomes, the value of evidence that can resolve uncertainty in expected or average effects for the patient population and/or it's subpopulations will decline (see Section Uncertainty, Variability, and Individualized Care). For all these reasons there will be a finite time horizon for the expected benefits of additional evidence, i.e., there will be a point at which the additional evidence that can be acquired by commissioning research today will no longer be valuable.

The actual time horizon for a particular research decision is unknown, because it is a proxy for a complex, and uncertain process of future changes. Nonetheless some judgment, whether made implicitly or explicitly, is unavoidable when making decisions about research priorities. Some assessment is possible based on historical evidence and judgments about whether a particular area is more likely to see earlier patent expiration, future innovations, other evaluative research, and the development of individualized care (e.g., where diagnostic technologies, application of genomics, and the development of evidence-based algorithms are rapidly developing). Information can also be acquired about trials that are already planned and underway around the world (e.g., various trial registries) and future innovations from registered patents and/or phase I and II trials as well as licensing applications, combined with historic evidence on the probability of approval and diffusion. For these reasons, an assessment of an appropriate time horizon may differ across different clinical areas and specific research proposals. The incidence of patients who can benefit from the additional evidence may also change over time, although not necessarily decline as other types of effective health-care change competing risks. However, in some areas recent innovations might suggest a predictable decline, e.g., the decline in the incidence of cervical cancer following the development of the HPV vaccine.

Research Prioritization Decisions

Two questions are posed when considering whether further research should be prioritized and commissioned: Are the

potential expected NHB of additional evidence (population EVPI) sufficient to regard the type of research likely to be required as potentially worthwhile; and should it be prioritized over other research that could be commissioned with the same resources? Of course, these assessments require some consideration of the period of time over which the additional evidence generated by research is likely to be relevant; as well as the time likely to be taken for proposed research to be commissioned, conducted and report.

One way to address the question is to ask whether the HCS could generate similar expected NHB more effectively elsewhere, or equivalently whether the costs of the research would generate more NHB if these resources were made available to the HCS to provide health care. Very recent work in the UK has estimated the relationship between changes in NHS expenditure and health outcomes. This work suggests that the NHS spends approximately £75 000 to avoid one premature death, £25 000 to gain one life year and somewhat less than £20 000 to gain one quality-adjusted life-year (QALY). Using these estimates proposed research that, for example, costs £2 million could have been used to avoid 27 deaths and generate more than 100 QALY elsewhere in the NHS. If these opportunity costs of research are substantially less than the expected benefits (population EVPI) then it would suggest that the proposed research is potentially worthwhile.

However, most research funders have limited resources (with constraints relevant to a budgetary period) and cannot draw directly on the other (or future) resources of the HCS. Therefore, even if the population EVPI of proposed research exceeds the opportunity costs it is possible that other research may be even more valuable. If similar analysis is conducted for all proposals competing for limited research resources it does become possible to identify a short list of those which are likely to be worthwhile and then select from these those that are likely to offer the greatest value.

Research and Reimbursement Decisions

It should be noted that the population EVPI represents only the potential or maximum expected benefits of actual research that could be conducted for two reasons: no research, no matter how large the sample size or how assiduously conducted can resolve all uncertainty and provide perfect information; and there are usually a large number of uncertain parameters that contribute to θ and are relevant to differences in NHB of the alternative interventions – most research designs will not provide information about all of them. Nonetheless EVPI does provide an upper bound to the value of conducting further research, so when compared with the opportunity cost of conducting research (e.g., the health equivalent of the resources required) it can provide a necessary condition for a decision to conduct further research while the intervention is approved for widespread use. It also provides a sufficient condition for early approval when approval would mean that the type of further research needed would not be possible or too costly to be worthwhile (e.g., because there would be a lack of incentives for manufacturers, or further randomized trials would not be regarded as ethical and/or would be unable to recruit). In these circumstances the population EVPI represents an upper bound on the benefits to future patients that would be forgone or the opportunity costs of early approval based on existing evidence.

What Type of Evidence?

The type of analysis described above indicates the potential value of resolving all the uncertainty surrounding the choice between alternative the interventions. However, it would be useful to have an indication of which sources of uncertainty are most important and what type of additional evidence would be most valuable. This can start to indicate the type of research design that is likely to be required, whether the type of research required will be possible once a new technology is approved for widespread use as well as indicating the sequence in which different studies might be conducted.

Expected Value of Perfect Parameter Information

The potential expected benefits of resolving the different sources of uncertainty that determine the NHB of the alternative interventions can be established using the same principles. For example, if the NHB of each intervention (j) depends on two (groups of) uncertain parameters ($\theta1$ and $\theta2$) that may take a range of possible values, the best decision based on current information is still to choose the intervention that is expected to offer the maximum net benefit (i.e., $max_j\ E_{\theta2,\theta1}\ NHB(j, \theta1, \theta2)$). If the uncertainty associated with only one of these groups of parameters ($\theta1$) could be fully resolved (i.e., with perfect parameter information), the decision maker would know which value $\theta1$ would take before choosing between the alternative interventions. However, the values of the other parameters ($\theta2$) remain uncertain so the best they can do is to select the intervention that provides the maximum expected NHB for each value of $\theta1$ (i.e., $max_j\ E_{\theta2|\theta1}\ NHB(j, \theta1, \theta2)$). Which particular value $\theta1$ will take is unknown before research is conducted so the expected NHB when uncertainty associated with $\theta1$ is fully resolved is the average of these maximum net benefits over all the possible values of $\theta1$, (i.e., $E_{\theta1}\ max_j\ E_{\theta2|\theta1}\ NHB(j, \theta1, \theta2)$). The expected value of perfect parameter information about $\theta1$ (EVPPI $_{\theta1}$) is simply the difference between the expected value of the decisions made with perfect information about $\theta1$, and a decision based on existing evidence (EVPI $= E_{\theta1}\ max_j\ E_{\theta2|\theta1}\ NHB(j, \theta1, \theta2) - max_j\ E_{\theta2,\theta1}\ NHB(j, \theta1, \theta2)$).

It should be noted that this describes a general solution for nonlinear models. However, it is computationally intensive because it requires an inner loop of simulation to estimate the expected NHB for each value of $\theta1$ ($E_{\theta2|\theta1}\ NHB(j, \theta1, \theta2)$), as well outer loop of simulation to sample the possible value $\theta1$ could take. The computational requirements can be somewhat simplified if there is a multilinear relationship between the parameters and net benefit. If the model is multilinear in $\theta2$, the parameters in $\theta2$ are uncorrelated with each other and $\theta1$ and $\theta2$ are independent then the inner loop of simulation is unnecessary (using the mean values of $\theta2$ will return the correct estimate of $E_{\theta2|\theta1}\ NHB(j, \theta1, \theta2)$).

Sequence of Research

This type of analysis can be used to focus research on the type of evidence that will be most important by identifying those parameters for which more precise estimates would be most valuable. In some circumstances, this will indicate which endpoints should be included in further experimental research. In other circumstances, it may focus research on getting more precise estimates of particular parameters that may not necessarily require experimental design and can be provided relatively quickly. This type of analysis can be extended to consider the sequence in which different types of study might be conducted, e.g., whether: no research; research about $\theta 1$ and $\theta 2$ simultaneously; $\theta 1$ first and then $\theta 2$ depending on the results of $\theta 1$ research; or $\theta 2$ first and then $\theta 1$ depending on the results of $\theta 2$ research, would be the most valuable research decision.

Informing Research Design

Identifying which sources of uncertainty are most important and what type of evidence is likely to be most valuable is useful in two respects. It can help to identify the type of research design that is likely to be required (e.g., an randomized controlled trial (RCT) may be needed to avoid the risk of selection bias if additional evidence about the relative effect of an intervention is required) and identify the most important endpoints to include in any particular research design. It can also be used to consider whether there are other types of research that could be conducted relatively quickly (and cheaply) before more lengthy and expensive research (e.g., a large RCT) is really needed (i.e., the sequence of research that might be most effective).

Estimates of EVPI and EVPPI only provide a necessary condition for conducting further research. To establish a sufficient condition to decide if further research will be worthwhile and identify efficient research design, estimates of the expected benefits and the cost of sample information are required.

The same value of information analysis framework can be extended to establish the expected value of sample information (EVSI) for particular research designs.

Expected Value of Sample Information

For example, a sample of n on θ will provide a sample result D. If the sample result was known the best decision would be to choose the alternative with the maximum expected net benefit when the estimates of the NHB of each alternative was based on the sample result (averaged over the posterior distribution of the net benefit given the sample result D). However, which particular sample result will be realized when the research reports is unknown. The expected value of acquiring a sample of n on θ is the found by averaging these maximum expected net benefits over the distribution of possible sample results, D, i.e., the expectation over the predictive distribution of the sample results D conditional on θ, averaged over the possible values of θ (the prior distribution of θ). The additional expected benefit of sample information (EVSI) is simply the difference between the expected value of a decision made with sample information and the expected value with current information.

The EVSI calculations require the likelihood for the data to be conjugate with the prior so there is an analytic solution to combining the prior distribution of θ with the predicted sample result (D) to form a predicted posterior. If the prior and likelihood are not conjugate, the computational burden of using numerical methods to form predicted posteriors is considerable. Even with conjugacy, EVSI still requires intensive computation if the relationship between the sampled parameters (end points in the research design) and differences in the NHB of the alternatives are nonlinear.

Optimal Sample Size and Other Aspects of Research Design

To establish the optimal sample size for a particular type of study these calculations need to be repeated for a range of sample sizes. The difference between the EVSI and the costs of acquiring the sample information is the expected net benefit of sample information (ENBS) or the societal payoff to research. The optimal sample size is simply the value of n that generates the maximum ENBS. As well as sample size the same type of analysis can be used to evaluate a range of different dimensions of research design such as which endpoints to include, which interventions should be compared, and the length of follow-up. The best design is the one that provides the greatest ENBS. The same type of analysis can also be used to identify whether a combination of different types of study might be required (an optimal portfolio of research). It should be recognized that the costs of research not only include the resources consumed in conducting it but also the opportunity costs (NHB forgone) falling on those patients enrolled in the research and those whose treatment choice can be informed once the research reports. Therefore, optimal research design will depend, among other things, on whether or not patients have access to the new technology while the research is being conducted and how long it will take before it reports (determined by length of follow-up and recruitment rates). It is also possible to take account of likely implementation of research findings in research design, e.g., if an impact on clinical practice depends on the trial reporting a statistically significant result for a particular effect size (and there are no other effective ways to ensure implementation) this will influence optimal sample size as well.

The Value of Commissioned Research

Research decisions require an assessment of the expected potential value of future research before the actual results that will be reported in the future are known. Therefore, using hindsight to inform research prioritization decisions is inappropriate for two reasons: (1) such an (*ex post*) assessment cannot directly address the (*ex ante*) question posed in research prioritization decisions; and (2) assessing the (*ex post*) value of research with hindsight is potentially misleading if used to judge whether or not the original (*ex ante*) decision to prioritize and commission it was appropriate. This is because the findings of research are only one realization of the uncertainty about potential results that could have been found

when the decision to prioritize and commission research must be taken.

It is useful and instructive, however, to reconsider the analysis set out above once the results of research become available by updating the synthesis of evidence, reestimating the NHB of the alternative interventions and updating the value of information analysis to consider whether the research was indeed definitive (the potential benefits of acquiring additional evidence does not justify the costs of further research) or whether more or different types of evidence might be required. Therefore, value of information analysis can also provide the analytic framework to consider when to stop a clinical trial, how to allocate patients between the arms of a trial as evidence accumulates (sequential and group sequential designs) and when other types of evidence might become more important as the results of research are realized over time.

Value of Implementation

Overall health outcomes can also be improved by ensuring that the accumulating findings of research are implemented and have an impact on clinical practice. Indeed, the potential improvements in health outcome by encouraging the implementation of what existing evidence suggests is the most cost-effective intervention may well exceed the potential improvements in NHB through conducting further research.

The distinction between these two very different ways to improve overall health outcomes is important because, although the results of additional research may influence clinical practice and may contribute to the implementation of research findings, it is certainly not the only, or necessarily the most effective, way to do so. Insofar as there are other more effective mechanisms (e.g., more effective dissemination of existing evidence) or policies (e.g., those that offer incentives and/or sanctions), than continuing to conduct research to influence clinical practice, rather than because there is real value in acquiring additional evidence itself, would seem inappropriate, because research resources could have been used elsewhere to acquire additional evidence in areas where it would have offered greater potential NHB.

Clearly, the potential health benefits of conducting further research will only be realized (health outcomes actually improve and/or resources are saved) if the findings of the research do indeed have an impact on clinical practice. Recognizing that there are very many ways to influence the implementation of what current evidence suggests, other than by conducting more research, is important when considering other policies to improve implementation of research findings instead of, or in combination with, conducting further research. However, the importance of implementing the findings of proposed research might influence consideration of its priority and research design in a number of ways. If it is very unlikely that the findings of proposed research will be implemented and other mechanisms are unlikely to be effective or used, then other areas of research where smaller potential benefits are more likely to be realized might be prioritized. If the impact of research on clinical practice is likely to require highly statistically significant results this will influence the design, cost, and time taken for research to report and therefore its relative priority. It maybe that a larger clinical difference in effectiveness would need to be demonstrated before research would have impact on clinical practice. This will tend to reduce the potential benefits of further research as well because large differences are less likely to be found than small ones.

Decisions Based on the Balance of Existing Evidence?

It should be recognized that restricting attention to whether or not the result of a clinical trial, a meta-analysis of existing trials, or the results of a cost-effectiveness analysis offer statistically significant results is unhelpful for a number of reasons: it provides only a partial summary of the uncertainty associated with the cost effectiveness of an intervention, nor does it indicate the importance of the uncertainty for overall patient outcomes or the potential gains in NHB that might be expected from acquiring additional evidence that could resolve it. Of course, failing to implement an intervention which is expected to offer the greatest NHB will impose unnecessary opportunity cost. This suggest that always waiting to implement research findings until the traditional rules of statistical significance are achieved (whether based on frequentist hypothesis testing or on Bayesian bench mark error probabilities) may well come at some considerable cost to patient outcomes and HCS resources.

However, once uncertainty and the value of additional evidence is recognized there are a number of issues that need to be considered before decisions to approve or reimburse a new technology can be based on the balance of accumulated evidence, i.e., expected cost effectiveness and expected NHB:

1. As already discussed, if early approval or reimbursement means that the type of research required to generate the evidence needed is impossible or more difficult to conduct then the expected value of additional evidence that will be forgone by approval needs to be considered alongside the expected benefits of early implementation.
2. Insofar as widespread use of an intervention will be difficult to reverse if subsequent research demonstrates that it is not cost effective (e.g., where it would require resources and effort as well as take time to achieve), then account must be taken of the consequences of this possibility (i.e., the opportunity costs associated the chance that research finding that the intervention is not cost effective but being unable to immediately implement these findings and withdraw its use).
3. If an intervention offers longer-term benefits which will ultimately justify initial treatment costs (e.g., any effect on mortality risk) its approval or reimbursement is likely to commit initial losses of NHB compensated by later expected gains. In these circumstances its approval or reimbursement commits irrecoverable opportunity costs for each patient treated. If the uncertainty about it costs-effectiveness might be resolved in the future (e.g., due to commissioned research reporting) then if may be better to withhold approval or reimbursement until the research findings are available even if the research could be conducted while the technology is in widespread use. This is

more likely to be the case when a decision to delay initiation of treatment is possible and associated with more limited health impacts (e.g., in chronic and stable conditions).

4. There is a common and quite natural aversion to iatrogenic effects, i.e., health lost through adopting an intervention not in widespread use tends to be regarded as of greater concern than the same health lost through continuing to use existing interventions that are less effective than others available. However, it should be noted that the consequences for patients are symmetrical and this 'aversion' also depends entirely on which intervention happened to have diffused into common clinical practice first.

These considerations can inform an assessment of whether more health might be gained through efforts to implement the findings of existing research or by acquiring more evidence to inform which intervention is most cost effective. Although there are many circumstances where approval or reimbursement should not be simply based on the balance of evidence (i.e., expected cost effectiveness or expected NHB), it should be noted that these considerations are likely to differ between decisions and certainly do not lead to a single 'rule' based on notions of the statistical significance of the results of a particular study, a meta-analysis of existing studies, or the results of a cost-effectiveness analysis. They can be, and have been, dealt with explicitly and quantitatively within well conducted value of information analysis.

Uncertainty, Variability, and Individualized Care

It is important to make a clear distinction between uncertainty, variability, and heterogeneity. Uncertainty refers to the fact that we do not know what the expected effects will be of using an intervention in a particular population of patients (i.e., the NHB of an intervention on average). This remains the case even if all patients within this population have the same observed characteristics. Additional evidence can reduce uncertainty and provide a more precise estimate of the expected effects in the whole population or within subpopulations that might be defined based on different observed characteristics. Variability refers to the fact that individual responses to an intervention will differ within the population or even in a subpopulation of patients with the same observed characteristics. Therefore, this natural variation in responses cannot be reduced by acquiring additional evidence about the expected or average effect. Heterogeneity refers to those individual differences in response that can be associated with differences in observed characteristics, i.e., where the sources of natural variability can be identified and understood. As more becomes known about the sources of variability (as variability is turned into heterogeneity) the patient population can be partitioned into subpopulations or subgroups, each with a different estimate of the expected effect of the intervention and the uncertainty associated with it. Ultimately, as more sources of variability become known the subpopulations become individual patients, i.e., individualized care.

Overall patient outcomes can be improved by either acquiring additional evidence to resolve the uncertainty in the expected effects of an intervention, and/or by understanding the sources of variability and dividing the population into finer subgroups where the intervention will be expected to be cost effective in some but not in others. However, a greater understanding of heterogeneity also has an impact on the value of additional evidence. As more subgroups can be defined the precision of the estimates of effect is necessarily reduced (the same amount of evidence offers fewer observations in each subgroup). However, the uncertainty about which intervention is most cost effective may be reduced in some (e.g., where it is particularly effective or positively harmful), but increase in others. Therefore, the expected consequences of uncertainty per patient, or value of additional evidence per patient may be higher or lower in particular subgroups. The expected value of evidence across the whole population (the sum across all subgroups of the population) may rise or fall. However, in the limit as more sources of variability are observed the value of additional evidence will fall. Indeed, if all sources of variability could be observed then there would be no uncertainty at all.

Value of information analysis can be applied within each subgroup identified based on existing evidence. Conducting an analysis of the expected health benefits of additional evidence by subgroups is useful because it can indicate which types of patient need to be included in any future research design and others that could be excluded. Although the potential value of additional evidence about the whole population is simply the sum of values for each of its subpopulations, the value of acquiring evidence within only one subgroups depends on whether that evidence can inform decisions in others. For example, if subgroups are identified based on differing base line risks then evidence about the relative effect of an intervention in one subgroup might also inform relative effect in others so the value of research conducted in one of the subgroups should take account of the value it will generate in others. However, evidence about a subgroup specific baseline risk might not be relevant and offer value in others. In principle, these questions of exchangeability of evidence can be informed by how existing evidence and ought to be reflected in how it is synthesized and the uncertainties characterized.

Therefore there is potential value of research which might not resolve uncertainty but instead reveal the reasons for variability in outcome; informing which subgroups could benefit most from an intervention, or the choice of the physician patient dyad in selecting care given their symptoms, history and preferences (i.e., individualized care). This type of research may be very different from the type of evaluative research that reduces uncertainty about estimates of effect. For example, it might include: diagnostic procedures and technologies, pharmacogenetics; analysis of observational data and treatment selection as well as novel trial designs which can reveal something of the joint distribution of effects. Much methodological and applied work has been conducted in this rapidly developing area. There is an opportunity to explore ways of estimating the potential value of such research (the expected benefits of heterogeneity) based only on existing evidence. This would provide a very useful complement to estimates of EVPI and EVPPI. It would allow policy makers to consider whether HCS resources should be invested in: providing early access to new technologies; ensuring the findings

of existing (or commissioned) research are (or will be) implemented; conducting research to provide additional evidence about particular sources of uncertainty in some (or all) subgroups; or conducting research which can lead to a better understanding of variability in effects. Of course some combination of these policy choices may well offer the greatest impact on overall health outcomes.

Value of Information and Cost-Effectiveness Analysis

The discussion of value of information analysis has been founded on a HCS which faces some constraints on the growth of health-care expenditure so additional HCS costs displace other care that would have otherwise generated improvements in health. In the UK recent estimates of the rate at which health-care cost displace health elsewhere (the cost-effectiveness threshold) are now available. However, in all HCS new technologies impose costs (or offer benefits), which fall outside the health care and displace private consumption rather than health. If some consumption value of health is specified then these other effects can also be expressed as their health equivalent and included in the expression for NHB. Impacts on health, HCS resources, and consumption can also be expressed in terms of the equivalent net private consumption effects or the equivalent HCS resources (these monetary values will only be the same if the estimate of the threshold is the same as some consumption value of health). Therefore the methods of analysis outlined above are not restricted to cost-effectiveness analysis applied in HCS which have administrative budget constraints and/or where decision making bodies disregard effects outside the HCS. It is just as relevant to an appropriately conducted cost-benefit analysis (one which accounts for the shadow price of any constraints on health-care expenditure).

Equally the principles of value of information analysis can be usefully applied even in circumstances where decision making bodies are unwilling or unable to explicitly include any form of economic analysis in their decision making process. For example, a quantitative assessment of the expected health (rather than net health) benefits of additional evidence is possible by applying value of information analysis to the results of standard methods of systematic review and meta-analysis. Insofar as there are additional costs associated with more effective interventions this will tend to overestimate the expected *NHB* of additional evidence. Also the endpoints included in the meta-analysis of previous trials may not capture all valuable aspects of health outcome. For example, although mortality following acute myocardial infarction maybe the appropriate primary outcome in the evaluation of early thrombolysis, it is not necessarily the only relevant outcome. Stroke and its consequences are also very relevant as well as length of survival and the type of health experienced in the additional years of life associated with mortality effects.

Specifying a minimum clinical difference required to change clinical practice is one way to incorporate concerns about potential adverse events and other consequences of recommending a more effective intervention, including the additional costs, albeit implicitly. This concept of an effect size has been central to the design of clinical research and determines the sample size in most clinical trials. The effect size does not represent what is expected to be found by the research, but the difference in outcomes that would need to be detected for the results to be regarded as clinically significant and have an impact on clinical practice. The same concept can be used to report estimates of the expected heath benefits of additional evidence for a range of minimum clinical differences (MCD) in outcomes. The value of additional evidence and the need for further research depends on the clinical difference in key aspects of outcome that would be need to be demonstrated before clinical practice 'should' or is likely to change. There are a number of circumstances where a larger MCD might be required. For example: (1) where the quantitative analysis is restricted to the primary endpoint reported in existing clinical trials but there other important aspects of outcome that are not captured in this endpoint (e.g., adverse events or quality of life impacts that have not been accounted for in the meta-analysis); (2) when there is an impact on HCS costs, out of pocket expenses for patients or the wider economy; and (3) it maybe that larger clinical difference in effectiveness would need to be demonstrated before research would have an impact on practice and the findings of proposed research would be widely implemented.

Requiring that further research must demonstrate larger differences in effect will tend to reduce its expected potential benefits because large differences are less likely to be found than smaller ones. Specifying an MCD through some form of deliberative process would implicitly account for the other unquantified aspects of outcome, HCS costs and other non-health effects. Of course decision makers would need to consider whether proposed research is still a priority at an MCD that is regarded as sufficient to account for these other effects. Importantly, whatever the policy context, the principles and established methods of value of information analysis are relevant to a wide range of different types of HCS and decision making contexts and should not be regarded as being restricted to situations where probabilistic decision analytic models to estimate cost effectiveness based on QALYs as a measure of health are available and routinely used within the decision making process.

Instrumental Variables: Informing Policy

MC Auld, University of Victoria, Victoria, BC, Canada
PV Grootendorst, University of Toronto, Toronto, ON, Canada

Introduction

Health economists frequently face the challenge of estimating causal relationships in the absence of controlled experiments. For example, a long-standing issue in economics and in other disciplines is unraveling the observed relationship between education and health. Countless studies have documented a positive correlation between these outcomes, but fewer have successfully addressed the causal impact of education and health. In principle, randomized controlled trials (RCTs) could be used, but it is difficult to experimentally manipulate levels of education. Instrumental variables (IV) methods can be used when the real world provides some quasiexperimental variation in education. In this article, the use and the limitations of the IV approach are discussed. The authors illustrate how IV approach works, review its relationship with the experimental approach, identify the properties of good natural experiments, and discuss the statistical properties of the IV estimator when the natural experiment is less than ideal.

The Instrumental Variables Estimator

An Intuitive Explanation for the Univariate Model

Consider the statistical properties of the linear IV estimator. For the sake of simplicity, the univariate case is presented, and the constant is suppressed by assuming that all variables are expressed as deviations from their respective sample means. Suppose that the effect of a broadly defined 'treatment,' x, on an outcome y is to be estimated. Data on y and x are collected for a random sample of n observations; y_i and x_i denote the values of these variables for the ith observation. The treatment affects the outcome according to a linear regression of the form

$$y_i = \beta x_i + u_i \qquad [1]$$

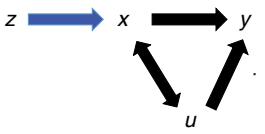
where β is an unknown parameter to be estimated and u_i is an unobserved error term, interpreted as all causes of y_i other than x_i. Here, β is interpreted as the causal effect of x on y, and x and u are possibly correlated. The variables u and x will be correlated if there are variables unobserved to the researcher which cause both x and y ('omitted variables' in econometrics, or 'unobserved confounders' in some other disciplines) or if y 'reverse' causes x. The researcher may attempt to address omitted variables by using standard multivariate regression specifications and adding more independent variables to the model, but commonly, as in the education and health example above, even very rich datasets will exclude information on countless personality, cognitive, background, and contextual variables that may affect both the outcome and the intensity of treatment. Moreover, controlling for additional variables does not help resolve the 'reverse' causation problem. Methods other than IV are sometimes available – such as regression discontinuity designs, or certain longitudinal data approaches – but attention here is limited to IV.

When a regressor is correlated with the error term u, it is said to be endogenous; if not it is said to be exogenous. If ordinary least squares (OLS) is used to estimate the parameters of this equation, then the OLS estimator of β, denoted $\hat{\beta}$, will be biased and inconsistent if x is endogenous. It can be shown that

$$\mathrm{E}(\hat{\beta}|x) = \frac{\mathrm{Cov}(x,y)}{\mathrm{Var}(x)} = \beta + \frac{\mathrm{Cov}(x,u)}{\mathrm{Var}(x)} \qquad [2]$$

where E is the expectation operator, $\mathrm{Cov}(x, u)$ is the covariance between x and u, β is the true value of the causal effect that is to be estimated, and $\mathrm{Var}(x)$ is the variance of x. That is, the distribution of the OLS estimator is centered on the causal effect of interest plus a term which depends on the extent to which unobserved causes of the outcome (u) vary with the treatment (x). Here, y may move with x even if x has no causal effect on y, either because y 'reverse' causes x, or because x and u share common causes, leading to biased and inconsistent OLS estimates of the causal effect of interest.

The method of IV can solve the problem in some circumstances. Suppose that z is a variable which has the property that z affects y only because z affects x, which in turn affects y, as illustrated in the diagram



If z affects y only through its effect on x, then correlation between the instrument z and the outcome of interest y implies that x causes y. Under this assumption, the effect of a one unit change in z on y is the product of the effect of z on x and the effect of x on y. The observed association between z and y reveals only the product of these two effects. However, the effect of x on y can be isolated by dividing the observed association between z and y by the observed association of z and x.

The derivation of the IV estimator can be shown more formally (using the method of indirect least squares) as

$$y = \beta x(z,u) + u \qquad [3]$$

expressing the treatment x as a function of the instrument z and the unobserved causes of y, u. Note that the key condition that z only affects y because z affects x is imposed. Differentiate with respect to z to find

$$\frac{dy}{dz} = \beta \frac{dx}{dz} \qquad [4]$$

as $du/dz=0$ by assumption. Rearrange to find

$$\beta = \frac{dy/dz}{dx/dz} \quad [5]$$

which tells one that the causal effect of interest is the ratio of the effect of z on y to the effect of z on x. If those effects are estimated using linear regressions, then

$$\beta = \frac{\mathrm{Cov}(y,z)/\mathrm{Var}(z)}{\mathrm{Cov}(x,z)/\mathrm{Var}(z)} = \frac{\mathrm{Cov}(y,z)}{\mathrm{Cov}(x,z)} \quad [6]$$

Replacing the population moments in the expression above with sample moments calculated from the data yields the linear IV estimator for this model, denoted $\hat{\beta}_{\mathrm{IV}}$,

$$\hat{\beta}_{\mathrm{IV}} = \frac{\sum_i z_i y_i}{\sum_i z_i x_i} \quad [7]$$

Note that, in contrast to the OLS estimator, the IV estimator depends in no way on the correlation between y and x, which is confounded by the common cause u and therefore does not tell us anything useful about the causal effect of x on y. Note also that, unlike the OLS estimator, the denominator of the expression above is a covariance rather than a variance, and it is therefore not bound away from zero. It is clearly required that $\mathrm{Cov}(x, z)$ be different from zero. The problems this issue causes are dealt with below in the discussion on 'weak' instruments, which arise when $\mathrm{Cov}(x, z)$ is not zero but is small.

General Linear Model and Two-Stage Least-Squares Interpretation

Now consider the general linear problem of estimating causal effects when there are k covariates, an arbitrary number k_1 of the covariates are endogenous (correlated with the error term u), and the remainder $k_2=k-k_1$ covariates are exogenous. Let X_{1i} denote the k_1-vector of observations on endogenous regressors for the ith sampled unit and X_{2i} the vector of k_2-vector of observations on the exogenous regressors, so that the model to be estimated can be expressed as

$$y_i = X_i\beta + u_i = X_{1i}\beta_1 + X_{2i}\beta_2 + u_i \quad [8]$$

It is possible to show that the parameters β_1 and β_2 can be estimated if there are $l \geq k_1$ variables, which are correlated (in a sense defined formally below) with the endogenous regressors X_1 but have no direct effect on y after conditioning on X_2, that is, these variables only affect y because, conditional on X_2, they affect the endogenous regressors X_1. If there are fewer than k_1 such variables, the model is said to be underidentified, and the model is not identified. If there are exactly $l=k_1$ such variables, the model is said to be exactly identified, and if there are $l>k_1$ such variables the model is overidentified.

Let $Z_i=(Z_{1i}, X_{2i})$ denote the $(l+k_2)$-vector of observations for all exogenous variables for the ith unit. Here, Z_{1i} is the vector of observations on l variables which only affect y because they affect X_1 – these variables do not appear in the equation that is being estimated (eqn [8]), so they are called the excluded instruments. The vector X_{2i} of observations on exogenous variables in eqn [8] can 'act as their own instruments.' The multivariate version of the estimator defined in eqn [6] is

$$\tilde{\beta}_{\mathrm{IV}} = (X'P_Z X)^{-1}X'P_Z y \quad [9]$$

where $P_Z=Z(Z'Z)^{-1}Z'$. It is possible to show that $\tilde{\beta}_{\mathrm{IV}}$ may be calculated by executing the following steps:

1. Separately for each of the endogenous regressors in X_1, regress the endogenous regressor on the complete set of exogenous variables Z. Save the set of predicted values, $\hat{X}_1$.
2. Regress y on $\hat{X}_1$ and X_2 using OLS.

The estimated coefficients in step 2 are numerically identical to $\tilde{\beta}$ defined in eqn [9]. For this reason, the linear IV estimator is sometimes referred to as the 'two-stage least squares' (2SLS or TSLS) estimator.

Statistical Properties of the IV Estimator

In this section, the sampling properties of the IV estimator are briefly described. Formally, the assumptions that the excluded instruments z_1 only (after conditioning on X_2) affect the outcome y through their effect on the endogenous regressors X_1 can be expressed as

$$\mathrm{plim}_{n\to\infty}\frac{1}{n}Z'u = 0 \quad [10]$$

where plim is the probability limit operator as the sample size n tends to infinity. The condition that the excluded instruments must be correlated with the endogenous regressors can be expressed as

$$\mathrm{plim}_{n\to\infty}\frac{1}{n}X'Z \text{ exists and has full rank } k \quad [11]$$

Under some further regularity conditions, which is omitted, it is possible to show that

$$\mathrm{plim}_{n\to\infty}\tilde{\beta}_{\mathrm{IV}} = \beta \quad [12]$$

that is, the IV estimator is consistent under these assumptions. If the sample size is allowed to grow arbitrarily large, the difference between the estimates and the causal effects of interest becomes arbitrarily small. Further, the estimator is asymptotically normal, permitting conventional inference with standard test statistics (such as the z-ratios and F-statistics). The covariance matrix can be estimated as $s^2(X'P_zX)^{-1}$ if the errors u_i are homoskedastic and serially uncorrelated, where s^2 is a consistent estimate of the variance of u; covariance estimators consistent in the presence of arbitrary heteroskedasticity and serial correlation are also readily available. Finally, the IV estimator is asymptotically efficient in the class of linear estimators.

Note that the IV estimator generally has no desirable small sample properties. It is possible to show that in exactly identified models (models with exactly as many excluded instruments as endogenous regressors),

$$E(\tilde{\beta}_{\mathrm{IV}}) \to \infty \quad [13]$$

that is, the estimator has no moments, its distribution has such 'fat tails' that the integral defining the expected value of the estimator does not converge. In practice, this means that

not uncommonly that one gets 'wild' estimates many standard deviations away from the causal effect of interest. Recall that there are k_1 endogenous regressors and l excluded instruments, and that l is required to be at least as large as k_1. The difference $(l–k_1)$ is the number of overidentifying restrictions. It is possible to show that the number of existing moments of $\tilde{\beta}$ is equal to the number of overidentifying restrictions. For example, if there is one endogenous regressor and one excluded instrument, the model is exactly identified and $\tilde{\beta}$ does not even have a mean. If one more excluded instrument is added, there is one overidentifying restriction and $\tilde{\beta}$ has a mean but not a variance nor any higher order moment, and so on.

The IV estimator is generally biased even when at least one overidentifying restriction exists. As the degree of overidentification rises, the bias of the IV estimator rises and approaches the bias of the OLS estimator as the number of overidentifying restrictions approaches the sample size. At the same time, it is possible to show that the dispersion of the IV estimator falls with the number of overidentifying restrictions.

Generally, researchers face a trade-off: The OLS estimator in the presence of endogenous regressors is inconsistent, but is less dispersed than the IV estimator. Which estimator is preferred depends on the trade-off the researcher is willing to make between bias and dispersion. Adding more excluded instruments (and thus increasing the number of overidentifying restrictions) decreases the dispersion of the IV estimator, but increases its bias.

Examples of Instrumental Variables in Health Research

In this section, some examples of applied IV estimation drawn from the health economics literature are discussed. RCTs are considered as a special case of IV models, and build to more complex models for, first, imperfect RCTs and then uncontrolled experiments.

Example 1: RCT with Perfect Compliance

As a trivial example of IV, consider interpreting standard analysis of an RCT with perfect compliance as an IV estimator. Suppose that y is the outcome of interest, x is a binary variable denoting treatment status such that $x_i=1$ if subject i is given the new therapy and $x_i=0$ if given the standard therapy. The researcher randomly draws a binary variable from a process independent of y (a figurative coin flip); z denotes the outcomes of this process. The researcher then assigns treatment statuses: $x_i=z_i$. In this scenario, z is determined independently of u, and z is perfectly correlated with x; z thus satisfies the conditions for an IV given above. In this special case, z completely determines x (subjects comply perfectly with their assigned treatment), so that x cannot be correlated with u. As x is exogenous in this case, the IV estimator is the same as the OLS estimator.

Example 2: RCT with Imperfect Compliance

Now consider a common problem with RCTs: suppose some subjects who are assigned to receive the standard therapy nevertheless take the new therapy; others assigned to receive the new therapy actually take the standard therapy. Generally, the difference in sample means across the treatment and control groups reflects both the causal effect of treatment and nonrandom selection into treatment, so it cannot be used to estimate the treatment effect. Assuming that assignment, z, affects the treatment decisions, X, of at least some people, treatment is not randomized because of the noncompliers, but it is *quasirandomized* in the sense that some of the variation in treatment status is a result of the coin toss. In the case with no other covariates, it is possible to show that the IV estimator defined in eqn [6] takes the form

$$\hat{\beta}_{\mathrm{IV}} = \frac{\overline{y}_{z=1} - \overline{y}_{z=0}}{\overline{x}_{z=1} - \overline{x}_{z=0}} \qquad [14]$$

where $\overline{y}_{z=i}$ denotes the sample mean of the outcome y in the subpopulation for which the assigned treatment status was i. The numerator is the difference in the average outcome between those assigned to the new therapy and those assigned to receive the standard therapy, regardless of the realized treatment status. This is the key object in 'intention to treat' analysis common in the medical literature. The denominator is the difference in the proportion who receive the new therapy across those assigned to new therapy and those assigned to the standard therapy. Note that the denominator is equal to one if compliance is perfect.

Example 3: The Causes of the Cholera Outbreaks in Victorian Era London

Even if one cannot run an RCT, the real world sometimes provides a mechanism that comes close to the experimental ideal. Perhaps the earliest IV application was that by John Snow, an epidemiologist who was interested in the causes of the cholera outbreaks that afflicted residents of London, England in the 1800s. Snow's hypothesis, which was not widely accepted at the time, was that cholera is a waterborne pathogen. In particular, Snow suspected that cholera was transmitted via contaminated drinking water. He noticed that one supplier of London's drinking water provided water contaminated by raw sewage, whereas another supplier provided relatively clean water. The reason was that these suppliers sourced their water from different points along the Thames River, one downstream of the city's sewer discharge and one upstream. Hence, the first condition for a good IV was satisfied: the identity of water supplier (z) resulted in marked variation in the quality of water consumed by households (x). Moreover, the source of water supply appeared to be independent of u, the other sources of the incidence of cholera. This was important because the quality of the water piped to households, though an important determinant of the quality of water consumed by households (x), was not the only determinant. The level of hygiene and cleanliness also played a role and this varied with household socioeconomic status. However, Snow observed that both the suppliers served a wide crosssection of Londoners, rich and poor alike. Thus Snow's instrument z was independent of u, the other determinants of y. A comparison of the rates of cholera of households that were supplied by the two water providers provided convincing evidence in support of Snow's hypothesis.

Example 4: Efficacy of Healthcare Treatments without Experimental Randomization

Several studies have compared the effectiveness of different types of healthcare used to treat particular health conditions. Conventional approaches must contend with the possibility that more severely compromised patients may be steered to one treatment over another. IV methods present a way forward when there is a mechanism that causes exogenous variation in the treatment received.

Some analysts have used the 'differential distance' to travel to obtain a particular therapy to treat a given health condition. Differential distance is the distance from the patient's residence to the nearest healthcare facility providing the treatment of interest minus the distance from the patient's residence to the nearest facility that provides any form of care to treat the condition. The idea is that, particularly for urgent problems such as acute myocardial infarction, the patient receives treatment from the nearest facility, regardless of the illness severity. If the nearest facility happens to provide the treatment of interest (i.e., zero differential distance) then the patient is more likely to receive it. The longer the differential distance, the less likely the patient will receive the treatment of interest. Differential distance is an invalid instrument if particularly ill patients relocate to be close to facilities that provide the treatment of interest.

Other analysts have exploited the marked geographic or interprovider variations in medical practice patterns that appear to be unrelated to medical need or patient preferences. These variations were first noted by Glover; he highlighted the striking geographic differences in the rate of tonsillectomy among British school districts. The literature, however, is most closely associated with the small-area variations research of Jack Wennberg. Brookhart, Rassen, and Schneeweiss review the ways in which analysts have used these variations to implement IV estimation of comparative treatment effectiveness. They note that to successfully implement IV, the practice variations must be independent of u, the unmodeled factors that affect patient health outcomes. These include the background characteristics of the patients themselves. It cannot be the case, for instance, that patients with particularly high values of u gravitate toward providers who tend to use the treatment under study. Moreover, practice style must affect health outcomes only through its influence on the treatment under study. Thus, providers who preferentially use one treatment must be of comparable quality and skill to those who preferentially use another treatment.

A third source of exogenous variation is changes over time in the availability of treatments. For instance, a new drug may become approved for use, or, conversely, a drug may be withdrawn from the market for safety reasons. Access to a treatment might also be temporarily impeded. For example, Evans and Lien use the disruption in the availability of public transit due to a bus strike to assess the impact of the use of prenatal care on birth outcomes. They focused on individuals for whom the disruption in bus service would impede access to prenatal care: pregnant black inner-city women. Analyses of this sort require a comparison of outcomes between two periods of time. To implement IV, the expected value of u must be the same in both periods. As Brookhart and colleagues note, to ensure that this condition holds, IVs based on calendar time are most reasonable in situations where a dramatic change in treatments occurs over a relatively short period of time.

Example 5: Effect of Education on Health

Return to the motivating example in the opening paragraph: To estimate the causal effect of an additional year of education on some measure of health status. Correlations or partial correlations between health and education do not reveal this causal effect because many personal and contextual characteristics (such as intelligence, conscientiousness, and family wealth) affect both health and education and are unobservable to the researcher, and because poor health while young may 'reverse' cause poor educational outcomes. That is, the effect of education on health is hard to estimate because of confounding on unobservables and because of 'reverse' causation. Neither conventional regression models such as OLS or logit nor matching estimators recover the causal effect of interest, and controlled experimentation on educational outcomes is restricted by both cost and ethical concerns.

In an influential study, UCLA economist Adriana Lleras-Muney employed an IV strategy to address this problem. She estimated regressions in which mortality is the health outcome of interest. Using large samples from the US census, she matched cohorts to the number of years of compulsory schooling specific to each combination of state government and year. Years of compulsory schooling acts IV: It is plausible that the only reason a change in years of compulsory schooling affects health is because (for some students) changes in years of compulsory schooling affects realized years of schooling. Intuitively, Lleras-Muney asks, "Is an adult who was required by law to take more schooling healthier, on average, than a statistically identical adult required to take less schooling?" Her estimates suggest that an additional year of schooling causes as much as a 1.7 year increase in life expectancy at the age of 35 years.

Problems with Instrumental Variables Estimation

In theory, it is easy to write down conditions (10) and (11) and derive that an estimator satisfying these conditions can recover causal effects from observational data. In practice, finding variables that satisfy those conditions can be very difficult or impossible. Worse, it turns out that even small deviations from those conditions can yield estimators with extremely poor properties.

The most difficult problem to overcome is instruments which are themselves endogenous, that is, correlated with the error term in the equation of interest, violating condition (10). It is possible to show that the IV estimator is inconsistent when the instruments are endogenous. Intuitively, if our condition that the only reason y varies with z is because z causes x fails, then observing that z and y move together is not evidence that x causes y.

For most problems finding variables that only affect the outcome of interest because they affect the endogenous

regressors is challenging. Consider, for example, one of the key problems in the social determinants of health literature: estimating the causal effect of personal income on health. A variable is required which affects health solely through its effect on income. It is unlikely that any personal characteristic satisfies that condition: personal characteristics such as education, smoking status, or cognitive ability all affect income, but all potentially affect health conditional on income, so none are valid instruments. Regional characteristics such as the unemployment rate may affect income, but may also affect health through other channels, such as provision of local public goods or through sorting of people across states. Researchers therefore need to be creative in finding valid instruments: one study, for instance, uses lottery winnings as an exogenous source of income to assess the effect of income on the health of lottery players. In other applications, valid instruments may simply not be available.

It may seem that variables which are almost, but not quite, exogenous may yield reasonable estimates, provided that there is a large sample and can thus rely on the consistency property of the IV estimator. In particular, from the formula for the probability limit of the univariate IV estimator presented above, it is possible to show

$$\text{plim}_{n\to\infty}\hat{\beta}_{IV} = \frac{\text{Cov}(y,z)}{\text{Cov}(z,x)} = \beta + \frac{\text{Cov}(z,u)}{\text{Cov}(z,x)} \qquad [15]$$

As long as Cov(z, u) is close to zero, then the ratio of Cov(z, u) to Cov(z, x) should itself be close to zero. This intuition is correct provided that Cov(z, x) is sufficiently large. If, however, there is only weak correlation between z and x then even small violations of exogeneity lead to very poorly behaved estimates. The reason is that Cov(z, u) is divided by a number close to zero, which has the effect of amplifying Cov(z, u). The result is that the IV estimator $\hat{\beta}_{\text{IV}}$ can be centered on a value wildly different from the true value of β, even as the sample size grows arbitrarily large. A low level of correlation between the instruments and treatment is known as the 'weak instrument problem.'

What is more, even if the instruments are exogenous, if the instruments are weak the IV estimator will tend to be badly biased in finite samples and, perhaps worse, the usual estimator of the covariance matrix, and test statistics based on that matrix, will be biased, leading to severe size and power distortions. The bias stems from the fact that the IV estimator is the ratio of two estimators – the numerator being the estimator of the effect of z on y and the denominator the estimator of the effect of z on x. In large samples, these estimators converge to their population quantities. In finite samples, however, sampling error in the two estimators can cause the ratio to behave erratically. The weaker the instruments, the greater is the sampling error.

In short, instruments with poor properties – either endogenous or weak – may be 'cures worse than the disease.' The good news is that in overidentified models it is possible to construct test statistics against the null that the instruments are exogenous, and it is always possible to test the strength of the instruments.

Heterogeneous Causal Effects

Over the past two decades the IV literature has focused on the following issue: If different entities or 'units' (people, firms, hospitals, etc.) experience different causal effects as a result of the same treatment, how are we to interpret IV estimates? It turns out that when treatment effects are heterogeneous, identification of causal effects using IV can be challenging.

Consider a slight modification to eqn [1],

$$y_i = \beta_i x_i + u_i \qquad [16]$$

which differs from eqn [1] only in that the slope coefficient β_i may vary arbitrarily across units. In the interest of simplicity, again suppose x_i is a binary indicator of whether unit i received treatment.

In this model, it is incoherent to refer to 'the' causal effect of x on y, as each unit generally experiences a different causal effect. Estimation of counterfactual outcomes in this model is also more complicated than in model (1). When treatment effects are constant, the outcomes of untreated units can be used to infer the counterfactual outcomes of those that were treated (and vice versa). This is not generally possible when causal effects vary across i. Therefore it is not possible to estimate the effect of treatment for any given unit. Researchers instead attempt to estimate features of the distribution of the causal effect, β_i, such as the population average treatment effect, $E(\beta_i)$, or the average treatment effect for those who actually received the treatment, $E(\beta_i \mid x_i = 1)$.

Without loss of generality, write $\beta_i = \overline{\beta} + \varepsilon_i$, where $\overline{\beta}$ is the population mean effect and ε_i is a zero-mean idiosyncratic effect specific to unit i. Substituting into eqn [16],

$$y_i = \overline{\beta} x_i + [x_i \varepsilon_i + u_i] \qquad [17]$$

Notice that the error term contains two components: unobserved causes of the outcome specific to unit i, μ_i, and the interaction between treatment status and unit i's return to treatment. If both μ_i and ε_i are uncorrelated with x_i, OLS estimation is consistent for the average treatment effect, $\overline{\beta}$. However, even when μ_i is uncorrelated with x_i, correlation between ε_i and treatment status creates an endogeneity problem and OLS does not recover the average treatment effect. In this case, 'essential heterogeneity' is said to exist. Essential heterogeneity commonly occurs in observational studies of treatment efficacy when individuals with the most to gain from taking a particular treatment are more likely to receive that treatment. Essential heterogeneity can also exist in RCTs with imperfect compliance. This occurs if subjects are able to: (1) determine the treatment to which they have been assigned, (2) predict better than chance which treatment will benefit them most, and (3) if advantageous, switch therapies. Condition (1) occurs if subjects are not blinded or if they are blinded, subjects can infer treatment status from side effects, or other physiological clues. The extent to which condition (3) holds depends on the context. Subjects assigned to the new therapy who wish to use the standard therapy can presumably obtain the standard therapy outside the trial. Conversely, subjects assigned to the standard therapy who wish to use the new therapy might be able to obtain the new therapy from friends enrolled in the trial.

Estimation using IV is complicated by essential heterogeneity. The instrument must be correlated with treatment status: It must move some people into or out of treatment. Even if all of the conditions defined in section The Instrumental Variables Estimator hold, the properties of the IV estimator depend on which people get moved into or out of treatment when treatment effects vary across people. Consider again example 2 in section The Instrumental Variables Estimator above, an RCT with imperfect compliance. Under a condition called monotonicity, which requires that there be no 'defiers' – people who only receive treatment if they are assigned not to receive treatment or vice versa – it is possible to show that the IV estimator converges to the average causal effect of treatment of compliers, that is, subjects who use the treatment that they were assigned to. This is called the 'local average treatment effect' arising from this treatment.

Intuitively, some people will always take the new treatment and others will always take the standard treatment, regardless of the assignment. The experiment does not change these people's behavior and therefore the experiment generates no information about the causal effects of treatment for these people. The IV estimator depends solely on the outcomes of subjects whose treatment status was experimentally manipulated; the estimator tells us the average effect only for that (unobservable) subpopulation. If the instrument takes many values instead of just two, it is possible to show that (under monotonicity) the IV estimator converges to a difficult-to-interpret weighted average of local treatment effects, in which units for which treatment status is most responsive to variation in the instruments receive the highest weights.

In addition to complicating the interpretation of conventional IV estimates, heterogeneous causal effects complicate specification testing. Most tests of the assumption that the instruments are exogenous are based on stability of the estimates as different sets of instruments are used to construct the estimator. Under homogeneous responses, all of these estimates converge to the causal effect. When effects are heterogeneous, different instruments recover different weighted averages of local effects, and will differ even if the classical conditions (10) and (11) hold, so rejection of the null can no longer be interpreted as evidence that the instruments are endogenous.

Example: Reinterpreting an Estimate of the Effect of Education on Health

Consider again example 5, above, of research using IV on the effect of education on health. Earlier, Lleras-Muney's estimates were interpreted as suggesting that an additional year of education causes an increase in life expectancy of 1.7 years at the age of 35 years. Lleras-Muney's estimates are based on variation in compulsory schooling laws, so she interprets her IV estimates as: among the subpopulation who only receive additional education if and only if they are forced to do so by law, an additional year of education increases life expectancy by 1.7 years at the age of 35 years. This subpopulation may experience substantially different health returns to education than other people who choose to go on to receive more than the legally mandated minimum schooling. Thus, Lleras-Muney's local average effect may not reflect the health returns to education for other groups. However, Lleras-Muney's estimates may be more relevant than results from a hypothetical RCT randomizing education if policy questions hinge on effects experienced by people whose educational outcomes are affected by changes in compulsory schooling laws, as the RCT would recover population average effects rather than effects for the subpopulation affected by policy changes.

Instrumental Variables: Methods

JV Terza, Indiana University Purdue University Indianapolis, Indianapolis, IN, USA

Introduction

Most empirical research in health economics is conducted with the goal of providing causal evidence of the effect of a particular variable (the causal variable – X) on an outcome of interest (Y). Such analyses are typically conducted in the context of explaining past behavior, testing an economic theory, or to evaluating a past or prospective policy. Common to all such applied contexts is the need to infer the effect of a counterfactual *ceteris paribus* exogenous change in X on Y, using statistical results obtained from survey data in which observed differences in X are neither *ceteris paribus* nor exogenous. In such nonexperimental sampling circumstances, statistical methods that essentially measure observed differences in Y per observed differences in X typically miss the mark because they fail to control for unobserved variables that are correlated in sampling with both X and Y. Such unobserved confounding variables, which vary in sampling with both X and Y, obfuscate the true causal effect (TCE) as it would have manifested if the value of X were exogenously perturbed *ceteris paribus*. Consider, for instance, attempting to obtain inference regarding the effect of cigarette smoking during pregnancy on infant birth weight using survey data. Suppose there exists an unobserved variable, say 'health mindedness' that causes pregnant women to both refrain from smoking and engage in other healthy prenatal behaviors. In such a scenario it is possible that observed smoking levels could be negatively associated with birth weight even though a *ceteris paribus* exogenous change in smoking (as might be brought about through policy intervention) would have no causal effect on birth weight. The present article discusses available regression methods designed not only to control for observable confounding influences but also to account for the presence of unobservables that would otherwise thwart causal inference.

The remainder of the article is organized as follows. The next section offers a more formal discussion of estimation bias due to unobserved confounding. In Section Instrumental Variables Methods, we consider a commonly implemented remedy for such bias – the use of instrumental variables (IV). Therein extant IV methods for both linear and nonlinear models are reviewed. The article concludes with a summary and some recommendations.

Unobserved Confounder Bias

At issue here is the presence of confounding variables which serve to mask the TCE of X on Y. The author begins by defining a confounder as a variable that is correlated with both Y and X. Confounders may be observable or unobservable (denoted C_o and C_u, respectively, – in the present discussion both are assumed to be scalars (i.e., not vectors)). In modeling Y, if the presence of C_u cannot be legitimately ruled out, then X is said to be endogenous. Observations on C_o can be obtained from the survey data, so its influence can be controlled in estimation of the TCE. C_u, however, cannot be directly controlled and, if left unaccounted for, will likely cause bias in statistical inference regarding the TCE. This happens because estimation methods that ignore the presence of C_u will spuriously attribute to X observed differences in Y that are, in fact, due to C_u. The author refer to such bias as unobserved confounder bias (henceforth C_u–bias) (sometimes called endogeneity bias, hidden selection bias, or omitted variables bias). One can formally characterize C_u–bias in a useful way. For simplicity of exposition, the author casts the true causal relationship between X and Y as linear and write

$$Y = X\beta + C_o\beta_o + C_u\beta_u + e \qquad [1]$$

where β is the parameter that captures the TCE, β_o and β_u are parametric coefficients for the confounders, and e is the random error term (without loss of generality, it can be assumed that the Y intercept is 0). In the naive approach to the estimation of the TCE (ignoring the presence of C_u), the ordinary least squares (OLS) method is applied to

$$Y = Xb + C_o b_o + \varepsilon \qquad [2]$$

where the b's are parameters and ε is the random error term. The parameter b is taken to represent the TCE. It can be shown that OLS will produce an unbiased estimate of b (here and henceforth, when the author refers to unbiasedness it is done so in the context of large samples). It is also easy to show, however, that

$$b = \beta + b_{XC_u}\beta_u \qquad [3]$$

where b_{XC_u} is a measure of the correlation between C_u and X. As is clear from eqn [3], C_u – bias in OLS estimation is $b_{XC_u}\beta_u$, which has two salient components: the correlation between the unobserved confounder and the causal variable of interest and the correlation between the unobserved confounder and the outcome. Equation [3] is helpful because it can be used to diagnose potential C_u – bias. Consider the smoking (X) and birth weight (Y) example discussed in the Section Introduction, in which C_u is health mindedness. In this case one would expect that b_{XC_u} would be negative and that β_u would be positive. The net effect of which would be negative C_u – bias in the estimation of the TCE via OLS.

Clearly an approach to estimation is needed that, unlike OLS, does not ignore the presence and potential bias of C_u. One such approach exploits sample variation in a particular type of variable (a so-called IV) to eliminate bias due to correlation between C_u and X (C_u – bias as characterized in eqn [3]). This is the subject of the following section.

Instrumental Variables Methods

As eqn [3] demonstrates, if the correlation link between the causal variable and the unobservable confounder were somehow broken, concomitant estimation bias would be eliminated. If the researcher could exert control over the sampled values of X, then such disjunction of C_u and X could be accomplished by random assignment of X values to the individual sample members. Under such randomization, b_{XC_u} would be equal to zero, by eqn [3] b would be equal to β, and conventional estimation methods like OLS, which ignore the presence of C_u, would be unbiased. Unfortunately, in applied health economics and health services research, as in other social sciences, explicit randomization (experimentation) is often prohibitively costly or ethically infeasible. A form of pseudorandomization is, however, possible in the context of survey (nonexperimental) data. If, for instance, a variable that is observed as one of the survey items is highly correlated with X but correlated with neither Y nor C_u (except through its correlation with X), then the sample variation (across observations) in the value of that variable can be viewed as providing variation in X that is not correlated with C_u – a kind of pseudorandomization for X. Such a variable is typically called an IV. In the context of our smoking birth weight example, cigarette tax is an arguably valid IV in that it should be highly correlated with cigarette consumption but not directly correlated with birth weight.

IV estimation methods all require observable confounder (C_o) control – typically within a regression framework akin to eqn [1]. Most often, however, the linear regression model in eqn [1] is not realistic in that it precludes cases in which the relationship between Y and the right-hand side variables (X, C_o, and C_u) is nonlinear – for example, when Y is limited in range (e.g., nonnegative and binary outcomes); and/or when such characteristics of the outcome induce interactions among the causal variable and confounders. In the following, the presence of a valid IV (call it W) in the relevant survey is assumed and IV estimation methods for both linear and nonlinear contexts are considered.

Instrumental Variables Estimation in Linear Models

By way of motivating the conventional linear IV estimator in the context of eqn [1], the author examines the underpinnings of the OLS estimator of the TCE for the case in which $\beta_u=0$ (i.e., the case in which there is no unobservable confounder). When $\beta_u=0$, eqn [1] becomes

$$Y = X\beta + C_o\beta_o + e \qquad [4]$$

and the formulation of the OLS estimator of β (and β_o), which involves data on observable variables only (viz., X and C_o), can be derived from the fact that X and C_o are not correlated with the error term e. A similar tack cannot, however, be taken when $\beta_u \neq 0$. In this case, eqn [1] can be rewritten as

$$Y = X\beta + C_o\beta_o + e^* \qquad [5]$$

where $e^*=C_u\beta_u+e$, and although C_o and e^* are arguably uncorrelated, the correlation between X and e^* is clearly nonzero because X and C_u are, by the definition of the term confounder, correlated. As a consequence of the undeniable correlation between X and C_u, the aforementioned derivation of the OLS estimator cannot be replicated for eqn [5]. This approach is not, however, entirely futile if an IV (W) is available in the data. By definition, the IV W is uncorrelated with both C_u and e. W is, therefore, not correlated with e^* so, analogous to the derivation of the OLS estimator based on eqn [4], it can be used to formulate an unbiased estimator of β and β_o (the so-called IV estimator). The IV estimator is available in all of the most widely used statistical and econometric software packages (e.g., Stata and SAS).

There are two relatively more intuitive two-stage versions of the IV estimator. Both of these approaches implement an auxiliary regression of the form

$$X = C_o\alpha_o + W\alpha_w + C_u \qquad [6]$$

where the α's are parameters. In the first stage of each of these methods, OLS is applied to eqn [6] to obtain estimates of parameters ($\hat{\alpha}_o$ and $\hat{\alpha}_w$) and the regression predictor of X ($\hat{X} = C_o\hat{\alpha}_o + W\hat{\alpha}_w$). One of these methods, called two-stage least squares (2SLS) has as its second stage the OLS estimation of β and β_o via eqn [5] with $\hat{X}$ substituted for X. The other approach, called two-stage residual inclusion (2SRI) calls for OLS estimation of

$$Y = X\beta + C_o\beta_o + \hat{C}_u\beta_u + e \qquad [7]$$

where $\hat{C}_u = X - (C_o\hat{\alpha}_o + W\hat{\alpha}_w)$ – i.e., the residual from first-stage OLS estimation of eqn [6].

When true causal model is eqn [1] both 2SLS and 2SRI produce estimates of the TCE (β) and β_o that are identical to those obtained via the IV estimator.

Instrumental Variables Estimation in Nonlinear Models

Although the linear IV estimator (or its equivalent versions 2SLS or 2SRI) is intuitive and simple to apply due to its availability, the linear true causal model (as specified in eqn [1]) on which it is based does not conform to most empirical contexts in health economics. In most applied settings, the range of the outcome is limited in a way that makes a nonlinear specification of the true causal model more sensible. For example, the researcher is often interested in estimating the causal effect of a policy variable (X) on whether or not an individual will engage in a specified health-related behavior. In this case, the outcome of interest is binary so that a nonlinear specification of the true causal model would likely be more appropriate. In the smoking birth weight example discussed in the Section Introduction, the outcome of interest (birth weight) is nonnegative and an exponential regression specification of the true causal model is more in line with this feature of the data than is the linear specification in eqn [1]. Another common example of inherent nonlinearity in health economics and health services research, is in the modeling of healthcare expenditure or utilization (E/U). It is typical to observe a large proportion of zero values for the E/U outcome. In this and similar empirical contexts, the two-part model (2PM) has been widely implemented. The 2PM allows the process governing observation at zero (e.g., whether or not the individual uses the healthcare service) to systematically differ

from that which determines nonzero observations (e.g., the amount the individual uses (or spends on) the service conditional on at least some use). The former can be described as the hurdle component of the model, and the latter is often called the levels part of the model. Both of these components are nonlinear – binary response model for the hurdle; nonnegative regression for E/U levels given some utilization.

To accommodate these and other cases, the generic nonlinear version of the true causal model in eqn [1] is written as

$$Y = \mu(X, C_o, C_u;\ \theta) + e \qquad [8]$$

where $\mu(X,\ C_o,\ C_u;\ \theta)$ is known except for the parameter vector θ. It is very often assumed that $\mu(X,\ C_o,\ C_u;\ \theta) = M(X\beta + C_o\beta_o + C_u\beta_u)$, where $M(\ )$ is a known function and $\theta = (\beta\ \beta_o\ \beta_u)$. In this linear index form the true causal models corresponding to binary and nonnegative outcomes are commonly written, respectively, as

$$Y = F(X\beta + C_o\beta_o + C_u\beta_u) + e\ (Y = \{0,\ 1\}) \qquad [9]$$

and

$$Y = \exp(X\beta + C_o\beta_o + C_u\beta_u) + e\ (Y \geq 0) \qquad [10]$$

where $F(\ )$ is a function whose range is the unit interval. It is noted here that for the generic nonlinear model characterized by eqn [8] the TCE is not embodied in any particular parameter (e.g., β) as in the linear models defined by eqn [1]. Instead, the TCE will be a nonlinear function of all parameters (θ) and all of the right-hand side variables (X, C_o, C_u) of the model. Moreover, the exact form of the TCE in nonlinear settings will differ depending on the researcher's policy relevant analytic objective(s). These issues will not, however, be discussed here. In the present discussion, focus is on estimation of the vector of parameters θ.

In the remainder of this section, various approaches to the estimation of θ in nonlinear models of the generic form given in eqn [8] are examined. The author begins by examining the feasibility and appropriateness of the generalized method of moments (GMM) estimator – the nonlinear analog to IV estimation in the linear model. Next, the nonlinear counterparts to the linear 2SLS and 2SRI are examined. Nonlinear 2SRI (N2SRI) is a member of a class estimators called control function estimators. Other control function estimators that are specifically designed for cases involving binary causal variables are discussed. This section concludes with a description of cases in which the maximum-likelihood method can be applied.

The generalized method of moments

To estimate of the parameters of nonlinear causal models like eqn [8], one may seek to apply the GMM as an extension of the linear IV approach, detailed in Section Instrumental Variables Estimation in Linear Models. Recall that the derivation in that section relied on two facts:

1. Equation [1] could be rewritten as eqn [5] – a linear regression representation involving observable variables only and an additive error term.
2. The IV W is correlated with neither C_u (the unobservable confounder) nor e (the random error term in eqn [1]).

Unfortunately, there is only one case (that we know of) in which such a derivation is feasible in the context of eqn [8] – the exponential regression version of the model given in eqn [10]. This model is discussed later. In (all?) other cases, it is the nonadditive involvement of C_u in eqn [8] that makes the derivation of a GMM-type estimator infeasible. The generic nonlinear form of $\mu(\ )$ precludes reformulation of the model as the sum of a nonlinear parametric component in the observable right-hand side data (X and C_o) with an additive error term. Some have suggested the use of an approximation to eqn [8] in which C_u is artificially cast in an additive role in the respecification of the model. For example, following this approach, models like eqn [9] would be rewritten as:

$$Y = F(X\alpha + C_o\alpha_o) + C_u\alpha_u + e^{\dagger}\ \{(Y = \{0,\ 1\}) \qquad [11]$$

In which case, the IV condition that W is correlated with neither C_u nor $e^{\dagger}$ would be sufficient to establish the appropriate GMM estimator. Clearly, however, eqns [9] and [11] are not equal; and the argument in favor of eqn [11] as a good approximation to eqn [9] is, at best, strained. Moreover, TCE estimation methods that incorporate GMM results obtained from such additive approximations are clearly biased. The extent of this bias has yet to be investigated.

As mentioned earlier, the only nonlinear context (of which one is aware) in which conditions like (1) and (2) are sufficient for derivation of an unbiased (in large samples) GMM estimator is the linear-index exponential case given in eqn [10]. Not only does this GMM estimator yield unbiased estimates of β and β_o but also unlike the additive approximations discussed earlier and exemplified in eqn [11], the exponential GMM results can be used to obtain unbiased estimates of the various policy relevant versions of the TCE.

Two-stage control function methods

In the Section The generalized method of moments, it is noted that extending the linear IV method to the generic nonlinear model in eqn [8] (i.e., the GMM estimator) is not generally feasible. Therefore, aside from the exponential case, we need a desirable (unbiased) feasible alternate to GMM. In search for such an alternative one turns to the discussion of the linear model in Section Instrumental Variables Estimation in Linear Models wherein the 2SLS and 2SRI estimators for β and β_o in eqn [1] are detailed. These estimators yield results identical to those produced by the linear IV method. Consider the feasible nonlinear analogs to linear 2SLS and 2SRI estimation. In the generic nonlinear context eqn [8] is supplemented with the following nonlinear analog to eqn [6]

$$X = r(C_o, W; \alpha) + C_u \qquad [12]$$

In 2SLS and 2SRI, the parameters of eqn [12] (α) are first estimated using an appropriate nonlinear regression estimator (e.g., nonlinear least squares (NLS)) and the following predictor of X is computed

$$\hat{X} = r(C_o, W;\ \hat{\alpha}) \qquad [13]$$

where $\hat{\alpha}$ denotes the parameter estimates. In the second stage of the nonlinear analog to 2SLS, an appropriate nonlinear regression estimator (e.g., NLS) would be applied to eqn [8]

with the predictor $\hat{X}$ substituted for X (this has also been called the two-stage predictor substitution (2SPS) estimator). In the second stage of the nonlinear analog to 2SRI, instead of substituting the predictor for X in eqn [8], C_u is replaced by the residual from eqn [13] ($\hat{C}_u = X - r(C_o, W; \hat{\alpha})$) and an appropriate nonlinear regression estimator (e.g., NLS) is applied to the following version of eqn [8]

$$Y = \mu(X, C_o, \hat{C}_u; \theta) + e^{2SRI} \quad [14]$$

where e^{2SRI} is the relevant regression error term. Unlike the linear case, the 2SPS and 2SRI estimators are not identical. Note that the actual value of X is used in eqn [14]. The 2SRI estimator is generally unbiased but the 2SPS estimator is not.

The 2SRI estimator is member of a general class of models called control function methods in which a specified function of the IV (W) (and some parameters) is used to 'control' for unobserved confounder bias. In the special (but very common) case in which X is binary, an alternative control function method is available. In this alternative control function framework eqns [8] and [12] are respectively replaced by

$$Y = \mu(X, C_o, C_u^*; \theta) + e \quad [15]$$

and

$$X = I(C_o\alpha_o + W\alpha_w + C_u^* > 0) \quad [16]$$

where $I(A)$ is equal to 1 if condition A holds and 0 otherwise, and the probability distribution of C_u^* is known. For example, if C_u^* is assumed to be logistically distributed, eqn [16] defines a conventional logit model. Similarly if C_u^* is normal eqn [16] is tantamount to a probit model. Given the known distribution of C_u^*, it can be 'integrated out' of eqn [15] and the resultant regression form can be used as the basis for nonlinear estimation (e.g., NLS) estimation of θ. When eqn [15] is linear and C_u^* is normally distributed, this control function method coincides with the classical Heckman-type dummy endogenous variable model estimator. Note that both 2SRI and this nonlinear extension of the Heckman approach are feasible and unbiased when X is binary (assuming, of course, that the respective sets of underlying assumptions hold).

Maximum-likelihood methods

When Y is a binary probit outcome and C_u^* is normally distributed, the control function approach described in the Section Two-stage control function methods leads to the bivariate probit model. In this case, the parameters of the model can be estimated using the maximum-likelihood method. Maximum-likelihood methods are also available for the special case in which the auxiliary regression is linear (akin to eqn [6]) and the outcome regression is a normal-based limited dependent variable model (e.g., probit or Tobit). These methods require joint normality of the random error terms in the outcome and auxiliary regressions.

Common factor models have also been suggested for the case in which X is qualitative. In these models, conditional on an unobserved 'common factor' (and the other conditioning variables), Y and X are assumed to be independently distributed. Moreover, these independent distributions and the distribution of the common factor are assumed to be of known form. The maximum-likelihood method can be used to obtain estimates of the parameters in this framework.

Summary

The most widely applied remedy for endogeneity in a causal modeling framework is the conventional linear IV (LIV) estimator described in Section Instrumental Variables Estimation in Linear Models. The popularity of LIV can be attributed to its off-the-shelf software availability, and to its intuitive appeal when cast as a two-stage method – 2SLS or 2SRI. The most attractive feature of LIV is that it need not be estimated in two stages and therefore does not require the specification of an auxiliary regression like eqn [6]. Very often, however, in applied health economics and health services research, endogeneity must be confronted in inherently nonlinear empirical contexts. For example, binary response outcomes, limited dependent variables, and two-part models with endogenous causal regressors abound in these fields. One might think that the GMM, which is the most direct approach to extending the LIV estimator to the nonlinear case, would provide a solution to the unobserved confounding problem in nonlinear models. Unfortunately, except for exponential regression models, the GMM is not feasible as a means of dealing with endogeneity in nonlinear settings.

The easiest to implement approach for such cases is the extension of the linear 2SRI estimator to nonlinear models. The primary drawback to the use of N2SRI is that it requires the specification and estimation of an auxiliary regression as defined in eqn [12]. The main advantages of N2SRI are that it can be applied in any nonlinear regression context and will produce unbiased estimates of the regression parameters (and, therefore, the relevant TCE) under general conditions.

There are alternatives to N2SRI for some specific cases. When the outcome is binary, the nonlinear extension to Heckman-type control functions can be used. These methods, although feasible, are not as simple to apply as N2SRI. A similar criticism holds for the maximum-likelihood common factor models.

When the outcome is limited in range (e.g., probit and Tobit) and the auxiliary regression is linear, maximum-likelihood methods can be applied. These methods, though packaged in Stata and therefore easy to apply, require the relatively strong assumption of joint normality between the outcome and the causal variable. N2SRI imposes no such joint distribution assumptions. Moreover, it is often difficult to justify the linearity of the auxiliary regression and the implied normality of the causal variable. It is typical, that the causal variable will itself be limited in range (e.g., binary and nonnegative), making both linearity and normality implausible.

Simulation-based performance comparisons of the models discussed in this article have yet to be conducted.

Glossary

Asymmetry of information A situation in which the parties to a transaction have different amounts or kinds of information, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances, or people seeking insurance have more reliable expectations of their risk exposure than insurance companies.

Coinsurance Coinsurance is the practice whereby the insured person shares a fraction of an insured loss with the insurer. For example, the insurance policy may require the insured person to pay 10 per cent of the expenses of medical care, with the insurer paying 90 per cent. The sum paid by the insured person is known as a copayment, so if the expenses are US$1000 and the coinsurance rate is 10 per cent, the copayment is US$100.

Copayment An arrangement, whereby an insured person pays a particular percentage of any bills for health services received, the insurer paying the remainder.

Deductible An insurance arrangement, under which the insured person pays a fixed sum, when healthcare is used in any year and the insurer pays all other expenses (usually with further copayments). Thus, if the deductible is US$100 and the coinsurance rate 10 per cent, should the event involve an expense of US$1000, the insured person pays US$190 (US$100 plus US$90 copayment).

Dual practice A combination of public and private practice by doctors, sometimes even within the same hospital.

Gatekeeping The process by which a professional, usually a general practitioner, select patients and guides them into secondary care. In many countries patients, other than emergency cases, cannot consult a specialist without being referred by a general practitioner.

Horizontal equity Horizontal equity is treating equally those who are equal in some morally relevant sense. Commonly met horizontal equity principles include 'equal treatment for equal need' and 'equal treatment for equal deservingness'. When applied to insurance, the notion that two individuals facing the same risks should have access to the same coverage at the same premium.

Infant mortality rate Deaths in one year of infants under one year of age divided by number of live births in that year, all multiplied by 1000.

Life expectancy The statistically expected remaining years of life for a representative person (usually in a specific jurisdiction and by subgroup – male, female, by ethnicity, etc.) at a given age (say, at birth, or having already reached 65), assuming that age-specific mortality remains constant.

Moonlighting Same as dual practice.

Moral hazard Moral hazard can occur when the insurer has imperfect information on the likely behavior of insured individuals. There are two main types. Ex ante moral hazard refers to the effect that being insured has on safety behavior, generally increasing the probability of the event insured against occurring. Ex post moral refers to the possibility that insured individuals will behave in such a way after an insured event has occurred that will increase the claim cost to insurers, partly because the user price of care is lower through insurance and demand may therefore rise. It is also often related to insurance fraud.

Potential years of life lost (PYLL) A measure of the burden of disease, preventable premature mortality, or potential benefit from an effective intervention to improve health. Its calculation involves summing deaths occurring at each age and multiplying them by the number of remaining years up to a limiting age, which is often 70 years.

Propitious selection Propitious selection is a phenomenon in insurance which compares people with different levels of risk aversion. Those with higher levels are more likely both to buy insurance and to exercise care. Those with low levels, or who are actually risk seeking, will tend to do neither.

RAND experiment The largest social science empirical trial of health policy options ever conducted. The aim was to examine the effect of health insurance on health care costs, utilization, and outcomes. More than 1974–79 families were randomly assigned to different insurance plans with a variety of limits and coinsurance rates. Its principal investigator summarized the main results that "For most people enrolled in the RAND experiment, who were typical of Americans covered by employment-based insurance, the variation in use across the plans appeared to have minimal to no effects on health status. By contrast, for those who were both poor and sick – people who might be found among those covered by Medicaid or lacking insurance – the reduction in use was harmful, on average."

Risk aversion The most common definition in economics is the extent to which a sure and certain outcome is preferred to a risky alternative with the same expected value. For example, risk-averse individuals may prefer to have US$45 for sure than face a gamble in which they may win US$100 or nothing, each with a 50% chance.

Introduction

The existence of duplicate private health insurance (DPHI), which is observed in many countries with a National Health Service (NHS), is paradoxical at first sight. NHSs are usually characterized by universal coverage of every resident, large and comprehensive benefit packages, very low copayments or free care at the point of delivery, progressive tax financing, and are strongly guided by principles of equity in access to health care. Additionally, residents cannot opt out of the NHS, meaning that they are not given the option of not contributing to the NHSs' financing and relying exclusively on other forms of health care. Why then would people be willing to pay for private health insurance (PHI) covering roughly the same services as the NHS? This is even more surprising because NHSs have been generally performing quite well over the last decades. This paradox is a major issue in health economics, which health economists have been trying to understand theoretically and to document through empirical work. This article presents these findings.

Before going further, it is important to define the concept of DPHI, often called also double coverage or substitutive PHI. Under DPHI, private insurers offer coverage for health care already available under public delivery systems. Note that DPHI differs from supplementary PHI (SPHI). Under SPHI, patients access additional health services not covered by the public scheme such as luxury care, elective care, long-term care, dental care, pharmaceuticals, rehabilitation, alternative or complementary medicine, or superior hotel and amenity hospital services. Also worthy of remark is that DPHI is distinct from complementary PHI, which complements the coverage of publicly insured services by covering all or part of the residual costs not otherwise reimbursed (e.g., copayments). It is worth noting that there is no full consensus as regards this terminology, as some authors use the concepts of SPHI and DPHI indifferently. DPHI should also be distinguished from 'parallel private health insurance' where individuals are covered by one among several parallel insurance systems. These roughly insure for the same health care but an individual is entitled to only one of the insurance systems' benefits. For example, in the US, an individual in need of health care as a consequence of a workplace accident is covered by the Workers' Compensation Board and not by Medicare.

Finally, note that an NHS is a necessary but not sufficient condition to observe the emergence of DPHI. According to a large review of health systems in Organization for Economic Cooperation and Development (OECD) countries, DPHI exists to different extents in the following countries with an NHS (percentages in parentheses indicate the percentage of people enjoying double coverage): Australia (43.5%), Ireland (51.2%), Italy (15.6%), New Zealand (32.8%), Portugal (17.9%), Spain (10.3%), and the UK (11.1%) (Paris *et al.*, 2010). At the same time, double coverage is absent in other NHS-type health systems like Denmark, Norway, and Sweden.

In Section 'Stylized Facts and Preliminary Insights,' some stylized facts that allow a preliminary overview about health systems' performance in the presence of double coverage are presented. Then, the main theoretical concepts that are indispensable to analyze this question are presented in Section 'Theoretical Concerns: Uncertainty and Information.' In the Section 'Empirical Evidence of Uncertainty and Informational Problems: Who Buys Duplicate Private Health Insurance?', the main results from empirical analyses that have tested several aspects of double coverage, in particular, who is more likely to purchase duplicate private insurance and why is displayed. Finally, Section 'Political and Financial Sustainability of a DHPI Health Sector' focuses on the political and financial sustainability of a system with duplicate private insurance.

Stylized Facts and Preliminary Insights

DPHI coverage is usually advocated for at least three reasons:

- It promotes population health.
- It limits public and global health expenditures.
- It increases population choice and health system 'responsiveness,' a term defined below in this section.

Roughly speaking, DPHI emerges because the NHS alone will fail to reach these aims. However, is there really a failure of NHS that justifies the emergence of DPHI? In this section, the preliminary evidence as regards these three objectives, for three NHSs, namely Portugal, Spain, and the UK, is provided. These countries are suitable cases for investigation because their public system has long lived without a significant DPHI – actually, the weight of DPHI on total health expenditures only became relatively significant ($>4\%$) after 2000.

It is of course very difficult to attribute good health outcomes to a health system, because population health depends on many factors. Nevertheless, at first sight, these three public schemes certainly do not do worse than the OECD average. The three indicators commonly used to assess health systems' performance are considered here: infant mortality, potential years of life lost (PYLL), and life expectancy at 65. In the 1960s, before the creation of the Portuguese and Spanish national services, Portugal had almost double that of Spanish infant deaths (43/1000) and four times those of the UK (22/1000) (**Figure 1**). Yet, since the late 1980s, Spain has reached UK levels, well below the OECD average, and Portugal has fallen below the OECD average since 1990. For the last 35 years both the UK and Spain have been constantly below the OECD female average as regards PYLL, whereas Portugal, starting from very high levels, has been approaching the OECD average (**Figure 2**). Finally, as regards life expectancy at 65 years, Spanish women live longer than any other, whereas UK women have a similar life expectancy as the OECD average. Portugal, however, has approached the OECD average in the last 20 years having started from significantly lower levels (**Figure 3**). It seems thus that health concerns might not be the major explanation for the development of DPHI.

Double coverage is commonly defended as a means to restrain total and public health expenditure. Consistently, Portugal, Spain, and the UK have for long been allocating a lower-than-the-average share of their gross domestic product (GDP) to the health sector. However, the pace of growth in these countries has been quite similar to that observed elsewhere. Values have even got further above the OECD average since the mid-1990s in Portugal and in very recent years in Spain and the UK, coinciding with the development of DPHI

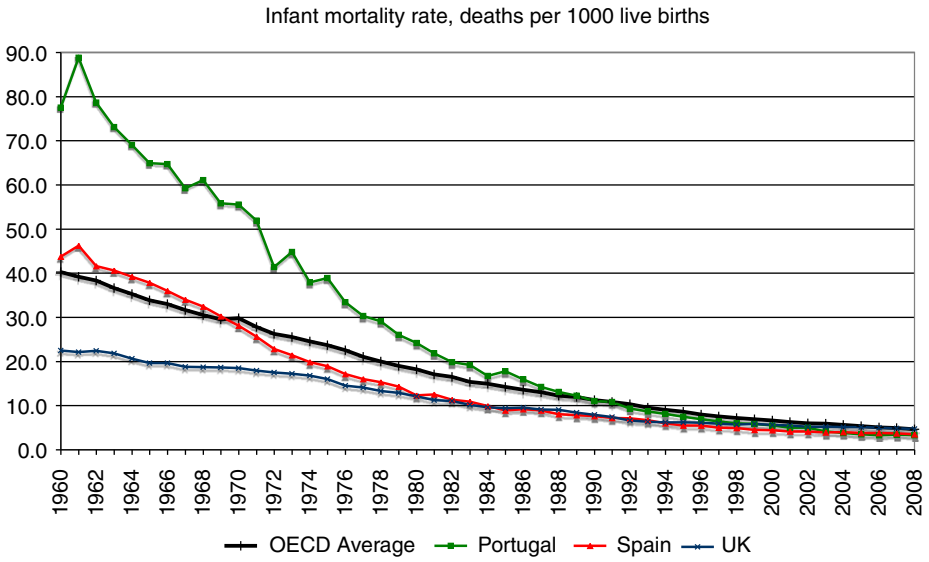

Figure 1 Infant mortality rates. *Source*: OECD Health Data (2011).

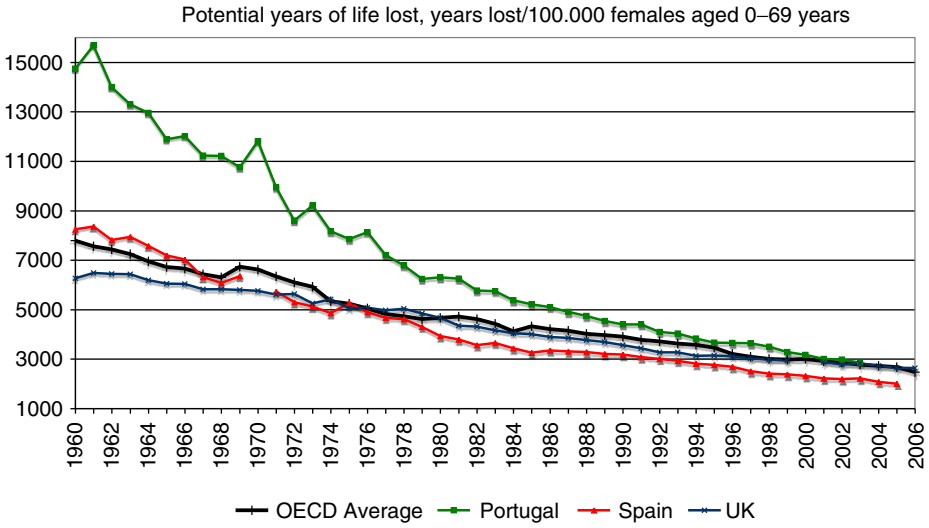

Figure 2 PYLL. *Source*: OECD Health Data (2011).

(Figure 4). Note also that the share of public expenditures is similar in those countries as compared to the average, and has not decreased with the development of DPHI (Figure 5). Instead, since early 2000 this indicator has been constant for Spain and Portugal and has even increased for the UK. Only a deeper analysis would allow one to draw more definitive conclusions. However, at first sight, public health expenditures were not particularly high before DPHI nor has DPHI been very effective in restraining public and general health care expenditures.

Finally, another argument relates to the supposed public service's inability to respond to specific aspects of demand, the so-called lack of responsiveness. The NHS is usually strongly guided by the principle of horizontal equity ('equal treatment for equal needs'); hence it provides comprehensive but needs-based uniform health care, which limits the possibility for patients to express their preferences, even if they are ready to pay for them (this rigidity may sometimes create unexpected and morally conflicting situations, see Box 1 'If you want to choose, go private'). Additionally, principles of rationality and efficiency have prompted these three countries to adopt measures such as gatekeeping, and access to GP and hospital mainly according to the area of residence, which further limit patients' choice. Finally, waiting lists are used to restrain health care use considerably, as a means to ration demand in the absence of significant copayments. In 2010, Portugal had 161 621 patients waiting a median time of 3.3 months for elective surgery (there were however, 248 404 waiting a median of 8.6 months in 2005); in Spain 374 000 patients were waiting an average 1.9 months in 2009; and the UK has

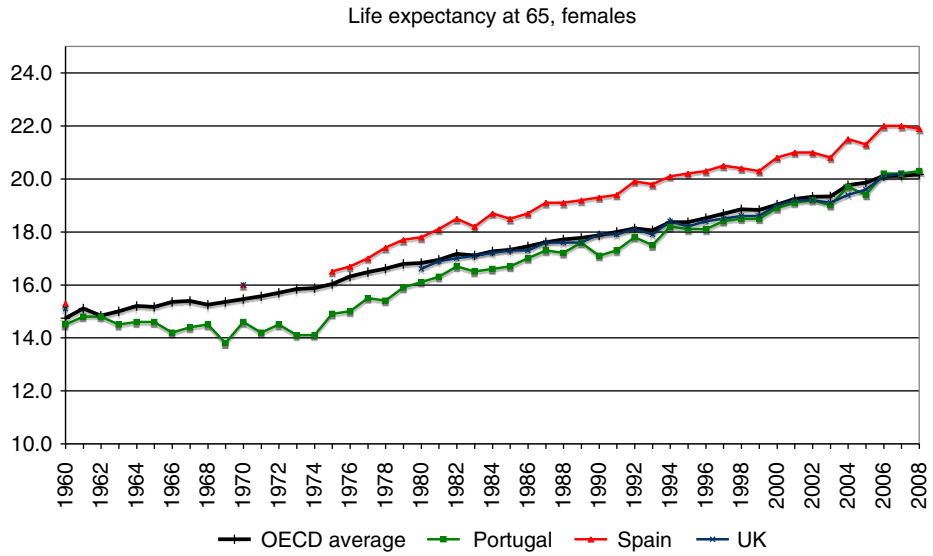

Figure 3 Life expectancy at age 65, females. *Source*: OECD Health Data (2011).

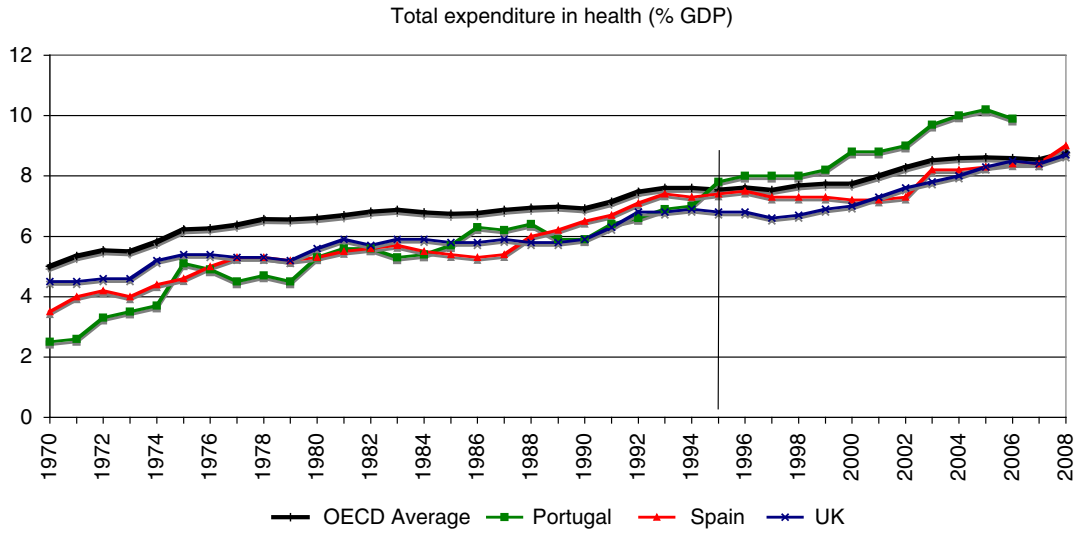

Figure 4 Total expenditure in health as a share of GDP. *Source*: OECD Health Data (2011).

decreased 900 000 patients waiting more than a median of 20 weeks in the 1980s to 620 000 patients waiting a median of less than 5 weeks in 2010. There are thus elements related to the rigidities of NHS-type systems that may favor double coverage. Note that recent decreases in waiting times have been in part obtained through contracts with private practices, so that the potential benefits of DPHI may play some role in these results.

Theoretical Concerns: Uncertainty and Information

To understand why DPHI coverage emerges, who buys it, and with which consequences, it is crucial to understand some economic concepts related to insurance in general and health insurance in particular. To start with, it is important to realize that the health care sector is affected by uncertainty in mainly two dimensions. First, there is unpredictability with respect to an individual health status and future health care needs. Second, there is uncertainty regarding the precise effects of a given health care procedure on a particular patient.

Regarding health status, some individuals are at a higher risk of developing diseases than others. Such a risk is the result of a combination of an individual's genetics, aging, behavior, and environmental context. Neither the individual, nor the physicians, nor the insurers know with exactitude the status of the patient's health. What is more, they may not even share exactly the same information but instead have 'asymmetric information' regarding the individual's health status. Indeed, prior to any screening test or medical intervention, it is common to

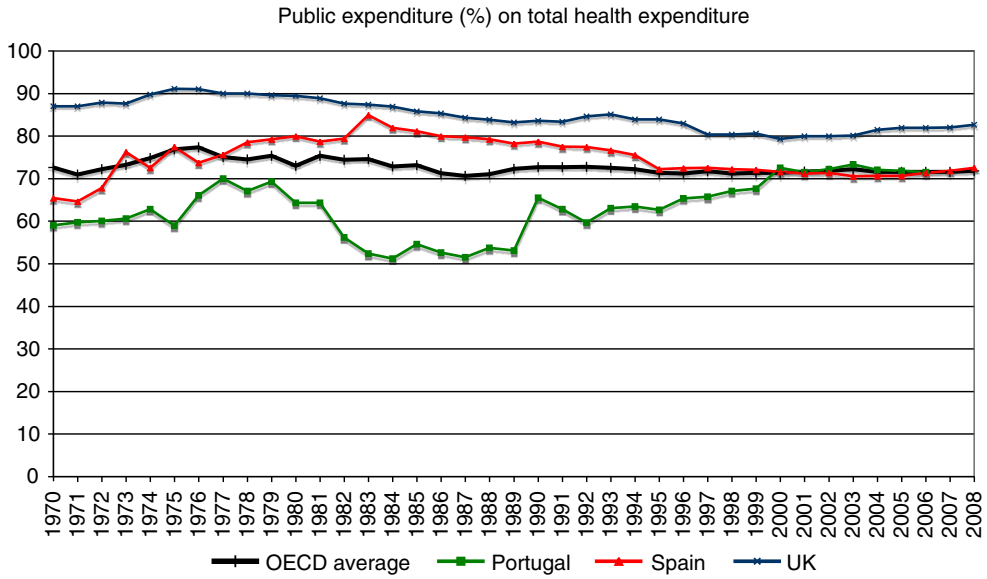

Figure 5 Share of public expenditure on total health expenditures. *Source*: OECD Health Data (2011).

Box 1 If you want to choose, go private

In 2008, Lynda O'Boyle, who suffered from bowel cancer, was not authorized to receive in her NHS hospital in England an expensive drug treatment, uncovered by the NHS, which she was however willing to pay. If she were willing to buy the treatment, she would have to opt out the NHS.

This case posed serious questions about the relationship between public and private systems, and about the trade-off between efficiency and equity. On the one hand, it reveals the rigidity of the NHS and its often criticized lack of responsiveness, emphasizing a major argument in favor of the DPHI: The freedom to choose about one's treatment and life. However, the denial of the drug was grounded on equity concerns, postulating that two equally needed patients treated in two NHS 'adjacent beds' should be treated equally. The use of an expensive drug, although paid by the patient herself, would lead to inequality in treatment, presumably increased by the necessity for doctors to administrate, monitor, and cure the adverse effects of the drug.

This case prompted England to modify drugs' cost-effectiveness threshold and to allow patients to pay privately for treatment without losing their entitlement to the NHS. It reveals the paradox of the DPHI: The equity concerns of the NHS, through the rigidity it creates, sustain the emergence and development of DPHI, which possibly provokes a much higher inequity than that one wanted to avoid.

assume that the individual is more informed about his chances of developing a disease or condition than anyone else. After all, the individual is more aware of one's family's health condition, one's own lifestyle, and one's environment than one's doctor or insurer may be. When facing the doctor, the individual may have all the incentives to disclose information – beyond everything, one wants to be treated – this is most often not the case when facing the insurer – ultimately one wants to be paid for all medical care expenses and would prefer to deny any responsibility of the events. The insurance companies' reaction to this asymmetric information depends very much on the structure of the insurance market but generally issues like 'adverse' and 'propitious selection,' 'moral hazard,' and 'insurance denial' emerge. Below, the Sections Adverse Selection, Risk Selection, Propitious Selection and Moral Hazard discuss the extent of these effects in a duplicate health insurance market.

However, the effects of a particular health care procedure on a patient are not certain. Additionally, physicians are better able to assess the effects of medical care than the patient or insurance companies, and it may not always be of their interest to reveal such information. For example, they may increase the number of consultations aiming at greater profits. Consequently, physician's 'induced demand' may arise. Section 'Supplier-Induced Demand and Dual practice' deals with induced demand in the context of duplicate insurance market.

Adverse Selection

Suppose some individuals in the economy have a high probability of disease and others a low one, known by the individual but unknown to the insurer. Adverse selection (also referred to as "screening" by some authors) may be a mean for insurance companies to force individuals to reveal their risk type. Indeed suppose they offer two types of contracts: One fully insuring individuals at a price reflecting high-risk individuals' probability of becoming sick; another offering incomplete insurance coverage at a price reflecting low-risk individuals' risk. The first contract is too expensive for low-risk individuals and therefore only the high-risk ones would be willing to buy it. The second would offer limited coverage at a price reflecting low-risk individuals' probability. It would therefore not be attractive to high-risk individuals who have a lot to lose for not being completely insured. Still, low-risk individuals would be willing to buy it. Thus, by limiting the coverage of one such contract the insurance company is able to force individuals to self-select by buying the contract intended for their type and hence distinguish low- from high-risk individuals. In the end, the 'bad' type, i.e., the high-risk individuals

end up being fully insured whereas the 'good' type, i.e., the low-risk individual, is prevented from being fully insured.

Note that insurance companies cannot break even by offering an insurance contract to all individuals at an average price that captures the average risk. Actually, low-risk individuals would find such a contract too expensive and therefore only high-risk individuals would end up buying it. Consequently, such a contract would not be financially viable.

The problem of adverse selection is that low-risk individuals are not fully insured by insurance companies even if they would be willing to pay for insurance. In the NHS, adverse selection is not an issue because uniform health care is provided to all resident population, irrespectively of their risk. Also, the effects of adverse selection in the insurance market are lessened when insurance takes the form of group policies. In this case a uniform coverage is offered to all individuals belonging to the group. This is the case of 50% of the duplicate insurance in Portugal, 20% in Spain, and 15% in the UK. Therefore, other things being equal, it would be expected adverse selection as being stronger in the UK and Spain than in Portugal.

It could be argued that adverse selection is not such an important issue in the context of a duplicate insurance market, as opposed to a complementary or supplementary one. In the context of a complementary/supplementary insurance market, insurance covers services not covered in the public system. Therefore, someone without insurance in this market is not insured for those services not covered by the NHS. In contrast, in a duplicate health insurance market, not being insured in the private market would not be so costly because individuals are ensured care in the NHS. Still, as stressed in the Section 'Stylized Facts and Preliminary Insights,' one of the reasons why individuals buy DPHI is because they are deterred by the NHS waiting lists to prompt health care. An NHS with waiting lists is thus offering incomplete health care provision just as a less-than-full coverage insurance contract is. Consequently, all individuals face incomplete health care provision at the NHS and, additionally, low-risk ones face incomplete insurance coverage at the private market due to adverse selection. Therefore, also under DPHI there are individuals never fully insured even if they are willing to pay for duplicate insurance.

Empirical evidence of adverse selection is tricky because its effects may be confounded with others (see the Section Empirical Evidence of Uncertainty and Informational Problems: Who Buys Duplicate Private Health Insurance?). Still, if adverse selection alone would be present in the private market, it would be expected to find empirical evidence that some individuals (high-risk ones) are fully insured at expensive prices and others (low-risk ones) only partially insured at lower prices. To assess adverse selection's unfavorable effects and its relative importance, it is important to identify which health care services are most affected by waiting lists or not provided at all publicly, and to understand which individuals suffer more from adverse selection.

Risk Selection

Another situation that should not be wrongly identified with adverse selection is when insurers select insurees or deny insurance on the basis of individual observable characteristics correlated to risk. For example, PHI is usually denied to individuals 65 years and older because being older is on average associated with higher medical expenses. Still, some of these individuals may be at higher risk of disease than others, which is then not observable. Hence even if insurance would not been denied, adverse selection would arise among the older.

In a duplicate insurance system individuals who are denied insurance coverage are nevertheless entitled to health care at the NHS. They may have to face long waiting times but in principle prompt care is guaranteed for emergencies and urgent situations. Yet, if they wish to buy duplicate insurance they are not able to do it. The situation is however better than in the case in which individuals have to pay the full price of health care if not insured, as it happens when the insurance market is complementary to public provision or in the absence of universal coverage.

Two arguments are commonly used to explain why risk selection exists and who might be denied insurance. First, according to theory, insurers either provide contracts based on true risks or provide different contracts to separate low- and high-risks. However, these are costly procedures which the insurers may not be willing to assume. Second, the empirical literature shows that the variance of health care costs increases with the mean, so that expenditures for high-risk groups are less predictable. Hence, insurers may prefer to provide contracts based on broad categories (age and sex) and then reject high-risk groups directly or indirectly.

In most cases selection is clearly stated in insurance contracts, for example, through an age criterion or through exclusion of benefits from preexisting conditions. Another more subtle form of selection derives from most contracts being short-term (usually 1 year), which enables insurers to modify conditions (or even avoiding renewal, even if this is usually forbidden) once a serious disease has been diagnosed. Contrasting the characteristics of the population receiving health care at the NHS with those relying on DPHI as well can also provide an indication of what constitutes a source of insurance denial. If insurance denial is a fact then there must be empirical evidence that NHS users share some characteristics that DPHI users do not. Still, results should be read with caution because asymmetries may be also due to differences in preferences regarding insurance or other issues.

Propitious Selection

'Propitious selection' in the insurance market occurs when low-risk individuals buy more insurance than high-risk ones. One possible explanation relates to risk aversion, that is, people with a higher risk concern would tend to be more cautious, hence more likely to purchase insurance. As they are more cautious, they also adopt more preventive behavior and are less prone to health hazards. Note that this is not a problem *per se*: It is just a consequence driven from the fact that individuals who have a stronger preference for being insured buy more insurance.

Propitious selection may also arise because high-risk individuals underestimate their risk, prompting them to purchase less insurance. A higher willingness to pay among wealthier persons could also explain propitious selection if wealth and health risk are negatively correlated, as it is usually observed.

The empirical testing of propitious selection is not trivial. On the one hand, we would expect to find evidence that those buying DPHI or higher coverage contracts are less prone to health accidents, and hence use less curative health care. On the other hand, if propitious selection is driven by preventive behavior, those who buy health insurance would use relatively more diagnostic tests and preventive health care. Hence empirical analysis requires reliable information on individuals' health conditions, behavioral, and environmental risks, which are generally difficult to obtain.

Moral Hazard

Moral hazard occurs when an individual facing risk changes one's behavior depending on whether or not one is insured. For example, dental care insurance may lead individuals to be less cautious about their mouth hygiene, which may be reflected in a higher probability of caries (*ex ante* moral hazard). Or, in a case a tooth is removed individuals may decide toward a dental implant only in case they are insured (*ex post* moral hazard).

To induce individuals to exert some effort in the limitation of damages (*ex ante* moral hazard) or to restrain medical care use (*ex post* moral hazard), insurance contracts typically impose the individual part of the incurred cost by making use of deductibles and/or coinsurance rates. This means that the consequence of moral hazard is partial insurance (incomplete coverage), just as in the case of adverse selection.

Because moral hazard consists of a reaction to insurance, it is present under an NHS just as in the private market, for the same level of insurance coverage. Still, the two sectors deal with moral hazard in very different ways. The NHS deals with it by rationing health care, for example, through waiting lists, gatekeeping, and limiting individuals' choices. Actually delayed access to health care is a sort of limited insurance coverage and can thus give incentives to prevention and consequent limitation of damages (*ex ante* moral hazard) or restrain individual use of medical care (*ex post* moral hazard). Similarly, in the private market, individuals are typically not fully insured (due to deductibles and coinsurance rates) and the same mechanism applies. The extent to which each sector is affected by moral hazard depends therefore on the importance of incomplete coverage of each sector.

Curiously, a duplicate insurance system may deal well with moral hazard. Indeed, if on the one hand individuals are twice insured, on the other hand, NHS health care and private insurance are mutually exclusive. In other words, as one owns an insurance policy for a given health event, if a patient goes to the NHS, the insurance coverage is not claimed and vice versa. In principle, the patient faces two sectors with incomplete coverage that deal better or worse with moral hazard. In contrast, complementary insurance destroys any incentives to promote prevention or deter unneeded care that may exist in the public sector because the individual is usually fully insured (because privately the individual is insured for the out-of-pocket payment).

To conclude concerning the presence of moral hazard: it is essential to test whether insurance contracts offering more coverage are associated with greater use of health care. Note that even though very different in their causes adverse selection and moral hazard lead exactly to the same observed market effect: Insurance contracts with less coverage are associated to individuals using less health care. As is discussed in the Section Empirical Evidence of Uncertainty and Informational Problems: Who Buys Duplicate Private Health Insurance?, it is not always easy to distinguish the two effects.

Supplier-Induced Demand and Dual Practice

We now turn to the implications of uncertainty regarding the effect of health care on patients. The physician is obviously the most informed and can use this information for his own benefit by increasing health care acts beyond what is adequate and necessary. Obviously physician behavior depends very much on the incentives faced. As a point of fact, supplier-induced demand (SID) is to be expected in the private market where physicians are usually paid by fee for service. Yet, insurance companies have been trying to redesign physicians' incentives to restrain such practice.

SID should be common to any health care system relying partially or fully in the private market. In this respect, there is no reason to think that a duplicate insurance system is more prone to SID than other systems are. After all, the determinant is the size of the private market and the incentives imposed by insurance companies. Still, in a duplicate insurance system an additional effect comes into action because physicians are often allowed dual practice, i.e., they provide health care both at the NHS and at the private market. There is general awareness that physicians deviate patients toward their private practice where they benefit from additional rents for the health care provided and can induce demand for private benefit. Additionally, SID can easily be transformed in a common and cultural practice because the same physicians act publicly and privately.

Finally, it is important to note that also in an NHS, SID may exist. In an NHS, physicians are usually paid on the basis of a fixed salary, but they may induce health care consumption due to the practice of defensive medicine with a view to avoiding malpractice liability.

It is a challenge to identify empirical evidence of SID. A strategy of identification would be to contrast health care provided across physicians for the same health condition, except that SID can be the norm. For example, in some countries, patients are given another appointment once the results of diagnostic tests are known whereas in others, results and accordingly prescription are given by postal mail or telephone (except for abnormal cases). Also, physicians may be members of a specific culture of medical practice that pushes them toward excess health care. Nonetheless, a duplicate health insurance system allows for the contrast between private and NHS medical practice where differences would be (partially) explained by SID.

Empirical Evidence of Uncertainty and Informational Problems: Who Buys Duplicate Private Health Insurance?

Testing for empirical evidence of uncertainty and informational problems in insurance markets is not easy because

Table 1 Empirical strategies and challenges in predicting uncertainty and informational problems

Analyzed concept	*Empirical strategies and challenges*
High-risk individuals are relatively less insured:	
Risk selection	● Not present in the NHS, probably present at the DPHI. ● 'Strategy': Identify the characteristics of individuals, such as age or declared diseases that prevent them from buying DPHI. ● 'Challenge': Differentiate risk selection from revealed preferences and propitious selection. Some characteristics may be correlated with risk-loving behavior, for example.
Propitious selection	● Not present in the NHS, probably present at the DPHI. ● 'Strategy': First, identify negative correlation between risk and insurance coverage. Second, identify reason of propitious selection: (1) Risk-aversion/preventive; (2) underestimation of risk by high-risk individuals; (3) higher willingness to pay of wealthier (and healthier) individuals. If (1) then should be found that those buying DPHI have less health hazards but tend to use more preventive medical care or adopt less risky health habits. If (2) then should be found more health hazards than *ex ante* predicted relatively more for high-risk individuals then for low-risk ones. If (3) then should be found that wealthier individuals should buy relatively more DPHI and have less health hazards. ● 'Challenge': Proxy for preferences; differentiate propitious selection from risk selection.
High-risk individuals are relatively more insured*:*	
Adverse selection	● Not present in the NHS, probably present at the DPHI. ● 'Strategy': Conclude whether in a DPHI context higher risk individuals buy insurance contracts with higher coverage and relatively more expensive than those bought by low-risk individuals. ● 'Challenge': Find a good proxy for risk; differentiate adverse selection from moral hazard.
Moral hazard	● Probably present both at the NHS and DPHI resulting in overconsumption of health care. ● 'Strategy': Identify change in preventive and curative health care use due to insurance. ● 'Challenge': Differentiate from adverse selection.
Supplier-induced demand	● Probably present at the NHS (defensive medicine) and DPHI (rent seeking) resulting in overconsumption of health care. ● 'Strategy': Identify different medical practices across competition contexts. ● 'Challenge': Differentiate SID from cultural medical practice.

several forces can be confounded. Yet, it is important to precisely identify which problems are present because each raises different equity and efficiency concerns and leads to different policy recommendations.

Table 1 summarizes the empirical prediction of each of the effects discussed in the Section Theoretical Concerns: Uncertainty and Information and helps in following the upcoming discussion. One should start to understand whether insurance coverage depends on the type of risk and then follow by inferring which mechanism is at the foundation of such outcome. If it is observed that high-risk individuals buy less DPHI than low-risk individuals it can be due to either risk selection or propitious selection. The empirical challenge consists precisely in identifying which of the two effects is in place because although risk selection and some causes of propitious selection may call for government intervention, that is less the case if propitious selection is due to more risk-averse individuals tending to buy more insurance – after all, individuals just act according to their own preferences.

If however, it is observed that high-risk individuals are relatively more insured, adverse selection may be at play and instead, it is low-risk individuals who are denied insurance. Still the measure of risk may be inconclusive. Indeed, in practice, it may just be observed that higher coverage insurance contracts are associated with more health care expenditures. This can be due to not only adverse selection but also due to moral hazard. In other terms, people with private insurance have higher expenditures either because high-risk individuals are more likely to purchase high-coverage contracts (adverse selection) or because people with higher coverage have lower incentives to parsimonious health care use (moral hazard).

A somewhat orthogonal problem to the risk issue is to what extent health care use is induced beyond what is adequate because physicians target higher profits. If this is the case there is SID. Incentives to induce demand may be related, for example, to generous fee for service reimbursement schemes under DPHI, or to very low copayments that ease the inducement process. Hence evidence on moral hazard may indeed be overestimated if the inducement of demand effect is not controlled for. The empirical strategy consists in identifying different medical practices across competition contexts but it is obviously a challenge to distinguish SID from cultural medical practice. Additionally, different medical practices may as well be explained by distinctive regional administrations or governances.

Although disentangling empirically the informational problems is challenging, some research has led to interesting results in the DPHI context. Confirming the seminal results of the Rand experiment, some UK studies have consistently confirmed a decrease in drug consumption which follows an increase in the copayment supporting the evidence of *ex post* moral hazard. Olivella and Vera-Hernández (2013) use data of the British Household Panel Survey for the period 1996–2007 to test empirical evidence of asymmetric information and distinguish the different effects at play. They contrast health care use of individuals having bought PHI with that of those who obtained PHI from their employer as a fringe benefit, using three measures of health care use: (1) hospitalization in a fully privately funded hospital, (2) hospitalization in publicly funded hospital, and (3) GP visits. Their reasoning is as follows. People with individual PHI are those who explicitly decided to buy it, and are called

'deciders'; the other group includes people who obtained PHI form their employer, i.e., they did not decide to buy it and are called the 'nondeciders.' Both deciders' and nondeciders' insurance contracts are equally affected by moral hazard and thus differences across the two groups cannot be due to moral hazard. Instead, if deciders use more health care services than the nondeciders, then adverse selection prevails (deciders use more care because they are in worse health, hence high risks are more likely to buy PHI). In contrast, if deciders use less health care services, propitious selection or risk selection prevails (deciders use less care because they enjoy a better health, hence low risks are more likely to buy PHI). The authors find that individuals having decided to buy a PHI use more health care irrespectively of the measure used, concluding on the existence of adverse selection.

In contrast with this latter finding, Doiron *et al.* (2008) suggest evidence of propitious selection in DPHI, using Australian data. They find that healthier individuals purchase relatively more DPHI. In this case, the difficulty is then to distinguish this effect from risk selection by private insurers, which would lead to a similar result. To do so, they observe that people engaging in risk-taking behaviors (smoking, drinking, and lack of exercise) demand less private insurance coverage. Thus the authors put forward that relatively more risk-averse individuals are more likely to buy DPHI. Additionally, the assumption that insurers deny insurance to high-risk individuals seems partly discarded by the higher insurance coverage among people with long-term conditions. These two studies, in different contexts, thus show opposite results. If an earlier literature is considerd, findings are more sustaining that DPHI is associated to a healthier condition, although these studies do not try to explain the correlation.

The empirical evidence of SID has long been and remains a subject of controversy among health economists. Recent natural experiments however show that substantial variations in copayments produce effects that are similar to those observed in the Rand experiment, whose design made the occurrence of SID very unlikely. Hence observed *ex post* moral hazard is certainly a more plausible explanation than SID for higher health care use under DPHI.

Other empirical issues related to DPHI deserve also to be mentioned, even if less related to the theoretical problems presented in the Section Theoretical Concerns: Uncertainty and Information. To begin with, the decision to buy DPHI cannot be analyzed without considering what happens in the NHS. The demand for private insurance depends on the perceived quality in both public and private sectors. One of the most popular indicators of NHS quality is waiting lists and waiting times, which are easy to obtain and to which people are usually highly sensitive. There is evidence that long waiting lists, expected waiting times, or more generally the perceived quality gap between the NHS and private provision are determinants for people to insure privately. These findings confirm empirically that responsiveness is a relevant factor for the emergence of DPHI.

Finally, most studies confirm the strong relationship between private insurance and high socioeconomic status, in particular, income and education. Supplemental or DPHI is without doubt a normal good, which is more purchased by richer people. Income is hence obviously one of the main determinants of the demand for PHI. This last finding poses crucial questions from a welfare viewpoint because then DPHI may contribute to inequity in health. If DPHI only allows for luxurious services unrelated to quality of clinical procedures (better amenities, faster care, etc.), this may not be such a relevant problem. However, if double coverage allows access to better care that unsatisfactory NHS cannot offer, this is a serious social concern. The higher use of physician services under double coverage would sustain the latter assumption. This conclusion would be reinforced if private insurers, through higher financial capacities, are able to attract better doctors under a dual practice regime. Unfortunately, to our best knowledge, no study has assessed the impact of DPHI on quality of care (probably because quality is quite difficult to measure). The higher health care use under DPHI also questions the efficiency of duplication in a context of scarce resources.

Political and Financial Sustainability of a DHPI Health Sector

So far, we have examined individual decisions with regard to purchasing private insurance and consumption of health care services in a context of double coverage. In this section, the potential impact of double coverage is discussed at an aggregate level, at the health system, or country level. What could explain the consensus in favor of double coverage? Does the existence of DPHI threaten the political sustainability of the NHS? What is the impact of double coverage on health care expenditures? Does it impose a higher financial burden on the NHS, or does it alleviate this burden?

First, political sustainability is considered. Suppose, as confirmed in the empirical literature, that richer people are more likely to purchase private insurance. These people will thus be paying higher taxes (assuming nonregressive taxation, as it is usually the case) without enjoying one of its major benefits, namely public health care provision through the NHS. Hence they may vote against the existence of an NHS, or at least against paying high taxes to finance it. As low-income people may also want to avoid large contributions and thus prefer lower level of health care provision, in the end the support for high public provision will decrease. However, three factors are likely to modify this finding of public under-provision:

- Opinion polls show the existence of a health-specific altruism and concern for equity in health, hence even richer people may support public provision of health care to the poor.
- Poor people are in most countries exempt from taxes and copayments, so that they favor a higher level of publicly-provided care.
- There is no perfect correlation between wealth and health, hence rich people experiencing poor health may also favor public care because its price will be lower than that of private insurance, even in a context of progressive taxation.

To conclude, the majority will vote for a lower level of public provision but would not choose zero public care. In a nutshell, this theory justifies the preference for a system with double coverage, although with a lower public provision

than the one in the absence of a private sector. To our best knowledge, political questions around double coverage have never received empirical validation. The only evidence so far is that people tend to favor increased public spending after it has decreased and the reverse after it has increased (Tuohy *et al.*, 2004). This result may emphasize the consensus for a target level of public expenditures compensated by private ones.

As regards financial consequences and economic sustainability, it is often put forward that DPHI may alleviate the burden on the public sector through providing care to a share of the population. This was one of the major motivations for the governments that favored the emergence of DPHI. However, the impact on total health expenditures depends on many factors. First, it depends on whether private providers are able to offer care at a lower cost than the one they would have experienced in the public sector, which is not that clear. Additionally, private insurers generally reimburse physicians through fee for service whereas salary payments have traditionally characterized NHS-type systems. Therefore physicians are more likely to tend to induce demand in the private sector. Second, double coverage is usually accompanied by dual practice, that is, physicians combining public and private practice, whose effects on health care expenditures are difficult to assess. However, dual practice enables doctors to earn additional revenue in the private sector allowing public institutions to pay lower wages, whereas attracting good doctors. Physicians in the public sector may also provide better care to build a reputation for their private activity, but perhaps also overtreat or induce demand. Physicians may also divert resources and patients from the public sector to their private practices. They may also 'import' more resource-consuming practice style of the private sector to their public activity. Finally, it is to be noted that evidence suggests a higher health care use for people with double coverage, in Portugal, Spain, Italy, Ireland, and the UK. In this regard, see **Box 2** – Opting-out as a solution for the duplicate insurance problems?

Box 2 Opting-out as a solution for the duplicate insurance problems?

An often argued solution for the adverse effects of DPHI is the opting-out system. Under opting out, patients buying private insurance are not entitled to NHS care or have to pay the full price for using it.

In Portugal, the first experience of opting out concerned the employees of Portugal Telecom (PT), the largest telecommunication company of the country. PT employees and retirees were enrolled in the PT-ACS (PT-Health Care Services Association) health insurance scheme. In 1998, the State paid PT-ACS a per capita value for its ensured individuals and PT-ACS became fully responsible for their health coverage. For services not provided by private facilities, patients were still entitled to use NHS health care but PT-ACS had to pay its full price.

This agreement however came to an end in 2008 and opting out failed as a solution to alleviate the NHS burden. Indeed the per capita value previously agreed came to be insufficient to cover health care expenditures. In particular, PT-ACS faced growing expenditures due to an increasingly larger share of retirees. Also, private facilities in Portugal did not provide care for a complete range of services so that PT-ACS insured individuals had very often to resort to the NHS.

In a nutshell, public–private interactions pass through a series of complex mechanisms whose final consequences are difficult to assess. A correlation between public and private health care expenditures is generally observed, but it can hardly be concluded that the former is driven by the latter given that both are influenced by the same determinants. What is granted is that health care expenditures in countries with double coverage have increased at a path that is common to most OECD countries, and its efficiency in achieving good population health is comparable too. Some studies report however that an increase in the private share of total health care expenditures is associated with a subsequent decline in public health spending as a proportion of total public expenditure. This would tend to sustain the hypothesis of the private sector alleviating the burden of the public sector in detriment of other theoretical assumptions. Yet studies consistently show that double coverage is associated with a higher use of health care services.

Glossary

Appearance, pulse, grimace, activity, respiration (APGAR) score A measure of infant health using a five component assessment completed immediately after birth.
Cross-sectional data Data observed for many subjects at one particular point in time.
Dynamic complementarity The notion that skills produced in one period increase the productivity of investment in later periods.
Ectopic pregnancy Implantation of the embryo outside of the uterus, usually resulting in a nonviable pregnancy and great health risk to the mother.
Elasticity of substitution A summary of how well one factor can be substituted for another in production.
Fixed effect model A type of statistical model intended to deal with omitted variables bias by using a dataset collected on multiple entities (e.g., individuals) over multiple time periods. To isolate the effect of some factor(s), the statistical model uses variation within entities over time.
Omitted variables bias Over- or underestimation of the impact of one variable on another that is caused by leaving out one or more important variables from the estimated model.
PROGRESA Income transfer program for the poor in Mexico.
Randomized-controlled trial A scientific experiment conducted to test the effect of an intervention by randomly assigning participants to a treatment and control group. Differences between the treatment and control group participants are interpreted as the causal effect of the intervention.
Regression discontinuity design A statistical technique used to address issues of omitted variables bias where assignment to treatment changes discretely based on some characteristic or set of characteristics. To estimate the effect of the treatment, groups of treated and untreated individuals with similar characteristics are compared. For example, college scholarships are frequently based on grade point averages. To estimate the effect of a scholarship, outcomes for individuals who had grade point averages that made them just eligible for the scholarship are then contrasted with the outcomes for individuals who had grade point averages that made them just ineligible for the scholarship.
Self-productivity The notion that skills acquired in one period persist into other periods and that higher levels of skills in one period can increase the amount of skills acquired in later periods.
Quasi-experiment or natural experiment A study where some entities (e.g., individuals) are exposed to an intervention outside of the researcher's control.

Introduction

Today an understanding of health is not complete without considering the role of *in utero* and intergenerational influences. The recent popularity of the fetal origins hypothesis, asserting that early life influences through the fetal environment (e.g., nutritional deprivation) have latent long-run effects on health, has nudged economists to think about the production of health beginning much earlier in life. This hypothesis, complemented with economic theories of parental investment characterizes how important early-life factors can be in explaining adult health.

The goal of this article is to give the reader a framework and an understanding of the strength of *in utero* and intergenerational influences. To provide a concrete structure to interpret these effects, the authors first outline a multiperiod investment model akin to the work of James Heckman that translates early life circumstances to health in adulthood. With such a mathematical model, one can be very specific about the roles of the *in utero* and intergenerational environments. Before discussing the various inputs into the health production function, the authors consider possible measures of health *in utero* and at birth. The bulk of the article then discusses how various inputs (e.g., maternal nutrition, sickness, maternal age, maternal education, family income, employment, maternal health behaviors, and environmental exposure) impact health using the Heckman investment model as a guide.

Theoretical Framework

Economic Framework for the Link between *In Utero* and Early Life Conditions and Later Health

Under traditional economic models of health, there is little room for early life and *in utero* events to impact later health. More recently developed models, however, demonstrate the importance of investment and events in early life for health production. Models such as Heckman (2007) provide the mathematical structure to understand how early parental

investment and initial endowments (e.g., health at birth) may affect adult health. These models invoke two important features: self-productivity and dynamic complementarity. Self-productivity embodies the notion that skills acquired in one period persist into other periods, and that higher levels of skills in one period can increase the amount of skills acquired in a later period. Dynamic complementarities embrace the idea that capabilities acquired in one period augment the productivity of investment in the future.

Consider a simplified model with two periods of childhood investment and a constant elasticity of substitution production function as Heckman (2007) does:

$$\boldsymbol{h} = f(b, \theta, [\gamma I_1^{\varphi} + (1-\gamma) I_2^{\varphi}]^{\frac{1}{\varphi}}) \qquad [1]$$

where $\boldsymbol{h}$ is a vector of adult capabilities in period 3 (adulthood), b are parental capabilities, θ is the initial endowment, I_t is investment in period t, $\frac{1}{1-\varphi}$ is the elasticity of substitution of inputs across periods, and γ represents the net effect of I_1 on $\boldsymbol{h}$ (the 'capability multiplier'). One can think of $\boldsymbol{h}$ as including health and other capabilities such as education in adulthood. Investments can include nutrition and medical care in childhood. Parental characteristics such as income and education influence the choice of inputs (i.e., I_1 and I_2), either by shifting tastes, acting as a constraint on the ability to purchase inputs, or changing θ.

Self-productivity implies that $\frac{\partial h}{\partial I_t} > 0$ for $t = 1,2$; that is, investment made in prior periods raises adult capabilities. Vaccinations would be one such example; the polio vaccine taken as a child nearly assures that as adult, an individual will not impeded by polio. Under dynamic complementarities, the function $\frac{\partial^2 h}{\partial \theta \partial I_t} > 0$, meaning that the effect of investment is an increasing function of capabilities. As an example of dynamic complementarities, consider an early childhood investment made in period 1 (e.g., Head Start). This investment may augment childhood capabilities in period 2, which then will make formal schooling following Head Start more productive.

Under some simplifying assumptions, this general model can generate some useful insights about the possible role of early and *in utero* investments. First, the larger the capability multiplier (i.e., γ) the higher the optimal ratio of early to late investment. Second, if early and late investments are perfect substitutes, disadvantage in period 1 can always be overcome with later investment. As the degree of substitution approaches ∞, optimal investment in period 1 is equal to optimal investment in period 2. Third, there is a tradeoff between investing in period 1 and investing in period 2. Owing to discounting, investment in period 2 is cheaper than investment of the same amount in period 1. This consideration pushes investment to period 2, but the productivity of investment in period 1 (i.e., the size of γ) encourages investment in period 1.

This model can explain why early life investments, even if they are small in magnitude, can have effects on more long-run outcomes. Moreover, although this article discusses the importance of early and *in utero* conditions collectively, it may be important to distinguish between these even further. Specifically, *in utero* investments, because of the extended period allowed for dynamic complementarities, may be more important than early childhood investments.

Fetal Origins Hypothesis – An Epidemiological Explanation for the Possible Connection between *In Utero* Conditions and Later Outcomes

The biological foundation for linking *in utero* conditions to later life outcomes is the fetal origins hypothesis. This hypothesis, championed by British physician David Barker, asserts that nutrient deprivation at the beginning of life can raise adult chronic disease risk. Looking across areas in England, Barker noted that infant mortality rates were correlated with later mortality rates of the same cohorts. The biological underpinnings of the fetal origins hypothesis suggest that nutrition during pregnancy affects fetal development. If a fetus is deprived of nutrients *in utero*, available nutrients are diverted for neurological development while the development of nonneurological systems are sacrificed. This tradeoff manifests itself later in life in the form of higher hypertension risk and increased insulin sensitivity.

Although the hypothesis has gained some acceptance, it is still highly disputed – partially because solid empirical support is difficult to come by. For one, the data demands of testing such a hypothesis require data on both early life conditions and later outcomes. This is an arduous demand given that the collection of high quality data in many countries is only a recent phenomenon. Probably the most foreboding critique of this hypothesis is that it was originally based on observational data and thus, is susceptible to typical omitted variables bias issues. However, it should be noted that animal studies (excluding humans) where the fetal environment is more easily manipulable generally show strong support of the fetal origins hypothesis.

The toolkit of economists is well-suited to addressing these two shortcomings of the public health and medical literature on this topic. Economists have used clever quasi-experimental strategies (many of which will be discussed later in this article) to identify causal relationships between early life conditions and later outcomes. A subset of these natural experiments include the 1918 and 1957 flu epidemics, maternal fasting during Ramadan, variation in malaria prevalence either due to seasonal variation or eradication campaigns, and the implementation of the federal Food Stamps program.

The application of the fetal origins hypothesis in the economics literature is broad. For instance, it is the most common explanation for the association between birth weight, a measure of *in utero* nutrition, and educational attainment, adult economic outcomes, and adult health outcomes. Some might argue that this is an incorrect interpretation of the fetal origins hypothesis because the hypothesis is specifically about how *in utero* circumstances have a latent impact which is only expressed in late adulthood, not in early adulthood.

It should be noted that although the fetal origins hypothesis provides a biological basis for the relationship between the *in utero* environment and subsequent outcomes, estimates of the relationship between early life circumstances and later outcomes will combine both the biological effect and the effects of any ensuing investment decisions. Several studies have been interested in whether investment responses are compensatory or reinforcing, but due to the difficulty measuring intermediate inputs the literature has not reached a consensus regarding which type of investment behavior is more predominant.

Measuring *In Utero* Health and Later Health

Of critical importance in the *in utero* and early life health literature is the measurement of health. Measurement of *in utero* health without intervention is nearly impossible. However, via blood samples, measurements of the maternal environment can be made (e.g., cortisol levels indicating stress). But such data are not part of standard datasets commonly used by economists.

As an alternative measure of *in utero* health, researchers frequently use measures of health at the time of birth. These include birth weight, appearance, pulse, grimace, activity, respiration (APGAR) score, length of gestation, and infant mortality. Most of these measures are likely a reflection of the effects of the *in utero* environment rather than the circumstances after birth. Although shifts in many of these outcomes (e.g., birth weight) may not be so meaningful, economists frequently are interested in the tails of the distribution of these outcomes. Low birth weight (<2500 g), very low birth weight (<1500 g), and premature birth (<37 weeks of gestation) are focal outcomes.

In the past 10 years, health economists have debated whether birth weight is an adequate measure of *in utero* health. Although the measurement of birth weight is easy, by itself, birth weight is not necessarily reflective of any health issues. Historically, interest in this measure by researchers is mainly predicated on the strong birth weight and infant mortality correlation. But such correlation does not imply causation. As an innovative approach to control for possibly confounding factors, researchers have compared birth weight differences between twins and have related those differences to within-twin-pair differences in infant mortality. A weaker birth weight and infant mortality relationship emerges from this approach. Nevertheless, the importance of birth weight as a leading health indicator has been reaffirmed with the many recent studies mapping a connection between birth weight and longer run outcomes such as educational attainment, wages, and rates of disability as adults.

Measuring early childhood health is equally difficult as measuring *in utero* health. Easily obtained health measures such as childhood mortality are rare, making it challenging to find effects of interventions on mortality. The most common chronic conditions in childhood are asthma, hay fever, and bronchitis, but they inflict less than 15% of children in a particular year. Aggregating these conditions to derive a single index measure of health is challenging because it is unclear how to combine these outcomes sensibly. For example, an outcome of the number of chronic conditions a child has would give equal weight to epilepsy as it does to bronchitis.

The Intergenerational Transmission of Health

The model outlined by eqn [1] allows for an intergenerational transmission of health via several different mechanisms. First, parental attributes can affect a child's health directly through changes in b, parental capabilities. Second, intergenerational relationships can arise because of genetics, θ in the model. Third, parental capabilities will likely affect investments represented by I_1 and I_2. Distinguishing between these three types of mechanisms is not possible empirically.

Arguably the best measures of the intergenerational correlation in health are those relating to birth weight. The correlation in birth weight across generations is typically smaller in the USA than the intergenerational correlation in wages. In a study using matched children–mother data from California, the likelihood that children were low birth weight increased by 50% if their mothers were low birth weight. These intergenerational relationships are slightly stronger among low socioeconomic status (SES) mothers.

Data on sibling mothers can help to understand how much of the intergenerational transmission in birth weight is genetic versus behavioral. Traditionally this is done by assuming a data-generating process where a child's birth weight is assumed to be an additively separable linear function of mother's birth weight and a mother's family fixed effect. The fixed effect is intended to capture genetic factors that mothers who are siblings share in common, but it also captures anything else the sibling mothers share. This assumed relationship is rather restrictive as it does not allow for a gene and environment interaction. Interestingly, based on nontwin mother sibling comparisons, family background characteristics do not explain the intergenerational correlation in birth weight. But some argue that these siblings are not nearly enough alike. Thus, other studies focus on twin sibling comparisons. Unlike in the case of sibling mothers, some of the intergenerational birth weight relation is explained by family background. The effect of mother's birth weight on child's birth weight in models that control for time-invariant features of the mother's family is approximately half the size of that from models that do not, suggesting a strong possible role for genetics.

This article continues by investigating maternal factors (e.g., income, nutrition) and other influences (e.g., environment, health care) that may explain these intergenerational correlations in health.

Factors Affecting *In Utero* and Later Health

Maternal Sickness and Stress

A natural empirical test of the fetal origins hypothesis (or the effect of the *in utero* environment more generally) is to examine influences on the maternal environment during pregnancy. These influences include maternal sickness, maternal stress, and maternal nutrition. The authors reserve discussion of maternal nutrition until later as the literature is more expansive on that topic. In general, it is difficult to isolate the pure effect of these factors because it is nearly impossible to conceive of a quasi-experiment that only manipulates sickness or stress. For example, terrorist attacks such as 11 September have been used to understand the effect of maternal stress, but one might imagine that these attacks could also have economic effects.

Of the maternal influences, maternal sickness is considered to be one of the most important. The 1918 flu epidemic provided a unique opportunity to examine the effect of prenatal flu exposure on long-run outcomes. This flu spread

rapidly and suddenly; 25 million people in the USA contracted the virus. Cohorts *in utero* at the time of the flu exhibited diminished health and economic outcomes as adults (i.e., higher disability rates, lower education attainment, and reduced wages). For the more recent Asian flu pandemic of 1957, it is possible to follow the effects of the flu across the lifecycle. In particular, unlike for the 1918 flu, one can test whether flu exposure is related to reduced birth weight, one of the underpinnings of the fetal origins hypothesis. Overall, the flu does not impact birth outcomes. However, these effects are quite heterogenous. The children born to smoking mothers or shorter mothers exhibit lower birth weights as a result of the flu. Effects on cognitive outcomes are present overall, not confined to a particular subgroup. Exposure to malaria *in utero* and during early childhood also has important consequences for long-run outcomes. Although today malaria is an issue in developing countries, in the early 20th century rates of malaria in the American South were comparable to those in developing world today. Exposed cohorts have lower educational attainment and higher rates of poverty.

Relative to maternal sickness, understanding the effect of maternal stress is more challenging. Measurement of maternal stress is typically indirect because measurement of stress is difficult. As a result, studies of the maternal stress often focus on events that are presumed to affect maternal stress. Terrorist attacks such as 11 September and armed conflict in Israel are two such examples. For these events, because they are more recent, evidence on the long-run impacts is limited. However, the stress-provoking events have substantial short-run effects on the incidence of low birth weight and prematurity. As an alternative to this case study approach, some research has measured maternal stress through cortisol levels directly. Sibling comparisons – effectively comparing maternal cortisol levels across births to the same mother and relating these within-family differences to differences in long-run outcomes are used. These cortisol differences have consequences for cognitive, educational, and health outcomes.

Overall, this literature evaluates the effect of negative shocks to the maternal environment. As such, these research findings may be less interesting for policymakers who are interested in deciding which policies are best to improve the fetal environment. Indeed more research is needed on positive shocks.

Maternal Characteristics

Maternal attributes such as education and age can impact early life health either directly or indirectly through the choice of familial inputs or endowments. For example, a mother's education may affect her knowledge regarding the health impacts of maternal smoking. However, in the presence of assortative mating, her education may influence the education of the mate she chooses.

There is a recent growing interest in the impact of maternal education within economics. This is in part due to an expanding focus on the nonwage effects of human capital. Moreover, maternal education is one of the strongest predictors of infant health. Based on USA data, an extra year of schooling reduces the rate of low birth weight by 10%. These effects are surprisingly linear, implying that the effect of a year of high school education is roughly equal to the effect of a year of college education.

Of course, these correlations do not necessarily imply that there is a causal relationship between maternal education and infant health. Omitted variables bias is a concern, particularly because maternal education is positively related to other attributes such as family background that might improve infant health.

The recent economics literature has made great strides in identifying the causal effect of maternal education. Two of the more frequently exploited quasi-experiments are the construction of new schools and the expansion of compulsory schooling. In the USA, the expansion of higher education through the building of new universities and colleges between 1940 and 1990 led to reductions in the rates of prematurity and low birth weight. Outside of the USA, the construction of new schools in areas without schools has resulted in similar improvements in infant health. When interpreting these estimates, however, one should think about these two settings as possibly identifying different effects of education in the case that there are nonlinear effects of maternal education.

Compulsory schooling reforms in the twentieth century led cohorts born close to one another to have different educational requirements. These compulsory schooling laws dictate when individuals can legally drop out of school. In countries where many individuals drop out at the minimum schooling age and the compulsory schooling laws are enforced, increases in the compulsory schooling age are useful instruments for maternal education. In the USA, the size of the population affected by compulsory schooling reforms is rather small. In contrast, in Britain, at least historically, most individuals drop out of school at the minimum schooling age. Thus, one can use regression discontinuity techniques where contrasts are made between individuals proximate in date of birth who might be otherwise identical except for their level of schooling. The British compulsory reforms generally point to no effects of maternal education on infant health.

The discussed quasi-experiments increase education by extending the end of schooling. Alternatively, an increase in educational attainment could be achieved by reducing the age at school entry. Increases in schooling via augmenting either the beginning or end of schooling could potentially estimate different effects of education. As for the latter, there could be a mechanical effect of extra schooling. Being in school longer may act as an incarceration effect, reducing rates of sexual activity and thus, result in delayed fertility.

This conceptual difference may be an explanation for the difference between the conclusions reached from using school entry policies and other studies. School entry policies impact the start of schooling. Despite their differences in acquired schooling, comparisons of individuals born before and after school entry dates (i.e., the date by which a child must have reached age 5 to enter school) show no evidence of effects of maternal education on infant health.

One difficulty often neglected in this literature is that an instrument for maternal education may affect both fertility and infant health. In the case that there are fertility effects of education, the measured effect of maternal education on infant health suffers from a selection problem.

Similar to that of maternal education, the effects of maternal age could be direct or indirect. Women at either end of the childbearing age spectrum experience worse infant health outcomes. Support of the biological effects of maternal age has been confirmed with animal studies, but maternal age may also influence the choice of prenatal and postnatal inputs. Women who give birth at earlier ages may not have the income or access to adequate medical care that older mothers do. Thus, the fact that maternal inputs vary with maternal age obfuscates the causal effect of maternal age. Specifically, women who give birth at younger ages are of lower SES than women who give birth at older ages. Thus, the adverse impacts of giving birth at a younger age may be overstated in the cross-section although the opposite is true for older ages.

The main empirical evidence of the effects of maternal age comes from sibling-based comparisons. That is, one can compare the outcomes of children born to the same mother. Such an approach effectively controls for fixed differences (e.g., SES which may be fixed) across mothers. However, to the extent that maternal age is correlated with other attributes that vary across a woman's lifecycle, these sibling contrasts will not capture solely the effect of maternal age. The sibling estimates do confirm the expected direction of biases – the effects of young maternal age are not as adverse as one would expect from correlations and the effects of advanced maternal age are worse than what the cross-sectional correlations imply.

Income

There is a well-documented, positive correlation between income and child health. Income is not a direct input into health production, thus the impact of parental income on child health must operate through either budgetary constraints or by shifting parental preferences. Higher-income parents can afford to purchase more food, health care, and safer environments for their children. Parental tastes for child health inputs may also vary by income, as evidenced by income gradients in smoking, drinking, and prenatal care.

The effect of income can operate through many channels and economists have distinguished between the effects of transitory and permanent income because each type may have a distinct impact on health outcomes. A temporary income shock (e.g., drought, famine, variation in rainfall) can have an immediate, one-time effect that lasts into adulthood, particularly if the shock occurs during gestation or just after birth. Permanent family income has a direct correlation with child health, with the impact of permanent income on health growing as children age into adulthood.

Disparities in health across socioeconomic groups are evident at birth. Low income children have a higher incidence of low birth weight, poorer reported health status, and higher rates of chronic conditions in childhood; however, there is little evidence that the impact of being low birth weight varies by SES. Researchers have documented an income–health gradient that steepens over time, indicating that the disparities in health between high and low income children grow with age. The hypothesized mechanism behind the steepening of the gradient is the prevalence of shocks experienced by low income children. Although a health shock does not differentially impact low income children, the higher frequency of shocks experienced by low income children causes the gap in health status to widen with age.

Temporary income shocks near the time of birth produce detectable effects on health in only some studies. Negative income shocks, such as the phylloxera infestation that destroyed 40% of French vineyards between 1863 and 1890 and the Dust Bowl phenomenon in the American Midwest during the 1930s have been found to have minimal effects on health in adulthood. Individuals born in a phylloxera-affected region were shorter than their unaffected peers; however, other measures of population health were unchanged. Health in old age was also unaffected for individuals born in the Dust Bowl era. Positive income shocks as measured by rainfall improved the adult health, height, and completed education of females in Indonesia who were less than 1 year old during the increase in rainfall. No results were found for men or for rainfall shocks while the child was *in utero*, suggesting that improved outcomes for women during high rainfall years may be related to gender bias in nutritional intake during infancy.

Means-tested government transfer programs provide an exogenous, measurable income shock to eligible families and have been shown to improve child health. Mexico's randomized-controlled experiment of PROGRESA provides cash transfers to households that comply with required behaviors including prenatal care, medical checkups, meeting nutritional guidelines, and attending educational meetings. Although it is not possible to separate the impact of the income transfer from the other features of the program, children born into the program have lower rates of illness than control families, are less likely to be anemic, and are slightly taller than control children. Furthermore, the impact of the program increased the longer the family received PROGRESA transfers. In the USA, it is unclear whether cash transfers to families participating in the Aid to Families with Dependent Children Program increased infant birth weight, whereas maternal participation in the Food Stamp Program (comparable to an income shock) increased the birth weight of infants at the low end of the birth weight distribution.

Macroeconomic conditions at the time of birth are related to both health at birth and long-run health and the relationship appears to have changed over time. Research using data on individuals born in the Netherlands between 1812 and 1912 finds that babies born in boom years have lower mortality rates later in life and live longer than babies born in recession years. More recent data suggest that the relationship between macroeconomic conditions and child health may have reversed. In the USA, a higher unemployment rate is associated with improvements in birth outcomes such as incidence of low birth weight and postneonatal mortality. During times of high unemployment, maternal health behaviors (smoking and drinking) improve and different types of women select into motherhood, which may explain the improved birth outcomes. Although aggregate birth outcomes improve during times of high unemployment, the impact of a job displacement for an individual family negatively impacts infant health. Comparing children in the same family, children born just after a parental job loss have lower birth weight than siblings born before the job loss.

Health Care

Prenatal care can improve infant health by identifying conditions that can harm health such as low weight gain and by providing health and nutrition information to the mother. Athough it is well documented by researchers that policy levers can improve rates of prenatal care utilization, it is still unclear whether increased prenatal care translates to better infant health. Examinations of Medicaid expansions yield mixed results, but other policy changes that increased care have resulted in improvements in birth outcomes. Access to prenatal care appears to improve birth outcomes for those most at risk for poor birth outcomes such as low-income women and minority women who would have otherwise had minimal or low-quality prenatal care. A primary mechanism through which prenatal care improves birth outcomes is to reduce maternal smoking, which is the leading cause of growth retardation for fetuses. Health care at the time of birth is associated with a decline in the neonatal mortality rate, likely a result of access to life-saving technology.

Public health insurance programs such as Medicaid in the USA and National Health Insurance (NHI) in Canada provide prenatal and delivery care with the goal of improving both infant and maternal health. Introduction of universal health insurance in Canada during the 1960s and 1970s reduced infant mortality by 4% and reduced low birth weight classification on average, with single mothers experiencing a substantial reduction in the incidence of low birth weight. In the 1980s and 1990s, Medicaid significantly expanded its eligibility threshold to include a larger share of low-income, pregnant women. The program expansion initiated cost-saving measures, changing the insurance structure from fee-for-service to managed care for some enrollees. Evaluations of the changes consistently show impacts on prenatal care utilization but yield differing results on birth outcomes, with some researchers concluding that the changes improved birth outcomes and others finding no effect. Physician incentives to provide care are influenced by the type of payment structure Medicaid uses. Of particular interest is the relative incentives of Caesarian versus vaginal deliveries. Reduced incentives to provide care have been shown to increase the probability of low birth weight, prematurity, and neonatal mortality; however, studies that examine increased incentives to provide care find no effect on infant health.

The 1964 Civil Rights Act mandated desegregation of hospitals and greatly improved the quality of prenatal care available to blacks, particularly in the southern USA where hospitals for non whites were of poor quality. Desegregation reduced postneonatal mortality rates with gains driven by reductions in preventable deaths from pneumonia and gastroenteritis. The health of infants at birth also improved, as evidenced by reduced incidence of low birth weight and improved APGAR scores for the cohort born after desegregation. The narrowing of the black–white test score gap in the 1980s can be traced back to improved health of black cohorts born after desegregation, indicating that access to care that improved birth outcomes translated to increased human capital development later in life.

Another way to identify whether increased care translates to better outcomes is to examine infants on either side of the 1500 g very low birth weight classification. Infants below 1500 g receive more intense care than infants just above the threshold, resulting in lower mortality rates for infants classified as very low birth weight. In line with the findings that improved care after desegregation increased the test scores of black children, very low birth weight infants just below 1500 g who received additional care outperform their peers with birth weights exceeding 1500 g.

Maternal Behaviors

Negative correlations between income and behaviors such as smoking, drinking, and drug use suggest that these habits may be a possible mechanism for transmission of health to infants. The decision to drink or smoke may be related to other maternal behaviors or characteristics that could affect infant health; therefore, an extensive set of control variables or a natural experiment that changes smoking behavior independent of maternal characteristics is necessary to isolate the impact of these behaviors' outcomes such as birth weight and infant mortality. Numerous studies have linked maternal drinking and smoking with reduced infant health and long-term human capital outcomes.

Alcohol

In a survey of Danish mothers who had recently given birth, women who reported drinking four or more drinks per week while pregnant were more likely to have a preterm delivery than women who reported drinking no alcohol. This finding may be a result of omitted variable if women who choose to drink during pregnancy are negatively selected on other attributes. Accordingly, there has been a shift to the use of quasi-experimental approaches to unraveling the alcohol and child outcome relation.

Variation in the legal drinking age across states and over time has been used to identify the causal effect of maternal drinking on infant health. A lower drinking age is associated with more alcohol consumption during pregnancy, an increase in premature births, and an increase in the probability of low birth weight. The reduction in health at birth can partially be attributed to changes in the composition of births, increasing the number of births without a father listed and suggesting that more unplanned pregnancies occur when drinking laws are less stringent.

Maternal alcohol consumption can have long-term effects on human capital development, as demonstrated by a policy experiment in Sweden. In 1967, grocery stores in certain regions were temporarily allowed to sell strong beer that was previously only available in government-run liquor stores. Children exposed the longest to the policy while *in utero* had lower completed education, lower earnings, and higher rates of welfare participation than children that were not exposed to the policy experiment.

Smoking

Smoking during pregnancy increases health risk for both the mother and infant in the form of complications such as miscarriage, membrane ruptures, ectopic pregnancy, pneumonia, and stillbirth. Women who smoke during pregnancy

have lower birth weight babies on average and are at a greater risk for having an infant classified as low birth weight. The seminal study of the impact of smoking on infant health is the randomized-controlled trial of Sexton and Hebel (1984), in which pregnant smokers were randomized into a treatment group receiving assistance quitting smoking and a control group receiving no intervention. Babies whose mothers were in the treatment group were on average 92 g heavier than control group babies.

The 1964 Surgeon General Report on Smoking and Health alerted the nation to the health hazards of smoking resulting in a reduction in smoking among pregnant women that was concentrated among higher-educated mothers. A study comparing birth outcomes of children before and after the release of the Surgeon General Report reveals that higher smoking rates are associated with lower birth weight. However, no effect of smoking was found on gestation, prematurity, or the likelihood of having a low birth weight baby. These results are similar to studies that use increases in cigarette excise taxes to estimate the impact of smoking on birth weight.

Nutrition

From famines in developing countries to supplemental nutrition programs in developed ones, studies consistently conclude that nutrition is a fundamental input into health production, impacting both short- and long-run health. Randomized-controlled trials that offer nutritional supplements to the treatment group have demonstrated that micronutrients play a key role in cognitive development. Assessing the direct impact of nutrition on health is difficult due to significant measurement error in the nutritional content of food items; therefore, most natural experiments examine how quantity of food relates to health outcomes. Research suggests that policies that improve the nutrition of pregnant women and infants will be effective at improving the health and human capital of the next generation.

The ideal setting for conducting research is the randomized-controlled trial, a technique that has been used in developing countries to study the impact of poor nutrition on cognitive development. In Jamaica, babies that were given nutritional supplements had higher mental development than the control group, indicating that lack of nutrition is a causal factor in stunted mental development. Children in Guatemala who received a nutritional supplement tested higher on knowledge, numeracy, reading, and vocabulary assessments than children given a placebo. The same children were followed up with as adults. Adults who were treated with the nutritional supplement as a child had higher reading comprehension, nonverbal and cognitive scores, and higher completed education (women only) than the control group.

The majority of economic research on nutrition in developing countries studies the impact of famines on health, education, and labor market outcomes. Famines are extreme events and estimating the impact of a famine can be confounded by selection because only survivors are observed. Furthermore, the health effects of a famine may not solely operate through nutritional deprivation – famines may affect other inputs to health and human capital such as disease-resistance and school attendance. The Chinese Famine of 1959–61 had a significant impact on children and babies *in utero* during the event. Children exposed *in utero* were shorter, lighter, and acquired fewer years of education than children born just before and after the famine. Exposure in early childhood had a detectable, yet smaller effect on long-term outcomes than *in utero* exposure. The famine also tilted the sex ratio in favor of girls, reduced the literacy rate, reduced employment, and reduced the marriage rate for children born during the time of the famine.

European famines during World War II had long-term impacts on health and human capital accumulation for individuals exposed early in life. Individuals who were *in utero* during the Dutch Famine experienced higher rates of chronic disease in adulthood. Children exposed to the Greek Famine during gestation and the first two years of life showed reduced educational attainment and literacy, with the largest impacts on children who were 0–12 months old during the famine. The impact of a famine can reach late into life – men exposed *in utero* to the Dutch Potato Famine of 1846–47 had a lower life expectancy at age 50 than cohorts born just after the famine.

Controlled nutritional deprivation for brief periods of time is associated with reduced physical and cognitive development, as evidenced by recent research into the outcomes of children *in utero* during Ramadan. Ramadan occurs for one lunar month per year and observance includes fasting between sunrise and sunset. In a study using data from the USA, Iraq, and Uganda, the authors document reduced birth weight, reduced gestation length, a decline in male births, reductions in educational attainment, and even increased rates of mental disabilities for children of Arab mothers *in utero* during Ramadan.

Even in developed countries, nutrition interventions can positively impact the birth outcomes of at-risk children as evidenced by analyses of the Supplemental Nutrition Program in the USA for women, infants, and children (WIC). WIC is aimed at low-income pregnant women and women with young children with the goal of improving the nutrition and health of this group. Consistently estimating the effect of WIC participation on infant health is difficult due to nonrandom selection into the program – unobserved maternal characteristics that affect infant health may be systematically different for mothers that choose to enter the program than for mothers who do not. Estimates that account for selection into the program yield a positive impact of WIC participation on birth outcomes such as incidence of low birth weight and gestation length. Infants at the low end of the socioeconomic and birth outcome distribution gained the most from WIC.

Environment

Environmental quality can be considered a direct input into health, with infant health responding to maternal exposure to pollution while *in utero* as well as post-birth. Isolating a causal relationship between pollution and health is challenging for many reasons. First, measurement error in pollution levels attenuates coefficients and makes a relationship difficult to detect. Second, there are numerous pollutants, many of which

are measured infrequently or not at all. Lastly, a number of confounding variables must be ruled out in order to interpret a relationship between environmental quality and health as causal. For example, families may sort into areas of varying pollution levels based on socioeconomic characteristics or business cycles may have an independent effect on both pollution levels and health. Furthermore, the relationship between health and pollution may be nonlinear, meaning that reductions in pollution below a given level may not improve health.

Researchers have exclusively relied on quasi-experimental designs such as policy changes or temporal variation in pollution levels to assess the impact of environment on infant health. The introduction of the Clean Air Act of 1970 reduced infant deaths in the most polluted counties. Similarly, infant mortality declined more in counties with greater reductions in total suspended particulates during the 1981–82 recession. The introduction of the EZPass toll system in the Northeastern USA reduced traffic and thus pollution levels near the freeway, subsequently increasing birth weight and reducing prematurity for newborns near the freeway. The Chernobyl fallout over Sweden did not detectably affect infant health; however, students that were *in utero* during the fallout experienced deficiencies in human capital as evidenced by lower test scores and high school graduation rates.

Conclusion

From both a theoretical and empirical perspective, there has been an increasing focus on the importance of *in utero* and early life conditions on later health and outcomes. Theoretical models emphasize the timing of investments. If investments are substitutable across periods, then disadvantage early in life can be overcome by later life investments. However, early investment is important if skills acquired during early periods can help beget skills in later periods. This article highlights several mechanisms through which transmission of health may occur – initial endowments, environmental influences, parental abilities, and investments. Researchers have relied heavily on quasi-experimental strategies such as policy changes, natural disasters, and sibling studies to identify a causal relationship between early life influences and health. This is an emerging and growing literature.

Internal Geographical Imbalances: The Role of Human Resources Quality and Quantity

P Serneels, University of East Anglia, Norwich, Norfolk, UK

Introduction

This article discusses internal imbalances of health care in low- and middle-income countries. Throughout this article, 'internal' refers to within country, and the emphasis will lie on the differences between rural and urban areas. Much of the work in this area focuses on the imbalance in the quantity of health workers, but recent evidence indicates that imbalances in the quality of health care are as important. The paper discusses both, focusing throughout on the human resources aspect of health-care delivery.

What Geographical Imbalances?

With poverty reduction taking a prominent place on the international agenda in the early-1990s – later resulting in a consensus around the 2015 Millennium Development Goals (MDGs) – there has been an increased interest in rural service delivery. Many of the poor live in the countryside, where poverty is at its deepest, and the emphasis placed on coverage of cardinal interventions makes access to services in rural areas key to reach the MDGs. But although health outcomes are unfavorable in rural areas, there is also less care provided in those areas. This is sometimes referred to as 'the inverse care law.' These geographical imbalances have mostly been discussed in terms of shortages of health-care workers, which is perhaps best illustrated by the World Health Organization guideline recommending 2.28 health professionals – including doctors, nurses, and midwives – per 1000 inhabitants to allow the delivery of quality health services. Contemporary work is concerned with both the quality and quantity of services. Evidence indicates that low numbers are not the single constraint for the delivery of appropriate services. A narrow focus on the numbers of health personnel is therefore misguided. It also stands in the way of thinking critically about health care in remote areas, particularly in the context of rapid urbanization, as is the case in most developing countries, which may require more fundamental changes to rural health policies, as discussed in the section Encourage and Support Self-Help among Rural Populations. In what follows, the paper discusses the evidence on quantitative and qualitative imbalances in human resources for health (HRH).

Imbalances in the Number of Health Workers

Although a focus on the quantity of health-care providers is not enough, considering the figures does provide a starting point and reveals striking differences. Table 1 illustrates the within-country geographical imbalances across the world for the countries for which there are data available.

The contrasts are stark. On average, more than 80% of doctors work in urban areas, and the remaining 20% works in rural areas. The figures are more favorable for nurses, midwives, and medical assistants, of whom approximately 40% work in rural areas. The distribution is more skewed for dentists, pharmacists, and radiographers, of whom 18%, 12%, and 18%, respectively, work in rural areas. This implies that urban areas count, on average, 15 times more physicians, 6 times more nurses, and 3 times more midwives and medical assistants for the countries in the dataset. This ratio is higher for radiographers, dentists, and pharmacists, who are typically employed in hospitals or in the private sector. With more than 45% of people living in rural areas worldwide, the overall distribution is highly skewed in favor of urban areas.

A number of shortcomings to the data limit the inference that can be drawn from these figures. First, the data are available for only a relatively small sample of countries, with sub-Sahara African countries very well represented but other continents heavily underrepresented, as is clear from Table 2.

The data also suffer from a number of biases. Countries with a weak administration, ill-functioning government, or in conflict are largely missing from the data; they are also likely to have higher concentrations of health professionals in urban areas. The same applies to regions within countries: areas with weak governance are more likely to have missing data. A second bias stems from the lack of data on private sector health workers as the figures only reflect public sector health professionals. Both types of bias will lead to underestimation of health professionals in urban areas, and thus an underreporting of the problem.

Studies at the regional level paint a similar picture, confirming the general pattern and also highlighting divergences between regions. A recent study on sub-Sahara Africa, where the problem is deemed most striking due to the relative high proportion of the population living in rural areas, illustrates this. The results summarized in Figure 1 show the concentration of doctors in urban areas for 13 countries. Densities are considerably higher in urban areas, a pattern that is confirmed by other country-specific studies. In Cote d'Ivoire, for example, 70% of all doctors work in the southern, urban regions that harbor only 40% of the population, and similar disparities are seen in data from Zambia, Sudan, and Uganda.

In Asia, the case of Thailand has been well researched. Several studies provide updated estimates of the geographic distribution of the country, illustrating that Bangkok has four times more nurses per 10 000 people than the North East, the most rural region. A similar picture emerges for Bangladesh, where 30% of nurses are located in four metropolitan districts that represent 15% of the population. An early study confirms the problem of urban–rural imbalances for Indonesia. China provides another interesting example because the majority of its nurses (98%) and doctors (67%) have been educated only

Table 1 Types of health professionals in rural and urban areas worldwide

Health professionals	*Share of health professionals in rural areas (mean)*	*Ratio of urban to rural health professionals (mean)*
Physician	0.20	15.6
Nurse	0.39	6.3
Dentist	0.18	18.1
Pharmacist	0.12	11.8
Midwife	0.39	2.8
Radiographer	0.18	23.4
Medical Assistant	0.37	2.9

Washington, DC: World Bank.

up to junior college or secondary education. This provides a unique setting in which the level of education for health professionals, often believed to be a major explanatory factor for reluctance to work in rural areas, is relatively low, and because this has resulted in having more doctors than nurses. Still, urban China has more than twice as many doctors and more than three times as many nurses per capita than rural China.

Evidence for Latin America also shows similar patterns, with health workers concentrated in the capitals and more affluent areas. In Argentina, which has one of the highest numbers of health workers per person, Buenos Aires counts seven times more doctors per capita than Formosa or Misiones. In Chile, approximately 60% of public sector health professional are concentrated in the region of Santiago, which hosts only 40% of the population. In Ecuador although the capital's province of Pichincha has 2 doctors per 1000 inhabitants, the more remote provinces of Galápagos and Orellana Esta have 0.56 and 0.43, respectively. In Guatemala, which has 0.9 doctors per 1000 inhabitants on average, 71% of health workers are concentrated in the metropolitan zone, whereas the more remote Quiche has a ratio of less than 0.1 doctors per 1000 inhabitants. A similar imbalance exists for all medical professions in this country. Nicaragua has 0.4 doctors per 1000 inhabitants on average, whereas its capital, Managua, has 1.1. In Peru, 53% of physicians, 40% of nurses, 44% of dentists, and 41% of technicians and health assistants were concentrated in the Lima Metropolitan Area, which represents close to one-third of the country's population. Stark differences in densities across professional groups are also reported for the Dominican Republic, with 0.41 nurses per doctor in Region 1 and 3.63 in Region III. A detailed analysis of Brazil also shows substantial inequalities in numbers of health workers.

Although this article focuses on low- and middle-income countries, it is useful to remember that the same problem exists in high-income countries. In USA, for instance, 9% of physicians work in rural areas, which represent 20% of the population. The figures for Canada are very similar (9% of physicians for 24% of the population). In France, the wealthy areas of Paris city and the South have considerably more doctors than the rest of the country. In Norway, the rural and remote Northern areas have historically been underserved, and there is long tradition of policy making to try to address this.

The pattern that emerges from the above descriptive statistics is clear, but also blunt. For a subset of countries with more detailed data, a more advanced analysis and decomposition of inequalities across and within subgroups is possible – for example, according to profession or gender. A 2008 study considers the Gini coefficient, Theil T, and Theil L measures for the distribution of health workers in China, and decomposes overall inequality in between and within province inequality. The findings indicate that underlying distributions can be very different across regions. Across the measures, within province inequality accounts for between 82% and 84% of intercounty inequality. A later study draws similar conclusions for sub-Sahara Africa, calculating the Concentration Index and Gini coefficient for doctors and nurses for nine sub-Sahara African countries. Although the Concentration Index for doctors varies between 0.25 and 0.48 (for Kenya and Senegal, respectively), that for nurses varies from 0.05 to 0.54 (for Kenya and Mauritania, respectively), and generally confirms that imbalances tend to be more severe for more educated health professionals. The results for both China and Africa illustrate how aggregate figures on numbers of health workers can be misleading and may provide a highly insufficient base for policy making.

Imbalances in the Quality of Care

With the development strategy of the past decades emphasizing increases in the supply of care, much of the debate has focused on gaps in the quantities of health-care providers. But there are also important imbalances in the quality of care that patients receive (often referred to as process quality), which is a function of the number of health workers, their performance, and the availability of complementary inputs. This chapter focus on performance differences stemming from human resources and abstracts from differences in the import of complementary inputs like the clinic's physical condition or the availability of drugs (often referred to as structural quality).

The significance of health worker performance – or better, underperformance – is perhaps best illustrated by the results of surprise visits to health facilities in six developing countries that found 35% of health workers to be absent on average. Although the study does not set out to compare between rural and urban areas, it finds that absenteeism is generally higher in poorer areas and among higher qualified health professionals (e.g., doctors). Results from qualitative studies in Ethiopia, Rwanda, and Ghana suggest that absenteeism is higher in rural areas mainly because of poor monitoring. Other work illustrates the importance of on-the-job performance. High health-care usage rates, combined with poor health outcomes often indicate problems with quality of care. A 2007 study provides direct evidence for underperformance of doctors in rural Tanzania. Measuring what doctors know (using a vignette) and comparing this with what they do (using direct observation as well as patient recall), the authors observe a substantial know–do gap. In other words, these doctors provide lower quality care than what they could provide. Qualitative studies in Ethiopia, Rwanda, and Ghana also find indications that health worker attitudes toward patients tend to be poorer in rural areas, whereas performance problems like corruption and embezzlement seem to be higher. This is supported by studies of corruption in the health sector in Tanzania. Further underlining the importance of taking quality of care into account, other studies find that households in Tanzania bypass low-quality facilities that are nearer and increase travel time to reach facilities with better care. Also relevant are study results on medical quality in urban and rural areas in five countries that find that households in poor areas not only have more access to private facilities that provide low-quality care, but are also more likely to receive low-quality care in any facility, particularly in the private sector. The inquiry also finds that indigenous patients that come from a poorer background receive less quality care in the private sector, and infers that this is due discrimination against those patients (rather than households choosing low-quality providers). A separate study shows how workload is not the reason for poor performance among health workers in Tanzania, observing that clinicians have ample amounts of idle time. The authors conclude that scaling up the number of health workers is unlikely to raise the quality of health care. Taken together, these study results provide strong evidence for quantitative and qualitative imbalances between urban and rural areas.

Implications of Imbalances for Health Outcomes

A number of studies have looked at the implications of quantitative imbalances. Evidence from cross-country regressions

suggests that the number of health workers has a strong relationship with health outcomes. Controlling for GNI, income poverty and female adult literacy, it has been found that HRH density is strongly related with especially maternal mortality, but also infant and under-five mortality. Decomposing the effect for doctors and nurses, there is a large association for the former and absence of such an association for the latter – except for maternal mortality where nurses do seem to play a role. Other work, looking at the disease burden, also tends to find a (negative) relationship. One study of the relationship between different health worker densities and DALY's (and DALY's disaggregated according to three different groups) finds a strong relationship with the number of doctors in particular, whereas the association for nurses and midwives is insignificant. A similar analysis argues that countries with fewer than 2.5 health workers per 1000 population are very unlikely to achieve a desirable 80% level of coverage for skilled birth attendance and measles immunization. A further inquiry, updating these studies by making use of an extended sample of 192 (instead of 177) countries, finds an aggregate relationship between health worker density and measles immunization and birth attendance, but no longer with infant and under-five mortality. It also observes a significant association for doctors but not for nurses, concluding that that the threshold should be 2.28 rather than 2.5 health workers per 1000 population.

Although the findings from these studies are indicative, they do not provide conclusive evidence for a causal relationship, as the analysis may suffer from omitted variable bias. The number of health workers may, for instance, be correlated with government expenditures on health, donor activity, the number of clinics, the availability of equipment and medicine, or the presence of conflict, none of which are included in the analysis. Other factors, such as skill mix, negative work environment, and weak knowledge base may also be important, and their omission may further bias the estimates upwards. Conversely, the lack of a relationship between nurses and health outcomes may also be due to unobserved factors – like absenteeism among health workers – which may bias the estimates downwards. Another potential problem is that the sample suffers from selectivity. Countries with good data tend to be better organized and may have surmounted other constraints that may matter more than the number of health workers. There is, finally, also a question as to how the limitations in data comparability across countries play a role. Different countries use distinct definitions, for instance for nurses, and this introduces both measurement error and unobserved heterogeneity. More sophisticated approaches are needed if one would like to test the robustness of these findings, as recognized by the authors of some of these studies.

To address some of the shortcomings associated with using aggregate cross-country data, more recent studies focus on within country variation using subnational data. One such analysis of China concludes that the density of doctors and nurses is significant in explaining differences in infant mortality across counties in China. A similar approach to data from Brazil finds that a 1% increase in health worker density is associated with a 0.12% increase in the coverage of antenatal care on average. The papers also illustrate that there is considerable variation in the level of coverage by municipality for a given number of health workers, thereby illustrating how the analysis suffers from similar shortcomings as the ones mentioned above. As a result, they do not provide conclusive evidence on the extent to which shortages of health workers cause poor health outcomes. Although identification of causality remains a challenge, it is necessary when informing policy making, especially when providing advice on target numbers of health workers.

An analysis of data from Ghana yield evidence on a causal relationship between the number of health workers and demand and usage of health care. Making use of exogenous policy changes in the late-1980s, it is found that increasing the number of doctors and nurses to three (representing a 50% increase from the mean) would lead to a 20% increase in the predicted probability of households choosing public health care. A recent study focusing on Indonesia also provides causal evidence that relates the number of health workers and quality of health care to health outcomes. Exploiting the fact that deployment of health staff in Indonesia is based on quantitative targets per facility although not related to quality or health outcome targets, it was found that increasing the number of MDs, nurses, and midwives increases adherence to clinical protocol, which in turn leads to improved child health (measured by length). The largest gains are made by increasing the number of MDs, followed by nurses, whereas increasing the number of midwives had no effect. As the study did not include the most remote areas in Indonesia, its estimates may well be conservative.

Recent evidence for Kenya shows how absenteeism causes poorer health outcomes. Using longitudinal data for rural health clinics, it is shown how women whose first clinic visit coincides with nurse attendance are approximately 60 percentage points more likely to be tested for HIV and 13% more likely to deliver in a hospital or health center, and how this in turn affects expected HIV status. The presence of other health workers may also increase the quality of care, as shown by one study interpreting Hawthorn effects in direct observation of doctor activity as evidence that performance increases when colleagues are present.

The above-mentioned literature confirms the causal relationship between quantities of health workers and quality of care on the one side and health outcomes on the other, but does not allow clear conclusions to be drawn on the relative importance of these factors. To identify pathways through which rural health outcomes can be improved, the next step is then to return to theory to better understand why quality of care and numbers of health workers are lower in rural areas and result in lower health outcomes.

Causes of Imbalances in Health Care: Theory and Evidence

From a theoretical perspective, there are a limited number of reasons why health outcomes in rural areas are lower. Abstracting from potential differences in disease burden, three factors play a role: poor infrastructure – including scarcity of clinics, lack of equipment, medicine, etc.; weak human resources which relates to the number of health workers, their presence and performance, as well as the combination of health worker types; and, finally, limited demand for health

care, which is related to households' information and health seeking behavior. There is currently limited understanding of the relative role of these factors, and where the binding constraints lie. This relationship can be presented in a more systematic way, by considering patient health outcomes (H) as a function of the infrastructure of the facilities in that area (K), the human resources in the facility (L), which entails number and different types of health workers (n), their presence (p) and performance (γ), as well as patient household characteristics in that area (hh). It is helpful to think of this relationship in terms of a production function where the inputs are imperfect substitutes, and write health outcomes as a product of these three factors, with their power reflecting their relative weight.

Health worker inputs (L) can thus be seen as the product of three factors: the number, presence, and performance of the respective health worker categories. A next step is to consider the determinants of these respective factors. This chapter focuses on two issues central to human resources: the quantity of health workers in rural areas (n) and their performance (γ). The paper refers to other work for in-depth discussion of absenteeism and issues not related to human resources, including infrastructure, availability of drugs, funding, and factors to do with demand.

Quantity of Health Workers (n)

Ultimately, the relatively low numbers of health professionals in rural areas is rooted in the choice of health workers themselves. Job choice is typically modeled as a process of matching between job attributes and preferences. Focusing on earnings and effort, in addition to other job attributes like social status, recent work adds motivation, which is especially relevant for professions where a personal mission is important, like in public service. Considering that health workers will choose to work in a rural area when they expect to derive more utility from a rural than an urban job, this framework predicts that, since earnings and amenities typically receive high weights, while differences in effort between rural and urban areas may be limited (even if weights to effort may be high), most health workers prefer an urban job. Only those with a mission that matches to working in rural areas, or those who attach a high value (weight) to living or working in a rural area, for instance because of proximity to family and friends, prefer a rural post. These predictions immediately illustrate the limited leverage that policy makers have at their disposal if they want to get more health workers into rural areas. Although in theory people can be compensated for unattractive job attributes, for most health workers, earnings will have to be very high to compensate for the disutility caused by poor amenities in rural areas.

This situation may be aggravated when taking a more dynamic perspective and consider health workers to be making a career rather than a job choice. Taking a lifetime perspective, the outcome is now determined by the discounted sum of utilities across different periods, allowing for health workers to change from rural to urban areas, with income in each period a function of human capital accumulated in the previous periods (h_{t-1}). If an individual expects that the accumulation of human capital is slower in rural posts, for example, due to lower opportunities for formal training or because the type of experience built is not rewarded in urban jobs, she may be even less likely to choose a rural post. In a more sophisticated approach, valuations of job attributes could be allowed to vary as staff gets older. The weight attached to amenities may change and health workers may stick higher values to jobs in urban areas at certain ages, for example, at marriage age because it offers access to a larger pool of potential marriage partners, at child-bearing age because it offers access to better child care, or when children reach school going age because of the proximity of better schools, etc.

The basic predictions of the above models are supported by empirical evidence. Results from comparative qualitative research illustrate why health workers in Ethiopia, Ghana, and Rwanda generally prefer jobs in urban areas. Although rural jobs may offer extra payment and benefits, these are usually insufficient to compensate for other disadvantages. Professional isolation, limited access to training, and poor working conditions characterized by limited access to equipment and infrastructure are seen as strong drawbacks. Urban postings also provide the possibility of working in a second job in the private sector, which is usually absent in rural areas. But the reasons why rural posts are unattractive go beyond job attributes, as factors like personal isolation, the general absence of infrastructure and amenities, including the low quality of housing and absence of good schools, also play an important role. Rural postings are associated with lower career perspectives as well, as they provide less access to training, limited access to equipment and modern technology, and thinner professional networks, among others. In some rural areas, salaries are often paid with delay. However, the lack of supervision from colleagues may give more freedom in rural posts.

A growing body of quantitative work analyses health worker willingness to work in rural areas, typically studying the role of wages and other job attributes. In the absence of incentive compatible study set ups, two types of methods have been applied contingent valuation and discrete choice methods. Each of these methods have their advantages and draw backs. While contingent valuation methods find the precise reservation wage to work in rural areas, discrete choice methods focus on trade-offs between different sets of attributes. A 1998 investigation of health worker willingness to work in remote areas in Indonesia uses the first method to find that modest cash incentives can make health workers more likely to work in moderately remote areas, but that it would be prohibitively expensive for staffing of very remote areas. Health workers who grew up in remote areas are found to require lower compensation to take up a remote position. Results from a cohort study with final year health students in Ethiopia also find that expected wages affect take up of a rural post. Here, in order to get 80% of health workers in rural areas (who harbor 80% of the population), salaries would need to increase with 83% for doctors and 57% for nurses, requiring an increase in annual health expenditures of 0.9%. The study also observes substantial heterogeneity, with health professionals who grew up in more remote areas, come from a less wealthy background, or are more motivated to help the poor being more willing to work in rural areas. Assessing what

other job attributes matter, the study finds that chances for promotion, access to professional training and access to schools for education of children turn out to be important. Other studies present very similar findings. A resurvey of the same Ethiopian health professionals 2 years later (when they had entered the labor market), finds that wages and other job attributes are only part of the story and that health worker characteristics like rural background and motivation play an important role, with the latter influenced by the type of school attended. An identical study with health students in Rwanda confirms these results with rural background and motivation to help the poor as important determinants of willingness to work in rural areas. Health workers who were participating in a local (church-based) bonding scheme were also more willing to work in remote areas. Another similar study in Ghana finds that doctors who grew up in a rural area, as well as those with higher motivation are more willing to work in rural areas.

Results from discrete choice studies provide further insights into the relative roles of job attributes. Focusing on doctors in Ethiopia, it has been found that doubling wages would increase the share of doctors willing to work in rural areas from 7% to more than 50%, whereas providing high-quality housing would increase it to 27% (the equivalent of a wage bonus of 46%). For nurses, doubling the salary would increase their number from 4% to 27%, whereas the nonwage attribute that is most effective in inducing take up of a rural post is the quality and availability of equipment and drugs, which would reach the same result as a salary increase of 57% for men and 69% for women. Focusing on Tanzania, another study finds that offering continuing education after a certain period of service, as well as increasing salaries and hardship allowances, would encourage health workers to work in rural areas. Decent housing and good infrastructure were also found to be important. Women were found to be less responsive to financial incentives and more concerned with factors that directly allow them to do a good job, whereas those with parents living in a remote rural area are generally less responsive to the proposed policies. When willingness to help others is a strong motivating factor, policies that improve conditions for assisting patients are effective. Analyses of similar discrete choice experiments with health students in Kenya, Thailand, and South Africa, underline that results can strongly differ between countries. Financial incentives are likely to have important effects, especially in poorer countries, but only if they are larger than a 10% salary increase as smaller raises were found to be ineffective in all three countries. Nonfinancial incentives are found to be important as well, especially access to training and career development opportunities. Improved housing and accelerated promotion were moderately effective. A study using propensity score matching also suggests that improving Clinical Officer's access to upgrade training would not improve their retention in rural areas. A study of the situation in Liberia and Vietnam has found that although in Liberia increased pay would be the single most-powerful incentive, long-term education was the primary factor in Vietnam, and considers the differences in cost effectiveness of implementing corresponding policies. A recent study of Uganda sets out to design packages able to get medical and nursing officers in rural and remote areas using discrete choice methods. The preferred package for medical officers is a 100% increase in salary (from a current base salary of 750 000 Uganda Shilling), improvements to health facility quality, a contractual commitment to the posting for 2 years, and full tution support for continued education at the end of the contractual commitment. For nursing officers, the most preferred package contains a 122% increase in salary, improvements to health facility quality, and improved support from health facility managers. These packages would get an estimated 82% of medical officers and 90% of nursing officers in remote areas. Other studies that do not focus directly on the rural–urban choice also shed light on the importance of job attributes. Evidence for Malawi showed that graduate nurses valued high pay, as well as the provision of housing and the opportunity to upgrade their qualifications quickly. In South Africa, earning more was most attractive, whereas better facility management and equipment were next. Nurses in rural areas were more concerned about facility management.

Both quantitative and qualitative evidence indicate that there is important heterogeneity in health workers' willingness to work in rural areas. Although the majority of health workers prefer not to work in rural areas, some do, in particular in provincial towns. Rural background in particular has been found to be strongly positively associated with willingness to work in rural areas in Indonesia, Ethiopia, Rwanda, and Thailand, among others. Higher-level health workers (e.g., doctors) are generally less willing to work in rural areas compared to lower-level ones (e.g., clinical officers or nurses), for example, in Ethiopia and Uganda. Female health workers are often less willing to work in rural areas, as shown by evidence from Congo and Ethiopia, often for security or marriage-related reasons. Younger health workers may also be more likely to take up a rural post as part of their training, although their willingness may fall rapidly when entering the labor force, as found for Ethiopia. A number of studies also observe heterogeneity in health worker motivation, with health workers who are more motivated to help the poor more likely to take up a rural post. Identical surveys among medical and nursing students in Ethiopia and Rwanda both find that helping the poor is an important explanatory factor for willingness to work in a rural job for a substantial minority of health workers. This result for intrinsic motivation is strikingly similar for the two countries, and indicates that some health workers prefer to work in rural areas because this provides for a better match between their own beliefs and the belief of the facility they work for. Recent work also finds evidence for mission matching in nonprofit organizations in Ethiopia. The higher motivation to work in rural areas in Ethiopia is also linked to the school where one was trained, with health workers trained at an NGO school more willing to work in a rural area. This suggests that either health workers get socialized into motivation, or that they self-select at an earlier stage and choose the school that matches their beliefs and motivations. Overall, this evidence underlines that certain types of health workers self-select into rural jobs.

Qualitative studies also suggests that other factors, like appreciation for a slower pace of life, may play a role, indicating that adverse selection may be important. A recent test of whether less skilled health workers – as measured by a medical knowledge test – are less likely to work in rural areas in Ethiopia finds no evidence for such adverse selection. Exploiting the

existence of a lottery for allocating doctors to jobs, however, another study finds that adverse selection may occur in a different way, with lottery participants, who are not able to use their first job as a signal of ability, having flat wage profiles and higher exit rates.

Although rigorous studies using revealed (rather than stated) preferences and identifying causal effects are currently absent in this area, the above evidence provides a base for an increased understanding of the labor market for health workers in low and middle-income countries. It also points already to three types of policies: those working on the demand side using wages and job attributes, those operating on the supply side focusing on certain profiles of health workers (such as those with a rural background), and policies considering matching of demand and supply and allocation of health workers to posts (or vice versa). The section Lessons for Policy Making and Ways Forward will discuss these policy options in more depth.

Performance of Health Workers (y)

The performance of health workers can best be understood in a classic principal agent framework, where it can be seen as a function of three factors: incentives (w), monitoring (s), and individual motivation (m). Like before, incentives are used in a broad sense, and monitoring includes both supervision and accountability to the local community; it can also include workplace, professional, and society norms regarding professional behavior.

Qualitative research suggests that performance problems of health workers may be more important in rural and remote areas taking the form of absenteeism, poor attitudes toward patients, engagement in corruption and embezzlement, or poor performance in general. Moral hazard seems mostly attributed to four factors: the perceived lack of compensation for personal and professional sacrifice; poor monitoring and enforcement; a culture of poor performance with weak norms; and lacking motivation. The public sector in general is associated with more corrupt practices, and in a number of places, a culture of corruption and free riding is deeply embedded in the public health sector.

Quantitative evidence on determinants of performance is scarcer. One study, using data for Tanzania, provides a good starting point, comparing performance of doctors in the public and private not-for-profit sectors. Like in much of the rest of Africa, these two sectors share a similar mission, often run similar health facilities, and many not-for-profit facilities also follow public sector salary scales. It was found that clinicians in the not-for-profit sector have almost exactly the same average competence as clinicians in the public sector, but their adherence to the prescribed script, an indicator of quality of care, is higher. Thus, although the not-for-profit sector hires clinicians with the same capacity as the public sector, clinicians in the not-for-profit sector perform better.

In other settings, it is more relevant to compare health workers in the public with those in the private, for-profit sector. This approach was used in a 2007 study of Delhi. It was found that, on the whole, private sector providers spend substantially more time and effort on patients. Public sector providers also do less than they know they could. This sector disparity further masks variations in the public sector, with public providers in smaller clinics and dispensaries performing substantially poorer than public providers in hospitals, who tend to do comparable to private practitioners.

Although these studies generate relevant insights into differences in performance, they do not provide guidance for ways forward. Differences in the observed average know–do gap between sectors, sometimes seen as a measure of motivation, can arise for a variety of reasons, as variations between sectors are many (including pay, type of contract, monitoring, work environment, funding available, etc). They may, in addition, arise from the different types of workers that they employ.

There is also useful evidence of how performance can change. Using the above-mentioned data for Tanzania and exploiting the presence of a Hawthorne effect, it has been shown that being observed leads to higher effort and that there exists a link between variation in doctor performance and ability and motivation. An exploration of ways forward shows that clinician performance can be improved by peer encouragement as well as token gifts. Unconditional encouragement, where doctors are asked to do more, seems at least as useful, and has at least the same long-run impact, as conditional encouragement, where doctors are incentivized to do more, although little is known about the long-term effects in either case. Assistant Medical Officers in particular are able to do much better without significant additional resources and have sufficient capacity but insufficient motivation.

Studies identifying a causal effect of incentives, monitoring, or motivation on health worker performance remain scarce, but two studies stand out, one on pay for performance, and one on community monitoring. The remainder of this section discusses each in turn. The first study reports the results of a quasi-experiment in Rwanda where part of the funding received by health facilities depended on their performance. Results from qualitative research have illustrated many performance challenges in Rwanda. Both health workers and users point toward serious problems with health workers' attitudes toward patients, which are often characterized by impolite and rude behavior. Absenteeism and shirking are common problems, and some public facilities have 'ghost doctors' who are on the pay roll but do not show up for work. Especially in urban areas, absenteeism seems mostly related to having a second job, usually in the health sector and often unofficial. In this context, linking part of the funding that facilities receive to their performance may have beneficial effects. Indeed, the study finds large and significant positive effects on deliveries and preventive care visits by young children and improved quality of prenatal care, but no effects on the number of prenatal care visits or on immunization rates. It was concluded that pay for performance had the greatest effect on services with the highest payment rates that required the least provider effort. Unfortunately, the study did not investigate how health worker behavior changed. Results from qualitative research shed some light, and suggests that performance pay decreased absenteeism as well as shirking and improved the work environment, to the general satisfaction of health workers.

The second study provides evidence from a randomized intervention on community-based monitoring of public

primary health-care providers in Uganda. Making use of local NGOs to encourage communities to hold their local health providers accountable, the study finds that 1 year after the intervention, child mortality had seen significant reductions and child weight had increased in treatment communities. Studying the underlying processes, evidence was found for increased monitoring from the community through existing and new channels (e.g., local councils, evaluations) and increased activity from health workers, including improved consultation of the community (suggestion boxes), better information provision (posters regarding family planning), better management of patient care (numbered waiting cards), and higher medical effort (immunizations). The study also finds a drop in absenteeism, an increased use of equipment, a reduction in patient waiting times. A follow-up paper analyses the heterogeneity in some of these treatment effects and argues that the local social context, for example, income inequality and ethnic fractionalization, plays an important role and negatively affects the community's drive to collective action, which in turn holds back improvements of service provision.

Lessons for Policy Making and Ways Forward

Although this field would benefit from more structured research that takes special care in identifying causality, the above studies have increased the understanding and suggest five possible ways forward to address geographical imbalances in both quality and quantity of care, focusing on human resources.

A first approach concentrates on the supply side of labor for health care, given demand. A second approach starts from the demand side, focusing on how facilities can acquire the human resources they want or need, given the available supply. A third approach looks at matching health workers and jobs and how health workers get allocated to jobs. Fourth, one can look at the coordination between public and private sectors. Finally, new directions can be explored to encourage self-help in rural populations. In what follows, each of these are discussed in turn. In a final section, the authors discuss how one can go about choosing between or combining these different alternatives.

Emphasizing Labor Supply

Most human resource policies in the health sector today focus on the supply side. Starting from a needs-based approach, they concentrate on how to attain the desired number of human resources in rural and remote areas. Although this approach may be justified in settings with extremely low numbers of health workers, it generally suffers from a number of problems. A key issue that remains unclear, for instance, is what the ideal number of health workers should be. As the precise causal relationship between the number of health workers and improved health outcomes is yet to be understood, current figures represent preliminary estimates. One underlying assumption is that existing human resources are fully used, whereas evidence indicates that this is not the case. This approach also abstracts from the quality of care, assuming that existing and new health workers all provide high-quality care, in contrast to existing evidence. It also tends to undervalue the potential role of modern technology (see section How to Choose the Appropriate Approach?). An exclusive focus on the quantities of health workers supplied thus misses several important points. As a result, policies grounded solely in this approach often disappoint and are not the silver bullet they are believed to be. A classic example is the training of more health workers, which is often presented as a promising strategy to address shortages in rural areas. However, if health workers are free to choose where they work, training more professionals does not necessarily lead to more health workers in rural areas.

An important step forward with supply-based policies lies, therefore, in recognizing the heterogeneity of health worker preferences. Although health workers generally prefer to work in urban areas, a clear picture is emerging of the type of health worker that is more willing and likely to take up a remote post. Having grown up in a rural area, giving more importance to helping the poor, being lower rather than higher educated (e.g., nurse vs. doctor), and possibly being young rather than middle aged (little is known about elderly), all play a role. Polices that target these workers may therefore be more effective. Evidence from Indonesia shows that much can be gained from stimulating nurses to take up rural jobs, rather than doctors, who are considerably less likely to work in rural areas. Not surprisingly, these types of policies are becoming more common. Thailand, for instance, focuses on recruiting health workers with a rural background. This can further be combined with more rural-oriented training and education, as is the case in a number of high-income countries, including the US and Norway, who have built specific institutions to provide training for rural health care.

Where increasing the number of health workers is appropriate, a detailed cost–benefit analysis is needed to assess what would be the best approach. In many cases, it may be more cost effective to increase health workers in existing facilities, rather than building new facilities. Indeed, one recent study illustrates how patients can bypass facilities to get to the ones with better services. A higher number of health workers per facility also increases monitoring and reduces professional isolation. Other evidence has also shown how increasing the number of health workers per facility improves outcomes.

Besides focusing on the number of health workers, one alternative solution is to improve the quality of care. Improved training is often raised as an important way forward. There are clear examples where the curriculum does not capture local disease realities, particularly the disease burden of the poor and those in rural areas, leaving ample room for improvement. Mozambique (nonphysician) surgeons for instance, until recently received no training in HIV/AIDS, even though it was the most common disease they treated. Over the past years, many countries have updated their curriculums, with the Malawi approach that tailors content of the training to meeting the community's most pressing needs, often as a model. Recent examples are South Africa's Walter Sisulu University, community-based programs at Jimma University in Ethiopia and University of Gezira in Sudan; as well as initiatives at Makere University in Uganda and the National University of Rwanda, who are making epidemiology-based curriculum revisions. Recent evidence indicates that, on the

whole, health workers know what to do; the failure lies in doing it. The role of training to improve this, for example, by ameliorating attitudes or shifting norms, remains unexplored.

An issue that is receiving increased attention both for quantity of human resources and quality of care is the role of intrinsic and altruistic motivations. A 2008 study finds that health workers in Ethiopia who attended a Catholic NGO school are more willing to work in a rural area. Similarly, evidence for Tanzania shows that motivations matter for performance. Neither study, however, can distinguish whether this is an issue of selection or socialization. Are health workers' motivations set at the time they enter the profession, or does their training and professional environment shape their motivation? In the latter case, there would be a role for training institutions shaping motivations to improve the quality of care (and possibly willingness to work in rural areas).

Demand-Side Policies

Policies focusing on the demand side try to attract more of the existing work force to and improve health care in rural facilities, taking labor supply as given. Like many other policies, human resources have seen a shift from a manpower and central planning approach to a market-based approach. In most countries, compulsory placement has been abolished. Demand-side policies that focus on human resources quantities usually start – implicitly or explicitly – from compensating differentials theory, which argues that undesired job attributes need to be offset by attractive job attributes. Although individual preferences play a role for the precise level that is considered acceptable for a job attribute, there seems agreement as to whether an attribute is desirable or not and a pretty clear picture is emerging as to what health workers want in their job. The studies reviewed in the section Causes of Imbalances in Health Care: Theory and Evidence indicate that raises in rural salaries do increase health workers' willingness to work in rural areas, but also that increasing salaries is not enough. In most low-income countries, the discrepancy in amenities between rural and urban areas may be too large to be compensated by salaries alone. Moreover, government budgets are tight and policy makers are nervous about creating precedents for salary increases among public servants, especially in highly unionized environments. Providing other benefits like housing, transportation, and especially access to training and promotion may bring some relief. Giving more certainty about future career opportunities might also help, as concerns about unsteady future postings, together with a fear for professional isolation and lack of access to training seem to prohibit health workers from planning their career and makes rural postings less attractive. It also seems to affect job satisfaction.

Alternative approaches on the demand side are to improve efficiency and to maximize the effort and quality of care provided by existing personnel. This may be done by adapting the type of contracts offered. Although evidence for the health sector remains scarce, it has been indicated that tying pay to performance can have major impacts. Studies outside the health sector also provide evidence. Qualitative research in Ghana, which implemented a pay for performance scheme, suggests that concerns that performance pay erodes intrinsic motivation and attract the 'wrong type' of health workers seem unwarranted. A deeper concern, namely, that linking individual pay and performance may skew health worker behavior along the dimensions by which performance is measured (which is imperfect and may be arbitrary) remains largely unaddressed. Recent approaches, like the one in Rwanda, try to address this by evaluating performance at the facility level and letting it determine the budget allocated to each facility (which the facility was free to use however it wanted).

Alternative changes in contract consist of increasing monitoring and accountability of health workers, both of which tend to be weak in remote areas. This can have two effects. First, it may affect the amount of effort and quality of care delivered. The Uganda research discussed in the section Performance of Health Workers shows how improved accountability and community monitoring can ameliorate quantity and quality of care. A second concern is whether current conditions induce adverse selection, attracting health workers with undesirable attitudes, for instance the less skilled, into rural posts. This has been investigated using test scores as an indicator for the potential quality of care, but no evidence has been found that nurses and doctors with lower test scores self-select into rural jobs. It may, of course, still be possible that health workers who are less willing to apply their skills self-select into rural posts.

Matching Health Workers and Jobs: Allocation Schemes

In most countries, the allocation of health workers to jobs happens on a voluntary basis, with health workers choosing freely what job to take. But alternative allocation mechanisms exist. One example is the use of a draft or lottery. The use of lotteries in public employment has mostly been abolished (although is still present in military draft), but remains operational in some countries, including Ethiopia where, until recently, a national lottery was used to allocate health workers to jobs. Although participation in the lottery was initially compulsory, this could no longer be enforced and an opt-out has been allowed since the early-2000s (though there is still an expectation to work for a fixed period in the public sector). Allocation by lottery has been shown to be inefficient, resulting in adverse selection with the best personnel opting out of the lottery.

Other types of compulsory placement, even if limited in time, often suffer from similar problems. An example is provided by 'bonding schemes,' where health workers are expected to work in a remote area for a fixed number of years, for example, 2 years, often as a way to repay their studies. Although most countries have moved away from coercive schemes, bonding schemes remain popular, and are usually organized by state or by private institutions, often religious organizations. They suffer from similar risks as other coercive schemes, including adverse selection, erosion of motivation, and low performance. Bonding approaches have been tried and tested but have not led to the success that was hoped for. This probably explains why most countries have moved away from this, or if not, have moved to a long-term contract where

compulsory rural service is limited in time and compensated by access to additional training.

Policies focusing on matching would benefit from a deeper understanding of health workers' job decision process in developing countries. A US-based analysis provides an excellent example. Having observed that the majority of health students in the US base their job choice on their internship experience, taking their first job at the facility where they did their internship, researchers developed a two-sided matching model to optimize the allocation. Although this approach may be technically demanding, much can be learned from this type of designed matching mechanism.

Combining Public and Private Sectors

The ultimate objective of health policies is to improve people's health outcomes. A growing literature highlights the complementary role of public, private not-for-profit and private for-profit sectors to reach this objective. Studies on rural–urban imbalances in human resources often abstract from private sector activity. Perhaps the inclination of policy makers to emphasize health-care delivery through the public sector plays a role. Another reason may be that private, for-profit facilities are mostly absent in rural areas. However, not-for-profit organizations tend to be active, and, in many settings, concentrate on rural areas. The design of human resource policies that give more weight to health worker choice also require taking private sector activity into account more explicitly. Making the private sector part of the analysis also encourages bold and creative thinking about new ways to bring private health care to rural areas, moving beyond the dichotomous view that public sector's main task is to correct the imbalances caused by the private sector (or lack thereof). Letting pharmacies and especially drugstores play a more important role is one example of how public–private cooperation can contribute. More analysis is needed that compares across sectors. Existing evidence for Tanzania shows that doctors in the private sector perform considerably better than their colleagues in the public sector. Health workers in the public and not-for-profit sectors had similar levels of knowledge, but the know–do gap was smaller among NGO workers. The know–do gap is found to be largest among public sector health workers, followed by private, for-profit professionals. Health professionals in the nonprofit sector in Ethiopia are found to be less skilled, but more motivated. These are some of the exciting findings from the scarce existing evidence. Future work in this area will generate new insights on strengths and weaknesses of the different sectors and lay the ground for creatively combined or complementary approaches. Developing a finer typology to move beyond the simple categorization of rural–urban could also bring this work forward, as it will show more clearly where private, for-profit sector activity is viable.

Encourage and Support Self-Help among Rural Populations

Geographical imbalances in health care occur in all countries, regardless of whether they are low, middle, or high-income. This in itself suggests that they may be hard to solve. Moreover, among high-income countries, both those with more regulated labor markets (cf. Norway, France) as well as with weakly regulated labor markets (see section Encourage and Support Self-Help among Rural Populations) have imbalances, indicating that regulation of health worker labor markets might have limited impact. Policies have therefore typically focused on minimizing these imbalances, rather than eliminating them. The way forward seems to concentrate more on health outcomes, and make rural health care less dependent on the physical presence of health workers. The training of community health workers has been a tried model as a way to increase self-help by rural populations. Although there is no structured evaluation of these types of programs, existing overviews indicate that this is not the panacea it was once believed to be. Whereas the involvement of community health workers may help address needs for health care, including for infants and children, its scope remains limited. Past experience has also taught that there are many pitfalls for the implementation of such programs. A central concern is whether and how good quality of care can be guaranteed. Careful selection and training seem to be crucial. Another key for success seems to be whether the program is embedded not only in the community, but also in the health system. Initiatives that are implemented in parallel to the health system seem to be the least successful; whereas those integrated into the existing health system seem more effective. The Brazilian Family Health Program provides the largest and best known example of this approach. Although involving community health workers has potential, more structured evaluations are needed to increase the understanding of what works and why.

The renewed interest in community health work seems to lead to a new generation of community health work interventions. At least two potentially promising directions emerge. First, existing work suggests that community health care is more effective when built on existing institutions. An example is provided by a community-based approach grafted onto an existing network of women self-help groups making a substantial difference to maternal and infant health. Second, so far, little attention has been paid to how new technologies may further strengthen this approach. An impressive hands-on example is provided by the CARE foundation in India, where village health workers are equipped with a basic mini computer that can perform some basic tests, but also contains software with algorithms to support diagnosis and treatment. Moreover, the computer is connected via a mobile network to a doctor who can be consulted remotely by the village health worker; the doctor also monitors – and, if needed, intervenes – remotely. Although further work is needed to evaluate and explore these approaches, they open up promising avenues for future health care in rural areas.

How to Choose the Appropriate Approach?

None of the above approaches is a silver bullet, and in most cases the best way forward lies in a smart combination of approaches adapted to the local context and informed by past experience. There is currently limited understanding of the relative payoffs of these approaches to inform and guide tradeoffs between them. Budget constraints, often seen as a nuisance, may help focus minds and identify where returns are

highest. This question seems particularly relevant in light of the rapid urbanization in developing countries. How to balance the strive for equal access to quality health care with the concern of investing in geographical areas that may soon contain even less people?

Like in other areas of policy making, there is no 'one size fits all' approach. Increasing overall numbers of health workers may, for instance, sound attractive where there is a general shortage and existing capacity is fully utilized, but it remains unclear whether it will improve rural health care (see discussion in the section Implications of Imbalances for Health Outcomes). And even if it does, an equally hard question is whether this the most effective way to improve health outcomes. Would the same funding bring about more changes when used in another way? The key question remains where government expenditures – and aid – are best spent.

A useful illustration of how one can make *ex ante* tradeoffs is provided by a study focusing on Ethiopia in the early-2000s. It describes two potential ways to increase service delivery in rural areas: building more health clinics or improving and extending the quality of health care in existing facilities. Using a simple model and applying it to household data on health-care usage in Ethiopia, the study argues that additional expenditures to improve the quality of care will most likely be more cost effective than building more clinics. The conclusion sits well with earlier reported results, which show that patients bypass ill-performing facilities, and also provides deeper meaning to the results on the Ghana study mentioned earlier. The strength of this approach seems twofold. First, by providing a simple model, one can test *ex ante* what would be the most effective approach. Second, designing a simple model helps to generate well-defined hypotheses that can be tested empirically and can also help select the best empirical strategy to address identification challenges (e.g., randomized control trials (RCT)).

Summary and Conclusion

This article discusses the commonly observed discrepancies in the quantities of health workers and the qualities of health care between rural and urban areas in developing countries. The key question is how to close the gap in order to improve rural health outcomes. There is little doubt that human resources matter. Studies providing causal evidence are scarce, but they confirm the importance of human resources, which affect both the quality of care and several health outcomes. This has often been interpreted as evidence that important health gains can be made by increasing the quantity of professional health personnel in rural areas. However, the understanding of the optimal number of health workers remains limited. Although a focus on numbers and shortages may be warranted in some situations, it is by no means the silver bullet it is often claimed to be. One reason is that one also observes substantial underutilization of existing human resources, both in urban and rural areas. A small but increasing number of studies have shown a real a gap between the knowledge and the practice of health workers. Quality of care thus emerges as a real concern and deserves more attention. Future work will clarify whether quantity or quality is a more important binding constraint, and under what conditions.

One key observation shows the limitations of a single focus on increasing numbers of health workers: health professionals prefer to work in urban areas. Although studies indicate that it is possible to attract more health workers to rural areas, exploiting health worker heterogeneity in preferences, and making use of an appropriate mixture of supply, demand, and matching policies, the omnipresence of these imbalances in rich as well as poor countries suggests it is very unlikely that the gap between rural and urban areas can be closed. More creative approaches are needed. One way forward may lie in combining the different sectors – public, private, not-for-profit, and for-profit sectors, whose complentarity has been studied, but deserves more attention. Another way forward lies in the next generation of community health worker programs which are grafted on existing institutions, as well as applying new technologies. Undoubtedly, future work will pay more attention to comparing the cost effectiveness of different approaches. Here, RCT can help in building a better understanding, provided they are informed by theory and designed to reveal why some approaches work better than others.

Glossary

Bilateral A relationship, such as a trading relationship, involving two partners, such as countries.
e-health The application of information and communication technologies across a range of health care services.
General Agreement on Trade in Services (GATS) An outcome of the 1995 Uruguay Round Negotiations and the basis of the global multilateral sector trading system.
Multilateral A relationship, such as a trading relationship, involving many partners, such as countries, trading with many others.
Teleconsultation A medical consultation that takes place when the patient and doctor are not in the same physical location.
Telemedicine The use of information and communication technologies to deliver clinical health care services at a distance.
World Trade Organization The global institution that deals with the rules of trade between countries.

Introduction

With increasing globalization, countries have opened up their borders to trade in goods and services, often including health services. This has given rise to heated debates in the media and the academic and professional literature, with proponents arguing that it can improve efficiency and facilitate the sharing of ideas, although opponents argue that international trade in health services will result in increased privatization and hinder domestic decision making. In reality, lack of data makes it very difficult to ascertain the volume of trade in health services and the effect it is having on health systems.

There are different ways in which health services can be traded internationally, involving either patients or health professionals traveling to another country to obtain/provide health services, countries investing in other countries' health services, and through the remote provision of health services. This article is concerned with the latter form of trade, the remote cross-border provision of health services, also known as international e-health, and its impact on the national health system of the countries involved in it.

The article reviews both the positive and negative contributions that international trade in e-health services may offer to national health systems. In doing this, it will briefly comment on the different types of trade relationships the countries may engage in, and in turn, how this can affect the impact international e-health has on their health systems.

This article is structured as follows. First, it defines e-health and outlines examples of its different uses. This is followed by an account of how national health systems of countries engaging in international e-health (both as exporters and importers) are affected by it e-health, before outlining the different types of trade relationship e-health can be traded under. The article concludes with key messages.

What Is E-Health?

E-health can be defined as the application of information and communication technologies across the whole range of health care services. Given that the scope of this article is on international e-health, it will be defined as the use of information and communication technologies to deliver health services across an international border.

Although traditional communication technologies can be used to deliver health services remotely – for instance, by using the postal service to send samples to be analyzed in remote laboratories – the term e-health is concerned with the use of nontraditional information and communication technologies. As it will be seen, most e-health services take place through the use of the Internet.

Table 1 shows the different uses of e-health, which can be clinical and nonclinical. Nonclinical health services include medical transcription, where doctors record their notes and these are transcribed remotely, often overnight, and electronic patient records. However, the most potential use for this type of trade in health services lies within the provision of clinical services. This is known as telemedicine. Telemedicine can be divided into different subsets, depending on the type of care that is provided, as shown in Table 1.

An important use of cross-border telemedicine is the remote provision of diagnostic services. The most popular of these has so far been teleradiology, where images, such as X-rays, are transferred electronically to radiologists remotely for interpretation. Teleradiology is often done across different time zones, which allows for images to be processed overnight, a process known as 'nighthawking.' Similarly, telepathology involves sending images of processed samples (such as microscope images) for interpretation.

A final (and emerging) use of telemedicine is to provide consultations at a distance. This can be done when the experts are physically located far from the patients. This practice has given rise to specialties such as teledermatology, telepsychiatry, and teleophthalmology, and has the benefit of permitting access to expertise to patients who would not have otherwise been able to travel for it. The use of cross-border provision of surgery and emergency services has been considered as a potential area of growth in the global e-health market, but its use has not been explored as yet in any major initiatives.

Table 1 Types of e-health

Nonclinical	*Diagnostic telemedicine services*	*Teleconsultations*	*Potential telemedicine uses*
Medical transcription Patient records	Teleradiology Telepathology	Teleneurology Telepsychiatry Teledermatology Teleophthalmology Telesurgery	Emergency services

An example of the cross-border use of telesurgery is shown on the following YouTube excerpt: http://www.youtube.com/watchv=d7IojFFHtiA ('Telesurgery – "Lindbergh operation"' YouTube video, 3:40, posted by Justin Kochi, 23 June 2009).

To What Extent do Countries Engage in E-Health?

The size of the global e-health market is difficult to estimate, as there is currently no systematic collection of data on the amount of e-health trade that takes place or the revenues made from it. However, estimates in the literature indicate that it is happening on a large scale and generating significant revenues, with the global e-health market estimated to be worth between US$1 billion and US$1 trillion (Mutchnick *et al.*, 2005). This lack of reliable data poses problems for health planners, as they are not aware of how much e-health trade is taking place, and for policy makers, who then base their decisions on ideology rather than evidence.

The World Health Organization's Global Observatory for e-health conducted a global survey of e-health in 2009 to map out all e-health initiatives that are currently taking place across the globe. The results from this survey are summarized in Table 2; they include all e-health initiatives (national and international), so the true size of the international e-health market will be smaller.

Of these initiatives, teleradiology, some tertiary care, and telepathology are the areas that currently hold greatest promise for international e-health trade.

Although e-health is not bound by physical location, there are some factors that influence which countries trade with which, such as common language and data management protocols. This has resulted in a significant proportion of e-health trade taking place regionally. Examples of such regional trade initiatives are summarized in Boxes 1 and 2.

How can Countries Benefit from International E-Health?

When discussing cross-border e-health trade, countries can be divided into 'exporting' and 'importing,' depending on whether they provide or 'purchase' e-health services, respectively. Exporting countries tend to be low- and middle-income countries, which have invested in technology and can provide services for a fraction of the cost of their higher income counterparts. The top three exporters of e-health services are India, the Philippines, and Cuba. However, the importing countries tend to be high-income countries, whose health systems are facing budget restrictions and efficiency calls. The USA is the top importer of e-health services. Given that the impact e-health has on countries is dependent on whether they are importers or exporters, it will be discussed separately.

Table 2 Number of e-health initiatives reported by the global survey of e-health

Subset of telemedicine	*Number of initiatives*
Teleradiology[a]	61
Tertiary care[b]	25
Teleconsultation[c]	17
Telesurgery	15
Home care and patient monitoring	9
Telepathology[d]	7
Others	8
Total	142

[a]Ultrasonography, cardiology, scintillography, and mammography initiatives have been included as teleradiology.
[b]Diabetes, obstetrics and gynecology, oncology, pediatrics, urology, etc.
[c]Includes dentistry, ophthalmology, and otolaryngology.
[d]Includes biochemistry, cytology, hematology, hepatology, histopathology, immunology, and laboratory services.

Box 1 Case study 1: The Implementing Transnational Telemedicine Solutions project

The Implementing Transnational Telemedicine Solutions project is a European initiative started in September 2012. It aims to implement 10 demonstrator transnational telemedicine projects across Scotland, Norway, Finland, Sweden, Ireland, and Northern Ireland, including the use of video consultation, mobile self-management, and home-based health services. The key objectives of the project are to improve health service coverage for remote communities, thereby reducing hospital visits, enhancing the use of technology, and increasing and fostering transnational collaboration. The project is a pilot and will be evaluated, but it is hoped it will form a sustainable telemedicine network among northern European countries. More information on this project can be found on the following website: http://www.transnational-telemedicine.eu/

Importing countries

The most important benefit the importing countries stand to gain from outsourcing health care services to exporting countries is a financial one. This is because most exporting countries are low- and middle income, and can therefore provide health services remotely for a fraction of what they would cost in the importing country, mainly due to the fact that the health professionals' salaries can be up to 10 times lower. This is particularly relevant in the current financial situation, where many importing countries are facing budgetary restrictions and are looking to make their provision of health services more efficient.

Box 2 Case study 2: India

India is one of the world's key players in e-health. It has currently more than 400 e-health platforms, made up of both public and private actors. Although the main focus of its e-health industry is the domestic population, India is also viewed as an important provider of international e-health services. Some of the more headline-grabbing examples of India's international e-health concentrate on the provision of services to the US, often through 'nighthawking' (see http://articles.economictimes.indiatimes.com/2006-08-03/news/27444693_1_hospitals-tele-radiology-teleradiology-solutions as an example); however, India's key international e-health market is made up of its neighboring countries and Africa. As such, the Government of India, through its Ministry of External Affairs, has launched two initiatives: the SAARC Telemedicine Network and the Pan-African e-Network Project.

The SAARC Telemedicine Network is implemented by the Telecommunication Consultant India (Ltd.), and it links one or two hospitals in each of the countries forming the SAARC region with up to four superspecialty hospitals in India. The initiative involves the provision of teleeducation and teleconsultations.

The Pan-African e-Network Project's objective is also to provide education and telemedicine, through teleconsultations, from India's superspecialty hospitals (10 are involved in this initiative). The aim is to provide services to 53 African countries. At the time of the launch of the second phase in August 2010, 47 African countries had already joined the project. More information on this initiative can be found on the project's website: http://www.panafricanenetwork.com/

The second means by which the importing countries can benefit from outsourcing health care services internationally is by decreasing the waiting time. The health systems of many high-income countries suffer from long waiting lists, particularly for elective procedures. By outsourcing some of their health services, such as diagnostics, the importing countries can significantly reduce waiting lists. In addition, the fact that the importing and exporting countries are often situated on different time zones allows for services to be carried out overnight, greatly improving the efficiency of the health care system in the importing countries. Furthermore, due to the importance of early diagnosis in certain conditions such as cancer, patients can be diagnosed and started on treatment sooner, which will lead to improved prognosis and lower costs.

A further advantage of engaging in e-health trade facing the importing countries is the improvement in coverage of remote areas. Remote populations are very expensive to serve and often hard to access. Therefore, providing the services remotely would greatly reduce costs and improve the quality of health care coverage of remote populations.

Finally, outsourcing of routine diagnostic and curative services to the exporting countries can reduce the workload of health care professionals in the importing country and allow them to concentrate on the more complicated cases and therefore, improve specialization and skill set in the country.

Exporting countries

Exporting countries can also benefit greatly from engaging in international provision of e-health services. Similar to the importing countries, the key benefit is a financial one, as they can generate foreign income. As highlighted earlier, the e-health market is of substantial size; although no official figures are available, it is estimated that the telemedicine market holds a huge potential for the importing countries. For instance, in India, it is estimated to be worth €37.4 million, with projections to reach €374 million (Financial Express. Telemedicine: An answer to ailing India. 5 November 2007; http://www.financialexpress.com/news/telemedicine-an-answer-to-ailing-india/236263/0). It can therefore particularly benefit the exporting country's health system if it is invested back in it. This is of particular importance given that the exporting countries are typically low- and middle income and often have underfunded health systems.

Exporting countries can also benefit from providing e-health services by reversing their 'brain drain.' The brain drain is a phenomenon caused by health professionals migrating in the pursuit of higher salaries, improved quality of life and career prospects. It particularly affects the low- and middle-income countries, which suffer severe shortages in human resources for health. It is also some of these countries that have started exporting health services, such as e-health, and can therefore take advantage of the higher salaries and career opportunities the e-health posts offer to attract some of these workers back to the country and thereby increase their human resource base in the health sector.

To be able to provide e-health services to the importing countries, the exporting countries need to remain competitive and meet international standards. They therefore often make significant investments in technology and on improving the available skill set of their health workforce. This will also benefit the local population as the technology and health professionals available will unlikely devote all of their time to providing e-health services to other countries, and can then be used to provide domestic services, thereby providing the opportunity of using the international market to subsidize their domestic services. In fact, some of the key exporters of e-health services, such as India, have important domestic e-health services, with considerable potential for expansion.

What do Countries Risk by Engaging in E-Health?

The section Exporting countries has highlighted the great potential that both importing and exporting countries have for benefiting from international e-health trade. Next, the risks these countries face when entering this type of trade in health services are discussed.

Importing countries

The key risk the importing countries face when engaging in e-health trade is data security and privacy. Data sent over to the exporting countries are extremely sensitive in nature as they include health records, and there must therefore be absolute guarantee that confidentiality will be preserved. In fact this tends to be the main barrier to engaging in this type of trade, with countries only trading with those who have similar or trusted data management protocols.

In addition, the importing countries also face the risk that the quality of the services provided by the exporting countries would be lower than that they themselves can offer. This can be further compounded by language and cultural differences,

as well as the different training the health professionals receive in different countries, which hinder the ability of health professionals to communicate with each other and the patients and agree on a course of action. A related concern is liability: Who is responsible if something goes wrong? If countries engage in e-health trade, malpractice will eventually occur, and when it does, it is not clear whose responsibility it would be. There are concerns that the importing countries would face expensive lawsuits, which would offset any savings made from e-health trade.

Finally, the importing countries risk job losses if some health services are performed in other countries. Furthermore, whereas allowing health professionals in the importing countries to specialize and concentrate on complicated cases is clearly an advantage, if all the uncomplicated cases are dealt with abroad, this may hamper the ability of new health professionals to be trained as they will not be exposed to them.

Exporting countries

Exporting countries also face some risks when providing international e-health services. Given the revenues to be made by providing e-health services to other countries, there is a risk that resources will be diversified toward this, at the cost of health services the domestic population needs. This may worsen rather than improve the national health system. In addition, if e-health services are provided through the private sector (as is often the case), the revenues generated may not be invested back into the health system.

Another risk the exporting countries face is the creation of an internal brain drain. The higher salaries and career opportunities offered by international e-health may not just attract health workers who had migrated, but also health workers currently employed by the public health system. This may actually exacerbate rather than ameliorate shortages in health professionals and again, worsen the domestic health system.

Trade Agreements

It is important to note that the potential risks and benefits countries face when engaging in e-health international trade outlined in this article are influenced by the type of trade relationship they engage in. There are three types of trade relationships countries can engage in: multilateral, regional, and bilateral. This section briefly summarizes each type of trade relationship and highlights how they can each influence the extent to which national health systems are affected by international e-health.

Currently, most e-health takes place under a multilateral system, where many countries trade with each other. This takes place under the General Agreement on Trade in Services (GATS), under the auspices of the World Trade Organization. The GATS categorizes services into four modes, which can all be applied to health services. Mode one covers the cross-border provision of services, which in the case of health would be e-health. Mode two involves consumption of services abroad (in the case of health medical tourism). Modes three and four deal with foreign direct investment (for instance, in a hospital) and the movement of natural persons (health care professionals), respectively. Under this form of trade agreement, countries can freely trade with others. The benefits and concerns described above mainly apply to the current system of multilateral trade, where it is more difficult to implement safe guards on data safety and quality of care and countries may find it difficult to define litigation procedures.

Cross-border e-health trade can also take place regionally. In fact, this seems to be the case in many instances. Countries are more likely to import health services from countries that have similar language, culture, and training standards. This has led to the development of different regional e-health initiatives, such as the Implementing Transnational Telemedicine Solutions project, the South Asian Association for Regional Cooperation (SAARC) Telemedicine Network, and the Pan-African e-Network Project initiatives described in Case studies 1 and 2.

The final type of trade relationship countries may engage in when importing/exporting e-health services is a bilateral one. This would take place between two countries, an exporter and importer, where a contract would be drawn between the two outlining conditions under which trade will take place. The benefits outlined above would still apply to this type of relationship. However, there is potential to capitalize on them, for instance, by stating clearly in the contract what proportion of the revenues has to be invested back into the health care of the domestic population of the exporting country. Furthermore, some of the risks can be averted or reduced. For instance, the contract can state what data management protocols will be used, the minimum-required qualifications of the providers, and a program for the exchange or training of human resources to alleviate shortages in the exporting country. Despite these apparent benefits, bilateral relationships in e-health (and health services more generally) tend to be underresearched and underutilized.

Conclusion

This article has covered the definition and different uses of e-health before outlining how countries – and their health systems – stand to gain or risk losing from engaging in this type of trade. The article then briefly reviewed the different types of trade relationships and how these can affect the impact international e-health trade has on both the importing and exporting countries. It is important to emphasize the dearth of data on e-health trade (and trade in health services in general), which makes it difficult for the health planners to plan their services, and base their decisions on ideology rather than evidence. Notwithstanding this, countries considering whether to engage in international e-health should consider bilateral initiatives, as these offer the possibility of controlling some of the risks, while still reaping the benefits from this type of trade.

International Movement of Capital in Health Services

R Chanda and A Bhattacharjee, Indian Institute of Management Bangalore, Karnataka, India

Introduction

There has been considerable debate in recent years regarding globalization of health services and its implications for exporting and importing economies. This debate has been sparked by the growing scope for cross border delivery of health services due to advances in information and communication technology, growing mobility of healthcare providers and patients, and commercialization of health services through foreign direct investment (FDI) and entry of domestic private players. Today, trade in health services takes place through telemedicine, medical value travel, cross border flows of healthcare workers, international capital flows, and transnational corporations in the health sector. There are also emerging opportunities in information technology (IT)-enabled delivery of health-related services, such as medical coding, transcriptions, and back-office health support services.

In light of growing healthcare challenges confronting governments worldwide due to rising healthcare costs and strained public sector budgets, aging societies, and growing demand-supply gaps in healthcare, globalization of health services is a potentially important means of providing quality healthcare, of ensuring financial sustainability of health systems, and enabling equitable access. However, given the scant and often anecdotal nature of information on trade in health services and lack of primary evidence or case studies, it is difficult to understand the trends and characteristics in any detailed manner or to draw any concrete conclusions regarding the associated risks and challenges. Hence, the debate on the implications of globalization of health services remains polarized, mostly based on conjectures and opinions rather than factual and empirical analysis. One side stresses the potential to benefit from increased foreign exchange earnings with positive implications for the domestic health systems and another side voices concerns regarding the potential adverse effects on equity and access to healthcare.

The discussion in this article focuses on one form of globalization of health services, namely, international capital flows and foreign commercial presence in the provision of health services. It consolidates the scattered, secondary information that is available on such flows in order to outline the broad trends and characteristics of this mode of health services delivery and highlights the perceived, and where available, realized impact of such flows.

The Section on Overview of Trends provides an overview of trends in foreign financing of healthcare services, highlighting key source and recipient countries as well as major firms providing health services across borders through overseas commercial presence. It also discusses the nature of such capital flows. The Section on Policies Governing Foreign Investment in Health Services highlights the regulatory environment affecting foreign investment in health services for a sample of countries. It also compares national policies with multilateral commitments made by selected countries on foreign commercial presence (mode 3) in health services under the General Agreement on Trade in Services (GATS) (the other three modes of supply in health services, under the GATS are: Mode 1 (cross border supply)). The discussion highlights the regulatory and other concerns characterizing the liberalization of health services. The Section on the Impact of Foreign Investment in Health Services discusses the benefits and challenges associated with the movement of capital in health services, drawing on existing studies and discussions with healthcare providers. Given various classification issues and interdependencies between trade in health services and other related services such as insurance, education, and IT-enabled services, the discussion on impact primarily focuses on capital flows in health services establishments such as hospitals, clinics, and diagnostic facilities. The Section on Concluding Thoughts concludes with the key policy inferences.

Overview of Trends

Financing of health services can come from sources within a country such as taxes, insurance funds, and private investment, or from external sources in the form of portfolio and equity investments, commercial loans, FDI, official aid, and non-governmental financing. As per the GATS, cross border capital flows are also a form of services trade captured under mode 3, which refers to the establishment of any type of business or professional enterprise in the overseas market in order to supply a service (Table 1).

The following discussion provides an overview of recent trends in international capital flows in health services, drawing upon a variety of multilateral and company-level data sources. A few points are worth highlighting. The first relates to the severe data limitations that constrain any efforts to analyze international capital flows in health services. Mode 3 data are not readily available from the Balance of Payments statistics and comprehensive data on measures of health resource flows are lacking. The Foreign Affiliates Trade in Services statistics provide this information, but are available for only a small

Table 1 Various modes of foreign investment in health services

	Forms of foreign investments in health services
Mode 3 in Health Services	Joint Ventures Technology tie-ups Acquisition of facilities Health insurance services Management contracts and licenses Medical education/training centers/research facilities Foreign participation or ownership of hospitals, clinics, medical facilities

group of countries. Moreover, such data are not disaggregated by activities and segments within the health services sector and there are potential overlaps with health-related ancillary services and even products. Hence, a comprehensive understanding of the magnitude and breakdown of investment flows in health services is difficult. The second issue concerns the scope of the analysis. This article takes a broad definition of commercial presence and considers any form or level of commercial involvement through greenfield investments, mergers and acquisitions, offices or subsidiaries, or any form of juridical presence as constituting mode 3. The underlying assumption is that there are associated capital flows and authorizations from the host country. Hence, the scope of the analysis is not directly aligned with the GATS definition of mode 3, and terms such as foreign investment, mode 3, and international capital flows are used interchangeably.

The Broad Picture of Capital Flows in Health Services

Although it is difficult to build a comprehensive picture of foreign investment in health services, the available data indicate that health services play only a marginal role in international capital flows in services. Inward and outward FDI flows and stocks in health services accounted for a meager 0.17% and 0.02% in total services FDI for developed economies, and for only 0.06% of the total inward stock of services FDI in developing countries, in 2005. However, the significance of health services in total services FDI has grown over time. Between 1990 and 2005, inward and outward FDI stocks grew by 762% and 380%, respectively, in developed countries. Data sources for this section include the International Trade Centre (ITC) investment map, the United Nations Conference on Trade and Developments (UNCTAD's) FDI statistics and Trans-nationality Index online databases, and the Fortune Global 500 index. (UNCTAD World Investment Reports).

Foreign Affiliates Trade in Services Statistics, which cover a variety of indicators (exports, imports, sales, turnover, and employment) regarding the activities of foreign companies in overseas markets indicate that developed countries have been the leading sources and destinations for FDI in health services. In 2000, the US was the main source as well as destination market in terms of the number of transactions and was the main recipient in terms of the value of transactions. Countries with public sector dominated health systems such as the UK and those with commercially oriented health systems such as the US have featured among the leading exporters and importers of FDI in health services (Waeger, 2007, Table 4, p. 14).

Recent data from the ITC's investment map confirm that developed countries remain the leading sources for investment

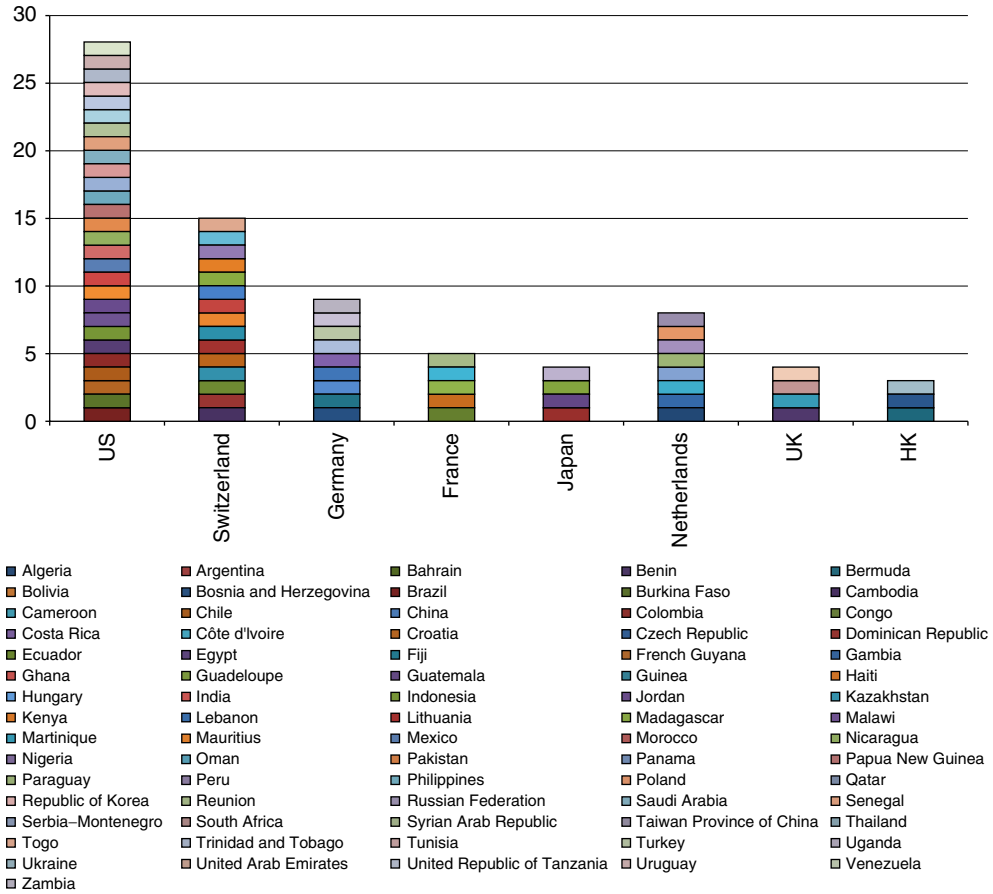

Figure 1 Top 8 leading home countries and their affiliates in host counties (health and social services). HK stands for Hong Kong (SAR China); UK for United Kingdom; US for United States. Available at: http://www.investmentmap.org/TimeSeries_Country_fdi.aspxprg=1 (accessed 24.05.11). Calculated from ITC investment maps.

in health and social activities, as measured by the number of overseas affiliates. The US is the leading investor, followed by Switzerland (Holden, 2002). However, the range of host countries for health services investment has grown considerably over the past decade. Of the 76 countries, which are host to health investments through affiliates, a large number are developing or least developed nations. Figure 1 shows the leading investor countries along with their corresponding developing country hosts for investment in health services.

ITC investment maps also provide information on FDI inflows, though this data is available for only a few countries over the 2000–10 period. The US is the leading recipient, with over US$300 million of FDI inflows (in 2010), in health and social services, significantly more than other countries. Figure 2 illustrates the FDI inflows in health services (including net sales of shares and loans to the parent company plus the parent firm's share of the affiliate's reinvested earnings plus total net intracompany loans – short- and long-term provided by the parent company) for some of the main recipient countries (excluding the US). The data show a sudden significant jump in inward FDI for some countries during this period, though it remains largely stagnant and low for many countries. It must be noted, however, that these FDI statistics pertain to health and social services. Hence, it is difficult to ascertain how much pertains to segments such as hospitals, diagnostics, and clinics directly related to healthcare provision and how much relates to health-related social services or sectors such as health insurance.

Figure 3 shows the number of foreign affiliates in the health and social services sector of the leading developing country hosts for health services FDI. The countrywise distribution indicates that the extent of foreign participation in the health services sector varies considerably across different developing countries, with Brazil, Reunion (Réunion is a French island in the Indian Ocean.), China, and Mexico hosting the largest number of such affiliates in 2009.

Transnational Activity in Health Services

Data on mergers and acquisitions in the health and social services sector show a similar upward trend in foreign commercial presence. The number of mergers and acquisitions in health and related social services reached US$14 billion in 2006 in terms of sales transactions, with an annual average value of M&A activity of US$3.9 billion during the 2004–06 period. The largest health services companies were based in and also operated in the developed countries such as the US, UK, and Canada (Cattaneo, 2009).

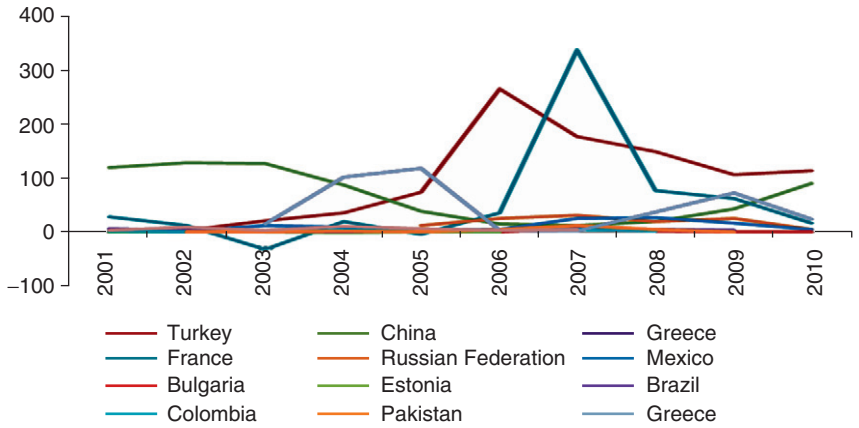

Figure 2 FDI inflows into health and social services of economies (in US$ million). Calculated from ITC investment maps for countries with data for at least 7 years. Available at: http://www.investmentmap.org/TimeSeries_Country_fdi.aspx?prg=1 (accessed 27.09.12).

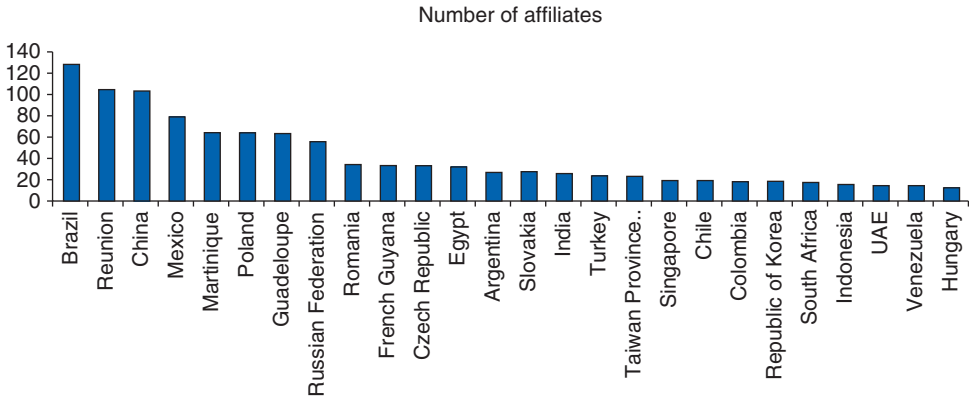

Figure 3 Number of foreign affiliates in host countries (health and social services). Calculated from ITC investment maps. Available at: http://www.investmentmap.org/TimeSeries_Country_fdi.aspx?prg=1 (accessed 24.05.11).

The growing internationalization of health services firms is also indicated by the Fortune Global 500 internationalization rankings of firms. Based on the Fortune Global 500 list for 2002, Holden (2005) had found that direct health services providers were the least internationalized whereas firms in areas like insurance and pharmaceuticals were the most prominent in internationalization rankings (Holden, 2005). Ten health service companies were listed on the Global 500 List in 205 and nine were ranked in 2006, 2007. The average ranking was 298, 262 and 245, respectively, for each of these years (http://money.cnn.com/magazines/fortune/global500/2010/index.html (accessed April 2011)).

Although the top ranked health services firms are mostly based in and also operate in developed countries (chiefly the US), M&A activity in the hospitals and clinical services segment reflects diversification of source and recipient markets. **Table 2** provides information on recent acquisitions of healthcare providers involving developing countries. It reflects the emergence of a small set of transnational hospitals and healthcare providers with both regional and global presence and the entry of several developing country health services firms based in Asia and Africa into foreign markets through M&As. It is also interesting to note the emergence of South–North and South–South flows of capital. The bilateral pattern of M&As indicates the significance of factors such as geographic and cultural proximity, regional markets, growth dynamics, and market size.

Box 1 highlights the growing regional and global presence of healthcare providers from selected developing and developed countries, and also outlines the formats and strategies adopted by these providers in overseas markets.

Entry into overseas markets is thus occurring through joint ventures, franchises, greenfield investments, acquisitions, tie-ups, contractual arrangements, and public–private partnerships. Linkages are also evident with other forms of health services trade.

Policies Governing Foreign Investment in Health Services

Increased transnational activity in direct health services reflects FDI liberalization in health services and the incentives given to private players in many developing countries. Since the 1990s, developing countries such as India, Indonesia, Thailand, Sri Lanka, Brazil, and South Africa have opened up their health service sectors to participation by foreign hospitals, diagnostic centers, and clinics. Privatization and deregulation of the healthcare sector in these countries have also contributed to the emergence of private healthcare providers who are globally or regionally competitive. Cambodia, for instance, permits cross border investment in hospital services and foreign ownership. It also permits management of private hospitals and clinics with the condition that at least one director is a national. Foreign firms are allowed to provide dental services through joint ventures with Cambodian legal entities. Similarly, Indonesia is open to foreign healthcare providers, allowing Singaporean, Australian, and Canadian firms to operate in its market. India has permitted automatic approval for 100% FDI in hospitals since 2000. Between 2000 and 2006, there were close to 100 approved FDI projects in hospitals and

Table 2 Recent acquisitions of healthcare providers involving non-OECD countries

Year	*Investor*	*Subsidiary*	*Exporting country*	*Importing country*	*Value of investment*	*Nature of investment*
2006	Netcare	General Healthcare	South Africa	The UK	GBP 2.2bn	52.6% stake
2007	Mediclinic	Emirate Healthcare Holdings	South Africa	United Arab Emirates	USD 46.4m	49% stake
2007	Mediclinic	Hirslanden	South Africa	Switzerland	USD 2.4bn	100% stake
2005	Bumrungrad International	Asian Hospitals	Thailand	Philippines		45.5% stake
2006	Bumrungrad International	Bumrungrad Hospital Dubai	Thailand	United Arab Emirates		49% stake (Joint venture with Istithmar)

Box 1 International health service provider firms from developed and developing countries

Developing countries

Singapore: The Parkway Healthcare Group is the biggest investment group for healthcare in Singapore and one the largest healthcare organizations in Asia. It has created Gleneagles International as an international brand. The company has been interested in acquisition of hospitals in Singapore, building up a base, and entering countries like India, Indonesia, Malaysia, Sri Lanka, and the UK, mostly through joint ventures with local partners. It entered the Indian healthcare market in 2003 through a joint venture with the Apollo Group and built the Apollo Gleneagles Hospital, a multispecialty hospital at a cost of US$29 million (Chanda, 2007a). It has formed a joint venture with the Mumbai-based Asian Heart Institute and has established a research center to provide medical excellence. It is in the process of setting up a specialized heart hospital in London.(Source : http://portal.bsnl.in/bsnl/asp/content%20mgmt/html%20content/business/business56857.html)

The Singapore-based Raffles Medical Group is building strategic alliances through triangular business associations with healthcare organizations from developed countries and venturing into developing countries in partnership with host country investors.

Thailand: Bumrungrad Hospital in Thailand has entered into management contracts with hospitals in Bangladesh and Myanmar. It has formed a joint venture with a hospital in the Philippines. Bangkok Hospital has 12 branches in Southeast and South Asia, located mostly in tourist towns (Arunanondchai and Fink, 2007).

India:The Apollo Group of Hospitals has centers of excellence in several countries like Nepal, Sri Lanka, Ghana, and Bangladesh. It has also entered into contract-based management of hospitals or clinics in the United Arab Emirates, Oman, Kuwait, Mauritius, Malaysia, Sri Lanka, and Nigeria (Mortensen, 2008a, and http://www.thehindubusinessline.in/2005/12/03/stories/2005120303200200.htm). It has established a telemedicine center in Kazakhstan. Apollo Hospitals has entered into a joint venture with Amcare Labs, an affiliate of Johns Hopkins International, to set up a diagnostic laboratory in Hyderabad.

South Africa: South African health services firms are present in the UK, Switzerland and the United Arab Emirates, and are also the main source of regional FDI in Southern Africa (Mortensen, 2008a). Some major firms include Netcare, Mediclinic, Life Healthcare, and the Afrox Healthcare Group. Mediclinic owns private hospitals in Namibia; Life Healthcare operates private hospitals and clinics in Botswana; and the Afrox Healthcare Group has operations in Botswana, Namibia, Zambia, and Mozambique. Netcare has a public–private partnership with the Lesotho government to build a hospital and refurbish two feeder clinics and run clinical services for the government.

Developed countries

US corporations are major players in the hospital sector. Hospital corporations own the for-profit hospitals that they operate. In small specialized clinics like eye clinics, rehabilitation centeres, and outpatient clinics, US firms enter through joint ventures with local specialist doctors or surgeons.

Columbia Asia Group, a Seattle-based hospital services company, a worldwide developer and operator of community hospitals, has started its first American-style medical center in Bangalore.

The Fresenius Medical Care group (FMS) is headquartered in Germany and is one of the leading foreign healthcare providers in the US. FMS has operations Belgium, France, Italy, the Netherlands, Portugal, Switzerland, and the UK. It has affiliates in Australia, Singapore, Malaysia, Thailand, Korea,Taiwan, Philippines, Hong Kong, and Japan, and representative or branch offices in New Zealand, India, Indonesia, and China (Outreville, 2007).

Source: Based on company reports, country-specific studies, miscellaneous newspaper reports.

diagnostic centers for a total of US$53 million from both developed and developing country sources (Chanda, 2007a). Thailand's open FDI regime for hospital services has resulted in several part foreign-owned hospitals, mainly in the Bangkok area, with investments from Japan, Singapore, China, Europe, and the US.

Table 3 summarizes the FDI policies in the health services sector for a representative set of developing countries and their GATS commitments in mode 3. It highlights the extent of liberalization that has been undertaken autonomously in health services and the public policy considerations associated with opening up this sector.

Table 3 indicates that restrictions in the form of limits on foreign equity participation, type of foreign commercial presence, economic needs tests, authorization, certification, and licensing requirements, discriminatory taxes, technology collaboration, and transfer conditions apply in many countries. A comparison of the national policies with the GATS commitments reveals a general unwillingness to legally bind existing FDI regimes or to even undertake GATS commitments in health services.

Countries have also made commitments in health services under bilateral and regional agreements. Obligations of fair and equitable treatment, and pre- and postestablishment national treatment undertaken in Bilateral Investment Treaties (BITs), may also have a bearing on foreign investment in health services, to the extent that health services are covered under the BITs. Overall, however, countries tend to leave health services uncommitted and outside the purview of investment obligations under such agreements. Evidence also suggests that liberalization of FDI in health services has not necessarily translated into increased FDI inflows as structural and regulatory factors continue to constrain foreign providers. (High establishment costs, shortage of quality manpower, and low insurance penetration can constrain foreign investors.)

Impact of Foreign Investment in Health Services

Several studies have discussed the welfare implications of trade in health services, including foreign commercial presence in health services. The effects discussed relate to the resource allocation and accumulation effects of trade liberalization in health services and the likely equity-efficiency tradeoffs. With regard to foreign investment in health services, most authors conclude that the impact on national health systems is shaped by (1) the existing structure of the health system and the extent of commercialization and private sector participation rather than the extent to which the investment is foreign or domestic, and (2) the national regulatory environment.

Table 3 GATS commitments and unilateral FDI policies in health services for selected developing countries

	Hospital Services		*National FDI Policy*	*Other Human Health Services*	
	Mode 3 Commitment under GATS Limitations on Market Access	*Limitations on National Treatment*		*Mode 3 Limitations on MA*	*Limitations on NT*
Bangladesh	No commitment made in GATS	No commitment made in GATS	Commercial presence requires that Foreign Service providers incorporate or establish the business locally in accordance with the relevant provisions of Bangladesh laws, rules and regulations. There is no fixed ratio of equity between local and foreign investors. Foreign equity to the extent of 100% allowed	No commitment made under GATS	No commitment made under GATS
India	Only through incorporation with a foreign equity ceiling of 51%	None	Since 2000, 100% FDI under the automatic route permitted, no government approval required as long as the Indian company files with the regional office of the RBI within 30 days of receipt of inward remittances and files required documents within 30 days of issue of shares to nonresident investors. Foreign Investment Promotion Bureau approval currently only required for foreign investors with prior technical collaboration, but allowed up to 100%	No commitment	No commitment
Jordan	One of the owners must be a physician except in a public limited company. Commercial presence subject to 51% foreign equity limitation. Starting no later than 1 January 2004, 100% foreign equity will be permitted	None	Foreign investors are treated equally as Jordanians. The only difference is that non-Jordanians should deposit bank drafts of no less than 50 000 JD. Hospital sector-foreign investors can have 100% of the property	None, except lab director must be a Jordanian national. Foreign equity participation limits same as under the GATS, full liberalization effective January 1, 2004	None
Malaysia	Hospital Services Private hospital services: economic needs test; only through a locally incorporated joint-venture corporation with Malaysian individuals or Malaysian-controlled corporations or both and aggregate foreign shareholding in the joint	Establishment of feeder outpatient clinics is not permitted	Limited to 30% participation. But commitment under ASEAN Framework Agreement on Services (AFAS) permits higher equity stakes for foreign investors from the ASEAN member countries – 51% in 2008, 70% in 2010	No commitment	No commitment

	Hospital Services		*National FDI Policy*	*Other Human Health Services*	
	Mode 3 Commitment under GATS Limitations on Market Access	*Limitations on National Treatment*		*Mode 3 Limitations on MA*	*Limitations on NT*
	venture corporation shall not exceed 30%; and the joint venture corporation shall operate a hospital with a minimum of 100 beds				
Nepal	Hospital services and direct ownership and management by contract of such facilities on a 'for fee' basis: none, except only through incorporation in Nepal and with maximum foreign equity capital of 51%	None	Needs to be registered and approved from Department of Investment, Department of Health and Company registrar's office. Foreign investors can own up to 100% equity in private health firms and are entitled to repatriate the investment and other earnings	No commitment	No commitment
Thailand	No commitment made under GATS	No commitment made under GATS	Must apply for and obtain a Foreign Business License before commencing operation. This category includes the business activity of leasing both fixed and nonfixed assets. Additionally, the activities in which representative offices and regional offices are allowed to engage in are all services that fall under this category	No commitment made under GATS	No commitment made under GATS
Vietnam	Foreign service suppliers are permitted to provide services through the establishment of 100% foreign-invested hospital, joint venture with Vietnamese partners or through business cooperation contract. The minimum investment capital for a commercial presence in hospital services must be at least US$20 million for a hospital, US$2 million for a policlinic unit, and US$200 000 for a specialty unit	None	Some foreign presence exists, though exact shares unavailable; largely complies with GATS commitments	No commitment	No commitment

Source: Based on GATS schedules of commitments in health services.

Hence, the consensus is that the costs and benefits may not be related to foreign investment per se but to the existing regulatory environment and the public–private mix characterizing the country's health system (Chanda, 2001; Smith, 2004; Janjararoen and Supakankunti, 2002).

Overall Cost-Benefit Dynamics

There are three dimensions along which the implications of foreign commercial presence in health services have been assessed. These relate to efficiency, equity, and quality.

Efficiency

Foreign commercial presence can help augment a country's health resources by bringing in additional financial resources, thereby enabling investment in capacity expansion and economies of scale, potentially alleviating the pressure on government budgets, and allowing public funds to be reallocated more efficiently. At the same time, foreign investment could create inefficiencies by encouraging overinvestment of resources in high-end and highly capital-intensive and specialized treatments and procedures with lower cost-effectiveness, while diverting funding from basic healthcare services. Inefficiencies may also arise, if domestic institutions compete by investing in such technologies and procedures at the expense of broader healthcare needs, and if the country's import burden increases. There could also be long-term outflows of payments to foreign investors. There may also be direct and indirect subsidization costs for incentives given to foreign investors. However, the efficiency gains or losses are likely to vary across different countries, depending on the regulatory environment governing such inflows and the infrastructural and human resource conditions, which would shape a country's ability to absorb foreign investment, and the extent to which the private healthcare segment is competitive and dynamic and in a position to derive benefits from the entry of foreign healthcare providers.

Quality

Foreign commercial presence in hospitals and health management may improve the quality of national health systems through the introduction of better management techniques and information systems, better technology, equipment, and infrastructure, and more opportunities for training and skill improvement of medical and management personnel. Foreign-owned or managed healthcare establishments are more likely to follow international standards and to get international certification. There could be positive spillover effects on domestic establishments, which may be incentivized to upgrade their standards, undertake technology investments, and get accredited. Investments in higher end technology and equipment could also provide greater exposure to healthcare professionals, thus helping improve their skills. Better quality small and midsize hospitals, diagnostic labs, and clinics are also likely to tie up with larger hospitals in terms of referral services, thus potentially improving outreach and quality of healthcare for all. Such improvements in the quality of the domestic healthcare system and presence of foreign healthcare providers of global standards could in turn benefit the country by reducing spending on expensive treatments overseas. Once again, these gains would be shaped by the regulatory environment for ensuring quality and standards, the ease with which technology and equipment can be accessed, and the dynamism of the domestic healthcare system.

Equity

Foreign commercial presence may have positive as well as negative implications for equity. Such establishments are more likely to cater to the urban and affluent segments of the population who can afford to pay, potentially aggravating existing inequities in access to healthcare between the rich and poor, between the urban and rural populations. Such establishments are more likely to focus on tertiary care, specialized treatments, and curative and intervention-oriented procedures rather than primary and preventive healthcare needs. There may be cost implications as foreign-owned and managed health providers are likely to be costlier given their higher capital intensity and focus on quality systems and processes and accreditation, which could adversely affect access by the poor out-of-pocket paying population. Foreign investment in health services, particularly in hospitals could also distort the healthcare market by encouraging brain drain of the most qualified and specialized health personnel toward such establishments and away from domestic establishments with offers of better pay and facilities. The latter could adversely affect the quality of medical manpower in competing institutions, particularly, public sector hospitals. Thus foreign commercial presence could accentuate the dualistic structure that often characterizes health systems. Such two-tiering could also weaken the constituency for improving public services.

But there are potential positive implications. The entry of foreign healthcare providers is likely to augment employment opportunities in the healthcare sector at all levels, with better remuneration, especially for specialized and senior medical professionals. Such establishments are also more likely to attract overseas medical professionals and returnees, who are internationally accredited, and could augment human resource capacity and quality in the host country. Some studies have highlighted that foreign healthcare providers may have greater scope to undertake cross-subsidization of poor patients, to do more outreach and extension services, and to establish themselves in second tier cities and towns, given their larger volumes and deeper pockets. Again, the equity implications, positive and negative, are likely to be contingent on factors such as the extent of health insurance penetration, how segmented is the prevailing healthcare system, whether there are regulatory requirements to cross-subsidize the poor and ensure access to the poor in foreign investor hospitals, and the overall quality and availability of human resources.

There are also externalities from foreign commercial presence in health services to other modes of health services trade. Foreign investment in health services can complement medical value travel, telemedicine, and movement of health personnel. Foreign commercial presence and setting up of internationally accredited and recognized hospitals could help attract foreign patients and augment medical value travel exports, reduce imports of health services through outflows of domestic patients, and encourage telemedicine exports.

Outward investment in health services through acquisitions, new ventures, and management and other tie-ups can also benefit exporting institutions through increased foreign exchange earnings, inflows of foreign patients, and greater exposure for their professionals.

Evidence from Selected Countries and Firms

The information in this section is based on company reports (Arunanondchai and Fink, 2007; Chanda, 2007a,b, 2010; Timmermans, 2002; Benavides, 2002; Janjararoen and Supakankunti, 2002; Wadiatmoko and Gani, 2002; Mortensen, 2008a,b), and miscellaneous newspaper articles.

Secondary evidence from a sample of transnational health services firms confirms the aforementioned implications of foreign investment in health services.

- South African hospital companies have succeeded in winning healthcare contracts abroad, including the UK's National Health Service. Netcare established its presence in the UK in 2001. It has helped in reducing wait lists in selected areas of the UK. In 2006, Netcare led a consortium that acquired General Healthcare Group owner of the largest independent hospital operator BMI Healthcare, making it one of the largest healthcare groups with 119 hospitals and almost 11 000 beds. Under this contract, Netcare sends teams of medical personnel from South Africa to its establishments in the UK for fixed periods, thereby enabling its employees to work 4–6 weeks at a time abroad, to get exposure to opportunities overseas, and to supplement their income with fixed term contracts abroad. Such ventures have also helped to reduce staff turnover and improve retention of skilled personnel in South Africa (see, http://www.netcareuk.com).
- Cuba has used joint ventures with Canadian, German, and Spanish companies to attract patients from these countries for specialized treatments. Such investments have helped it to become a hub for teleconsultation and telediagnostic services for the Central American and Caribbean market and have facilitated the establishment of specialized Cuban clinics in Central and Latin America where Cuban physicians and nurses are employed.
- In its bid to become the medical center of the Arab world, **Jordan** has provided incentives for national and foreign private investment in the health sector. This has led to the establishment of several private hospitals with foreign financing and tie-ups, benefiting the Jordanian health system through state-of-art technology, computerized links with prestigious health centers in Europe and North America, and medical value travel exports to the region.
- India's Apollo Group of Hospitals highlights the linkages between mode 3 and other forms of trade in health services. Apollo's mode 2 exports have been facilitated by its overseas marketing offices and management contracts with hospitals in the UAE, Saudi Arabia, Oman, Kuwait, Mauritius, Tanzania, UK, Sri Lanka, Bhutan, Nigeria, Pakistan, and Bangladesh. Apollo Gleneagles, which is a joint venture with the Singapore-based Parkway Group, exports health services to patients from neighboring countries like Bangladesh, Nepal, Bhutan, and Myanmar. It also provides telemedicine services such as medical consultation, diagnostic, telepathology, teleradiology, and scanning services. Apollo also provides contract research and medical education and training services through its overseas subsidiaries, using a combination of cross border supply (online training and research services) and temporary onsite deployment of professionals at its subsidiaries, thereby benefiting its own professionals and also host country professionals.
- In India, Hindustan Latex Ltd and Acumen Fund (USA) have created a joint venture to develop a small chain of high-quality and affordable (30–50% of regular price) maternity hospitals to serve the low-income population in underserved Indian regions. The aim is to make this a global model for increasing access to qualitative and affordable healthcare for the poor.
- The public and the private sectors in China have jointly developed a strategy to attract foreign health providers to set up commercial presence. Chinese institutions have entered into joint ventures with partners in the medical profession and with local authorities overseas. Traditional Chinese Medicine facilities have been established in more than twenty countries. Such joint ventures help spread Traditional Chinese Medicine overseas, enable the deployment of Chinese health workers and their exposure to other systems under contractual arrangements, and help attract patients to China.
- Evidence from some ASEAN countries shows that foreign investor hospitals can aggravate the existing inequities in the host country's healthcare system. Most of these hospitals have located in and around the main cities such as Bangkok and Jakarta and target the upper income segment. The Indonesian government has thus imposed fewer regulatory requirements on foreign investors in regions with weak public health infrastructure to attract foreign investors to islands other than Java and to the smaller cities. The Indonesian government has also imposed a requirement to accommodate at least 200 beds in foreign investment hospitals.

Primary Evidence on Impact: Case Study of India

A survey of 25 hospitals conducted in 2007 across several major cities in India examined the realized or perceived impact of foreign investment in Indian hospitals on quality, affordability, infrastructure, range of services, technology, accessibility, and prices. The survey findings largely corroborate earlier studies (Chanda, 2007a,b).

Services and infrastructure

Foreign investor hospitals were found to focus on more advanced and specialty services compared to domestic hospitals, indicating a greater emphasis on niche areas and on high revenue generating curative and surgical interventions as opposed to preventive care. The survey also revealed that foreign investor hospitals tend to invest more heavily in high-end technology and state-of-the-art equipment, which in turn leads to a difference in approach to medical care, with more intensive use of medical equipment in order to recover

investments. On average, foreign investor hospitals were also found to have more medical facilities, more equipment, and to be larger in terms of the number of beds, rooms, ambulances, and Intensive Care Unit infrastructure. Foreign funded institutions also reported greater availability of postoperative care facilities and critical care services. There was also greater availability of medical staff for critical care and specialized services as opposed to general care.

Human resources: Remuneration and quality issues

The survey findings showed that foreign investor hospitals pay higher salaries to their medical staff at all levels and particularly to senior specialists, suggesting the possibility of internal brain drain from domestic private as well as public sector hospitals to foreign investor hospitals. The findings on remuneration also suggest that there could be positive implications for employment and income opportunities for medical personnel. Hence, there is evidence on a likely two-tiering impact.

Costs of services

The data on costs of different procedures and treatments indicated that foreign investor hospitals tended to be more expensive than comparable domestic health providers. Indepth discussions with industry experts revealed that hospitals were on average 15–30% costlier than small and medium size healthcare providers.

Spillover effects

The study found a strong spillover effect on medical value travel. Increased foreign investor presence in hospitals was seen as facilitating medical value travel to India by enabling tie-ups with foreign health insurance providers and development of customized insurance products for elective surgeries by overseas patients in India with follow-ups abroad. Foreign investment in hospitals was seen as encouraging the entry of multinational insurance companies, which would be more comfortable in dealing with foreign funded corporate hospitals that were accredited and accountable. Respondents also noted that foreign investment in hospitals would spur expansion of activities in other areas such as medical transcriptions, back-office medical outsourcing, and telemedicine as well as promotion of opportunities in other areas such as clinical trials outsourcing, research and development, and medical training and education. Several respondents noted the likely boost to telemedicine from foreign commercial presence, given investments by foreign players in IT systems. Strong positive externalities were also perceived in the form of technology and knowledge transfer through tie-ups for research and development, technology sharing, professional exchange, and continuing medical education.

Concerns

The survey highlighted some areas of concern, along the lines suggested by other studies. Increased foreign investment in hospitals was seen as aggravating the internal brain drain of medical personnel from public to private healthcare establishments and making it more difficult for the public sector to retain doctors and teachers in affiliated medical colleges. It was noted that the increased focus on earning money would mean less focus on teaching and research, especially on issues relevant to local conditions. Several respondents highlighted the fact that small and medium size nursing homes would face greater competition from the large corporate hospitals, have difficulty retaining staff, and would become less attractive as they would not be able to provide many services under one roof. Hence, many would have to close down or would be acquired by the larger players. Similar concerns were expressed for independent pharmacies and diagnostics/labs. It was also felt that as foreign funded hospitals provide better remuneration, their expansion would put upward pressure on wages and salaries of medical personnel and thus increase competition for quality manpower. A third concern was related to costs, affordability, and relevance of healthcare following increased foreign investment in hospitals and possible adverse effects on the poor who might be squeezed out of the system. Several respondents expressed concern that foreign investment in hospitals and the focus on profits and returns for shareholders would lead to increased healthcare costs, increasing the existing income and geographic divide in healthcare delivery.

Concluding Thoughts

Foreign investment in health services has grown over the past decade, taking a variety of forms and involving a growing number of developed and developing countries. Although it is difficult to quantify the impact of foreign investment on national health systems, several general studies highlight the likely pros and cons of such investment. There is broad agreement on the various positive and negative implications. An important conclusion of these studies is that the impact on national health systems is a function of regulatory frameworks, the prevailing market structure, and the extent of commercialization. Although foreign investment may have adverse implications for equity, affordability, and on the public sector, the real underlying cause could be the prevailing distortions in the healthcare system and not foreign investment.

A key policy inference is that it is possible to shape the impact of foreign investment on national health systems and that possible negative fallouts should not lead to a restrictive approach to such investments. The negative effects can be mitigated and prevented. The positive effects can be facilitated through appropriate policies and regulations. For instance, public–private partnerships and facilitation of linkages between the public and private health services segments with regard to medical education, training, staff and information exchange, can be encouraged to reduce the scope for two-tiering. Initiatives to increase insurance penetration and conditions requiring foreign investors to provide medical outreach and extension services in less served areas, could mitigate the negative equity fallouts.

Clearly, more research is required across a mix of countries with different health systems and regulatory environments to draw more definitive, evidence-based conclusions. More dialog is also required between the commerce and health ministries and investment boards to enable an integrated social and economic perspective and to accordingly frame an appropriate mix of investment incentives and conditions to balance the tradeoffs.

International Trade in Health Services and Health Impacts

C Blouin, Institut national de santé publique du Québec, Québec, Canada

Glossary

General Agreement on Tariffs and Trade (GATT) The predecessor of the World Trade Organization (to 1994).
General Agreement on Trade in Services (GATS) GATS were an outcome of the 1995 Uruguay Round Negotiations and basis of the global multilateral sector trading system.
Medical tourism A term describing the travel of individuals to countries solely for the purpose of receiving health care.
Multilateral A relationship, such as a trading relationship, involving many partners, such as countries, trading with many others.
Multiplier The fiscal multiplier measures the eventual change in national income that results from an initial change in a component of aggregate demand in the economy.
Telemedicine The use of information and communication technologies to deliver clinical healthcare services at a distance.
World Trade Organization The global institution that deals with the rules of trade between countries.

Introduction

The first section of this article reviews the risks associated with cross-border trade as well as legal consequences of trade treaties, focusing on World Trade Organization (WTO) agreements. It also discusses three features of the WTO agreements, which provide space for addressing the tensions between the economic objectives of trade policy and public health objectives. The second section of the article reviews how the WTO has been adjudicating disputes which have had health implications; indeed, the WTO dispute settlement mechanism is a venue whose explicit function is to weigh the objectives of facilitating international trade with other objectives included in these same treaties such as the protection and promotion of human health. The article concludes with some illustrations of ongoing exercises of global health diplomacy where tensions between trade and health policy objectives are being negotiated.

How Can Trade Affect Health?

When we examine the impact of trade on health, we are looking at two types of independent variables. First, it can refer to international trade rules as they are embodied in multilateral, regional, and bilateral trade and investment treaties negotiated by national governments. Second, it includes the impact of economic integration, i.e., increased cross-border flows of goods, services, and capital. Trade agreements can increase economic integration and the intensity of these cross-border

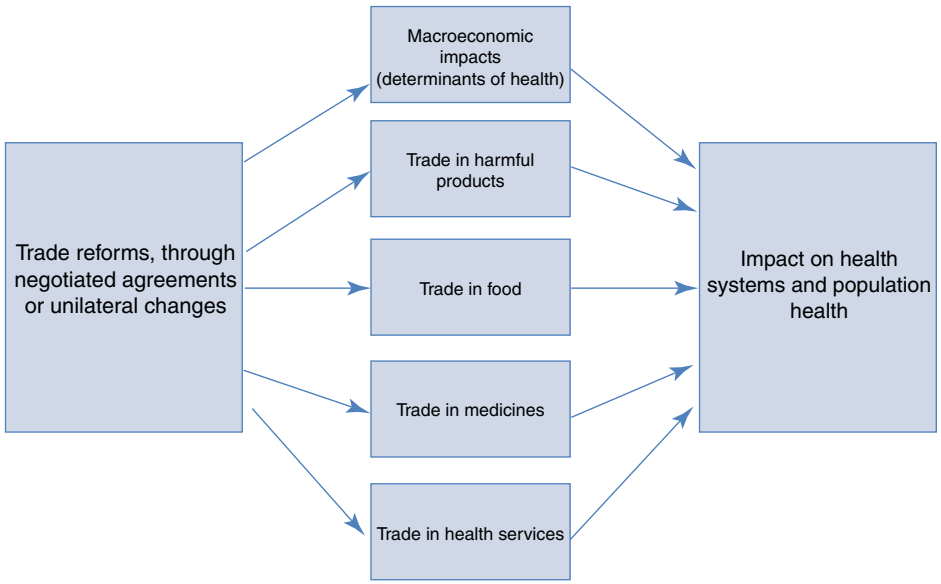

Figure 1 Trade and health key linkages.

flows; however, these may take place in the absence of treaties and should be considered as a separate analytical entity. Trade so defined can have impact on health systems and population health through a number of transmission channels. There are five main causal chains (see Figure 1). Trade reforms can have an impact on the macroeconomic conditions of a country to facilitate or hinder population health through changes in characteristics, such as poverty and inequality. Trade reforms can also ease or restrict access to harmful products, such as tobacco, weapons, or toxic waste. Third, trade policy in the agricultural sector can affect population health through its impact on food security, diet, and nutrition. Fourth, trade agreements also influence access to medicines by including patent protection such as we find in the WTO's Agreement on Trade-related Aspects of Intellectual Property Rights (TRIPS). This is the trade-health linkage that has received most attention from academics, policy makers, and civil society organizations in the last 15 years. The final section of the article focuses on a fifth channel, trade in health services.

National health systems can be transformed by the introduction of cross-border suppliers and investors. Trade in health services can take four different forms. First, the services can be provided electronically with both the patients and the providers remaining in their own jurisdictions; telemedicine across border is an example of such a trade. This is called Mode 1 of the General Agreement of Trade in Services (GATS) of the WTO.

Second, patients can travel abroad to receive care; health tourism or medical tourism has received a lot of attention in research and policy circles in recent years. There are good indications that there is a steady increase of health tourism, even though the actual scale is not well measured. Concerns have been raised regarding the quality of care and equity, in terms of the impact of such trade on the health system of the countries to which patients travel. Indeed, health tourism has been presented as an economic opportunity for many middle-income countries that are struggling with relatively weak health systems. The main concern is the risks of reallocation of resources away from local patients toward higher quality care supplied to affluent domestic and foreign patients.

However, Mode 2 trade can become an important source of foreign exchange earnings and add to the multiplier effects of tourism-related activities in the host economy. Promoting health tourism can also lead to efficiency gains for importing countries. According to one estimate, the health care system in the US would save $1.4 bn annually if only one in ten patients were to go abroad for a limited set of 15 highly tradable, low-risk treatments.

Another potential positive contribution is that some of the revenues from health tourism be harnessed to improve access to health care services for the local population. Typically, advocates of health tourism will recommend that governments in developing countries "put in place universal access policies that require private providers to contribute to a health care fund" (Mattoo and Rathintran, 2005). However, a review of the literature and the institutional frameworks related to health tourism failed to identify such a mechanism. Neither in the more established health tourism destinations like India, Jordan, Thailand, nor in countries that are more recently involved in this form of service exports (the Caribbean, Mexico, Costa Rica) has an explicit mechanism to allocate some of the additional income generated from health tourism been used to increase access to health care services for local patients. The only country found to have mentioned a specific tax on health tourism is New Zealand, where the government was considering in 2009 to apply on specific levy on private hospitals catering to foreign patients which would contribute to the Accident Compensation Corporation, a public agency which provides a comprehensive, no-fault injury insurance to all New Zealanders and visitors (reference http://www.imtj.com/news/EntryId82=166606).

The third mode of cross-border supply of health services according to the GATS relates to the movement of capital, such as foreign investors investing in the establishment or the management of a clinic or a hospital. The potential benefits of Mode 3 trade in health-related services are to generate additional investment in the health care sector, contribute to upgrading health care infrastructure, facilitate employment generation, and provide a broader array of specialized medical services than those available locally. However, the potential downside risks of Mode 3 trade once more include growing inequality in access and the emergence of a two-tiered health care system. This two-tiered system may result from an internal 'brain drain,' as foreign commercial ventures may encourage health professionals to migrate from the public to the private health care sector.

Trade in health services can also take place through the temporary movement of natural persons (so-called Mode 4 of the GATS); a nurse, physician, or other health professional practice abroad on a temporary basis. Mode 4 trade is still limited relative to its potential due to a number of regulatory barriers posed by recipient countries. These barriers include immigration rules, discriminatory treatment of foreign providers, and the nonrecognition of foreign qualifications. Virtually all countries impose restrictions on temporary migration and the quotas are usually substantially lower than the actual demand for entry. The cross-border movement of health care professionals may promote the exchange of clinical knowledge among professionals and therefore contribute to upgrading their skills and medical standards. The potential downside risks of Mode 4 trade arise from the danger that such mobility may be of a more permanent nature, such that health care professionals often trained at considerable home country expense are for ever lost, thus reducing the availability and quality of services on offer to home country consumers of health care services.

Trade rules can affect the cross-border supply of health services. Indeed, the main reason national governments agree to sign trade treaties is to increase access to foreign markets and facilitate international trade. Governments make commitments in trade agreements such as GATS, where they guarantee access for foreign investors interested in establishing a new clinic or health insurance company with a view to facilitate and increase cross-border flows of services and capital. Governments can unilaterally adopt reforms where they allow foreign services providers to compete in the domestic markets through one or all of the four modes of supply; however, including this reform into the binding commitments of a trade agreement decrease the likelihood that this policy will be reversed in the future.

Type restriction	
Market access	
# of beds	Austria, European Community, Latvia, Malaysia, Oman
Investment	Croatia, Vietnam
Needs test	Croatia, European Community, Lithuania, Malaysia, USA
Other regulation	Pakistan, St Vincent
Ownership	India, Jordan, Malaysia, Mexico, Nepal, Saudi Arabia, Chinese Taipei, USA, Vietnam
Prior authorization	Austria, European Community, Latvia, Lithuania, Slovenia, Turkey
Registration/licensing	Jamaica
Residence/nationality	Cambodia, Latvia, Poland, Chinese Taipei
National treatment	
Access to financial support	Lithuania, Poland, Slovenia
Legal entity	Malaysia
Other regulation	Oman
Registration/ licensing	Albania

Type of restriction	Defination
# of beds	Restriction on the number of beds in a health care facility.
Access to financial support	Restrictions on the access to financial support from public resources
Language	Requirement for the knowledge of a specific language.
Legal entity	Restrictions on the type of legal entity that can supply a service or benefit from a specific provision.
Investment	Requirements for the type and amount of foreign investment
Needs test	Requirements for local or economic needs tests.
Other regulation	Reference to a specific domestic legal act or regulation affecting market access or nationa l treatment.
Ownership	Requirements for the percentage or amount of foreign equity.
Prior authorization	Requirements for prior authorization for establishment or other activity from a ministry or another authoritative body.
Recognition of qualifications	Requirements regarding qualification and examination equivalents.
Registration/licensing	Registration or licensing requirements.
Residence/nationality	Requirements regarding the residency or nationality of service suppliers, the board of directors or other employees.
Operational experience	Requirement on the length of operational experience.

Figure 2 Summary of GATS Mode 3 commitments and restrictions in hospital services (updated in November 2009).

In the case of health-related services, WTO members have made relatively few and limited commitments in the GATS. One can argue that one option for policy makers to address the tensions between trade and health has been to prefer unilateral trade reforms rather than to include liberalization of health-related services into multilateral trade treaties. In that manner, they maintain a greater flexibility to experiment with cross-border health services provision and reverse reforms if they fail to deliver the desired outcomes. The detailed nature of these trade commitments in services provides a second avenue for government to address the tensions between their trade and public health objectives. Indeed, WTO member states can fine-tune their GATS commitments according to which of the four modes and specific health-related services they want to include in their list of commitments. They can also decide whether they want to commit to national treatment (no discrimination against foreign providers vs. domestic ones) or to market access (removing barriers to entry). They can also stipulate specific conditions for entry for foreign providers. For instance, the European Community and

Malaysia have stipulated in their commitments that entry of foreign investors in hospital services is subjected to an economic need test and to limits to the number of beds in the hospital (see Figure 2). These provisions can allow health authorities to channel foreign investments in hospitals in regions and of the size required as to their health care system planning.

Given the flexibility built into its design, it can be argued that the GATS provides the margin for maneuver for policy makers to harness the positive impacts of trade in health services, while mitigating the associated risks. However, we should note that other trade agreements do not have the same design and do not offer the same level of flexibility. For instance, governments have become parties to a vast network of investment agreements which aims to offer a predictable environment for foreign investors by protecting them against some kinds of state actions, such as discrimination and expropriation without compensation, and, as a result, to encourage foreign investment. These agreements, whether they are integrated in larger trade agreements or are stand-alone bilateral investment treaties, can exclude some sectors, but they tend to have a broader coverage with fewer exceptions and carve-outs, hence offering less space for addressing potential tensions between trade and health.

A third manner in which tensions between trade and health can be negotiated is at the national level with the adoption of domestic public policies which mitigate the negative impacts and harness the positive consequences. For instance, in Thailand, the increase in health tourism had a negative impact on the human resources for health in the country as nurses and physicians were attracted to work in the large urban hospitals catering to foreign patients, exacerbating the urban–rural gap in terms of access to health care services. To address this problem, the government significantly increased admissions in nursing and medical schools. These 'flanking' policies can take many forms, but they all require policy coherence, i.e., national authorities need to make their policy choices and the impacts of these choices explicit, realizing the potential divergence and trade-offs to be made between the realization of economic/trade policy objectives and public health goals, at least in the short term.

How has the WTO Managed the Tensions between Trade and Health?

When the agreements of the WTO came into force in 1995, they included a new dispute settlement mechanism which has become, since its creation, a key forum for managing the tensions between trade and health. Indeed, member states of the WTO have brought a number of disputes to the Panel and its Appellate body, which involved measures designed to protect human health, or claiming to do so.

How have these WTO panels and the Appellate body arbitrated disputes where the objectives of trade and the public measures to promote and protect public health clash? First, the WTO has defended the right of national governments to adopt public measures, even if they violate WTO rules, by claiming that these measures were necessary to protect human health under the exception found in General Agreement on Trade and Tarriffs (GATT) Article XX(b). Thus, when in 1998 Canada challenged France's ban on asbestos, the Panel estimated that the measure violated the national treatment principle in the GATT (Article III:4) which prevent parties from discriminating foreign products in favor of domestic products. In this case, the Panel judged that the French-made products containing polyvinyl acetate (PVA), cellulose, and glass fibers were similar to foreign products containing asbestos fibers (and therefore were like products as defined by Article III:4 of the GATT). Even though they deemed the measure discriminatory, the Panel agreed that the ban on asbestos was justified, given the health exception in Article XX(b) of the GATT. The Appellate body supported that view but went further and concluded that in determining whether products are similar, health impacts should be considered; hence, considering that products containing asbestos fibers should not be seen as similar to products containing PVA, cellulose, or glass fibers.

The WTO health exception specifies that the measures to protect human health should not be "applied in a manner which constitutes a means of arbitrary or unjustifiable discrimination or a disguised restriction on international trade." In 2007, the WTO concluded that Brazil was applying its ban on import of used tires in a discriminatory manner. The arbitrators did not challenge the right to adopt measures to protect public health, even though they were violating the national treatment principle. In this case, the ban on imports was adopted in order to limit the breeding grounds for diseases-transmitting mosquitoes created by stockpiling of discarded tires. The problem was that Brazil has allowed some imports from South American neighbors, whereas other countries such as the members of the European Union were under the complete import ban.

An earlier case involving an American regulation on gasoline had affirmed the capacity of WTO members to restrict trade to protect human health as long as trade-restricting health measures do not discriminate in violation of the national treatment principle (GATT Article III:4) by treating imported products less favorably than like domestic products. "Trade-restricting health measures that violate the national treatment principle may still be legitimate under GATT Article XX if such measures (1) fall within one of Article XX's enumerated exceptions, and (2) are applied in a manner that does not constitute unjustifiable discrimination or a disguised restriction on international trade." (Fidler, forthcoming).

Beyond the health exception, another principle which has been key in guiding WTO arbitrators when they have to manage the tensions between trade rules and public health objectives is the need for scientific risk assessment when adopting a sanitary and phytosanitary (SPS) measure. Indeed, the SPS Agreement (Article V) requires domestic regulation to be based on a risk assessment which takes into account available scientific evidence. The appropriate level of protection should be determined in consideration of economic factors such as the loss of production, the cost of control or eradication, the cost of alternative approaches, and with a view of minimizing negative trade effects.

The first WTO dispute involving the SPS agreement was initiated in 1996, by the US and Canada who complained that the prohibition enacted by the European Communities (EC) on

the importation and sale of meat treated with growth hormones in order to protect human health violated the SPS Agreement. The Panel and the Appellate body agreed with Canada and the US that the EC had violated Article 5.1 of the SPS Agreement and that the evidence presented by the EC's risk assessment did not support a total ban on meat with growth hormones. The other WTO dispute which related to the SPS agreement, the dispute around the EC *de facto* moratorium on biotech products such as genetically modified food, did not challenge the European assessment of the risks associated to the products. The European measures were violating procedural requirements of the SPS agreement.

Finally, the TRIPS agreement includes a clause (Article 30) which allows members to adopt policies that contravenes other provisions of the agreement, which has been used in a health-related dispute. This exception was tested by the disputes between Canada and the EU on patent protection for pharmaceuticals which began in 1999. With a view to reduce prices and improve access, generic pharmaceutical manufacturers in Canada were allowed to produce a drug under patent without the patent holder's permission in order to (1) obtain regulatory approval for the generic pharmaceutical product, and (2) produce a stockpile of generic drugs to sell when the patent expired. The government argued that even though these rules were violating some aspects of the TRIPS agreement, they fell within the exceptions provided by Article 30 of TRIPS. The WTO Panel partially agreed with Canada, ruling that allowing stockpiling before the expiration of the patent could not be justified under the public health exception.

Global Health Diplomacy in On-Going Trade Negotiations

Trade negotiations which can have an impact on health systems and population health through the five channels illustrated in Figure 1 are still on-going in a diversity of global and regional contexts. For instance, the European Union has been negotiating economic partnership agreements (EPA) with four regional groups in Africa since 2007. Because the EPAs touch on a wide range of trade-related issues, some have expressed concerns that they can potentially have a negative impact on health in sub-Saharan Africa. Four main areas of concern have been raised in this case: The impact of trade liberalization on public revenues and therefore the public expenditures for health; the risks of increasing patent protection in terms of access to pharmaceutical drugs; the opening of health services to foreign investment; and the impact of agricultural liberalization on food security and poverty.

What are the means of balancing these concerns against the potential economic benefits associated with trade liberalization? One means proposed is the use of health-impact assessments (HIAs) of proposed trade reforms. HIA are a set of procedures for assessing the potential impact of public policies on population health and the distribution of these effects on the population. It has been proposed they can be a useful tool as it can make the linkages between trade and health more visible to policy makers, it can improve the quality of evidence available to them, it can influence how the goals of trade policy are perceived by policy makers, and it can be used by various interest groups as an instrument for advocacy and mobilization. Equipped with the information from an HIA, trade negotiators are better positioned to decide to forgo certain trade commitments, to include some restrictions and limitations on their commitments or again, to adopt domestic policies which will ensure that trade policy does not impede the realization of national health objectives.

Except for the impact of patent protection on access to medicines, the linkages between trade and health are still an underexplored area of research and policy debates. Trade negotiations may be stalled at the WTO, but there are a number of trade and investment treaties being negotiated at the regional and bilateral levels which requires a more explicit approach to address the tensions between trade and health policy objectives.

International Trade in Health Workers

J Connell, University of Sydney, NSW, Australia

Introduction

The international migration of skilled health workers (SHWs) has grown rapidly since the 1970s, become more complex, more global, and of concern to countries that lose workers from fragile health systems. As health care has become more commercialized, so too has migration, as part of a wider globalization of health services. Few parts of the world, either as sources, destinations, or both, within a now global healthcare chain, are unaffected by the consequences. Most migration is to developed Organization for Economic Cooperation and Development (OECD) countries, in Europe, North America, and also the Gulf. Countries most affected by emigration are relatively poorly performing economies in sub-Saharan Africa, alongside some small island states in the Caribbean and Pacific, though absolute numbers are greatest from such Asian countries as India and the Philippines.

The international migration of SHWs parallels somewhat similar international migration of other professionals. The emergence of regional trading blocs and agreements, notably the European Union (EU), has expanded opportunities for international migration. International migration is linked to the General Agreement on Trade in Services, established in 1995, to liberalize international trade in services, including the movement of the so-called 'natural persons.' Many countries have eased their legislation on the entry of highly skilled workers, introduced points systems where skills facilitate entry, and actively recruited overseas. Such professional services as health care are part of the new internationalization of labor, and migration has largely been demand driven (or at least facilitated) by the growing global integration of healthcare markets. Forty years ago doctors – mostly men – were the main migrant group, but nurses – mostly women – have increasingly become dominant.

Demographic, economic, political, social, and, of course, health transformations have had significant impacts on international migration. Restructuring, often externally imposed, has affected health systems of developing countries, contributing to concerns over wages, working conditions, training, and other issues, all of which have stimulated migration. The health sector is different from other skilled sectors because most employment remains in the public sector. More dramatically, migration literally involves matters of life and death. Technology cannot easily replace workers, while the rise of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS) and non-communicable diseases and the aging of populations have placed new demands on health workforces. There is now a greater range of jobs for women, other than in a sector that is seen by some as dirty and dangerous (and unrewarding), sometimes difficult and demanding, and perhaps degrading. SHWs are in global demand.

Migrants move primarily for economic reasons, and increasingly choose health careers because they offer migration prospects. Migration has been at some economic cost, has depleted workforces, diminished the effectiveness of healthcare delivery, and reduced the morale of the remaining workforce. Countries have sought to implement national policies on wage rates, incentives, and working conditions, but these have usually been canceled out by global uneven development and national economic development problems. Recipient countries have been reluctant to establish effective ethical codes of recruitment practice, or other forms of compensation, or technology transfer, hence migration may increase further in future, despite the development of a Global Code.

Around the turn of the century, accelerated recruitment from developing countries, where populations are aging, expectations of health care are increasing, recruitment of health workers (especially nurses) is poor, and attrition considerable, contributed to a labor force crisis in source countries, raising complex ethical, financial, and health questions. The costs of training healthcare workers in developing countries are considerable, hence migration has been perceived as a subsidy from the poor to the rich. Migration issues are not only linked to financial issues, serious though these are, but are critical for the delivery of health care.

A Geography of Need

Human resources are central to healthcare systems, and have long been unevenly distributed. The need for health care is at least as uneven. Though definition and measurement of needs and shortages is complex, and the competence and effectiveness of workers hard to assess, demand for health care is greatest in the least-developed countries and regions, most of which are tropical, and, in a perfect example of the 'inverse health care law,' these needs are less well served than those in developed countries. The link between 'health workforce density' and health outcomes has been clearly demonstrated: Lack of health workers contributes to poor health status, and provision of such basic functions as adequate coverage of immunization or attendance at births. The disease burden is especially great in sub-Saharan Africa. World Health Organization (WHO) has shown that North and South America contain only 10% of the global burden of diseases, yet almost 37% of the world's health workers live in this region, whereas Africa has 24% of the global burden of diseases, but just 3% of the health workforce and less than 1% of global financial resources. At a national scale, the sub-Saharan countries of Uganda and Niger have 6 or 7 nurses for 100 000 people, whereas the US has 773, yet migratory flows – a perverse flow – are invariably from the former to the latter.

The WHO estimated that in 2005 some 57 countries had critical shortages of SHWs, equal to a global deficit of 2.4 million doctors, nurses, and midwives, let alone pharmacists, dentists, radiologists, and others. Some 36 of 47 sub-Saharan African countries fell short of the minimum. Moreover, most

 doi:10.1016/B978-0-12-375678-7.00614-3

SHWs are concentrated in urban areas and usually in the often primate city: A consequence of economies of scale, urban bias, and the social preferences of SHWs.

A Brief History of Migration

In the nineteenth century, migration of SHWs from more developed countries to their colonies was part of a colonial endeavor and missionary practice that remained in place until quite recently. In the 1940s and 1950s the direction reversed, from south to north, and the first flow of health workers began to migrate from developing countries, mainly to the UK and the USA, and mainly of doctors from larger countries such as India, Iran, and Pakistan. Nurses also migrated and were later recruited for emerging Gulf states. Britain, Australia, and Canada were experiencing both the immigration of doctors, mainly from the Philippines, India, Pakistan, Iran, and Colombia, and their emigration, usually to the USA. The Philippines had already contributed the largest number of overseas doctors in the USA, with training increasingly oriented to overseas needs. By then the ethnic distinctiveness of this skilled migration into Britain was evident, and a geographical pattern had emerged that scarcely changed substantially in later years. Over time what were then relatively simple migration flows, reflecting linguistic, colonial, and postcolonial ties, became steadily more complex. This new phase of migration was the start of what became widely recognized as a 'brain drain,' a term first applied by Oscar Gish at the end of the 1960s to the movement of doctors and scientists.

Such early flows were also characterized by active recruitment (notably of nurses from the Caribbean), and the employment of the migrants in the lower echelons of the health service. By the 1960s, the less-developed countries were experiencing the greatest costs from emigration, as SHWs left emphasizing the disparity in the number of medical workers per capita alongside the heavier burden of disease. In the 1970s, because of growing concerns over uneven flows and development, the WHO mounted a path-breaking study by Alfonso Mejia and others of migration from some 40 countries. Then, as now, the migration of SHWs was of greater concern than other skilled international migration flows, and the idea of a brain drain largely emerged from analysis of migratory health workers.

After a period of quiescence demand for SHWs in developed countries again increased in the 1990s, resulting from aging populations, growing demand and ability to pay, inadequate training programs, and high attrition rates (for reasons ranging from patient violence to discontent with working conditions, etc.), as jobs in the health sector were seen in many developed countries as too demanding, poorly paid, and lowly regarded (in line with reduced public sector funding, and disregard for the public sector). Reduced recruitment of health workers also followed declining birth rates in developed countries: There were fewer young people and more diverse employment opportunities for women, many with superior wages and working conditions, and greater prestige and respect. Significantly, these influences are similar to the reasons for attrition and migration in source countries.

Contemporary international recruitment of health workers is increasingly global. Where, a quarter of a century ago, it was mainly a movement from a few developing countries to a small number of developed countries, most countries are now involved. New movements of nurses occur between relatively developed countries, notably within the EU. Ireland, once an exporter of SHWs, has become an active recruiter. The new complexity of international migration is evident in Poland, as much a sending country as a recipient, where its source countries are eastern European countries (Ukraine, Belarus, Russia, and Lithuania) and the Middle East (Syria, Yemen, and Iraq), although Polish nurses migrate westwards. China has entered the market as a supplier of nurses, and its considerable interest in becoming more involved has the potential to profoundly influence the future system.

Over the past 30 years, the key receiving countries have remained remarkably similar, dominated by the UK and the USA. Whereas demand in the Gulf has stabilized, other European and global destinations (including Canada and Australasia) have grown in importance. Despite policies of localization, the Gulf states still employ 20 000 migrant doctors, and many more nurses, mostly from south Asia, but also from neighboring and poorer Middle Eastern states such as Egypt and Palestine.

In most developed countries, the proportion of foreign-trained medical workers in the health workforce has usually risen slowly: for example, in the USA and the UK, foreign doctors now represent approximately 27% and 33%, respectively, of their medical workforces; similar percentages occur in Australia and New Zealand, whereas comparable estimates are approximately 7% for Germany and France. Other OECD countries have become significant recipients. Hitherto Japan, virtually only one of the countries that have experienced substantial postwar economic growth and aging populations, has largely managed its health services without resorting to overseas workers, but has recently entered into agreements with the Philippines.

Throughout this time the Philippines has remained the main global source of SHWs for almost every part of the world, alongside India. Sub-Saharan Africa has emerged as a major supplier, and a major source of concern. Relatively recently other Asian states have become sources of SHWs, whereas much smaller Caribbean and Pacific states have become sources. Eastern Europe supplies Western Europe, whereas Latin America has tended to experience proportionately less emigration, though Latin America nurses have moved north to the USA and Europe, especially Spain.

Patterns of health worker migration from sources of supply such as sub-Saharan Africa have also changed. In the 1970s, SHWs were from a relatively small number of African countries (the larger states of South Africa, Nigeria, and Ghana) and predominantly went to a few developed countries outside Africa. Subsequently migration has become much more complex, involving almost all sub-Saharan countries, including intraregional and stepwise movement (e.g., from the Democratic Republic of Congo to Kenya, and from Kenya to South Africa, Namibia, and Botswana), because of targeted recruitment, by both agencies and governments, as much as individual volition. Globally, the 20 countries with the greatest emigration factors in the mid-2000s (the ratio of emigrant

to resident doctors) included 6 in Africa (Ghana, South Africa, Ethiopia, Uganda, Nigeria, and Sudan), 3 in the Caribbean (Jamaica, Haiti, and the Dominican Republic), the Philippines, India, and Pakistan, a cluster of countries perhaps best characterized by crisis (Sri Lanka, Myanmar, Lebanon, Iraq, and Syria), and also New Zealand, Ireland, Malta, and Canada. Migration is now shaped by both market forces and cultural ties, and deeply embedded in uneven global development.

The greater complexity of migration is evident in the interlocking chains of recruitment and supply, some of which were in place 30 years ago. Canada recruits from South Africa (which recruits from Cuba), as it supplies the USA. Kenyan nurses first went to southern African countries such as Botswana, Zimbabwe, and South Africa, and then moved on as 'step migration' to Britain. Something of a hierarchy of global migration – the global care chain – links the poorest sub-Saharan, Asian, and island microstates, to the developed world, culminating in the USA. New transport technology and reduced costs have produced variants of 'commuter migration' with SHWs taking on brief assignments elsewhere.

Migration is constantly in flux depending on labor markets, domestic pressures, evolving global legislation and codes of practice, and individual perceptions of amenable destinations. Migration links languages, training institutions, educational regimes, often in the context of other migration flows, sometimes characterized as chain migration in the context of a 'transnational corporation of kin.' Language proficiency is more crucial in the health sector than in any other arena of migration, skilled or unskilled. Although recruitment has crossed new borders, as trade barriers have disappeared and the Internet become accessible, potential migrants are also more likely to be informed about global job opportunities and be in some position to choose more widely than hitherto. Migration ranges from fixed-term contract migration (typified by that from the Philippines to the Middle East), usually negotiated between governments, and more personal, individual migration that may last a lifetime.

Rationales for Migration

Migration is primarily a response to global uneven development, usually explained in terms of such factors as low wages, few incentives, or poor social and working conditions. Poor promotion possibilities, inadequate management support, heavy workloads, and limited access to good technology including medicines have been widely recognized as 'push factors.' Such pressures are intensified in rural areas, where health workers feel they and their institutions are too often ignored, victims of institutionalized urban bias in development. Cultural factors have emphasized some migration flows. Tamil doctors have been more likely than majority Sinhalese to migrate from Sri Lanka for more than 30 years. Recruitment, by both agencies and governments, has played a critical facilitating role. However, all these various, specific factors are embedded in the broader context of social and economic life, family structures, and histories and broader cultural and political contexts.

Consequently, migration of SHWs occurs for many reasons, despite remarkable uniformity across quite different regions and contexts. Reasons include incomes, job satisfaction, and career opportunities, alongside social, political, and family reasons. The last of these factors, though often neglected, is particularly important since few migrants make decisions as individuals, but are linked to extended families and wider kinship groups. The migration of SHWs is rarely unique but exists within the context of wider migration flows. This is evidently so in India, the Philippines, and most small island states, like those of the Caribbean and Pacific, where there have been steady and diverse migration streams for several decades. In such circumstances, there is effectively a 'culture of migration' where most individuals at least contemplate migration at some time in their lives.

Yet migration is usually constrained in certain ways. Even for those with skills it is rarely easy to cross political boundaries. Where political circumstances have changed, as in the expansion of the EU, migration from poorer eastern states to those in western Europe quickly became substantial. Violence, coups, crime, warfare, and persistent social unrest have predictably hastened migration from countries such as Zimbabwe, Fiji, and Lebanon.

Intention to migrate may occur even before entry into the health system. In the Philippines, at least some people sought to become nurses, partly and sometimes primarily, because that provided an obvious means of international migration. By the end of the 1980s, a medical degree at the Fiji School of Medicine was widely seen as a 'passport to prosperity' and in Kerala (India) a nursing diploma is considered an 'actual passport for emigration' thereby raising the status of nursing. Specific careers may be chosen that optimize migration opportunities; in the Philippines and Pakistan, male doctors have retrained as nurses, and fewer people choose a medical career, as nurses have superior migration opportunities. The initial overseas destination may not be the intended final destination, especially for health workers in the Gulf, who seek to move on to the USA. Migration is not solely of SHWs; for some SHWs a career in health is seen as a way to move the whole family. This step migration points to the challenges in source countries of trying to develop an effective national workforce, when substantial proportions of those being trained may migrate.

Health workers have not usually entered the profession solely for income benefits, but also out of some desire to serve and be of value in the community. However, such feelings do not sustain a career, as workers become frustrated by low pay and poor (or biased) promotion prospects, especially in remote areas. As, increasingly, people do join the health sector for economic reasons, migration becomes even more likely. Income differentials are therefore invariably key factors in migration, as they are in decisions to join or later leave the health profession. Many decisions are simply rationalized in this way, since income differences between countries are often increasingly evident. Income differences are often such that even significant wage increases have had little effect on reducing the extent of migration. Econometric studies, at least for the Pacific island states, have shown that migration demonstrates considerable sensitivity to income differences, but complicated by the structure of household incomes.

In countries where there have not been specific surveys of migration, anecdotal evidence and, in some cases, the rationale for strikes by health workers, emphasize the significance of wage and salary issues. Similarly, the general movement of doctors, dentists, and others from the public to the private sector marks the quest for better incomes and conditions.

Income is firmly linked to the structure of careers and promotion, which many health workers see as being more about 'who you know than what you know' – nepotism and favoritism – and longevity in the system, rather than ability. SHWs have been critical of the lack of a transparent career structure, preferring to move to a meritocracy where skills and accomplishments will be rewarded. Where health workers are stationed outside the main national urban center, the perception that they are being ignored for promotion is even stronger as many consider themselves to be 'out of sight and out of mind.' Inadequate opportunities for promotion constitute not only an incentive to migration, but a constraint to productivity and innovation in the health system.

After income, the actual conditions of employment are influential for migration. Migrants, and potential migrants, frequently complain about the work environment in terms of insufficient support, through inadequate management (lack of team work, poor leadership and motivation, limited autonomy and support, and little recognition and access to promotion and training opportunities) or through the outcome of poor 'housekeeping' (limited access to functioning equipment and supplies). A desire to acquire further training and gain extra experience is a key factor influencing migration. Long hours of overtime, double shifts, working on the early morning 'graveyard' shift or on weekends, especially when these do not receive proper income supplementation, further influence migration. Shift work is a universal source of complaint, and particularly so in more remote places, where fewer staff are available and pressures on those remaining are greater. Inadequate working conditions may also entail the risk of contracting disease. The rise of HIV/AIDS made the nursing profession especially much less attractive than hitherto and, notably in Africa, created a more difficult working climate as the workload increased.

In several developing countries economic restructuring, sometimes externally imposed by international agencies, has led to reductions in the size of the public sector workforce and restrictions on the hiring of new workers. Changes in the health sector take place in a wider context where negative balances of payments and high levels of debt servicing place huge resource constraints on many developing countries. This has sometimes meant the deterioration of working conditions rather than the greater efficiency it was intended to encourage. Ironically, in the mid-2000s, in Kenya, for example, though half of all nursing positions were unfilled, a third of all Kenyan nurses are unemployed, as International Monetary Fund pressure encouraged national wage restraint. In several countries lack of resources, or alternative priorities, has resulted in low wages and poor conditions, with simultaneous vacancies, unemployment, and migration.

Many migrants have left rural areas to take advantage of superior urban and international educational, social, and employment opportunities. These factors reinforce each other, especially in the health sector. The widespread education bias enables young and skilled migrants, with fewer local ties, to migrate more easily. Most nurses, and many other SHWs, are women and may face particular constraints related to partners' careers and family obligations, which may make remote postings and overseas migration difficult. Consequently, the most likely migrants are young single workers followed by married workers without children. In contrast, Indian nurses from Kerala have migrated because their ability to earn and retain significant incomes gave them high status and the consequent ability to find high-status partners in the 'matrimonial market.' In many contexts, gender relations have been restructured following migration. Social ties may result in pressure to migrate, to support the extended family, but may sometimes make migration more difficult to achieve.

Recruitment

Developed destination countries offer real alternatives to political and economic insecurity in many source countries. A high standard of living with higher wages, better career prospects, good education, and a future for children are offered in recruitment campaigns, and often verified by those migrants established overseas. The structure of migration has become increasingly privatized through the expansion of recruitment agencies, and their regular use by recipient countries and by particular hospitals. Recruitment has existed since the 1940s but grew rapidly around the turn of the century. Irrespective of any existing intent to migrate, active recruitment has put growing pressure on, and impressive opportunities in front of, potential migrants. Recruitment agencies smooth the way in attending to bureaucratic issues, satisfying concerns over distant and different countries and cultures, and sometimes providing their own induction training in destinations.

Little information exists on the operations of recruitment agencies, and therefore there is no evidence on whether they exaggerate the potential of overseas employment, although they increase its probability. Recruitment has been particularly significant in sub-Saharan Africa, though there, as elsewhere, it would not have been successful unless other reasons for migration existed. In the early 2000s, half of all overseas nurses in Britain were there because they had been recruited. Recruitment has significantly extended migration beyond its postcolonial routes, for example, taking Chinese nurses to the Gulf and Fijian nurses to the Bahamas and the United Arab Emirates.

Recruitment is competitive, resulting in 'selective depletion' of the more qualified workers from several countries. In recruiting health workers for the UK many agencies engaged in some forms of exploitation. Both in source and recipient countries agencies operate beyond the extent of effective regulation. Such issues resulted in regional attempts to construct and use codes of practice for ethical recruitment, spearheaded by the Commonwealth Secretariat for former British colonies, thus covering significant parts of the Caribbean, Pacific, and sub-Saharan Africa.

The finalization by WHO of a Global Code in 2010 emphasized continued migration concerns and universal agreement to mitigate its harmful effects, notably that migration

did not disrupt health services in source countries. However, migration is a human right and occurs in contexts that do not necessarily involve health issues; there are no incentives for recipient countries and agencies to be involved in ethical international recruitment and all codes are voluntary which limits their impact. Recruitment and migration are both likely to continue.

Consequences of Migration

The trade in, and migration of, SHWs has diverse impacts, from more obvious effects on the delivery of health services and the economic consequences of the loss of locally trained skilled workers, to more subtle social, political, and cultural impacts. Migrants tend to be relatively young and recently trained, compared with those who stay. Many leave after relatively short periods of work, but long enough to gain important practical experience. They often include the best and the brightest. Because migrants move to improve their own and their families' livelihoods, they are usually the key beneficiaries of migration. Recipient countries benefit from having workers who fill shortages in the healthcare system. Conversely, sending countries and their populations, especially in remote areas, lose valuable skills unless those skills are an 'overflow' or are otherwise compensated for.

Healthcare Provision

Migration affects the provision of health care both in quality and quantity. Links exist between migration and the reduced performance of healthcare systems, though actual correlations between emigration and malfunctioning healthcare systems are difficult to make, because it is impossible to quantify what is not there. However, India and the Philippines, both long-term providers of migratory health workers, in circumstances initially described as an overflow, now appear to have become negatively affected, whereas sub-Saharan Africa and many small states experience critical problems, but not simply or even primarily because of migration.

In some circumstances, the quantitative outcome of migration is obvious. In Malawi, the loss of many nurses to the UK in early 2000s brought the near collapse of maternity services even in Malawi's central hospitals, with 65% of nursing positions being vacant. Maternal health care has been similarly affected in Gambia and Malawi with increased workloads, waiting and consultation times, and poorer infection control. In Jamaica, wards have been closed, male and female units have been merged raising cultural issues, and immunization coverage and *in situ* training have both been declined. Although such data are fragmentary, and often depict worst-case scenarios reported in the media, and are not solely the outcome of international migration, they point to difficult circumstances.

Reduced staff numbers mean that workloads of those remaining become higher, and less likely to be accomplished successfully. Many anecdotal reports emphasize longer waiting times with the implication that this raises opportunity costs of medical care, and may also result in medical attention coming too late. In Zimbabwe, in the 2000s, over a quarter of health workers believed that longer waiting times, and shorter opening times, had resulted in unnecessary deaths that prompt attention could have prevented. Foreign aid programs expanded in sub-Saharan Africa in the mid-2000s, to provide drugs to millions affected by tuberculosis and AIDS, yet were hard to implement because too few nurses existed to administer them effectively.

A further consequence of health worker migration is that of some patients traveling overseas for health care, as part of the growing phenomenon of medical tourism. Where such referrals are paid by the state, the cost is considerable. Even where they are not, as is usually the case, resources are nevertheless transferred overseas. In several African countries, referrals have increased at the same time as health worker migration, resulting in an unprecedented increase in the expense of care to fewer people and in the use of foreign currency, which could have been used for other development programs or for the motivation and retention of the country's health workers. The lack of health personnel may not always be the primary motivation for traveling overseas for treatment, but it nonetheless represents a substantial loss of scarce resources, especially because some of the source countries of medical tourist are impoverished nations such as Yemen. Even in countries that are relatively well supplied with health personnel, the cost of referrals is considerable, making the task of financing local health systems and organizing more labor-intensive preventive health care more difficult.

Rural and Regional Issues

The impact of emigration is usually most evident in remote regions, where losses tend to be greater (and where resources were initially least adequate), and has therefore fallen particularly on the rural poor (and sometimes therefore on cultural minorities) who are most dependent on public health systems, and where health needs are often greater, further emphasizing urban bias and the 'inverse care law.' The impact of emigration is complicated and compounded by ubiquitous internal migration, and a parallel movement from the public to the private sector. The movement of SHWs to the private sector has disadvantaged the poor, most of whom cannot afford higher private sector costs, alongside growing evidence of less adequate public sector services. This is poorly documented and it is primarily the evidence of inadequate stocks of health workers in the regions, and very different staff: patient ratios, which suggests the extent of adequate provision and migration (and attrition) in remote areas. The WHO has developed distinct strategies for developing and stabilizing regional workforces. Internal migration exhibits a similar rationale to international migration, but poses distinct problems where the internal migration is of those with particular skills, such as radiologists or pharmacists, and where few are required; hence the loss of even a small number may be crucial.

The Economics of Migration

Training SHWs is costly because of the long duration and high costs and is a burden on relatively poor states, whether directly

or through overseas scholarship provision. When trained workers migrate and the process is repeated, costs mount further. However, there have been few estimates of the costs of the ensuing brain drain, or the possible gain in skills through return migration, and a variety of methodologies and conclusions. The impact on healthcare provision of the emigration of doctors may be remarkably slight, compared with that of nurses, who provide the bulk of health care in many places, and especially in regional areas, where needs are considerable, but not necessarily complex.

A series of estimates of training costs suggest that low-income African countries subsidize high-income countries by as much as $500 million a year through the migration of SHWs, whereas equally fragmentary data from developed countries indicate considerable cost savings involved in hiring overseas-trained SHWs rather than training locally. This has been described as a perverse and unjust subsidy from relatively poor countries to relatively rich ones. These estimates are based solely on the costs of training rather than additional costs based on foregone health care, lost productivity, the under use of medical facilities, etc. However, they usually ignore possible remittances and their consequences. Where the remittances of health workers have been calculated, as in the Pacific island states, they are substantially above training costs, though they flow into the private sector rather than the public sector where most training takes place, and make no contribution to equitable human development.

Where return migration of SHWs occurs, the relationship between income losses, return, and the acquisition of human capital becomes more complex. Return migration of SHWs is relatively limited in many countries; however, if migrants return from overseas, with enhanced skills, knowledge, experience, and enthusiasm (and perhaps also some capital), there can be major gains from migration, including a positive transfer of technical knowledge. However, significant return migration fails to occur for the same reason that migration occurs: Migrants are less likely to be tempted back by a system they left because of its perceived failings. The overall number of return migrant nurses and doctors is modest, and many return because of perceived benefits, such as business opportunities, outside the healthcare system.

A further outcome of migration can be a skill loss when migrants with specific skills do not use them, which may result from failure to recognize qualifications, discrimination, or a preference for jobs with better wages and conditions. The most significant skill loss comes where nurses are employed as caregivers in nursing homes rather than working in hospitals. Expensive training is largely wasted and neither health systems, the migrants, nor their kin at home, who wait for remittances, make real gains.

Social Costs

The social costs attached to the migration of SHWs are complex but often considerable, especially where women move as individuals, leaving families at home. Many migrant workers, especially women within and outside the health sector, experience deprivation and discrimination. Recruitment agencies may impose unforeseen costs, and SHWs experience difficult circumstances, especially where cultures differ from those at home. Numerous examples exist of their experiencing racism in developed countries, and being ignored or experiencing reprisals when complaining of such problems, alongside being denied parity with local workers, promotion, or wage gains.

Health workers are often recruited for, and directed into, positions and locations that are unattractive to local health workers, and peripheral geographical placement is common. Consequently, new migrants are unlikely to be involved in specialist activities despite previous experience, and are most likely, at least initially, to be in the least attractive fields of health care and in outlying parts of the country, and with limited autonomy and authority. Stresses may occur for the families of migrants. Children may have to make complex adjustments to parental absences, and experience what has been called a 'care deficit.' However, migrants and their families usually gain in status through the material benefits of migration.

Migration of SHWs has made it necessary for less or non-qualified people, such as nurses' aides, to perform tasks that are normally beyond their training. This poses risks of incorrect diagnoses and inappropriate treatment. Patients have also reverted to the informal sector with sometimes costly, uncertain, and ineffective outcomes. In many countries, migrant nationals have been replaced by other international migrants, as part of the cascading global care chain, though the direct economic costs may be considerable (in both recruitment and salaries) and they may be less effective because of language and cultural differences, which restrict their ability to provide health services, contribute to training, and enable sustainability.

The Future Global Healthcare Chain

Shortages of SHWs exist in most countries in the world, and have been remedied mainly by migration from poorer countries rather than by strategies for improved retention and recruitment, hence the development of a Global Code of recruitment by WHO to encourage a more regulated migration, bilateral reciprocity, and greater international cooperation. Countries such as India and the Philippines, that previously exported an 'overspill,' have experienced some adverse effects from their 'export policies.' Migration has been problematic for relatively poor countries as the costs of mobility are unevenly shared, and the care chain becomes more global and hierarchical. Greater complexity increases the challenge of achieving more equitable outcomes.

An open international market is said to offer efficiency and economic gains. However, gains in economic efficiency tend to be localized in receiving countries and, as the evidence of costs to national health, economic, and social systems has mounted, there has been somewhat greater interest in developing policies to diminish and mitigate the impacts of migration. Nonetheless, international migration is not the main cause of healthcare shortages in developing countries, nor would a significant reduction in emigration remove human resource problems.

The onus for a more equitable global distribution of SHWs has gradually shifted toward recipient countries, where demand occurs. Few recipient countries have taken effective measures to increase recruitment and reduce attrition of SHWs, at a time of greater demand, either by increasing the number of training places or improving wages and working conditions. Continued migration has thus led to be renewed calls for ethical recruitment guidelines, adequate codes of practice binding countries, and/or compensation for countries experiencing losses; yet compensation is inherently implausible and impractical, although ethical arguments confront political realities. Better regulation, and more ethical recruitment, alongside bilateral relationships suggest some partial solutions, in terms of more effective managed migration.

The principal occupational flows of SHWs are primarily of nurses, where the evidence of losses in developing countries is substantial; however, there are more poorly documented flows of all cadres of health workers, such as radiologists and pharmacists. Failures of governance, broadly the inadequate delivery of services, whether health or education, and weak or nonexistent political will, constrain the development and retention of national workforces. Various possibilities exist for more effective production and retention of SHWs, ranging from diverse financial incentives (inside and outside the health system), strengthening work autonomy, and improving the status of health workers, increasing recruitment capacity, introducing intermediate categories of workers, such as nurse practitioners, and ensuring an effective 'fiscal space' for health services, but only rarely have these been effectively implemented in a concerted manner.

The international migration of SHWs has increased because perceptions of inadequate local conditions have grown, diaspora 'host' populations are generally increasing in destination states, demand has increased and recruitment intensified, and because health skills are valuable commodities in international migration. Yet paradoxically almost everywhere fewer people are being attracted to health careers. Wages and conditions are increasingly seen as deterrents to entry as other sectors become more attractive. Potential employees witness the frustrations of health workers and there is a wider range of job options. In both developed and developing countries, careers in health are now less attractive, other than as a means to migration.

Sending countries have not always been able to discourage migration, which is widely perceived as a human right. Indeed, several remittance-dependent countries, such as Cape Verde, the Philippines, and Kiribati, have not challenged migration but nurtured it because of its economic role. Unions have supported the rights of members to better their circumstances by migration, while also pressing governments to act locally to improve working conditions. Migration is increasingly embedded in national and international political economies. It is more resilient to cyclical downturns than other sectors. Few recipient countries have taken realistic and effective steps to increase national market supply, and any solution requires multilateral consensus rather than a national or bilateral approach. Migration of SHWs, and its complex consequences, will probably continue.

Latent Factor and Latent Class Models to Accommodate Heterogeneity, Using Structural Equation

AJ O'Malley, Harvard Medical School, Boston, MA, USA
BH Neelon, Duke University, Durham, NC, USA

Heterogeneity

In statistics and econometrics, heterogeneity typically refers to a random variable, parameter, or distribution that varies across a population of interest. It can involve the mean, variance, or other features of a distribution and may arise from observed and unobserved causes.

Observed heterogeneity is variability in an outcome (or dependent variable) attributable to observed predictors (Skrondal and Rabe-Hesketh, 2004). In the simple linear regression model,

$$y_i = \beta_0 + \beta_1 x_i + \boldsymbol{\varepsilon}_i \quad [1]$$

heterogeneity in the expected value of the outcome y_i, denoted $E[y_i|x_i]$, is accounted for by the predictor x_i across subjects $i=1,\ldots,n$. The parameter β_1 quantifies the magnitude of heterogeneity. Random variability in y_i that cannot be explained by x_i is denoted by $\boldsymbol{\varepsilon}_i$, the error term, which is assumed to have mean zero and a constant (or homogeneous) variance $\text{var}(y_i|x_i)=\sigma^2$. In parametric modeling, the most common distribution assumed for $\boldsymbol{\varepsilon}_i$ is a normal or Gaussian distribution, which has many appealing features including characterizing the ordinary least squares (OLS) estimation method.

Now consider a model with two predictors and an interaction effect,

$$y_i = \beta_0 + \beta_1 x_{1i} + \beta_2 x_{2i} + \beta_3 x_{1i} x_{2i} + \boldsymbol{\varepsilon}_i \quad [2]$$

In eqn [2], the effect of a one-unit change in x_{1i} on $E[y_i|x_i]$ is $\beta_1 + \beta_3 x_{2i}$, illustrating that the effect of x_{1i} depends on x_{2i}. A consequence of effect heterogeneity is that any statement of the effect of x_{1i} must be accompanied by the value(s) of x_{2i} at which it is computed and vice-versa. If x_{2i} is not observed and the model in eqn [1] is estimated, the OLS estimate of β_1 is a weighted average of the true heterogeneous effects of x_{1i} with respect to the likelihood of each value of x_{2i} (Angrist, 1998). When x_{1i} and x_{2i} are uncorrelated by design (e.g., x_{1i} is assigned at random in a randomized trial), the OLS estimate under eqn [1] corresponds to the average effect of x_{1i} over the individuals in the sample, otherwise being more difficult to interpret.

Other forms of heterogeneity are accommodated by relaxing the assumptions of the linear regression model, yielding a wider array of models and possibly requiring specialized estimation methods. For example, if $\text{var}(y_i|x_i)$ depends on x_i (directly or via $E[y_i|x_i]$), the assumption of equal variance at all values of the predictors required by OLS is violated. This phenomenon, referred to as heteroscedasticity, may be accommodated in the context of OLS by dividing y_i and x_i by the standard deviation of the residuals, $\text{var}(y_i|x_i)^{0.5}$, and then applying OLS (weighted least squares). If $\text{var}(y_i|x_i)$ is known, the process is straightforward, otherwise $\text{var}(y_i|x_i)$ must be estimated. Point estimates of β that do not account for heteroscedasticity are estimated imprecisely whereas confidence intervals (frequentist inference) and credible intervals (Bayesian inference) are likely to be incorrectly calibrated. When the objective is to estimate a tail probability or quantile (e.g., in immunoassays seeking to determine whether the concentration of a substance in blood serum exceeds a critical threshold), estimation of the variance function is key. Substantial progress on variance function estimation methods has been made in the context of analyzing assays (Davidian *et al.*, 1988; O'Malley *et al.*, 2008).

Unobserved Heterogeneity and Measurement Error

Unobserved heterogeneity, the variability in y_i arising from unobserved sources, cannot be accommodated without much difficulty as direct adjustment for the cause of the heterogeneity is not possible. To illustrate the difficulties that may arise from unobserved heterogeneity, suppose that to relate an individual's health, y_i, to his/her intelligence quotient (IQ), u_i, but in lieu of u_i, the educational attainment, x_i, is observed. Because u_i is unobserved directly but essential to the model, it is referred to as a latent variable. The situation is represented by the following equations:

$$\begin{aligned} &\text{health:} \quad y_i = \beta_0 + \beta_1 u_i + \boldsymbol{\varepsilon}_i \\ &\text{education:} \quad x_i = u_i + \delta_i \end{aligned} \quad [3]$$

where, by assumption u_i is unrelated to $(\boldsymbol{\varepsilon}_i, \delta_i)^T$, and δ_i is unrelated to $\boldsymbol{\varepsilon}_i$. Equation [3] is a classical measurement error model (Carroll *et al.*, 1995). The observed data regression,

$$y_i = \beta_0 + \beta_1 x_i + \tilde{\boldsymbol{\varepsilon}}_i \quad [4]$$

is problematic because x_i is correlated with the error, $\tilde{\boldsymbol{\varepsilon}}_i = \boldsymbol{\varepsilon}_i - \beta_1 \delta_i$, in violation of the OLS assumption that the predictors are unrelated to the errors. Here x_i is said to be endogeneous. It can be shown that the quantity being estimated by applying OLS to eqn [4] is $\rho\beta_1$, where $\rho = \text{var}(u_i)/(\text{var}(u_i) + \text{var}(\delta_i)) < 1$ is the attenuation factor (Bedeian *et al.*, 1997). Thus, if the heterogeneity in x_i, arising from δ_i is ignored, the estimated coefficient of x_i will be an inconsistent estimator of β_1.

An alternative model arises when u_i varies according to x_i; i.e., $u_i = x_i + \delta_i$, where x_i is independent of δ_i. For example, x_i is the setting of a machine, the control variable, and u_i is the actual level at which the machine operates. This situation, known as Berkson measurement error (Berkson, 1950) is less problematic, at least in linear models, because the OLS estimate of β_1 under eqn [4] is unbiased, and so the only consequence of this form of measurement error is that $\text{var}(\tilde{\boldsymbol{\varepsilon}}_i) \geq \text{var}(\boldsymbol{\varepsilon}_i)$, which leads to a reduction in statistical power.

Returning to the classical measurement error model, the availability of replicate observations on x_i allows u_i and hence var(δ_i) to be identified, thus enabling an estimate of $\rho\beta_1$ to be decomposed into estimates of ρ and β_1. If replicate observations are not feasible or available, an instrumental variable (IV) – a variable z_i that is related to u_i conditional on u_i being unrelated to γ_i – facilitates estimation. In the case of linear relationships, the first condition for z_i to be an IV implies $u_i = \theta_0 + \theta_1 z_i + \gamma_i$ with $\theta_1 \neq 0$ and u_i being uncorrelated with the random error γ_i. Substituting for u_i in eqn [3] yields:

$$\gamma_i = \tilde{\beta}_0 + \tilde{\beta}_1 z_i + \tilde{\varepsilon}_i \quad [5]$$

$$x_i = \theta_0 + \theta_1 z_i + \tilde{\delta}_i \quad [6]$$

where $\tilde{\beta}_0 = \beta_0 + \beta_1\theta_0$, $\tilde{\beta}_1 = \beta_1\theta_1$, $\tilde{\varepsilon}_i = \beta_1\gamma_i + \varepsilon_i$ and $\tilde{\delta}_i = \theta_1\gamma_i + \delta_i$. Under the second IV condition, z_i is uncorrelated with the errors $(\tilde{\varepsilon}_i, \tilde{\delta}_i)^T$, ensuring that OLS yields unbiased estimates of the parameters in eqns [5] and [6]. Hence, consistent estimates of β_0 and β_1 can be deduced from the relations $\beta_0 = \tilde{\beta}_0 - (\tilde{\beta}_1/\theta_1)\theta_0$ and $\beta_1 = \tilde{\beta}_1/\theta_1$. Alternatively, one may use two-stage least squares (2SLS): apply OLS to eqn [6] and compute predicted values of x_i, denoted $\hat{x}_i$, then apply OLS to eqn [4] but with x_i replaced by $\hat{x}_i$. The impact of measurement error is a decreasing function of the fraction of variation in x_i is explained by z_i. The readers are referred to the article on instrumental variables and to the econometric text by Wooldridge (2002) and that by Angrist and Pischke (2009) for further discussion of IVs, 2SLS, and related methods.

Classic Structural Equation Models

Broadly speaking, a structural equation model (SEM) is a model involving relationships between latent variables. Latent variables generally represent true values of a variable and so relationships between them are often considered to be truisms or causal (Lee, 2007). The use of SEMs to estimate causal relationships has a long history (Pearl, 2000). Latent variables must have associated observed (or manifest) variables in order to identify the model. Traditionally, an SEM is characterized by continuous-valued observed (or manifest) variables, continuous-valued latent (or unobserved) variables, and linear relationships among the latent variables. The linear SEM has the form

$$\mathbf{y}_i = \mathbf{\Lambda}_y \boldsymbol{\eta}_i + \boldsymbol{\varepsilon}_i \quad [7]$$

$$\mathbf{x}_i = \mathbf{\Lambda}_x \boldsymbol{\mu}_i + \boldsymbol{\delta}_i \quad [8]$$

$$\boldsymbol{\eta}_i = \mathbf{A}\boldsymbol{\eta}_i + \mathbf{B}\boldsymbol{\mu}_i + \boldsymbol{\upsilon}_i \quad [9]$$

where $\boldsymbol{\varepsilon}_i$, $\boldsymbol{\delta}_i$, and $\boldsymbol{\upsilon}_i$ are mutually independent error terms with zero means and constant covariance matrices (Jöreskog, 1973). Equations [7] and [8] are measurement models relating the observed variables, $\mathbf{y}_i$ and $\mathbf{x}_i$, to their latent counterparts, $\boldsymbol{\eta}_i$ and $\boldsymbol{\mu}_i$, whereas eqn [9] contains the structural model relating the latent construct $\boldsymbol{\mu}_i$ to the latent construct $\boldsymbol{\eta}_i$. Here $\mathbf{\Lambda}_y$, $\mathbf{\Lambda}_x$ and $\mathbf{B}$ are matrices of regression coefficients whereas $\mathbf{A}$ is a matrix of parameters that affects both the mean and covariance of $\boldsymbol{\eta}_i$. The involvement of $\boldsymbol{\eta}_i$ on both sides of eqn [9] allows for direct relationships between its elements, inducing correlations between them and imposing correlation structure on $\boldsymbol{\eta}_i$ and thus $\mathbf{y}_i$.

The measurement error model in eqn [3] is a special case of an SEM in which the effect variable is $\mathbf{y}_i$ (as observed). Therefore, with replicated measurements, the classic measurement error model in eqn [3] corresponds to $\gamma_i = \eta_i$, $\mathbf{A} = 0$, $\mathbf{B} = \beta_1$, and $\boldsymbol{\mu}_i = \mathbf{1}u_i$, i.e., eqns [8] and [9] reduce to $\mathbf{x}_i = \mathbf{1}u_i + \boldsymbol{\delta}_i$ and $\mathbf{y}_i = \beta_1\mathbf{1}u_i + \boldsymbol{\varepsilon}_I$, respectively, where $\mathbf{1}$ denotes a vector of 1's. For model identifiability, the dimensions of $\mathbf{y}_i$ and $\mathbf{x}_i$ must exceed those of $\boldsymbol{\eta}_i$ and $\boldsymbol{\mu}_i$ respectively; the larger the differences, the better. The regression models in eqns [1] and [2] are simple cases of SEMs.

SEMs have been used extensively in the social (e.g., economics, sociology) and behavioral (e.g., psychiatry, psychology) fields. For example, in an analysis of the relationship between job satisfaction and organization commitment to job turnover, Williams and Hazer (1986) use a SEM having the exact forms of eqns [7]–[9]. The measurement models relate observed values of the final outcome (job turnover), intermediate outcomes (intention-to-quit, job satisfaction, organizational commitment), and four exogeneous measures of work environment to their true values. The structural model relates the true values of the outcomes (the endogeneous variables) both to outcomes themselves and to the true values of the work environment variables in order to test hypothesized causal models as depicted by a flow diagram. For a thorough description of the traditional SEM, readers are referred to the classic text by Bollen (1989), the manual of the Linear Structural Relationships (LISREL) software package (Jöreskog and Sörbom, 1996), and the recent text by Lee (2007). Modern SEMs extend well beyond linear models, including a wide-range of generalizations of SEMs to outcomes that are not normal (e.g., binary, ordinal, categorical outcomes) (Rabe-Hesketh *et al.*, 2004). Next, models with continuous-latent variables in linear and nonlinear contexts are discussed (see Section 'Latent Factor Models'), following the same trend for discrete-latent variables (see Section Latent Class and Finite Mixture Models').

Latent Factor Models

Exploratory factor analysis (EFA) decomposes the covariance or correlation matrix of the centered values (residuals if the model includes covariates) of a sample of multivariate observations by relating these values to a smaller number of latent variables ('factors') that are interpreted on the basis of their relationships ('loadings') with the observed variables. Among various applications, EFA is used to generate hypotheses with regard to the dimensions underlying the data, to construct summary scales for reporting information, and to eliminate redundant items from questionnaires or survey instruments. The EFA model has the form

$$\mathbf{y}_i = \mathbf{\Lambda}\boldsymbol{\eta}_i + \boldsymbol{\beta} + \boldsymbol{\varepsilon}_i \quad [10]$$

where $\boldsymbol{\eta}_i \sim N(\mathbf{0}, \mathbf{I})$, $\boldsymbol{\varepsilon}_i \sim N(\mathbf{0}, \mathbf{\Psi})$, $\mathbf{0}$ is a vector of m zeros, $\mathbf{I}$ is an $m \times m$ identity matrix, $\mathbf{\Psi}$ is a diagonal matrix, and $\boldsymbol{\eta}_i$ and $\boldsymbol{\varepsilon}_i$

are independent vectors of $m<r$ and r random variables, respectively (Johnson and Wichern, 1998). Therefore, $\text{cov}(\mathbf{y}_i,\boldsymbol{\eta}_i)=\boldsymbol{\Lambda}$ and $\text{var}(\mathbf{y}_i)=\boldsymbol{\Lambda}\boldsymbol{\Lambda}^T+\boldsymbol{\Psi}$.

Ambiguity arises with factor decompositions when $m>1$ as the model is not identified by the data. To illustrate, let $\mathbf{T}$ be an $m\times m$ orthonormal matrix; i.e., $\mathbf{T}\mathbf{T}^T=\mathbf{I}$. Then $\boldsymbol{\Lambda}\boldsymbol{\eta}_i=\boldsymbol{\Lambda}\mathbf{T}\mathbf{T}^T\boldsymbol{\eta}_i=\boldsymbol{\Lambda}^*\boldsymbol{\eta}_i^*$, where $\boldsymbol{\Lambda}^*=\boldsymbol{\Lambda}\mathbf{T}$ and $\boldsymbol{\eta}^*=\mathbf{T}^T\boldsymbol{\eta}_i$, illustrating that the factor loadings can be 'rotated' using an orthonormal basis without changing the fitted values of $\mathbf{y}_i$ in eqn [10]. In practice, factor rotation is useful as it provides a means to obtain more interpretable factor loadings. For example, the commonly used factor rotation procedure Varimax seeks to split the factor loadings into two groups, the elements of the one tending toward zero, and the elements of the other toward unity, thereby making it easier to align variables with factors. In an analysis of Joint Committee data on the Accreditation of Health Care Organizations in the US, a hospital-level EFA with factor rotation was integral to developing two optimal scales (treatment and diagnosis, counseling and prevention) for the quality of hospitals' treatment and care delivered to patients with acute myocardial infarction, congestive heart failure, and pneumonia (Landon *et al.*, 2006).

Latent factor models generalize eqn [10] by allowing the expected value of $\mathbf{y}_i$ to depend on a matrix of covariates $\mathbf{X}_i$ for subject i; i.e.,

$$\mathbf{y}_i=\boldsymbol{\Lambda}\boldsymbol{\eta}_i+\mathbf{X}_i\boldsymbol{\beta}+\boldsymbol{\varepsilon}_i \qquad [11]$$

The latent variables $\boldsymbol{\eta}_i$ are known as latent factors due to the joint dependence of the multiple elements of $\mathbf{y}_i$ on the elements of $\boldsymbol{\eta}_i$. To identify the model, the variances of the latent variables may be set to 1 (typical in EFA), or an element of each row of $\boldsymbol{\Lambda}$ may be set to 1 (typical in latent factor models). The latter anchors the model and makes the variance parameters representative of the strength of the correlation between the outcomes (Skrondal and Rabe-Hesketh, 2004). One of the appealing features of eqn [11] is that model estimation is simplified because the independent assumptions on $\boldsymbol{\eta}_i$ and $\boldsymbol{\varepsilon}_i$ imply that the elements of $\mathbf{y}_i$ are conditionally independent given $\boldsymbol{\eta}_i$. Therefore, the distribution of $\mathbf{y}_i$ conditional on $\boldsymbol{\eta}_i$ has the convenient form

$$f(\mathbf{y}_i|\boldsymbol{\eta}_i,\mathbf{X}_i)=\prod_j f(y_{ij}|\boldsymbol{\eta}_i,\mathbf{x}_{ij}) \qquad [12]$$

where $f(y_{ij}|\boldsymbol{\eta}_i,\mathbf{x}_{ij})$ is the probability distribution of $\mathbf{y}_i$ given $\boldsymbol{\eta}_i$. In SEM terminology, latent factor models are measurement models in which the outcomes are directly affected by covariates and jointly dependent on shared latent traits. Because $\boldsymbol{\eta}_i$ is in the model for outcome j ($j=1,\ldots,r$), models that factorize like eqn [12] are referred to as shared-parameter models (Vonesh *et al.*, 2006; Reich and Bandyopadhyay, 2010). In practice, there may be little interest in the factor structure, in which case if $m>1$, the nonuniqueness of the fitted model is a nuisance. A simple uniqueness condition such as $\boldsymbol{\Lambda}^T\boldsymbol{\Psi}^{-1}\boldsymbol{\Lambda}=\mathbf{D}$, where $\mathbf{D}$ is a diagonal matrix, may be imposed to identify the model.

Latent factor models are being used increasingly in applications involving complex data and study designs and, therefore, apply to a broader array of settings than EFA. For example, Hogan and Tchernis (2004) used a latent factor to obtain a model-based index of material deprivation at the census tract level in Rhode Island. They supposed that for each area on a map, four manifest variables (standardized to z-scores) are conditionally independent given a one-dimensional latent factor with spatial correlation incorporated through the latent factor. The model was fit using Bayesian methods and the model-based material deprivation index was defined as the posterior expectation of the latent factor given the observed data. A model-based index confers several advantages over ad hoc methods of combining indices into a single score, including optimally weighting the constituent indices and the computation of their inferences.

Hierarchical Models

Latent factor models accommodate clustered data and longitudinal data. To illustrate, the authors have presented the latent factor model in terms of individual observations

$$y_{ij}=\lambda_j^T\boldsymbol{\eta}_i+\mathbf{x}_{ij}^T\boldsymbol{\beta}+\varepsilon_{ij}$$

where j denotes measurement type (ordered the same across subjects), and $\boldsymbol{\lambda}_j^T$ and $\mathbf{x}_{ij}^T$ are the jth rows of $\boldsymbol{\Lambda}$ and $\mathbf{X}_i$ respectively. The random intercept model

$$y_{ij}=\eta_i+\mathbf{x}_{ij}^T\boldsymbol{\beta}+\varepsilon_{ij}$$

where $\eta_i\sim N(0,\tau^2)$ is then seen to be the special case of the latent factor model in which $\lambda_j=1$, a scalar, $j=1,\ldots,m$. The importance of the latent factor is quantified by τ^2; larger variances are indicative of individuals that differ extensively in unmeasured ways (widely varying η_i). The random intercept–random slope model

$$y_{ij}=\mathbf{z}_{ij}^T\boldsymbol{\eta}_i+\mathbf{x}_{ij}^T\boldsymbol{\beta}+\varepsilon_{ij}$$

is a latent factor model with known factor loadings if $\mathbf{z}_{ij}=\mathbf{z}_j$; i.e., the covariates with random coefficients are balanced in that they do not vary across subjects. Balanced covariates for the random effects may arise when each subject is evaluated by the same set of raters (e.g., radiologists evaluating images) or, in a longitudinal setting, when observations are made at regular intervals. Regularly spaced longitudinal data is common. For example, participants in a study are examined weekly; the Federal Reserve sets interest rates quarterly; quarterly financials are released by companies.

In hierarchical models, latent variables can be incorporated at multiple levels to account for correlation within clusters (Raudenbush and Sampson, 1999). For example, in a study of academic achievement, students may be nested within classes and classes are nested within schools. A hierarchical latent factor model contains latent factors at one or more levels of the hierarchical structure.

Multivariate Mixed Outcome Models

A natural extension of the latent factor model is ascribed to situations where the outcome variables have mixed types (Dunson, 2000). Under the decomposition in eqn [12], a

generalized linear model is used to model y_{ij} with the link function

$$h_j(E[y_{ij}|\boldsymbol{\eta}_i, \mathbf{x}_{ij}]) = \boldsymbol{\lambda}_j^T \boldsymbol{\eta}_i + \mathbf{x}_{ij}^T \boldsymbol{\beta} \quad [13]$$

where $h_j(\cdot)$ is a monotone function that maps its argument to an unrestricted random variable. For example, in medical device trials of coronary-artery stents, the key outcomes often include a clinical (binary) and an angiographic (continuous) outcome, leading to one binary and one linear equation (O'Malley *et al.*, 2003). The logit link function was used for the binary component (the probit link would have been an alternative) whereas the linear link (or identity function) was used for the continuous outcome. Other common link functions (associated data types) include the logarithmic link (count data, nonnegative data such as costs or expenditures, time-to-event or survival data) and the log–log link (extreme-event or maximal-outcome data such as in flood prediction).

For discrete-valued (e.g., binary, count) outcomes, additional identifiability constraints are required as the mean and variance are no longer free parameters. However, it is important not to inadvertently restrict the parameter space of the model when imposing identifiability conditions. As a general rule, λ_j should only be constrained if the variance of outcome j is determined by its mean (e.g., as for a binary random variable), in which case setting $\lambda_j = 1$ is appropriate. But when applied, such an identifying constraint can lead to insolvable identifying conditions (e.g., equations that can only be solved by allowing a variance to be negative).

Joint modeling of multiple outcomes may yield more precise results than separate analyses as information on one outcome can be brought to bear on the analysis of another outcome. However, if the sets of covariates depend on the information by which two outcomes are found to be identical, then point estimates are minimally affected, and unaffected for all outcomes in the case of linear models (Teixeira-Pinto and Normand, 2009).

In a related family of models, the covariates may be modeled through the latent variable (Sammel *et al.*, 1997). Therefore, the coefficients of the covariates are proportional across outcomes and thus represent overall associations with the underlying construct generating the data (O'Malley *et al.*, 2003). Although such proportionality makes it easier to summarize the impact of a covariate, it might be too restrictive in many applications. Furthermore, the regression coefficients affect the marginal variance of the outcomes, because of which estimates are more sensitive to the correlation structure than under eqn [13].

Joint Models Involving Censored or Missing Data

In longitudinal analyses where outcomes may be censored due to death, the censoring mechanism is nonignorable (i.e., informative) if unobserved factors are correlated with those outcomes that are correlated with survival. One approach for overcoming this problem is to jointly model the outcome and survival time, conditioning on a latent factor to account for unmeasured common causes (Vonesh *et al.*, 2006).

The above approach may be adapted to account for missing values of the outcome (or potentially of covariates) in other contexts. In general, if the number of distinct missing data patterns across the sample is small (e.g., if the outcome is the only variable ever missing, there are only two missingness patterns), missing data can be modeled using a categorical random variable that is the subject of one (set of) equation(s) whereas the outcome is the subject of another equation, both equations depending on observed predictors and a latent factor (Tsonaka *et al.*, 2009). Shared-parameter models provide one of the few methods applicable when the missing data mechanism is not-missing-at-random (Little and Rubin, 2002). For example, in the case when the outcome is the only variable with missing values, a binary regression equation relates $d_i = I(y_i = \text{missing})$ to the observed covariates and a latent variable whereas a second model relates the nonmissing values of y_i to d_i, the observed covariates and the same latent variable.

In observational studies, latent factor models may be used to account for unmeasured confounders affecting the selection of treatment and the outcome. In place of a censoring or missing data indicator, a problematic (i.e., endogeneous) predictor is modeled in conjunction with the outcome. Therefore, models to account for nonignorable treatment selection emulate SEMs by modeling the relationships between latent variables and, like the measurement error model in the Section 'Unobserved Heterogeneity and Measurement Error', these models involve simultaneous equations. This scenario is expanded in the Section 'Bivariate Probit Type Models'.

Categorical Outcome Variables

When the outcomes under the model in eqn [13] have the same form but are binary (or ordinal) as opposed to continuous, the model reduces to an item response theory (IRT) model. The most common IRT model assumes a single latent factor with r categories, $\mathbf{x}_{ij} = (I(j=1), \ldots, I(j=r))^T$, and a logit link:

$$\text{logit}\{\Pr(y_{ij} = 1|\eta_i, \mathbf{x}_{ij})\} = \gamma_j(\eta_i - \tilde{\beta}_j) \quad [14]$$

where $\tilde{\beta}_j = \beta_j/\gamma_j$. Thus, the model includes an intercept and slope parameter for every measurement type (e.g., a type of test) along with a single underlying latent variable for each subject (e.g., true level of ability). The specification of the model in eqn [14] is completed by assuming η_i is normally distributed. The same form of model is commonly used to model ordinal responses (see article on models for ordered data).

Although eqn [14] generalizes to allow an m-dimensional latent factor, it is rare to have more than two dimensions. If η_i is treated as a fixed effect parameter, then eqn [14] is the well-known Rasch model (Rasch, 1960), often used in education or other situations where multiple informants provide ratings of an individual (Horton *et al.*, 2008).

Bivariate Probit Type Models

An alternative to the method in Section 'Categorical Outcome Variables' for modeling when outcomes are not normal is to define latent continuous variables y_{ij}^* that underlie a discrete-valued y_{ij}. The multivariate normal latent factor model is assumed for y_{ij}^*. The bivariate probit is an example of this type of

model. Let y_{i1} and y_{i2} denote binary realizations of underlying normally distributed random variables y_{i1}^* and y_{i2}^* respectively. The bivariate probit model can then be defined as

$$y_{ij}^* = \mathbf{x}_{ij}^T \boldsymbol{\beta}_j + \rho_j \eta_i + \boldsymbol{\varepsilon}_{ij} \quad [15]$$

where $y_{ij} = I(y_{ij}^* > 0)$ for $j = 1,2$ and $\rho_1 = 1$ for identifiability. The latent factor η_i denotes an unmeasured confounding variable and $\rho^* = \rho_2/(1-\rho_2^2)^{0.5}$ is a measure of the extent of confounding (the selection effect) standardized to [–1,1]. In the absence of covariates, ρ^* is the correlation between two continuous random variables that are estimated from observing two binary realizations, commonly referred to as a tetrachoric correlation (Bonett and Price, 2005). A $\rho^* > 0$ indicates that unobserved factors are such that larger values of y_{i2}^* are associated with larger values of y_{i1}^*. Bivariate probit models are often used when observations of a binary outcome are available only for a subset of individuals in a study. For example, in a study of the impact of financial incentives on quality of care delivery by physicians, a quality indicator may be available only for individuals with certain health experiences. Whenever a quality measure for an individual depends on unmeasured factors possibly relating to quality of care, then a bivariate model can be fit to account for nonrandom selection into the sample. The outcome equation is augmented with a latent variable that being also a predictor in an equation, describes the likelihood that individual with certain characteristics is sampled. If the regression equations and the probability distribution of the observations are correct, unbiased estimates of the effects of interest (in this case, physician financial incentives) are obtained.

A generalization of the bivariate probit in eqn [15] yields the family of models developed in Heckman (1978), in which one or both of y_{i1}^* and y_{i2}^* may be observed, y_{i2}^* may be a predictor of y_{i1}^* and vice-versa, and y_{i2} may be a predictor of y_{i1}^* and y_{i2}^*:

$$y_{i1}^* = \alpha_1 y_{i2}^* + \theta_1 y_{i2} + \mathbf{x}_{i1}^T \boldsymbol{\beta}_1 + \eta_i + \boldsymbol{\varepsilon}_{i1} \quad [16]$$

$$y_{i2}^* = \alpha_2 y_{i1}^* + \theta_2 y_{i2} + \mathbf{x}_{i2}^T \boldsymbol{\beta}_2 + \rho_2 \eta_i + \boldsymbol{\varepsilon}_{i2}$$

The model in eqn [16] accommodates both continuously valued and discrete-valued endogeneous variables, the latter being referred to as a structural-shift. In general, for the model to be identifiable, restrictions on the parameters are needed. The special case of $\alpha_1 = \alpha_2 = \theta_2 = 0$ (all predictors observed) is a parametric alternative to nonparametric IV methods when the endogeneous predictor is binary. In addition, if y_{i1}^* is observed but y_{i2}^* is not observed, the Heckit model (Arendt and Holm, 2006) arises. If $\theta_1 = \theta_2 = 0$ and y_{i1}^* and y_{i2}^* are observed, a linear simultaneous equations model is obtained. The article on discrete outcomes includes a detailed review of discrete outcome models with endogeneous predictors.

Latent Class and Finite Mixture Models

In many applications, the study population can be decomposed into a finite number of distinct groups with respect to a variable, y_i. If the variability in the data arises primarily from differences between groups rather than those within groups, the marginal distribution of y_i can be represented by a mixture of distributions of the same parametric form but with unique parameters, $\{\theta_k\}_{1:K}$:

$$p(y_i|\mathbf{x}_i) = \sum_{k=1}^{K} \pi_k(\mathbf{x}_i) p(y_i|\theta_k, \mathbf{x}_i) = \sum_{k=1}^{K} Pr(C_i = k|\mathbf{x}_i) p(y_i|\theta_k, \mathbf{x}_i), \quad i = 1, \ldots, n \quad [17]$$

where $\pi_k(\mathbf{x}_i) = Pr(C_i = k|\mathbf{x}_i)$ is a latent class probability or mixing weight associated with latent class k, and C_i indicates, conditional on subject i having covariates $\mathbf{x}_i$, the subpopulation k ($k = 1, \ldots, K$) to which subject i belongs.

The model in eqn [17] is referred to as a finite mixture model, a latent class model (because it partitions subjects into one of K latent classes), or a discrete-latent variable model (because C_i denotes a latent variable with a finite number of values). When x_{1i} is observed and x_{2i} is a discrete-valued unobserved covariate, the interaction effect model in eqn [2] is a latent class model (i.e., the coefficient of x_{1i} takes on different values across the latent classes that are defined by the unobserved x_{2i}).

Latent class models are useful when the research goal is to cluster patients into distinct subpopulations, or if one believes that the data-generating process can be modeled by first assuming that subjects fall into one of K latent classes; then, conditional on class-k membership, the outcome y_i is drawn from $p(y|\theta_k)$ for subject i. When $\mathbf{x}_i$ only consists of the scalar 1, eqn [17] assumes that the class-membership probabilities are identical for all n subjects – that is, $Pr(C_i = k|\mathbf{x}_i) = \pi_k$ for all i – and the model reduces to the model-based clustering approach of Fraley and Raftery (2002). In general, however, these probabilities vary as a function of subject-level predictors, $\mathbf{x}_i$. In this case, the class-membership probabilities are typically assumed to follow a multinomial logit or multinomial probit model.

As an illustration, consider a hypothetical study in which y_i denotes the annual medical expenditures for the ith patient. Suppose, further, that the investigators propose to model the data using the following two-component mixture of normal distributions:

$$(1-\pi) N\left(y_i; \mu_1, \sigma_1^2\right) + \pi N\left(y_i; \mu_2, \sigma_2^2\right), \quad i = 1, \ldots, n$$

where π denotes the probability of class-2 membership and $N\left(\mu_k, \sigma_k^2\right)$ denotes a normal distribution with mean μ_k and variance $\sigma_k^2 (k = 1,2)$. Note that $\mu_2 > \mu_1$ implies that the mean expenditures for class 2 are higher than those for class 1. Further, $\sigma_2^2 > \sigma_1^2$ implies that class 2 is more dispersed than class 1. Then subjects for whom $\pi > 0.50$ are more likely to be in a class characterized by high average spending and increased variability relative to class 1. A comprehensive review of latent class models is given in the texts by McLachlan and Peel (2000) and Frühwirth-Schnatter (2006). In the remaining part of this section, four types of latent class models have been considered.

Latent Growth Models

Latent class models can be applied to longitudinal and clustered data. In the longitudinal setting, the classes are

characterized by average trajectories (or 'growth curves') over time. Consequently, these models are often referred to as latent growth models (LGMs). For example, a basic linear LGM for a normal outcome variable would take the form:

$$f\left(y_{ij}|\eta_{ijk},\sigma_k^2\right)=\sum_{k=1}^{K}\pi_k N\left(y_{ij}|\eta_{ijk},\sigma_k^2\right) \quad [18]$$

where $\eta_{ijk}=\beta_{0k}+\beta_{1k}t_{ij}$ and y_{ij} denotes the response at observation j for individual i; t_{ij} denotes the time (e.g., from baseline) of the ijth observation; β_{0k} and β_{1k} denote the intercept term and the trajectory slope for class k respectively; and σ_k^2 is the class-k variance of y_{ij}. Such models presume the existence of an unobserved discrete-valued variable that has both a main effect and an interaction effect with t_{ij} on the outcome. If the discrete-valued variable is observed, then eqn [18] reduces to a linear regression model with both main effects and time-interaction effects as yielded by the levels of that variable. Therefore, the defining feature of the latent growth model in eqn [18] is that the class to which an individual belongs is a discrete-valued latent variable that is unknown.

Extensions to nonlinear trajectories are straightforward. LGMs are especially popular in developmental psychology, where they have been used to model the progression of physical violence (Nagin and Tremblay, 1999) and criminal behavior (Roeder *et al.*, 1999). They have also been applied to joint longitudinal outcome–survival models (Lin *et al.*, 2002), where latent factor models are an alternative to the shared-parameter model approach to censored or missing data.

Growth Mixture Models

LGMs can be broadened to include subject-specific random effects. Such models are called growth mixture models (Muthén *et al.*, 2002) or heterogeneity models (Verbeke and Lesaffre, 1996). Growth mixture models assume that individuals are first placed into one of K latent classes that are defined by a mean trajectory curve (as in LGMs); then, around these mean trajectories, individuals are given their own subject-specific trajectories that are defined by a set of random effects with class-specific variance parameters. As such, growth mixtures can be viewed as finite mixtures of random effect models.

To continue with our previous example, the authors can extend the model in eqn [18] to include subject-specific intercept and slopes:

$$\begin{aligned} f\left(y_{ij}|\eta_{ijk},\sigma_k^2\right)&=\sum_{k=1}^{K}\pi_k N\left(y_{ij}|\eta_{ijk},\sigma_k^2\right),\\ \eta_{ijk}&=(\beta_{0k}+b_{0i})+(\beta_{1k}+b_{1i})t_{ij},\\ \begin{pmatrix} b_{0i}\\ b_{1i}\end{pmatrix}|C_i=k&\sim N_2(\mathbf{0},\boldsymbol{\Sigma}_k) \end{aligned} \quad [19]$$

where b_{0i} and b_{1i} denote, respectively, a random intercept and random slope for subject i. Conditional on subject i belonging to class k (i.e., $C_i=k$), the vector $(b_{0i}, b_{1i})'$ is assumed to follow a bivariate normal distribution with mean $\mathbf{0}=(0,0)'$ and class-specific covariance matrix $\boldsymbol{\Sigma}_k$. Growth mixture models have been applied in various contexts, including studies of class-specific prostate specific antigen trajectories (Lin *et al.*, 2000), daily affect (i.e., emotional expression) scores (Elliott *et al.*, 2005), and mental health expenditures (Neelon *et al.*, 2011).

Causal Inference via Latent Class Models

Latent class models have similarities with the principal stratification approach to causal inference (Frangakis and Rubin, 2002). The connection is illustrated in the context of a randomized controlled trial compromised by noncompliance. A subject's compliance status is formulated as a categorical variable with four levels on the basis of compliance behavior of the subject under both potential treatment assignments (Frangakis and Rubin, 1999). Under both assignments, compliers take the assigned treatment, always-takers take the experimental treatment, never-takers take the control, and defiers take the opposite treatment to that assigned. For example, in a randomized trial comparing the efficacy of two antipsychotics for refractory schizophrenia, compliers might be defined as individuals who would take the assigned treatment for the entire follow-up period whereas the other three groups characterize those individuals who would switch treatment under one (always- and never-takers) or both (defiers) treatment assignments (O'Malley and Normand, 2005). Because compliance status does not depend on the outcome, the same definitions would apply to a health economic outcome such as aggregate mental health cost of treatment. In general, compliance status can be considered as a latent class because it is unobserved (compliance behavior is observed only under the assigned treatment) and the expected outcome from treatment may vary with compliance status (compliers form one principal stratum, never-takers form another stratum, etc.). Thus, a model such as that in eqn [17] could be used. However, in causal inference, the more common approach is to identify the model by imposing structural assumptions as opposed to parametric assumptions, which cannot be completely tested from the data. It is typically assumed that defiers do not exist, an assumption referred to as monotonicity, and that treatment assignment only affects outcomes through the treatment received, the exclusion restriction. Unbiased nonparametric moment-based estimators are then available for the effect of the treatment received on the outcome. In this sense, treatment assignment is an instrumental variable and, under the additional assumption that one individual's treatment does not affect another's outcome (the stable unit treatment value assumption), the estimand is a local-average treatment effect (Angrist *et al.*, 1996).

Model Fitting

Two techniques that are especially well-suited to estimation of models with latent variables are the expectation-maximization (EM) algorithm for frequentist inference and Markov-chain Monte Carlo (MCMC) for Bayesian inference. Their suitability arises from the fact that the values of latent variables (continuous-latent factors or categorical latent classes) can be considered as the missing data. Estimation for latent factor and latent class models proceeds by treating the latent

variables as missing data and applying either the EM algorithm (Dempster *et al.*, 1977) or, in the Bayesian context, MCMC (Gelfand and Smith, 1990).

EM and MCMC computations can be conceptualized as applying a regular regression (linear or otherwise) on the basis of imputed values of the latent variables (the complete data analysis) and subsequently using all of the information in the data as well as the fitted model to impute the latent variables. In the second step, the EM algorithm yields 'best' values of the latent variables by maximizing the complete data likelihood function whereas the MCMC algorithm yields random realizations of the latent variables from the corresponding joint posterior distribution (also referred to as data augmentation) (van Dyk and Meng, 2001).

Prior Distributions for Bayesian Modeling

To fit a Bayesian model, prior distributions need to be specified for the model parameters that have not already been assigned probability distributions (essentially all parameters other than the latent variables). As for the regression coefficients of the observed predictors, the coefficients of the latent factors (the factor loadings) are often assigned normal distributions. When the outcomes y_i or their unobserved continuous counterparts (e.g., in the bivariate probit model) follow a normal distribution, a normal prior yields a normal posterior distribution, which simplifies the MCMC procedure by allowing posterior samples to be drawn directly. However, unless the parameters are restricted to ensure that the model is identifiable, the computational issues discussed in the Section 'Computational Challenges' can hinder convergence of model fitting algorithms. An advantage of Bayesian modeling is that prior distributions can often easily accommodate constraints for making the model identifiable by data. For example, in an analysis of monthly international exchange rates, Lopes and West (2004) specify independent normal priors for the factor loadings with two restrictions: the loadings above the diagonal are 0 (thus the factor loading matrix is block lower triangular); and the diagonal elements are nonnegative.

In the latent class model, the class prevalence or mixing probabilities, the π_ks, are typically assigned a Dirichlet prior, which leads to a convenient closed-form conditional posterior distribution. Covariance matrices are often assigned inverse-Wishart prior distributions or variants thereof, although alternative specifications are becoming more common (O'Malley and Zaslavsky, 2008).

Computational Challenges

Several numerical challenges that arise in fitting SEMs, inclusive of latent factor and latent class models, are due to the fact that the parameterization of latent factor and latent class terms being permuted without affecting the fitted model. This problem is partly resolved in the latent factor case through the use of a uniqueness condition (see Section 'Latent Factor Models'). However, under MCMC estimation, a related problem called label-switching (Stephens, 2000) arises when the order of the factors varies across the draws from the joint posterior distribution, in which case, posterior summaries resulting from naïve Monte Carlo averages will be nonsensical. To enable inference concerning latent factors, postprocessing is necessary in order to obtain a consistent order of the factors across the posterior draws before computing posterior summaries. Postprocessing may also be applied to the draws of the latent class parameters to account for the possibility that 'Class 1' in one draw is 'Class 2' in another, corresponding to equivalence classes at which the likelihood function has equal maximal values.

Software for implementing latent factor and latent class models includes Mplus, Latent Gold®, WinBUGS, and R packages for specific families of models. The SAS procedure Proc Traj fits LGMs for panel data, including whenever observation times are unevenly spaced (Jones and Nagin, 2007).

Model Comparison and Checking

A general way of comparing single-level models (models that do not include random effects or latent variables) is the Akaike Information Criterion (AIC) or the Bayesian Information Criterion (BIC), also known as the Schwarz Criterion. The AIC and BIC balance the level of fit (quantified in terms of the log-likelihood) with model complexity (a penalty for using the sample data to estimate the model parameters). A challenge in applying these methods to SEMs lies in the estimation of latent variables and their effects wherein amounts of information (i.e., degrees-of-freedom) being used are different from those utilized during the estimation of observed predictors and their effects. Therefore, assessing model complexity on the basis of the number of estimated parameters is not appropriate.

In Bayesian analysis, model comparison on the basis of Bayes factors (Kass and Raftery, 1995) is the most principled approach though computational problems may be encountered. Because Bayes factors rely on the marginal likelihood of the data under a presumed model, they only exist if the prior on the model parameters is proper. To allow the use of improper priors, an alternative to Bayes factors, such as the intrinsic Bayes factor (Berger and Pericchi, 1996) has been proposed. The pseudo Bayes factor (Gelfand and Dey, 1994) offers a computationally convenient numerical approximation but has been criticized due to its dependence on the harmonic mean (Neal, 2008). An alternative to Bayes factors is the Deviance Information Criterion (DIC) (Spiegelhalter *et al.*, 2002), which can be regarded as a Bayesian counterpart to the AIC. In response to ambiguity over the appropriate way of accounting for latent variables in finite mixture models, Celeux *et al.* (2006) have proposed several alternative DIC measures with improved inferential properties. However, discerning and implementing the appropriate measure of DIC is not straightforward in many situations.

Once a model is selected, Bayesian posterior predictive checks can be used to compare the observed data to the one replicated from the posterior predictive distribution under the model (Gelman *et al.*, 1996). If the model fits well, the replicated data would resemble the observed data. To quantify the degree of similarity, the percentile of the predictive distribution corresponding to the observed value of a discrepancy measure

that reflects an aspect of model-fit important to the area of study is evaluated. If the percentile, a Bayesian predictive *p*-value, is near 0 or 1, the model exhibits lack-of-fit. For more details of Bayesian model specification, model fitting, and model checking, refer to the article on Bayesian analysis.

Limitations of SEMs

One of the most common criticisms of models involving latent variables is that model identifiability stems from the distribution specified for unobserved variables. Because such assumptions cannot be completely tested by the data, there is a concern that models with latent variables are unscientific. This is of particular concern in models involving structural assumptions such as instrumental variable assumptions. Such concerns have motivated research on nonparametric and semiparametric methods (Lee, 1995), including alternatives to parametric hierarchical (or mixed effect) models (Heagerty and Zeger, 2000).

In studies involving structural assumptions, deciding between nonparametric and parametric SEMs entails a trade-off between assumptions. For example, in IV analyses, the trade-off is between identifiability of model parameters via the exclusion restriction (typically supported by a theoretical model and, in the case of multiple IVs, partially tested empirically using a test of over-identifying conditions) or via the joint probability distribution of the outcome variable and the endogeneous predictor (O'Malley *et al.*, 2011). In practice, one approach may be a sensitivity analysis for the other.

Summary

The intersection of heterogeneity and SEM encompasses a diverse range of models. Before concluding, several models that are equally important though more loosely connected to the central theme of this article are mentioned. These include two-part models and spatial models. Two-part models account for outcome distributions having multiple parts, distributional heterogeneity. For example, when analyzing medical costs, it is often the case that the outcome distribution is part discrete (zero costs arising when no service is performed) and part continuous (a broad range of nonzero costs associating with different services). Such 'semi-continuous' data may be modeled using two-part models with one component of the model being dedicated to the likelihood that the outcome (e.g., cost) is 0 while the other one to the expected outcome of being nonzero (Neelon *et al.*, 2011; Olsen and Schafer, 2001). For more details, refer to the article on modeling expenditure and utilization data.

Analogous models exist for zero-inflated count data. One such model is the Poisson hurdle model, which is a two-component mixture consisting of a point mass at zero, followed by a truncated Poisson for nonzero observations (Mullahy, 1986). Other count distributions, such as the negative binomial, can alternatively be used. A related model is the zero-inflated Poisson (ZIP) model, which consists of a degenerate distribution at zero and is mixed with an untruncated Poisson distribution (Lambert, 1992). The ZIP partitions the zeroes into two types: 'structural' zeroes (e.g., those that occur because patients are ineligible for health services) and 'chance' zeroes (e.g., those that occur by chance among eligible patients) (Neelon *et al.*, 2010). For more details on modeling count data, refer to the article on modeling ordinal outcomes.

In spatial analysis, heterogeneity refers to how a variable y_i varies across a region of space. Two common types of spatial data are point-referenced data and areal data. For point-referenced data, y_i is measured at a set of geo-referenced locations, $\mathbf{s}$, and the covariance of y_i at locations $\mathbf{s}_1$ and $\mathbf{s}_2$ is assumed to be a function of the distance between $\mathbf{s}_1$ and $\mathbf{s}_2$. For areal data, the spatial unit is an aggregated region of space, such as a Census block or a county, and y_i is typically a count or average response among individuals residing in that region. Popular models for analyzing areal data include the simultaneously autoregressive (SAR) and conditionally autoregressive (CAR) models. Foundational work in the field of spatial modeling has been conducted by Whittle (1954) and Besag (1974). The field of spatial econometrics includes a literature on network autocorrelation as well as other models for the sake of estimating peer effects (Anselin, 1988). For a comprehensive discussion of spatial models, see the text by Banerjee *et al.* (2004) and the Encyclopedia entry on spatial analysis.

In line with the general emphasis in the statistics and econometric literature, our focus has been on models for the mean (or transformations thereof). One of the few exceptions are mixed effect location-scale models, where the variance as well as the mean of the outcome depends on latent variables (Hedeker *et al.*, 2009). Such models allow shrinkage to an overall variance in addition to shrinkage to an overall mean.

Although it is always possible to specify SEMs by writing out a series of equations or a path diagram, the recent explosion in computing power and development of computer software programs to harness this power have made it possible to fit a wide range of models. This has enabled many extensions to traditional models including accounting for missing data, clustered or hierarchical data, and other heterogeneous features of models to be accommodated. SEMs can yield powerful improvements over traditional approaches to regression, covariance decomposition (or factor) analysis, grouping (or clustering) subjects, and separating cause from association. In the future, the authors predict that the uptake of SEMs will continue to expand into new areas of application.

Learning by Doing

V Ho, Rice University, Houston, TX, USA

Glossary

Endogeneity A situation where an explanatory variable in a regression equation is correlated with the error term, because of an omitted variable, measurement error, or simultaneity.

Fixed effects In a dataset with multiple observations of the same health care facility over time, unobserved factors specific to that facility that do not change over time can be modeled in a regression equation by specifying a dummy variable (fixed effect) for each facility.

Instrumental variables (IV) In a regression equation with an endogenous explanatory variable, an IV is a variable that is correlated with the endogenous variable, but is uncorrelated with the error term in the regression and is excluded from the regression.

Introduction

Learning by doing is viewed as an important determinant of success for many professions requiring high skill. Over the years, researchers have come to realize that teams and firms can also exhibit learning by doing. Even in cases where annual output does not increase over time, a firm can experience reductions in unit costs or improvements in quality that cannot be attributable to economies of scale, but cumulative experience instead. The presence of learning can have important implications for overall growth in a nascent industry. Differential learning across workers and firms can also have important implications for competition in the market. Health economists have been particularly interested in learning, because current and emerging medical technologies are complex, requiring both individual and team-based skills which are likely to benefit from experience.

Social scientists have been examining the impact of learning by doing on production technology for several decades. The concept of a learning curve was first described in 1936, when a study determined that as the quantity of manufactured units doubled, the number of direct labor hours required to produce an individual unit decreased at an uniform rate (Wright, 1936). Another early study concluded that the aircraft industry's rate of learning, or reduced labor requirement, was 80% between doubled quantities of airframes (Alchian, 1963).

The standard equation that is used in the literature to characterize a learning curve takes the form:

$$y_i = \alpha x_i^{-\beta} \tag{1}$$

where y represents the resources (hours or costs) required to produce the ith unit, α is the amount of resources required to produce the first unit, x is the cumulative number of units produced through the current time period i, and β is the learning rate (Argote, 1999). Taking natural logs yields a regression that can be readily estimated:

$$\ln y_i = \alpha - \beta \ln x_i \tag{2}$$

Most economic studies of learning by doing have employed this general framework by estimating the effectiveness of cumulative output production in reducing average costs. For example, it has been determined that on average each doubling of plant scale was accompanied by a 11% reduction in unit costs in the chemical industry (Lieberman, 1984). In the health economics literature, learning by doing has been tested for insurance plans, hospitals, and doctors. One study determined that clinical costs decline 10–15% with each doubling of experience for insurers administering managed behavioral health plans (where experience is measured as the cumulative number of managed care claims processed in a state by a particular health plan) (Sturm, 1999). However, most health economic studies have attempted to measure the effects of cumulative experience on patient outcomes (primarily mortality) rather than unit costs.

Hospital-Level Studies

Hospital-level studies of learning by doing have examined specific complex operations or procedures performed on patients. These studies focus on specific procedures in order to control for heterogeneity across treatments provided in hospitals. Patient outcomes (mostly patient mortality) are the dependent variable of interest, and regressions include both cumulative output and annual output as explanatory variables. Cumulative output is hypothesized to represent learning by doing, whereas annual output is hypothesized to reflect economies of scale. Because many of these studies do not have access to patient data dating back to when a particular operation was initially introduced for medical care, these studies often proxy for cumulative output using lagged values (e.g., number of operations performed 1, 2, or 3 years ago at a particular hospital) as a proxy for cumulative output.

Most published studies of learning by doing at the hospital level are based on two procedures for heart disease: Coronary artery bypass graft (CABG) surgery, and percutaneous transluminal coronary angioplasty (PTCA) (Gaynor *et al.*, 2005; Ho, 2002; Pisano *et al.*, 2001; Sfekas, 2009). CABG is a form of open heart surgery in which the rib cage is opened and a section of a blood vessel is grafted from the aorta to the coronary artery. PTCA is a procedure performed to improve blood supply to the heart. A balloon-tipped catheter is inserted into

an artery in the groin or shoulder and threaded to the blocked artery. The balloon is then inflated to flatten atherosclerotic plaque against the artery wall, reopening the artery. Health economists have focused on these procedures, because heart disease is the leading cause of death in the United States. Therefore, these procedures are performed frequently by many hospitals, so that data are readily available. The data are usually derived from one or multiple US states, which allow researchers access to detailed data from hospital discharge abstracts for all admissions for several years. These data specifications are required, so that researchers can accurately count the cumulative and annual number of procedures performed for each hospital. CABG and PTCA have also been the focus of interest for learning by doing studies, because there is a large body of medical literature that specifies the information that is necessary to control for patient characteristics that influence patient mortality and other outcomes for these two procedures. The required variables, which include multiple demographic and clinical characteristics, are also available in hospital discharge datasets.

Multiple studies find no support for learning by doing at the hospital level for either CABG or PTCA. Lagged volume or cumulative volume tends not to be statistically significant in explaining mortality for patients who undergo these procedures. This conclusion has been found for studies analyzing data from Arizona, California, and Maryland for various sample periods spanning the years 1983 through 2001 (Gaynor *et al.*, 2005; Ho, 2002; Sfekas, 2009). All of these studies include hospital specific fixed effects (dummy variables for each hospital in the sample) in the regression specifications in order to control for unobserved heterogeneity across hospitals which are constant over time. For example, some hospitals may benefit from exceptional and long-tenured nursing staff, or highly talented administrative staff. These factors can influence patient outcomes, but they are not observable in hospital discharge abstracts. The inclusion of hospital fixed effects means that the regressions estimate the effects of increases or decreases within the hospital in procedure volume over time, rather than the effects of differences in cumulative volume across hospitals on patient mortality. The fixed effect specification will more accurately capture the learning by doing effect which is hypothesized in the underlying economic model. However, precise estimation requires a sample of hospitals with data from a sufficient number of time periods in order to observe significant variation in procedure volume across time. Thus, these prior studies may have failed to precisely estimate a learning by doing effect. The samples in these studies contained data from only one or two states. Samples of this size may not have enough hospitals that experienced noticeable changes in procedure volume across years.

One study of 16 institutions that began performing a new procedure for minimally invasive heart surgery found that the amount of time required to perform the operation declined as the cumulative number of procedures increased (Huckman and Pisano, 2006). This result is tangible, even with the inclusion of hospital fixed effects in the regression models. The patient-level data were collected during the first 2 years after which the procedure was first approved by the Food and Drug Administration. Thus, this study may have been able to detect an institution-specific learning by doing effect, because the analysis was performed just after the technology was introduced; when the greatest amount of learning most likely occurs.

Although health economists have had little success identifying a tangible effect of cumulative volume on patient outcomes, a large literature in both medical and health services research journals finds a significant association between procedure volume and patient mortality. In addition to CABG and PTCA, this 'volume-outcome' relationship has been documented for a wide range of procedures and treatments, including carotid endarterectomy, hip replacement, lung cancer resection, liver transplantation, and neonatal intensive care (Halm *et al.*, 2003; Luft *et al.*, 1979; Birkmeyer *et al.*, 2002). When this relationship was first identified in the medical literature, learning by doing was mentioned as a likely explanation for this finding. Researchers suggested that if experience was the underlying source of the volume-outcome effect, then complex operations should be 'regionalized,' so that patients would benefit from improved outcomes at a select number of facilities that would be able to gain greater experience. The absence of a significant effect of cumulative volume on patient mortality for CABG and PTCA casts doubt on the learning by doing hypothesis, particularly for common cardiac procedures.

One other challenge faced by health economists trying to identify a learning by doing effect is that cumulative volume and annual volume are highly correlated. Hospitals that perform a large number of procedures in 1 year tend to do so in subsequent years. In at least one instance, an analysis of hospital data for PTCA could not explicitly test for the effect of learning by doing on average costs per patient, because inclusion of both cumulative and annual volume as explanatory variables led to multicollinearity (Ho, 2002). This issue might be resolved if researchers were able to analyze data from multiple states simultaneously, with data stretching over many years. Gathering a much larger sample would increase the likelihood that one could find hospitals that experienced sufficient variation in volume (e.g., due to entry or exit of competitors), which would weaken the collinearity between cumulative and annual volume.

It is also interesting to note that learning by doing studies in the economics literature have tended to focus on patient outcomes as the dependent variable of interest rather than costs. This focus contrasts with the general industrial organization literature, where there is much less research on the relationship between learning by doing and product quality. Some research has analyzed data on nuclear power plants (Lester and McCabe, 1993). Both reactor-specific learning and spillovers across reactors have been found to be important determinants of nuclear reactor performance. Learning by doing as measured by cumulative output has also been associated with fewer complaints in the aircraft production industry (Argote, 1993).

There may be fewer studies of the effect of learning by doing on costs in the health economics literature, because it is difficult to obtain datasets that provide both detailed information on patient outcomes and the costs of care. Hospital discharge abstracts often contain information on the total charges for a patient admission. These data can be linked with

hospital cost reports that contain the cost-to-charge ratio for each hospital, so that an estimate of costs per patient admission can be calculated. However, the saliency of patient mortality as a dependent variable of interest may have led to the greater focus of learning by doing studies on health outcomes for patients.

Physician-Level Studies

Many fewer published studies have attempted to estimate the volume-outcome effect at the surgeon level. The lack of studies stems in part from the fact that it is difficult to identify hospital datasets that provide consistent identifiers of physicians across patients and time. Only one published study included cumulative surgeon volume as an explanatory variable to explain patient mortality for CABG, and it finds no evidence of learning by doing (Huesch, 2009). In fact, this study also finds no association between annual surgeon volume and patient outcomes, although a small number of studies in the medical literature find that surgeons who perform more complex operations achieve lower mortality rates. Another study of approximately 4000 patients who received LASIK surgery in the early 2000s in the country of Colombia also found no effect of cumulative surgeon procedure volume on patient outcomes (Contreras *et al.*, 2011). The presence of learning by doing effects at the hospital versus the individual doctor level is likely to vary by medical intervention. For some operations, the surgeon's technical skill and discretion over specific intraoperative processes are likely important determinants of patient outcome. In other operations, hospital-based services (intensive care, pain management, respiratory care, and nursing care) are more likely to determine inpatient mortality.

Endogeneity

One may be concerned that the absence of a learning by doing effect may reflect endogeneity in the volume-outcome effect. There may be factors that are unobservable to the researcher, which influence both procedure volume and patient outcomes, leading to an observed association between these two variables in a regression model. For example, some facilities may be more quick to invest in newer surgical devices, which allow them to treat more patients and achieve better outcomes simultaneously. Endogeneity may also result from selective referral. The reputation of higher quality hospitals or surgeons may become well known in the community, attracting more patients seeking care.

Some learning by doing studies have accounted for potential endogeneity using instrumental variables techniques (Gaynor *et al.*, 2005). The variables that are hypothesized to influence procedure volume but are otherwise uncorrelated with patient outcomes include: The number of patients residing within a fixed geographical radius of a hospital, the number of other hospitals offering the same procedure within a fixed geographical radius of a hospital, and the predicted number of patients to choose a hospital for treatment, based on distance from the patients' residences to each particular hospital. These instruments are significant predictors of patient volume, but specification tests cannot reject the null hypothesis that procedure volume is exogenous in explaining patient outcomes. Therefore, concerns regarding the potential endogeneity of procedure volume are not supported by current empirical analyses.

Forgetting

The general industrial organization literature has also tested for the presence of forgetting in firm production (Benkard, 2000; Thompson, 2007). This literature considers the possibility that productivity gains from learning can depreciate over time. More flexible regression specifications capture the fact that cost per unit of output can rise during significant production troughs that may occur in the life cycle of a product. Only one published paper has attempted to test for forgetting in the health economics literature, and it found almost complete forgetting from prior experience among recently trained surgeons performing CABG (Huesch, 2009). More studies need to be performed to validate this finding. The industrial organization literature identified forgetting in the context of airplane manufacturing, where there can be noticeable declines in production in the life cycle of a particular model of airplane. In contrast, most hospitals are not likely to experience noticeable troughs in the performance of a procedure. It would be useful to identify a large sample of hospitals that had experienced the entrance of a nearby competitor for the same procedure to precisely estimate a forgetting effect. Determining the extent to which forgetting exists in the performance of complex medical treatments has important implications for patient care. If there is little depreciation in learning, then one can be more certain that hospitals or surgeons who are currently high quality will remain so in the future. If forgetting does exist, further studies would be needed to determine why learning depreciates. Quality could depreciate over time, because the skill set of surgeons could depreciate with lack of use, or because multidisciplinary teams of caregivers become less coordinated if they treat fewer patients.

Other Forms of Learning

Past industrial organization studies have also identified forms of learning other than learning by doing. For instance, in a study of the semiconductor industry, firms learn three times more from an additional unit of their own cumulative production than from an additional unit of another firm's cumulative production (Irwin and Klenow, 1994). The reductions in unit costs associated with increases in other firms' cumulative production or industry cumulative output are referred to as spillover effects. In this context, a firm's own learning by doing is referred to as proprietary learning. It is plausible that spillover learning could occur in the context of complex medical procedures. For example, a hospital performing a small volume of procedures in a city with several large facilities nearby may have better outcomes than a

comparatively small facility in a rural area. The small urban hospital may be able to benefit from nearby expertise.

Cost reductions associated with calendar time rather than production quantity have been referred to as 'learning by watching.' Hospitals may be able to improve outcomes by learning from the experience of other facilities. For example, a hospital which began performing 50 PTCAs per year in 1996 is likely to have better outcomes than a comparable hospital in 1986, because the former facility could benefit from the knowledge and experience gained over the previous decade. One study that found little evidence of learning by doing based on the cumulative number of PTCAs performed by hospitals over time found substantial evidence of learning by watching for this procedure (Ho, 2002). Outcomes improved year by year for all hospitals, regardless of the cumulative number of angioplasty procedures they performed. Learning by watching has also been identified for the performance of LASIK (Contreras *et al.*, 2011). Significant improvements in outcomes were observed at two points in the sample period analysis when all physicians in a practice performing this procedure met to update surgical plans based on patient characteristics.

Determining the relative magnitude of learning by doing, spillover learning, and learning by watching is important for assessing the relative success of small versus large firms. If most learning is nonproprietary and few economies of scale exist, then small firms can more easily compete with large firms. Health economics lacks a comprehensive set of studies that test for learning by doing for a range of procedures and for hospitals or physicians in multiple states. The studies so far find little evidence for learning by doing, whereas there is more convincing evidence for learning by watching. These findings suggest that there is little support for 'regionalizing' complex surgical procedures at a select number of high volume hospitals that would benefit from greater experience.

Conclusion

Researchers have identified learning by doing that reduced unit costs in industries ranging from chemical processing to semiconductors. And there are hundreds of papers in the medical literature finding an association between higher hospital or surgeon procedure volume and lower mortality rates. However, most rigorous econometric analyses of health care data have been unable to formally identify learning by doing. Perhaps health economists lack sufficient data to distinguish between annual and cumulative output measures when testing for learning by doing in mortality and/or costs. Analysis of a wider range of newly emerging medical treatments, as well as more detailed data on costs would help to explain the role of learning in influencing the costs and quality of medical care.

In the meantime, policy makers should be cautious of recommendations to centralize complex surgical procedures based on existing volume-outcome studies. Although larger providers tend to yield better patient outcomes, making them even larger will not likely lower hospital mortality rates further. More research is required to determine the underlying reasons for the volume-outcome relationship. One should also keep in mind that learning by watching effects appear to be significant in health care. All providers tend to improve over time, regardless of volume. Given the potential beneficial effects of competition in maintaining quality and lower costs, patients may in fact be better off without centralization of complex treatment.

Long-Term Care

DC Grabowski, Harvard Medical School, Boston, MA, USA

Introduction

Long-term care is a set of services delivered over a sustained period of time to people who lack some degree of functional capacity. Put alternatively, long-term care is the help needed to cope, and sometimes to survive, when physical and cognitive disabilities impair the ability to perform activities of daily living (ADL), such as eating, bathing, dressing, using toilet, and walking. Unlike the provision of general health services, which are often targeted toward acute medical problems, long-term care must be continually provided and is, thus, continually expensive.

Long-term care services are needed by a diverse set of individuals who receive care from an equally wide array of providers. As the result of declining functioning, older individuals – especially the very old – are the primary recipients of long-term care services, but in some instances, younger individuals with physical or cognitive limitations also require services. The primary providers of long-term care services in most countries are 'informal' providers such as family members and friends. Formal providers include nursing homes, board and care homes, home health care agencies, assisted living facilities, adult foster and day care homes, home- and community-based providers, and continuing care retirement communities (CCRCs). Across these different formal providers, a number of different payer types exist including out-of-pocket, public and private insurance. Because consumers are often thought to lack information regarding the quality of services provided, an immense amount of government regulation exists within institutional long-term care settings in countries such as the US.

Long-term care has been an active and distinct subfield of health economics for some time. To paraphrase an old line 'long-term care economics is like health economics, only more so,' several of the key features that make the economics of health different from the economics of other goods and services are even more pronounced in the study of long-term care. That is, the assumption of the well-informed, rational consumer is more dubious; the role of government as a payer and regulator is more prominent; the response to financial incentives such as insurance is exacerbated for certain services; and the external costs of illness are often more formidable.

This article provides a broad discussion of the basics of long-term care: who needs it; who provides it; who pays for it; and some background on government regulation of these services. Next, this article provides an overview of some of the central issues in the economics of long-term care: The nonpurchase of private long-term care insurance; long-term care quality; pay-for-performance in long-term care; cost-effectiveness of home- and community-based services (HCBS); effects on informal caregiving; and the integration of long-term care with other health care services.

Who Needs Long-Term Care?

The key to long-term care is functioning. Unlike acute health care where a number of highly technical medical services are typically provided to patients, long-term care is assistance with daily tasks of living. Long-term care personnel have divided these tasks into ADLs, such as eating, using toilet, dressing, bathing, and locomotion and instrumental ADLs (IADLs), such as cooking, cleaning, doing laundry, handling household maintenance, transporting themselves, reading, writing, managing money, using equipment such as the telephone, and comprehending and following instructions. Clearly, the need for assistance with multiple ADLs might necessitate more intensive long-term care such as a nursing home, whereas the need for assistance with one or two IADLs may potentially be provided in the home or community. However, more than health dictates the need for more intensive long-term care services, an individual's wealth, and presence of family caregivers will also influence the site of care. For example, disabled individuals who are married and have children have been found to have a lower risk of nursing home entry.

Most elderly persons are physically active, able to care for themselves, and do not need long-term care. However, the prevalence of disability rises steeply with age. For example, in the US, only approximately 1 in 10 individuals aged 65–74 years is disabled, but roughly 7 in 10 individuals aged 85 years and older are disabled. Additionally, not all disabled persons are old. For example, individuals under the age 65 years with spinal cord injuries, advanced multiple sclerosis, traumatic brain injuries, developmental disabilities, and mental illnesses may all require some form of long-term care.

Who Provides Long-Term Care?

Although many people associate long-term care with nursing homes, the predominant provider of long-term care is the family. The predominant providers of care within a family have historically been spouses and adult children of elderly individuals and parents of younger individuals in need of services. Although several recent societal trends have worked against informal provision of services (e.g., greater female labor force participation and geographic dispersion of families), this is still the dominant type of long-term care. Among the community-dwelling US elderly with long-term care needs, 95% receive some informal care and two-thirds rely solely on informal care.

Elderly individuals almost universally prefer receiving care in their homes from family members. However, health, familial, and financial issues often precipitate the need for care from a formal provider. A broad continuum of services constitutes the formal long-term care marketplace. Although

 doi:10.1016/B978-0-12-375678-7.01002-6

nursing homes serve less than a quarter of the disabled elderly in the US, they are certainly the most expensive long-term care option and thoroughly studied.

In the US, roughly 1.6 million residents live in nearly 17 000 nursing homes. About two-third of all nursing homes are investor owned, about a quarter are nonprofit, and the remaining are government-owned facilities. Roughly half of all nursing homes are members of a chain and approximately 6% are hospital-based facilities. The average-sized facility has approximately 100 residents and the overall occupancy rate is approximately 88%. Historically, occupancy rates have been much higher within this industry because of the presence of supply constraints such as certificate-of-need (CON) and construction moratorium laws that attempt to limit the growth in beds in an effort to hold down the Medicaid expenditures. However, the recent growth in alternatives to nursing home care has likely competed away some of the 'healthier' nursing home residents to other care settings and lowered nursing home occupancy rates.

For individuals who can still live on their own, home care can range from periodic help with shopping and cleaning to full-time nursing help. Social support services such as meals on wheels, adult foster care, and adult day care, may enable individuals in need of long-term care to remain in the community. Assisted living facilities are residential settings that provide more supportive services than boarding houses but less medical care than a nursing home. Assisted living may provide lodging; meals; protective oversight; activities; and some assistance with medications, personal care, and ADL.

From an economic perspective, one intriguing development within the US long-term care market is the blurring of the roles of provider and insurer in CCRCs. Under this model, residents pay a large initial fee on entry and rent an apartment for an additional monthly fee in a community setting designed specifically for elderly individuals. As health declines, the individual may move on from the independent living section of the CCRC to onsite-assisted living and onsite nursing home care for additional charges. Given that this model is typically geared toward wealthier individuals, CCRCs make up a relatively small part of the US market.

Who Pays for Long-Term Care?

Similar to acute health care services, long-term care is paid by a number of sources. What is most striking about this sector in the US, relative to the acute health sector, is the lack of private insurance coverage. Less than 5% of all long-term care expenditures are paid by private insurance. Individuals who use long-term care typically pay it out of their own (or their family's) income and assets, or they must qualify for public coverage. Thus, long-term care represents the largest source of catastrophic costs for the elderly in the US. Although Medicare does cover some rehabilitative (or short-stay) nursing home care, the primary payers of long-term care services are state Medicaid programs. For example, Medicaid accounts for about half of all expenditures on long-stay nursing home services, which amounted to approximately $45 billion nationwide in 2009. Individuals must qualify for Medicaid by meeting income and asset criteria at the time of nursing home entry or by 'spending down' during their stay.

Although HCBS have been found to be associated with lower long-term care expenditures for individuals with certain care needs, most state Medicaid programs are more generous in covering nursing home services because of a perceived moral hazard problem. Individuals generally do not want to enter a nursing home, with research suggesting that these services are relatively price inelastic with respect to Medicaid eligibility policy. However, HCBS attracts some individuals who otherwise would have received care from family members and friends in the community. Thus, in recognition of this potential moral hazard problem, states are more likely to cover nursing home services relative to HCBS. Nevertheless, spending for Medicaid HCBS has grown substantially, increasing from $4 billion in 1992 to $22 billion in 2007. Nursing home expenditures have also increased over this period, HCBS grew from 14.5% to 31.6% of Medicaid long-term care spending between 1992 and 2007.

The emotional, physical, and financial burden on informal caregivers can be quite high. Historically, US long-term care policy has not financially reimbursed informal care provision by family members and friends. Although such services are not reflected in the national health accounts, never trigger a payment from an insurer; do not inflate the federal deficit, and are rarely included in any calculation of the overall cost of long term care; they nonetheless represent a genuine opportunity of cost burden. For example, if an adult child is taking care of an elderly parent, this individual is forgoing other work and leisure opportunities. Policymakers in the US have experimented with several measures to support informal care by family and friends with the idea that these savings might offset higher cost institutional services. For example, the 'cash and counseling' program, currently active in 15 states, provides Medicaid beneficiaries with a budget to hire their own personal care aides. Recent economic research in the US and elsewhere has begun to calculate the direct (e.g., opportunity cost) and indirect (e.g., health implications) costs of informal caregiving.

Government Regulation of Long-Term Care

Reflective of government spending over the past several decades, regulation in the US long-term care sector has largely been defined by the regulation of nursing homes where government continues to play a vital role in protecting a potentially vulnerable resident population. The reason for the high degree of government intervention and oversight is often thought to relate to the inability of many nursing home consumers to monitor quality effectively. Dating back over three decades, a number of reports and studies have documented low-quality care within this industry. In response to this issue, the US government has placed a number of restrictions on the industry. For example, the Nursing Home Reform Act was passed in 1987 mandating that nursing facility care should be more consistent with expert recommendations for assuring quality care. These recommendations included reduction in the use of physical restraints, prevention of

pressure ulcers, reduction of psychoactive medications, and some minimal staffing standards including the stipulation that a registered nurse must be on duty 24 h a day and all nurses' aides must be certified.

The US government is also an overseer of care via the survey and certification process. To accept the Medicaid and Medicare recipients, a nursing home must be annually certified via Centers for Medicare & Medicaid Services survey. Several alternative remedies may be imposed on facilities that receive a high number of deficiencies. These punishments include civil money penalties of up to $10 000 a day, denial of payment for new admissions, state monitoring, temporary management, and immediate termination. In addition to this survey process, certified nursing homes must fill out Minimum Data Set (MDS) assessments for every resident on a quarterly basis. Thus, the government generates an immense amount of quality information at a substantial cost. One estimate suggested that the survey and certification process costs the government nearly $400 million annually, which equates to approximately $22 000 per nursing home or $208 per nursing home bed. This figure does not include the indirect costs to the facility of the certification process, such as interacting with the regulatory agency, preparing for and hosting survey visits, gathering and providing data, and responding to complaint investigations. Experience from other sectors of the economy suggests that the indirect costs of the certification process to the nursing home are likely greater than the direct costs to the government.

Beyond setting and enforcing quality standards, examples also exist of market entry and price regulations in the US long-term care sector. Regulated barriers to entry are present in many long-term care markets via state CON laws and construction moratoria. Most of these state laws focus on nursing home beds, although states are increasingly grappling with whether and how to expand these policies to other long-term care settings, such as assisted living facilities. A CON law constrains market growth by employing a need-based evaluation of all applications for new construction. A construction moratorium is even more stringent in that it effectively prevents any market expansion. The stated rationale for these regulations is that lower capacity ultimately results in lower public expenditures, although research suggests that the repeal of these policies does not lead to increased state Medicaid long-term care expenditures. As a related barrier to entry, some states exercise greater scrutiny over the ownership status of nursing homes (e.g., New York State does not allow out-of-state for-profit chains to operate facilities in the state). Although infrequently used, an example of price regulation in the US long-term care sector is nursing home rate equalization laws. Both North Dakota and Minnesota prohibit nursing homes from charging a private-pay price above the state Medicaid rate.

Key Economic Questions in Long-Term Care

Nonpurchase of Private Long-Term Care Insurance

As noted above, relatively few individuals in the US purchase private long-term care insurance. Researchers have explored a number of potential supply- and demand-side explanations for this nonpurchase. On the supply side, research has observed that long-term care insurance premium pricing has relatively high loads compared to other types of insurance – that is, a lower portion of the premium dollar translates into benefits. These high loads are consistent with several supply-side market failures including transaction costs, imperfect competition, asymmetric information, and a range of dynamic contracting problems. Empirical support exists for the asymmetric information and dynamic contracting explanations. However, these supply-side factors cannot entirely explain the limited size of the market. Research suggests that even if actuarially fair policies (i.e., policies with zero load) were made available, the majority of elderly individuals would still not purchase these policies. Thus, research suggests that most of the nonpurchase relates to demand-side factors.

On the demand side, one explanation for the nonpurchase of long-term care insurance is incomplete information on the part of consumers. Many studies have found that individuals underestimate their need for long-term care or mistakenly assume it is covered by Medicare. Another possible demand-side explanation is that the form of the utility function may not be constant in the context of chronic health conditions. That is, individuals may place a lower value on consumption while in a nursing home than when healthy at home, which would serve as a disincentive to purchase long-term care insurance. Demand for long-term care insurance may also be limited by the availability of imperfect but less costly substitutes such as unpaid care provided by family members. Another potential explanation is that illiquid housing wealth can be used to insure long-term care. An individual may prefer to use their housing wealth in the event of a health shock rather than pay long-term care insurance premiums out of liquid wealth.

One prominent demand-side theory is that the Medicaid program 'crowds out' the purchase of long-term care insurance. Using simulation models, one study found that the implicit tax imposed by Medicaid (i.e., the part of the premium going to benefits Medicaid would have otherwise provided) explains why more than 60% of the wealth distribution does not purchase a policy. Importantly, the same researchers note that reducing the implicit tax of Medicaid on long-term care insurance would likely be an insufficient mechanism to expand the market, in part, because of the consumer misperceptions and supply-side failures described above.

Long-Term Care Quality

A number of studies have suggested poor quality of care in long-term care markets, especially the US nursing home market. A large health economics literature has focused on the economic explanations for low-nursing home quality. Economists have generally focused on four explanations for variation in the quality of nursing home care: public payment generosity; supply constraints; asymmetric information between nursing homes and patients; and macroeconomic factors.

The health economics literature on nursing home quality of care in the 1980s and 1990s was largely based on Scanlon's model in which nursing homes face two markets. One market

is for private-pay residents with downward sloping demand, and the other is for Medicaid residents who are insensitive to price. Scanlon's empirical work suggested the Medicaid side of this market could be characterized nationally by an excess demand. CON and construction moratoria policies had constrained growth in the supply of nursing home beds, and nursing homes preferred to admit the higher paying private patients. As a result, when a bed shortage existed, it was the Medicaid patients who would be excluded.

At the time, many noneconomists thought that the problem of quality in nursing homes could only be solved by raising Medicaid reimbursement rates. By incorporating a quality variable into Scanlon's model, several early research papers showed that raising Medicaid rates in a market with excess demand would result in nursing homes facing a reduced incentive to use quality of care to compete for the private patients. The decline in nursing home occupancy rates, repeal of CON laws in certain states, and emergence of improved data over the past decades have all contributed to a renewed interest in the relationship between the Medicaid payment and nursing home quality. Unlike the earlier research on this issue, results from more recent studies have generally found a modest positive relationship between the state Medicaid payment rates and nursing home quality. Importantly, the more recent studies provide little support for a negative relationship between the Medicaid payment level and quality.

Asymmetric information may also be a potential explanation for low-quality nursing home care. Although nursing home care is fairly nontechnical in nature, monitoring of care can often be difficult, and the quality learning period may be nontrivial relative to the length-of-stay in some instances. The nursing home resident is often neither the decision maker nor able to easily evaluate quality or communicate concerns to family members and staff. Furthermore, elderly individuals who seek nursing home care are disproportionately the ones with no informal family support to help them with the decision process. Finally, relatively few transfers occur across nursing homes. Movement among homes may be impeded by tight markets due to supply constraints such as CON and construction moratorium laws and health concerns regarding relocation (termed 'transfer trauma' or 'transplantation shock'). Thus, consumers may not be able to 'vote with their feet' by taking their business elsewhere.

To address this perceived lack of consumer information, the US government publishes a web-based nursing home report card initiative called 'Nursing Home Compare' (www.medicare.gov/NHCompare), which contains information on nurse staffing, regulatory deficiencies, and MDS-based quality indicators. If consumers use this information to make informed decisions about nursing home entry, then public information may help to improve quality. The existing literature to date suggests that the Nursing Home Compare report card initiative has led to a modest (but inconsistent) positive effect on nursing home quality of care. Key factors that may impede the use and efficacy of nursing home report cards include the heterogeneity in the preferences of short-stay and long-stay consumers; potential difficulties in accessing report card information during times of crisis; potential difficulties in interpreting report card data when the measures conflict or fail to provide a clear signal; key role of hospital discharge planners in the selection process; and limited choice set many nursing home consumers face due to rural markets, price, high occupancy, or other extenuating circumstances.

Macroeconomic factors such as wage rates for nursing home staff may also be important toward explaining the level of quality. For example, one study measures the extent to which nursing homes substitute materials for labor when labor becomes relatively more expensive. From a quality perspective, factor substitution in this market is important because materials-intensive methods of care are associated with greater risks of morbidity and mortality among nursing home residents. Indeed, as the market wage rises, nursing homes are more likely to employ labor-saving practices such as the use of antipsychotics.

Pay-for-Performance in Long-Term Care

Through the Medicare and Medicaid programs, the US government purchases significant amounts of nursing home services. Moreover, an emerging literature suggests poor nursing home quality results in higher Medicare spending for acute care services. As such, the government seeks to obtain high-quality services for Medicare beneficiaries. However, administrative pricing arrangements mean that – for many residents – nursing homes cannot charge higher Medicare or Medicaid prices for better quality. Moreover, the government cannot simply ask for a level of quality for Medicare beneficiaries. This set of circumstances can be analyzed using a principal agent model. In this instance, the 'principal' is the government, whereas 'agent' is the nursing home.

This principal–agent model in economics is useful in analyzing circumstances in which providers, such as nursing homes, are not driven by market forces to the level of quality desired by the purchaser and, further, where the purchaser cannot contract directly for a given level of provider quality. One way to induce nursing homes to improve quality is to make payments at least partly contingent on an indicator of nursing home effort to deliver high-quality care. Such indicators of nursing home effort are embodied in various structural (e.g., staffing), process (e.g., physical restraint use), and outcome (e.g., pressure ulcers) measures. These indicators only measure a few of the many dimensions of quality that a health care purchaser (and consumers) might care about, and each of them may require separate, costly efforts to generate improvement. That is, the structures and processes that create improvements in pressure ulcers might be largely distinct from what is needed to raise performance in lowering resident pain or depression. Purchasers must decide which dimensions of quality to target and consider how outcomes on unrewarded dimensions of performance might be affected. Pay-for-performance schemes in this way introduce a form of price flexibility that rewards desirable performance. Theoretically, the effectiveness of payments contingent on quality measures depends principally on the relative magnitude of expected costs and benefits to the provider of improving quality. That is, do expected incremental nursing home payments exceed the costs to facilities of supplying the desired level of quality? Costs should be thought of broadly here and may include, for

example, the value of additional unreimbursed time spent with patients or investments in information technology.

Pay-for-performance arrangements also have the potential for unintended consequences. Critics of paying for quality in health care have identified a number of drawbacks that might arise from the introduction of such schemes. The principal category of unintended consequences that might result from pay-for-performance is generally termed gaming where participants find ways to maximize measured results without actually accomplishing the desired objective of improved quality of care. In the nursing home setting, providers or administrators might 'game' incentive systems by miscoding diagnoses or services or selecting patients on the basis of the likelihood of a positive outcome or compliance with treatment protocols rather than need. Selecting healthier patients for treatment may reduce aggregate health benefits; miscoding may also have longer run effects on quality because of missed opportunities to identify and improve low quality. A second major concern with paying for quality is known in the economics literature as the multitasking problem. If the goal of the payer is multidimensional and not all dimensions can be measured and 'paid on' (e.g., resident quality of life), compensation based on available measures will distort effort away from unmeasured objectives that may be important to patient well-being. Finally, concerns have been raised about the impact of paying for quality on intrinsic motivation, cooperation, and professionalism, particularly among physicians.

Recent concerns have also been raised about the impact of market-based approaches for quality on racial and ethnic disparities in health care. In the context of the nursing home market, published research has described its two-tiered nature, with the lower tier consisting mainly of residents with Medicaid-financed care and having fewer nurses, lower occupancy rates, and more health-related deficiencies. These low-performing facilities are disproportionately located in the poorest communities and are more likely to serve African-American residents than are other facilities. Even within markets, African-American and poorly educated patients have been found to enter the worst-quality nursing. Although pay-for-performance initiatives are typically aimed at improving quality of care broadly, it is important to monitor whether these initiatives further disadvantage poor performing providers and the individuals they serve.

Cost-Effectiveness of Home and Community-Based Services

Individuals generally prefer care in least restrictive setting possible, and for certain individuals with less intensive care needs, it may be possible to provide lower per capita cost care at home or community relative to a nursing facility. However, the historic institutional bias in long-term care coverage relates partially to a perceived moral hazard problem (or woodwork effect) whereby publicly financed noninstitutional services substitute for informal services previously provided by family members and friends. Program administrators have found it very difficult to structure coverage such that only individuals who otherwise would have entered nursing homes utilize noninstitutional services. States have employed targeting (or screening) mechanisms in an attempt to limit care to only those individuals who otherwise would have accessed nursing home care.

If targeting were perfect, then the noninstitutional treatment model would need to be only marginally less costly than the institutional model to generate savings. However, as targeting becomes less perfect, the aggregate savings from noninstitutional care needs to increase in order to cover the increased costs associated with the moral hazard effect. The empirical literature has generally supported the idea that spending from increased HCBS utilization typically exceeds the savings from decreased nursing home utilization. However, this type of cost analysis is distinct from a cost-effectiveness analysis, in which differences in costs are benchmarked against differences in outcomes. Even if rebalancing toward HCBS is associated with higher aggregate costs, the services may still be cost-effective due to an even greater increase in aggregate effectiveness. Toward the end, a number of research studies have supported the idea that psychosocial outcomes such as life satisfaction, social activity, social interaction, and informal caregiver satisfaction were higher under HCBS. Moreover, unmet needs have been shown to decrease under HCBS. To date, research has not formally balanced the costs and benefits of HCBS.

Effects on Informal Caregiving

Economic theory suggests a range of supply- and demand-side factors may influence the provision of informal caregiving. On the supply side, given the potential substitution of formal and informal care services, changes in the generosity of public payment for home health care services may influence the provision of informal care. Research suggests that older US adults with functional limitations who were exposed to more restrictive payment caps offset reductions in Medicare home health care with increased informal care, although this effect is only observed for lower income individuals. Direct public payment of family caregivers may also influence informal caregiving. The US 'Cash and Counseling' program, currently active in 18 states, provides Medicaid enrollees with a monthly cash allowance to purchase personal assistance and related goods and services. The majority of recipients purchase this care from family members. In a randomized three-state demonstration evaluating Cash and Counseling against the traditional agency-directed model of home care, the program was found to reduce some unmet needs and greatly enhance quality of life, but Cash and Counseling increased overall program spending.

Several economic analyses have considered the effect of demand-side factors on the provision of informal care services. Using US data, the availability of immediate family such as a spouse or adult children, being male, being a minority, and owning a home were all associated with a greater likelihood of informal care use. When income is treated as exogenous, studies have found that higher income is associated with a lower probability of informal care use. However, when the Social Security 'benefit notch' was used as instrument for income, higher permanent income is not found to have a statistically meaningful effect on the provision of informal care among older adults with lower education.

Integration of Long-Term Care with Other Health Services

Individuals who require long-term care services typically also require a mix of primary, acute, postacute, and palliative services at different times. The coordination of these different services has become a major issue within the US health care system. Importantly, the coordination of health care services at the delivery level relates directly to the financing and payment of those services.

At the financing level, the presence of multiple payers in health care is known to introduce conflicting incentives for providers, which may have negative implications for cost containment, service delivery, and quality of care. The fundamental issue is that the actions of one payer may affect the costs and outcomes of patients covered by other payers. These 'external' costs and benefits can occur both within and across health care settings, and little incentive exists for a payer to incorporate them into payment and coverage decisions. As a result, the behaviors of health care payers – even public payers – often deviate substantially from the social optimum.

This observation is particularly relevant in regards to the coverage of acute and long-term care services in the US The federally run Medicare program provides a set of insurance benefits for virtually all individuals age 65 years and older, regardless of income, and for younger people with disabilities 2 years after they qualify for Social Security's disability benefit. Medicaid, a state-run program jointly funded by the state and federal governments, provides coverage for its low-income enrollees that supplements Medicare coverage. Many individuals who are dually eligible for both Medicare and Medicaid require both extensive acute and long-term care services. However, given the bifurcated coverage of acute and long-term care under Medicare and Medicaid, neither program has an incentive to internalize the risks and benefits of its actions as they pertain to the other program. Each program has the narrow interest in limiting its share of costs, and neither program has an incentive to take responsibility for care management or quality of care. For example, under the traditional benefit structure for duals, little incentive exists for state Medicaid programs to enact policies to lower Medicare-financed hospitalizations because they do not accrue any of the potential savings. Indeed, state Medicaid programs often enact policies such as bed-hold payments that increase hospital and postacute expenditures for the Medicare program. A model that blends Medicare and Medicaid financing introduces a stronger incentive to minimize transitions for dually eligible beneficiaries from Medicaid-financed nursing home care, for example, to higher cost Medicare-financed hospital care.

Payment structure also has implications for the coordination of care. Cost-shifting occurs for reasons beyond the fragmentation of financing across programs. For example, the high rate of 30-day hospital readmissions from Medicare-financed skilled nursing facilities is an example of poor coordination within the Medicare program. Traditional fee-for-service payment creates little incentive for providers to manage the volume and intensity of services because providers are rewarded with greater revenue when they deliver more services. Indeed, hospitals are rewarded with higher revenue when beneficiaries are readmitted to the hospital.

Through risk-based capitation, managed care potentially encourages more efficient care delivery. Under this model, a single entity receives a fixed predetermined monthly payment (i.e., capitation rate), which provides the incentive to minimize wasteful care. Ideally, under capitation, hospitals would not be rewarded when individuals are readmitted. Similarly, other risk-based models such as accountable care organizations, bundled payment, global budgeting, and medical homes also provide similar incentives to coordinate care in ways that could reduce inefficient medical and long-term care service use.

With respect to care delivery, the coordination of financing and payment can be thought of as necessary, but not sufficient, conditions for the coordination of services. For example, at the delivery level, care coordination activities might include case management, team-based care models, patient education, management of care transitions, communication protocols for providers, and shared clinical and social information. However, without an alignment in payment and financing in which providers can internalize the costs and benefits of their actions, there is little reason to suspect any sustainable coordination in service delivery at the ground level.

Long-Term Care Insurance

RT Konetzka, University of Chicago, Chicago, IL, USA

Glossary

Activities of daily living Self-care tasks required on a regular basis, such as bathing, dressing, toileting, transferring in and out of bed, and eating.
Formal long-term care Paid care.
Informal long-term care Unpaid care provided by family or friends.
Instrumental activities of daily living Tasks related to the ability to live independently, such as housekeeping, using a telephone, shopping, preparing meals, and money management.
Long-term care Assistance with functional and/or cognitive impairments on an ongoing basis.
Medicaid crowd-out Reduced demand for private insurance due to the availability of Medicaid as an alternative.
Policy lapse Intentionally or unintentionally allowing an insurance policy to expire or become invalid.

Introduction

Long-term care is a sector of the healthcare industry that is growing in importance with the aging of populations around the world. In the United States, according to the Congressional Budget Office, expenditures on long-term care totaled US$135 billion in 2004 and are expected to double in several decades. People with long-term care needs generally have chronic conditions and associated functional and/or cognitive limitations that require assistance with activities of daily living (bathing, dressing, toileting, transferring, eating) or instrumental activities of daily living (housekeeping, using a telephone, shopping, preparing meals, money management). These types of needs can be served in a variety of settings: in the home (formally by paid home care or informally by family and friends), in a nursing home, in an assisted living facility, or in an adult day care center, among others. Although the lines between acute care, postacute care, and long-term care have become blurred for long-term care recipients as more and more high-tech services formerly provided only in hospitals are now administered in a variety of settings, an ongoing need for assistance with functional or cognitive limitations remains the defining feature of an individual with long-term care needs. Although some recipients of long-term care are under the age of 65, the majority are elderly.

Long-term care is growing in importance not only due to demographic shifts but also due to the emergence of chronic conditions as a primary healthcare challenge. Much of the developed and parts of the developing world, having experienced both the eradication of many infectious diseases and the benefit of technological advances that lessen the mortality from the largest causes of death in earlier eras, are now struggling with a growing prevalence of chronic health conditions, sometimes exacerbated by poor health behaviors. These are often costly conditions that require ongoing care over many years, and failure to access appropriate chronic care can lead to a greater need for acute care. Nonetheless, payment systems have generally not adapted to the growing importance of chronic conditions and associated long-term care needs. In the United States, Medicare, the publicly run health insurance system for the elderly, was designed to cover temporary acute care and explicitly disavows responsibility for covering long-term care. Medicaid, designed to cover healthcare needs of the poor, has by default become the dominant public payer in long-term care (approximately two-thirds of nursing home residents at any given point in time are on Medicaid), but as this was not the original intent of the program, substantial gaps and inefficiencies remain. In addition to lack of recognition or foresight about the growing financial burden of long-term care, many societies express some ambivalence about who should be responsible for long-term care, as much of it is relatively low-tech and can potentially be provided by family members. The resulting lack of intentional and systematic financing is a key feature of the economics of the long-term care sector that distinguishes it from other healthcare sectors involving the elderly and sets the stage for a private long-term care insurance market.

Developed nations around the world face similar situations in terms of demographic change and a growing need for long-term care that was not entirely recognized or anticipated when coverage for acute care needs was evolving. Depending on their resources, cultural norms, ideology, and existing healthcare delivery and payment infrastructure, countries have followed a variety of approaches to covering long-term care. Several have opted for national long-term care insurance systems (e.g., Germany, Japan); others have incorporated some long-term care services, especially home- and community-based services, into existing social insurance programs (e.g., Denmark); and some rely on a combination of self-funding, private long-term care insurance, and a safety net of public funding as a payer of last resort (e.g., the United States). Countries that rely mainly on private financing – or would like to ease the burden on public coffers – have a stake and interest in the existence and survival of private long-term care insurance markets.

The risk of needing long-term care is, in theory, an appropriate risk to be insured against. The average probability among aging individuals of needing long-term care is not trivial and is associated with substantial and unevenly distributed cost, but which individuals will experience the highest costs is seemingly random when viewed at the typical age of insurance purchase (50–65). On average, individuals

 doi:10.1016/B978-0-12-375678-7.00921-4

turning 65 will need some type of long-term care for 3 years, but half will have no private out-of-pocket expenditures, due to lack of either need or the availability of informal care to meet low-level needs. However, more than 1 in 20 is projected to spend more than US$100 000 out of pocket in 2005 (Kemper *et al.*, 2005). According to MetLife Mature Market Institute (2008), nursing home care costs more than US$70 000 per year on average, which implies that only a small minority of individuals can finance an extended stay out of pocket. The skewed distribution of uncertain costs associated with long-term care is a feature that would normally bode well for a robust insurance market.

Despite the conceptual appropriateness of a robust long-term care insurance market, only approximately 13% of the elderly population in the United States reports having long-term care insurance. Most policies are purchased on the individual-payer market, as group long-term care insurance policies are relatively rare. Benefit eligibility is usually triggered with medical certification of a minimal level of functional dependence, defined as assistance needed with activities of daily living. The vast majority of policies cover home care as well as nursing home care for a given number of years, but benefits are generally paid as a set per diem amount to be applied toward a given service as opposed to covering the total cost of the service. Many policies adjust benefits for inflation over time. Policies typically cost several thousand dollars per year, but costs can range substantially depending on age and health status. Individuals who exhibit signs of existing or imminent long-term care need (e.g., those who already have mild cognitive or functional impairment) are generally ineligible for policies at any price. Long-term care insurers are generally not allowed to raise premiums over time for an individual whose health risk increases, but they can adjust for changes in risk for an entire class of policyholders if payouts are higher than expected. Individuals who fail to pay premiums (policy lapse) forfeit all benefits and all premiums paid previously; few policies to date have built in nonforfeiture benefits that would allow individuals to recoup some of the investment in a lapsed policy. Most state insurance regulations include safeguards that help to avoid unintentional lapse.

Theory of Demand for Long-Term Care Insurance

Economists have generally modeled the behavior of consumers in the decision to purchase insurance using a standard expected utility framework; i.e., insurance will be purchased if expected utility with insurance is greater than without insurance. The theoretical underpinnings of long-term care insurance differ from these standard theories of insurance purchase mainly due to the role of family and bequests. That is, when consumers consider purchasing insurance against the risk of long-term care costs, they consider not only the direct expected utility of smoothing consumption but also the utility elicited through the behavior of a spouse or children and the altruistic utility derived from leaving a bequest to heirs.

The prominent theoretical model in this area is Pauly (1990), with an extension by Zweifel and Struewe (1998). Assuming imperfect annuity markets, Pauly considers expected utility optimization under several scenarios: single elderly with no children and no bequest motive, with differential quality, and with adult children and a possible bequest motive. Expected utility in the presence of a spouse is also discussed briefly. The model is aimed at explaining purchase (or nonpurchase) of long-term care insurance among middle-income individuals, as nonpurchase is obvious among very poor individuals likely to qualify for Medicaid and among richer individuals who can easily self-insure. The expected lifetime utility function (EU) to be maximized is given as

$$\max_{C_t} \mathrm{EU} = \sum_{t=1}^{H} p_t^h U(C_t) + \sum_{t=1}^{H} p_t^s \overline{U}^s \, s.t. \, \overline{W} \geq \sum_{t=1}^{H-S} C_t + S\overline{X}$$

where H is the maximum length of life, p_t^h is the probability of surviving to period t in the healthy state and p_t^s in the sick state (in need of long-term care), C is dollars of consumption, and $\overline{U}^s$ is the level of utility if one is in need of long-term care and consuming $\overline{X}$ dollars worth of care, the only type of desired consumption in the sick state. $\overline{W}$ represents initial wealth, which is assumed to be substantially larger than $S\overline{X}$ such that the individual initially has enough wealth to pay his or her maximum long-term care costs and is unlikely to qualify for Medicaid. Individuals choose C to maximize expected utility.

The model under each scenario predicts that the low demand for long-term care insurance may be rational. The case in which single elderly individuals have no children and no bequest motive is straightforward given the assumptions of the model. Because Medicaid exists as a safety net when wealth is exhausted, the only benefit to purchase of long-term care insurance is to increase consumption in the sick state, the marginal benefit of which is defined to be zero. Although this assumption is restrictive, one might imagine that the marginal benefit of additional consumption while in need of nursing home care is at least low if not zero, in which case the same conclusion would result.

The case in which private insurance enables access to higher quality nursing home care than that obtained under Medicaid funding is a realistic one in that nursing homes with large Medicaid populations are generally considered to be of lower quality. Thus, one might expect middle-class individuals to purchase long-term care insurance if they value quality. However, Pauly argues that this would rarely be the case because one cannot pay an incremental premium to purchase an incremental quality supplement to Medicaid. Rather, the purchase of private insurance replaces Medicaid. Thus, a consumer would have to value the incremental quality of a privately financed nursing home over and above a Medicaid-financed nursing home stay enough to outweigh the additional cost of foregoing Medicaid completely and paying private long-term care insurance premiums. Relatively few individuals are likely to have this high valuation for incremental quality.

A similar argument applies to the case in which bequests are valued, i.e., the individual receives utility from leaving wealth to his or her heirs. One would expect that valuing bequests would lead to a higher propensity to purchase long-term care insurance, as private insurance for nursing home care allows an individual to retain wealth in the sick state in contrast to relying on Medicaid, which requires the exhaustion

of one's wealth before coverage begins. However, the value of bequests would have to be quite large in order to lead to purchase, for two reasons. First, purchase of insurance decreases consumption not only at time t but also in the future if the person remains in a healthy state, so additional savings may provide greater utility than insurance purchase when bequests are valued. Second, although insurance may be preferable to savings if the individual lives a long time with chronic illness, this scenario is unlikely because chronic illness is generally associated with earlier mortality. Thus, even if bequests are valued, purchase is unlikely unless the utility from bequests is high and does not decline sharply with age.

The bequest argument is more complicated when a spouse is involved rather than just adult children. In this case, Pauly argues that both household consumption and income may be affected if one spouse enters a nursing home, depending on the extent to which these are joint. Demand for long-term care insurance may be relatively high if consumption of the nonsick spouse is substantially affected by the nursing home stay of the sick spouse.

Finally, perhaps the most important contribution of Pauly's paper is the introduction of intrafamily bargaining into the conceptualization of demand for long-term care insurance, drawing on earlier work in the bequest literature, which posited that parents use bequests to elicit desired attention or caregiving from children. Pauly modifies this premise somewhat to argue that, once in the sick state, parents will have little control over consumption or bequests, such that parents choose whether to purchase insurance in the healthy state but that children control the level of care in the sick state. Parents may prefer care from children and may want to purchase long-term care insurance to preserve bequests that the parent values altruistically and with which to elicit caregiving behavior on the part of children. However, as children decide on the level of care in the sick state, children are subject to moral hazard associated with the presence of insurance. That is, children will choose more formal care (nursing home placement) in the presence of insurance than what the parent would prefer because the price they face is lower than in the absence of insurance. Anticipating this moral hazard effect on the caregiving behavior of children, the parent may be better-off not purchasing insurance and getting the higher level of care from children.

Zweifel and Struewe (1998) formalize this intrafamily bargaining argument using a principal-agent framework and a two-generation model that is independent of assumptions about altruism. The elderly parent chooses consumption and whether or not to purchase long-term care insurance to maximize expected utility, and the amount of care provided by children is an argument in the utility function in the sick state. The child maximizes his or her own expected utility, choosing consumption and the amount of care to provide if the parent enters the sick state. By providing care, the child is presumed to forego work in the labor force but also to expect a higher bequest, as less will be spent by the parent on formal long-term care. Zweifel and Struewe show that, under these circumstances, the child's response to purchase of long-term care insurance depends heavily on the child's wage rate. At low wages, where one might expect the most caregiving, the presence of insurance is most likely to produce a moral hazard effect. Anticipating this response, purchase of long-term care insurance is often not in the best interest of parents who desire caregiving by their low-wage children, for the same reasons that Pauly posited.

The Pauly model is general and intuitive in many respects, explaining its pervasive use and longevity in the study of long-term care insurance. However, it has some limitations and may be dated in some ways. First, it does not formally model joint decision-making with a spouse, one of the most common scenarios among potential purchasers. Second, it is assumed that parents prefer care from children, which may be an outdated notion for many families. Preferences may depend importantly on the severity and type of long-term care needs, on the relationship between the parent and the child, and on the extent to which a parent prefers to stay independent and not burden the child. Third, Pauly models long-term care insurance as only nursing home insurance, whereas the vast majority of long-term care insurance policies now cover home care and other community-based options as well as nursing home care. Home care is generally considered much more desirable than nursing home care, so more parents may prefer it to informal care, and it may entail a completely different set of family dynamics; for example, informal care may be a complement to formal home care rather than a substitute for it. Thus, there exists a need for updated theoretical models of the demand for long-term care insurance that consider these factors.

Theory of Supply of Long-Term Care Insurance

Research on long-term care insurance to date has focused largely on the demand side, with relatively little theoretical or empirical work on the supply side. As in other insurance markets, insurers consider the potential for adverse selection and moral hazard in deciding whether to offer a product, at what price, and with what attributes. One of the few papers to consider this perspective is Cutler (1993), which discusses both adverse selection and moral hazard as important potential market failures in long-term care insurance markets. Adverse selection may be a more serious concern in long-term care insurance than in acute health insurance because the elderly and near-elderly population is naturally more heterogeneous in health status than a younger population, and this heterogeneity may not be observable to insurers. Thus, there is greater potential in this population for the existence and use of private information leading to a sicker risk pool than anticipated by insurers when setting price. Cutler also raises the issue of long-term intertemporal risk. In other types of health insurance in which premiums are set annually, prices can be reconciled with unanticipated trends in claims and provider prices fairly quickly. In long-term care insurance, however, because the event being insured today may not occur for another 20 years, insurers face the risk of rising prices over time that cannot be diversified across a risk pool. Thus, insurers generally shift this risk to consumers. Fears about the extent of adverse selection and moral hazard, coupled with this intertemporal risk and a lack of claims experience for this relatively new product, has led to strict underwriting, indemnity policies, high administrative loads, and consequently 'expensive'

premiums that may not seem affordable or of good value to many potential purchasers.

Distinctive Features of the Long-Term Care Insurance Market and Related Empirical Evidence

Long-term care insurance has several key features distinguishing it from acute care insurance: the role of the family (especially adult children), low prevalence of insurance, and greater concern about adverse selection. A relatively small but growing body of empirical work on long-term care insurance reflects these features and can be broadly categorized into research on intrafamily decision-making, price and other determinants of purchase and nonpurchase (including Medicaid crowd-out), and adverse selection. As a whole, the evidence is consistent on a few aspects of this market – for example, that Medicaid crowd-out exists – but on other aspects, the evidence is often sparse, inconsistent, incomplete, and inconclusive. Each of these categories is discussed below, followed by a discussion of the remaining theoretical and empirical gaps.

Intrafamily Decision-Making

As established by Pauly, the role of families in decision-making, insurance purchase, and provision of long-term care is a feature of the long-term care insurance market that distinguishes it from other types of health insurance. However, empirical research has not been able to substantiate the contention in Pauly's model that children will be more likely to institutionalize parents in the presence of insurance, a key premise underlying the rational nonpurchase of long-term care insurance among parents with adult children. The main study to address this issue (Mellor, 2001) used Health and Retirement Study (HRS) data in a longitudinal study design; the HRS is one of the few national data sets to include questions on long-term care insurance and is used in the vast majority of studies noted in this article. Mellor found point estimates generally in the expected direction – institutional long-term care use was more likely in the presence of insurance – and with potentially meaningful magnitudes, but the results lacked statistical significance. However, the study used a measure of insurance from the early years of HRS that was later shown to be subject to measurement error and included a shorter panel of data than is now available, limiting power. Thus, current evidence cannot establish conclusively how the presence and preferences of adult children impact long-term care insurance purchase and subsequent long-term care provision, and the need for further research remains.

Evidence on the role of family in long-term care insurance and provision is also tied to the bequest literature, as the desire to leave a bequest to one's heirs has often been posited as a potential motivator for long-term care insurance purchase. If a bequest is desired, one might think of long-term care insurance as bequest insurance, because in the absence of insurance, one's saving may be needed for long-term care costs, thus reducing or eliminating the prospect of a bequest. Early empirical evidence using direct queries about the desire to leave a bequest found no support for such a bequest motive in insurance purchase decisions (Sloan and Norton, 1997). A recent working paper, however, looks indirectly at long-term care insurance purchase to distinguish precautionary savings motives from bequest motives in savings behavior late in life (Lockwood). The main premise is that a precautionary savings motive is consistent with purchase of long-term care insurance, as the underlying goal would be to ensure availability of resources for healthcare needs. Low levels of long-term care insurance purchase are therefore indicative of a strong bequest motive in savings behavior, as the precautionary savings motive is ruled out. The author reconciles the strong bequest motive with low levels of long-term care insurance by suggesting that insuring the bequest is not valuable enough to justify the purchase of currently available long-term care insurance policies. This may explain the apparent lack of support for the bequest motive found in earlier studies.

Determinants of Purchase and Nonpurchase

Compared with acute care health insurance, the demand for which is generally thought to be a function of health, income, price, and risk aversion, the demand for long-term care insurance appears to be more complicated. The low prevalence of long-term care insurance has engendered numerous studies of why people do or do not purchase it. Evidence on private long-term care insurance (LTCL) prevalence suggests that among the elderly and near-elderly, the younger, healthier, and more educated people are more likely to have LTCI, and that there is some relationship, most likely nonlinear, between purchase of LTCI and income and assets. Although those in the lowest income and asset groups are not likely to purchase LTCI because it is expensive (generally several thousand dollars per year) and because they face a lower 'price' of Medicaid in terms of spending down assets to qualify, those in the highest income and asset groups may also not purchase insurance because they can self-insure. Therefore, it is often the 'middle' income and asset groups that are the most likely purchasers. Earlier studies cited Medicaid crowd-out, underestimation of risk, and the presence of adult children or bequest motives as potential reasons for nonpurchase but found mixed or inconclusive empirical results. Norton (2000) provides a useful summary of these arguments and the earlier evidence on purchase and nonpurchase. Many of these studies were limited by reliance on cross-sectional analyses, which precludes the establishment of a causal link between the predictors and the outcome.

More recent studies have taken advantage of exogenous variation in Medicaid policy and state and federal tax policies to move toward causal inference in estimating the demand for long-term care insurance and specifically to examine the issue of Medicaid crowd-out, i.e., the substitution of private insurance for public insurance when public insurance exists. Because Medicaid has become a primary payer of long-term care services, both in nursing homes and in the community, crowd-out is a potential obstacle to any expansion of the private long-term care insurance market. These recent studies generally find that Medicaid crowd-out is substantial and suggest that even a tightening of Medicaid eligibility rules would not be effective in mitigating crowd-out. Brown and Finkelstein (2008) argue, using a utility-based model and simulation, that

Medicaid crowd-out can explain nonpurchase of long-term care insurance for at least two-thirds of the wealth distribution. The large crowd-out effect stems from the large 'implicit tax' that Medicaid imposes on private insurance benefits in that the majority of private insurance benefits go toward covering services that Medicaid would have paid in the absence of private insurance. Thus, consistent with Pauly's reasoning, the value of a private policy to consumers is incremental whereas the premium derived from the total package of benefits is not. Although one might argue with the extent of the income distribution that is potentially affected, the existence of some degree of crowd-out is a reasonable conclusion. As Medicaid is generally incomplete insurance relative to private coverage, Medicaid crowd-out of private long-term care insurance may increase the overall risk exposure of the population.

It has often been posited that supply-side market failures contribute to low demand for long-term care insurance because these market failures result in undesirable policy attributes and a perception by consumers that the policies are not of good value. Value of an insurance product may be perceived as low if the administrative load is high, i.e., if the discounted expected present value of premiums far exceeds the discounted expected present value of benefits. In turn, concerns about substantial adverse selection, moral hazard, and, in the case of long-term care insurance, undiversifiable intertemporal risk may contribute to high administrative loads; these are the market failures. Brown and Finkelstein (2007) calculate that the average administrative load on long-term care insurance is 51%, substantially higher than loads estimated in other private insurance markets. This estimate includes the probability of lapse, in which case consumers generally forfeit all benefits. However, the authors also argue that despite these high loads, supply-side factors cannot explain the majority of nonpurchase of long-term care insurance. The argument is based mainly on the fact that administrative loads vary substantially by gender, with women facing much lower loads, yet women still do not purchase long-term care insurance at much higher rates than men. Thus, it is demand rather than supply that drives the behavior. In particular, the effect of Medicaid crowd-out is possibly much stronger than the effect of supply-side attributes.

Several studies have attempted to estimate a price elasticity of demand for private long-term care insurance. Cramer and Jensen (2006) combined HRS data with estimated prices derived from published rate schedules of several major insurers to calculate an estimated price elasticity of −0.23 to −0.87, indicating that new purchase of long-term care insurance is relatively price inelastic. Courtemanche and He (2009) also used HRS data, but derived an exogenous change in price using a change in federal tax treatment of long-term care insurance (new eligibility of long-term care insurance premiums to be deductable as a medical expense under the Health Insurance Portability and Accountability Act of 1996) combined with marginal income tax rates. They found a price elasticity of −3.9, indicating that purchase of long-term care insurance is highly elastic. These disparate results may perhaps be explained by the fact that identification was derived from different parts of the income spectrum, but in any case, the need for further research in estimating the determinants and elasticities of demand remains.

Adverse Selection

The potential for adverse selection is a concern for insurers of any type of event. Under adverse selection, potential purchasers have more information about their own risk than what is available to insurers and use this private information to assess the value of a policy. Because premiums do not account for the private information, riskier individuals are more likely to find the policy of value than less risky individuals, with the result that the pool of actual purchasers is riskier than what insurers would expect given an actuarially fair premium – a situation that is not sustainable in the long run. The potential for adverse selection is arguably greater in long-term care insurance than in other types of healthcare insurance for several reasons. First, the typical purchaser of long-term care insurance is elderly or near-elderly, and health states become more heterogeneous with age. Thus, the potential for private information about one's health risk is greater in an elderly population than in younger populations. Second, the market for long-term care insurance is small and largely based on individual policies rather than group policies. Thus, the broad diversification that can be achieved through, for example, employer-based group health insurance is not currently possible in long-term care insurance. In the one rigorous and broad-based study of this issue, Finkelstein and McGarry (2006) find empirical evidence in the HRS for this type of adverse selection in that individuals with private information that they are at high risk are more likely to purchase long-term care insurance. However, they find that it is balanced by favorable selection into insurance by individuals who have private information that they are more risk averse (but healthier). Thus, although adverse selection exists in long-term care insurance, the overall insured pool is not sicker than what insurers expect when calculating premiums.

The emergence of personalized medicine and genetic testing has led to increasing interest in genetic adverse selection. The availability of genetic tests for several serious diseases associated with long-term care needs makes this an especially salient issue for the long-term care insurance market, and the small size and individual-payer nature of the market has proved to be useful in studying this type of adverse selection. Recent evidence finds that, not surprisingly, people found to be at genetic risk for Huntington's disease or Alzheimer's disease are much more likely to purchase or to plan to purchase long-term care insurance than others – 2.3 times as likely in the case of Alzheimer's disease (Taylor *et al.*, 2010) and five times as likely in the case of Huntington's disease (Oster *et al.*, 2010). Although the absolute prevalence of these genetic markers in the population is small, this evidence provides a challenge not only for insurers but also for policymakers interested in balancing privacy rights against the need for a sustainable insurance market.

A related issue to adverse selection at the time of purchase is that of dynamic adverse selection. Because long-term care insurers are generally not allowed to raise premiums over time for an individual whose health risk increases, one can conceptualize purchase of long-term care insurance as insurance against reclassification into a higher risk category, much as in life insurance markets. In theory, if premiums are actuarially fair when purchased but are paid over time, individuals may decide to drop insurance (lapse) if their risk ex post appears

lower in later years than when they bought the policy. Lapse thereby becomes a mechanism for ex post adverse selection, a dynamic inefficiency in the insurance market that puts upward pressure on premiums for those remaining in the risk pool. Finkelstein *et al.* (2005) examine this issue in long-term care insurance markets, conceptualizing lapse as a rational response to a reevaluation of health risk. Empirically, the authors find that respondents who have 'ever let a LTCI policy lapse' are less likely to have a nursing home stay within 5 years than similar respondents who bought and kept policies, providing support for their hypothesis that lapse represents *ex post* adverse selection. However, the results may also be explained by a moral hazard effect. Using more years of data and testing for a broader variety of covered services and health status measures not subject to moral hazard, Konetzka and Luo (2011) find that lapse is driven more by financial reasons than health-related reasons, resulting in a healthier insured pool remaining. Individuals who lapse are generally poorer, less educated, less healthy, and more likely to be racial and ethnic minorities than those who retain their policies. Thus, although *ex post* adverse selection may occur for some groups of purchasers, it is not a primary driver of lapse and lapse as a whole is unlikely to affect the risk pool adversely. In addition, lapse rates are generally considered low in long-term care insurance relative to other insurance markets.

Given the aging of the population and the associated need for solid theory and evidence to inform public policy, the need for further research on long-term care insurance markets is great. Because long-term care insurance is different in marked ways from acute care health insurance, lessons learned in those markets may not be transferrable. To date, however, the theoretical foundation and empirical evidence on purchase and retention of long-term care insurance policies is far from complete. Although a growing body of evidence supports the existence of some degree of Medicaid crowd-out, the other determinants of policy purchase and retention remain murky, and evidence on the extent and nature of adverse selection is sparse. Two areas in particular are in need of better theoretical understanding and empirical research. First, although the role of the spouse and extended family is central in long-term care issues, still very little is understood about how intrafamily decisions are made with respect to long-term care insurance purchase and long-term care utilization. More sophisticated modeling of joint decision-making about this issue is paramount. Second, the literature on private long-term care insurance largely ignores moral hazard. Clearly, insurance ownership is only one key attribute of the market. Equally important is how insured individuals behave once they become insured. The significance of moral hazard – the utilization of long-term care services that are due to the presence of insurance and that would not be purchased without insurance – parallels the significance of adverse selection. Both are important because they could alter the cost of the insurance and thus the amount of the payout relative to the premiums.

Public Policy and Long-Term Care Insurance

Because long-term care is arguably the largest uninsured healthcare risk facing the United States (and many other countries) but political support for additional public coverage has been weak, policymakers have long been interested in finding ways to expand the private long-term care insurance market. The most established and well-known program designed to encourage purchase is the Partnership for Long-Term Care program, a state-based program developed in the late 1980s and first implemented in California, Connecticut, Indiana, and New York. The Deficit Reduction Act of 1995 enabled expansion of the program to other states. Under this program, purchasers of private long-term care insurance policies that cover a given number of years of care are afforded some degree of asset protection if and when they turn to Medicaid after their private policy benefits are exhausted. (Normally, Medicaid requires that individuals 'spend down' the majority of their assets before qualifying for benefits.) The specific rules about the degree of asset protection vary from state to state, but the two main models include a dollar-for-dollar matching of the amount of maximum benefit purchased with the amount of assets protected and a total asset protection model, which requires the purchase of a fairly comprehensive policy in return for total asset protection under Medicaid. Although there have been no rigorous evaluations of the program in the economics literature, estimates of take-up and potential Medicaid savings have been fairly small, as most people who purchased policies would have bought them in the absence of the program. Policymakers therefore appear supportive of the program but do not expect large expansions of private long-term care insurance coverage as a result.

A second tactic employed by US policymakers in pursuit of expanded private coverage is tax breaks, both state and federal, designed to lower the effective purchase price of private long-term care insurance policies. The Health Insurance Portability and Accountability Act of 1996 allowed long-term care insurance premiums to be deductable as a medical expense in calculating federal income taxes, similar to treatment of other medical expenses and insurance. Courtemanche and He (2009) studied the effect of the federal tax change on purchase behavior and found that the tax deduction led to significantly higher probability of purchase, on the order of a 25% increase among those eligible for the tax break. However, that effect translates to only a small increase in coverage across all seniors. Furthermore, they found that the loss in revenue to the government exceeded the potential savings to Medicaid in long-term care costs, leading to a net revenue loss. Similarly, Goda (2011) examined the impact of state tax incentives on private long-term care insurance coverage and the resulting effect on Medicaid expenditures, finding that the average state tax subsidy raised coverage by 28% and that the lost tax revenue exceeded the savings to Medicaid. In both cases, the net revenue loss was attributable largely to the fact that the part of the wealth and income distribution that responds to the tax incentives is generally not the part that relies on Medicaid.

Perhaps the most significant US public policy on this issue to date was the Community Living Assistance Services and Supports (CLASS) Act, passed as part of the Patient Protection and Affordable Care Act of 2010 but subsequently repealed when it was found to be financially unviable. CLASS was intended to reduce the uninsured risk of substantial long-term care costs by establishing an entirely voluntary, private-premium-funded, but publicly administered long-term care

insurance program. By statute, individuals who paid premiums for a minimum of 5 years and were working for at least 3 of those years would have been potentially eligible for benefits if they stayed in the program and reached an appropriate level of need, levels that would be similar to eligibility triggers used in private long-term care insurance. It was designed to be an 'opt-out' system such that employers could choose to participate or not, but if they chose to participate, employees would be automatically enrolled with the option to drop out if they chose. The benefits would be worth at least US$50 per day and would be available for a variety of long-term care services, not just nursing homes, but the benefit would be tied in some way to long-term service use (as opposed to a pure cash benefit). Most of the details of the design of the program were left to the 'discretion of the Secretary' (of Health and Human Services), but key restrictive attributes were written into the statute, including a requirement that the program be financially self-sustaining with no taxpayer subsidies for 75 years. Given the minimal requirements for eligibility and voluntary nature of the program, serious concerns about the potential for adverse selection made it impossible to design a premium structure that would meet the sustainability requirement. It was also unclear how the existence of a program like CLASS would affect the private long-term care insurance market as it stands today, but the rise and demise of CLASS underscores the need to better understand the private long-term care insurance market and the role that it can play as public policy toward long-term care financing evolves.

Conclusion

Theories and empirical evidence drawn from other types of health insurance may not apply to private long-term care insurance, as long-term care is distinct in several key ways. Family members, especially spouses and adult children, are hypothesized to play significant roles in decisions about long-term care insurance, yet the empirical evidence on the role of family is remarkably inconsistent and sparse. The market is small relative to other types of health insurance, with only 12% of the elderly population in the US holding policies. However, other than Medicaid crowd-out, the evidence on why people purchase or do not purchase policies is fairly weak, and policy efforts to expand the market have not been very successful. Given the existence of Medicaid as a safety net payer and the ability of the upper end of the wealth and income distribution to self-insure, it may be that the current size of the private long-term care insurance market is somewhat of a steady state. If that is the case, then the potential for market failures such as adverse selection and moral hazard – already of more concern in long-term care insurance markets than in other health insurance markets – becomes more of a threat to the stability of the market. Increases in adverse selection through advances in technology such as genetic testing, for example, could have serious implications for the existence of the market if it remains small.

Economists have identified and focused on these distinct features of long-term care insurance in a growing body of work. But despite the importance for public policy of economic theory and empirical evidence on long-term care insurance, significant gaps remain in the understanding of this market. As states and nations struggle with strategies to reduce the substantial individual and public risk of long-term care costs associated with aging populations, it will become increasingly important to fill these gaps.

Glossary

Asymmetric information A situation in which the parties to a transaction have different amounts or kinds of information as when, for example, physicians have a greater knowledge than patients of the likely effectiveness of drugs while the patients have greater knowledge of the likely impact of drugs on their family circumstances.
Externality An externality is a consequence of an action by one individual or group for others. There may be external costs and benefits. Some are pecuniary, affecting only the value of other resources (as when a new innovation makes a previously valuable resource obsolete); some are technological, physically affecting other people (communicable disease is a classic example of this type of negative externality); some are utility effects that impinge on the subjective values of others (as when, for example, one person feels distress at the sickness of another, or relief at their recovery).
Market failure Markets in healthcare are notable for 'failing' on a number of grounds, including asymmetry of information between producers (medical professionals of all kinds) and consumers (patients actual and potential); distorted agency relationships, failure of patients to behave in accordance with the axioms of rational choice theory; incomplete markets, especially those for risk; monopoly; externalities and the presence of public goods.
Obese Individuals are classified as obese when their body mass index (weight in kilograms divided by squared height in meters) exceeds 30.
Oligopoly A departure from competitive markets, where the number of sellers is small, so that each adopts strategic behaviour by taking into account the behaviour of others.
Overweight Individuals are classified as overweight when their body mass index is between 25 and 30.
Productivity The amount of output or effect per unit of input in a period of time.
Utility Variously defined in the history of economics. Two dominant interpretations are hedonistic utility, which equates utility with pleasure, desire fulfilment, or satisfaction; and preference-based utility, which defines utility as a real-valued function that represents a person's preference ordering.

Introduction

Rapid increases in overweight and obesity prevalence rates over the last few decades, accompanied (and caused) by widespread dietary imbalances, are imposing huge burdens on health care systems and reducing the quality of life of populations around the world. These trends are not limited to the developed world alone, where there is talk of an 'obesity epidemic,' but also apply to several developing, transition, and middle-income countries. Between 1991 and 2008, the obesity prevalence rate in the UK grew from 14% to 25.4%, whereas in the US the percentage of obese individuals rose from 23.3% to 35.4%. Several countries undergoing economic transition have also witnessed a parallel 'nutrition transition,' characterized by significant increases in energy density, fat, sugar and salt content of local diets, and spiraling rates of overweight and obesity prevalence and associated disease costs. For example, 77% of Mexican men and 66% of women are now overweight, and Mexico is in the top tier of countries in obesity league tables.

In this article, the authors discuss the main macroeconomic causes and consequences of poor diets, obesity, and associated noncommunicable disease. The counterfactual implications of a movement toward better diets, and policy measures available to governments to improve diets are also discussed. Attention is restricted to the aggregate level – sector, economy, or population-wide issues – with microeconomic, individual/household level issues discussed only when relevant to the aggregate picture (government policies, applicable at the population level, are considered macro even if they work by affecting incentives at an individual level).

Causes

The debate about the attribution of obesity to economic factors has grown along with obesity rates in developed countries. A variety of factors – including genetic, psychological, and social drivers – have been put forward as potential causes. These are all relevant in explaining heterogeneity in weight within a cross section of people, but are consistent only to a limited extent with the speed of observed rise in the overall proportion of overweight and obese individuals over the last two decades. Because rapid changes are more likely to be rooted in socioeconomic factors, the role of economics in explaining the so-called obesity epidemic has gained prominence. Weight change is a function of the difference between calorie intake change and energy expenditure (physical activity) change (although some researchers also attribute a role to diet quality, for example, proportion of energy sourced from fat). Estimates of average daily per capita calorie intakes over the period 1991–2007 show a 7.8% increase

 doi:10.1016/B978-0-12-375678-7.00611-8

for the UK, a 6.8% increase for the US (and a 9.9% increase for developing countries, although in their case a proportion of this is a welcome improvement to the calorie intakes of the undernourished). The US has also experienced a substantial rise in fat intake (+14.1%). Economic drivers are seen as fundamental to these changes.

Technological Change and Commodity Prices

The argument that has gained most consensus in explaining the growth in obesity rates is related to the impact of technological change. Technical progress has rapidly increased agricultural productivity and lowered the cost of food. Furthermore, this trend has been uneven across foods, as the relative price of industrial and processed foods (and raw inputs like sugar) has declined at a faster pace compared to raw foods like fruits and vegetables. Figure 1 shows how productivity in the cereal sector has sharply risen over the last two decades, even in countries like the UK (+15%) and the US (+47%), where yields were already very high and much higher than the world average (+29%).

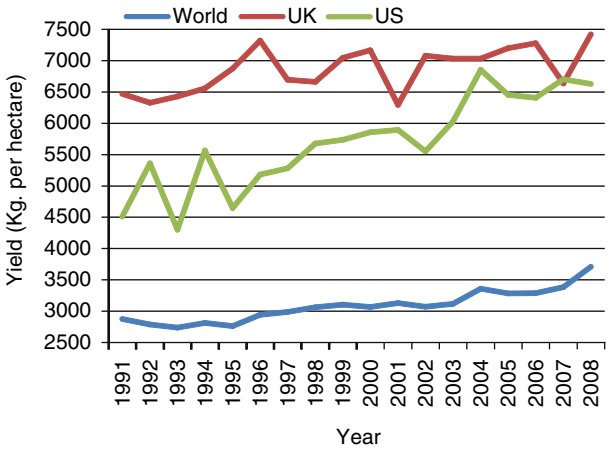

Figure 1 Cereal yields. Based on data from World Bank, World Development Indicators (2011).

The sharp decline in real commodity prices shown in Figure 2, together with the relatively small but regular increase in incomes, has contributed to the rise in calorie intakes observed in developed countries. In developing countries – especially in transition countries where income growth has been much more substantial – the effect on calorie intakes is even stronger, which explains why many of these countries are now experiencing rapidly rising obesity rates while still being affected by food insecurity. Technological change also matters to the other term in the weight change equation, calorie expenditure, and this effect is possibly even more influential than commodity price decline or income growth. There is strong evidence that jobs have become much more sedentary, and that physical activity has been transferred from paid working time to costly leisure time.

In summary, technological change has made calorie consumption progressively cheaper, whereas raising the costs (including time costs) of calorie expenditure.

Food Availability and Globalization

On the supply-side, particularly in developed countries, the increased availability of 'junk food,' defined as calorie-dense foods high in fats, sugar and salt has been also blamed (in developing and transition countries, increased livestock product consumption has similarly been blamed). From an economist's perspective, unless one accepts the asymmetric information assumption or some sort of oligopoly due to market segmentation, an increase in production of junk foods can be explained either by higher profitability for the industry or by the increased consumer demand. The former explanation can be traced back to the technological change hypothesis, as processing of commodities into energy-dense packaged foods has become cheaper over time. Growing demand (and consumption) would reflect changing preferences toward these foods compared to healthier dietary options, but no data exists to test this hypothesis over time.

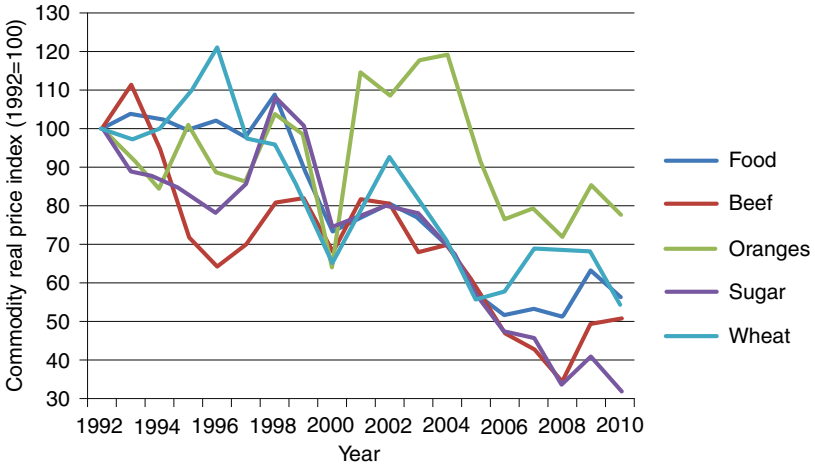

Figure 2 Real food commodity prices (relative to the price of all primary commodities). Based on data from International Monetary Fund, World Commodity Prices (2011), our processing.

Increased globalization and trade openness have played an important part, particularly in many developing countries. This is partly considered a cultural (demand-side) effect, sometimes called 'coca-colonization,' wherein unhealthy dietary patterns first established in developed countries are emulated by developing country consumers, with increased globalization and trade openness facilitating availability. On the supply-side, returns to scale afforded by new developing country markets can be exploited by large food manufacturers and multinationals, enabling even cheaper production of processed food already benefiting from lowered cost of production as a result of technological change.

Other Factors

A strong association between obesity rates and income disparities, which has been observed based on geographical comparison, may well hold across time considering that inequalities have been increasing in several countries over the years. Increase in female labor participation has been also proposed as a potential explanation for the decline in dietary quality and the consequent weight increase, especially for the younger generations. However, the link is not as clear as for technological change. Although there are studies showing that such an effect exists, it only explains a small portion of the observed growth in weight. Rapid urbanization is a further factor that has been associated with increasing obesity rates in developed countries mainly because life is thought to be more sedentary in cities, although it is difficult to define the causal direction of this relationship. Other economics-related explanations lie in the dramatic progress in medical treatment for obesity-related conditions, with a consequent decline in perceived risks which may work as a rational disincentive to conducting a healthy lifestyle.

Insufficient or biased (asymmetric) information (e.g., through advertising), often invoked as a driver for unhealthy behaviors at the individual level, is an unlikely determinant at the aggregate level, unless one assumes that the quality of nutrition and health information has worsened over the last two decades, despite most obesity policies having been targeted at public communication. The same argument holds for the role of education, an important explanatory factor for micro-level heterogeneity, but not particularly relevant (or even beneficial) when looking at the time series of obesity rates.

More recently, the focus of economists has turned to individual behavioral factors – especially behavioral failures – such as inconsistent time preferences, addiction, and lack of self-control. As in the case of genetics or other biological factors, it is quite difficult to bring conclusive evidence on the role played by these individual-level factors. To do so, one has to once more accept that behavior at the population level (or its distribution) has rapidly changed over time, for which there is insufficient evidence, given available data.

Effects

Unhealthy diets in combination with lower physical activity levels and obesity have been linked to a range of noncommunicable diseases (NCDs), including several types of cancer, coronary heart disease, stroke, type II diabetes, osteoporosis, and osteoarthritis. There are a number of pathways from diets and physical activity to these diseases. Primarily through calorie balance (although there is some evidence that diet quality matters too), there is an impact on overweight and obesity, which are directly linked to many of these diseases. Overweight and obesity may also operate through intermediary conditions, such as hypertension and dyslipidemia to raise the risk of contracting some of these diseases. In addition, diets and physical activity may directly (rather than operating through an effect on risk of obesity) affect NCD risk, or through intermediary conditions as noted above. These effects impose a range of costs on the macroeconomy, classified as direct (medical) and indirect (productivity), as described below. Available estimates are largely for developed countries (see, e.g., http://www.youtube.com/watchv=mfnwZrLKfoo), and there is a significant paucity of developing country cost estimates.

Direct Costs

The bulk of cost estimates relating to unhealthy diets and obesity relates to direct costs arising from increased medical expenditure on diagnosis, treatment, and management. A range of methods have been used in estimating these, ranging from cohort studies, where medical costs arising among groups of subjects varying by body mass index (BMI) ranges are examined over several years, to regression models, to studies based on dynamic simulation models of the relationship between BMI and NCD risks. These studies frequently extrapolate from study samples to the national population. Costs accruing to the national economy have been found to be substantial, as can be seen from **Table 1**, although it is worth noting the comparability across studies is complicated by

Table 1 A selection of estimates of obesity costs

Country	*Direct costs*	*Indirect costs*	*Notes*
UK	$3 billion	$10.5 billion	2001 costs of elevated BMI
China	$5.8 billion	$43.5 billion	2000 costs. Includes separate diet, activity, and obesity pathways
USA*	$147 billion		2008 estimate

*Indirect costs for US not included here because available estimates are dated and/or partial in coverage.

differing protocols, methods and pathways and components taken into account (e.g., consideration of costs arising from obesity alone vs. costs arising from diet quality as well as obesity). A key issue in cost estimation relates to 'lifetime costs' – whether medical cost savings due to early mortality caused by obesity offsets the increased medical costs accrued during the lifetime of overweight and obese individuals. The limited research available on this issue is inconclusive, and this remains an area for future research.

Indirect Costs

Indirect costs of obesity estimated in the literature encompass a range of nonmedical costs relating to productivity loss. These include absenteeism, disability, premature mortality, and presenteeism. Absenteeism and disability costs arise from time taken out of work due to obesity-related conditions. Premature mortality costs arise when workers die before retirement age due to obesity-related disorders. Presenteeism captures lowered efficiency at work arising from obesity-related disorders. There is debate about the extent to which lost time at work equates to lost productivity, because harder work from those present at work may compensate for time–input loss arising from obesity. As in the case of direct costs, available studies differ in terms of what they cover under indirect costs, and there are numerous measurement problems, prominent among these being distinguishing correlation from causation in measuring the effect of obesity on indirect costs. Table 1 shows that indirect costs can be very substantial, and can exceed direct costs by a significant margin in some countries.

Available estimates of the total burden of overweight and obesity, including direct as well as indirect costs, range from 0.2% to 0.6% of GDP in the developed west. For China, the estimate is as high as 4% of GDP.

Contemplating Hypothetical Scenarios: What Would the Implications of Improved Diets Be?

The flip side of the earlier discussion on how changes in food consumption patterns have contributed to unhealthy dietary outcomes and NCDs, are the questions: (1) what would the larger sectoral/economy-wide implications of improved diets be and (2) what policies are needed to get there?

A sparse literature exists that estimates (simulates) the implications of moving toward recommended dietary norms, such as the World Health Organization (WHO) guidelines, at the population level. These show that the biggest negative consumption impacts would be on the animal products (meat, animal fats, and dairy products), vegetable oil, and feed cereal sectors. In Organization for Economic Cooperation and Development (OECD) countries, for example, consumption of animal products would shrink by between 15% and 30%, if WHO norms are to be met. However, the largest global effects would be generated by lowering meat consumption in rapidly growing economies such as China rather than in OECD countries.

Health benefits from such adherence to norms are likely to be substantially higher in developed and transitioning countries, where overnutrition is a more pressing concern, than in developing countries. However, patterns of international trade in agricultural products and general equilibrium effects imply that the effects of consumption changes in any large country or sets of countries are likely to be felt in other parts of the world, particularly developing countries. For example, a significant reduction in meat consumption in major markets, such as the EU, US, Canada, and Japan would have a substantial effect, notably a sharp increase in short-run unemployment in a large meat-exporting country such as Brazil. There is little evidence available to indicate that a global movement toward healthier diets can do much to enhance food and nutrition security in developing areas. The key implications of such movements are for meat consumption and for cereals used as feed. Although meat-exporting developing countries may suffer from reduced export opportunities, wheat and rice, the main staples used in developing countries have been shown to be little affected by such changes. However, it must be noted that the potential supply response from developing countries of a movement toward increased fruit and vegetable consumption is an area that has not been investigated thoroughly.

Policy for Better Diets

If overweight and obesity are accepted to be the outcome of individual utility maximizing decisions, then the economic rationale for public policy intervention has to be market failure. Foremost among these is externalities; people who choose to be overweight do not bear the full social cost of their actions, they are partially borne by others to the extent that health care is subsidized and employment law guarantees wages are paid when obesity-related ill health forces time off work. A second market failure occurs if information is imperfect, perfect information being a precondition for the informed choice underpinning utility maximization. Finally, food markets may display imperfect competition, specifically resulting in competition centered around advertising; food is an advertising-intensive industry, particularly fast food, confectionary, savory snacks, and soft drinks, largely viewed as principal culprits of the growth in obesity, particularly in the developed world.

In reality, governments also justify intervention for noneconomic reasons, notable among these being the correction of health inequalities (the socially deprived show a higher prevalence of obesity). Acting to change social norms has been used as a further justification for action; essentially this means changing people's utility functions so that they choose to weigh less, comparison being made with the successes in changing attitudes to drunk-driving, smoking in public places, and wearing seat belts when driving. Children are often seen as a special case for whom more overt intervention to control is justified. More recently, behavioral economists have focussed attention on widespread systematic divergence from the rational behavior assumed by neoclassical economic models, arguing that such 'behavioral failures' have been exploited by the food industry to encourage higher consumption

Table 2 Classification of policy actions

Nutrition-related standards
Government action to encourage private sector action
Availability measures for disadvantaged consumers

of processed foods; benevolent paternalism, it is argued can similarly exploit such behavioral failures to nudge people toward choosing healthier lifestyles they themselves would prefer (helping them to maximize their individual utilities).

The policy responses can be usefully grouped into two main categories, those actions centered around information and those which more directly intervene in markets. The actions which have been taken are shown in Table 2.

Of the information actions, public information campaigns exploit media communication and other social marketing tools to improve individual and social knowledge about health issues connected to food habits, and may be directed at any kind of target population. It is by far the most common healthy eating policy, together with education interventions. The aims may be simply to better inform people (e.g., about the health risks of obesity), or to change social norms. Advertising controls (bans) could in principle be used to limit advertising to adults and children if it was believed that all ages were encouraged to overeat by commercial advertising, though in practice, the measures have only been applied to children, presumably because it would be considered overly paternalistic to take such measures for adults. Nutrition education actions could likewise be used for adults or children, but have in practice only been used for children in schools. Nutrition labeling is essential to informed choices because the nutritional composition, notably number of calories, in foods, particularly processed foods, cannot be easily assessed, even by food scientists. Some form of labeling of the nutritional content of processed foods is compulsory in many developed countries and common even when not compulsory; the debate now is over the most effective form of communication using simplified messages, such as traffic lights to represent high, medium, or low levels of the major nutrients. There is a move toward extending labeling to food eaten outside the home in restaurant chains selling standardized products such as hamburgers.

Market intervention measures are less common. Fiscal measures have been proposed and widely assessed (simulated) by economists. On the positive side, taxes on unhealthy foods could be used to make people pay the full social cost of the food they eat, including the health care and economic productivity loss costs. Subsidies for healthy foods such as fruits and vegetables could be similarly justified as aligning social and private costs. The counterargument is that taxes would be regressive (the poor spend a higher share of their incomes on food), though there is some debate as to whether a fiscally neutral system where the subsidy cost exactly matches the tax revenue would suffer in this way. In any case, the measure would be highly unpopular with the food industry, and governments have not gone down this route, though small taxes, especially on soda, are widespread in the United States. One fiscal measure that has been employed, albeit to a limited extent, is subsidies, in the form of vouchers, to low-income households for the purchase of specific healthy foods. This is a promising area as it also addresses the issue of health inequalities, but may be deemed too expensive to apply in anything other than a very limited manner.

The other measures are all designed to influence the availability of foods, or rather nutrients. These tend to be targeted at diet quality more often than obesity per se, particularly measures to encourage food reformulation to reduce levels of salt, saturated fat, and trans fat in processed food; and measures to promote convenience stores in low-income areas to carry fruits and vegetables (the premise being that people in these areas without cars cannot access healthy food). The school food environment is commonly regulated to control the availability of junk foods (in canteens or vending machines) and the menus of meals (less chips, sausages, chicken nuggets, and hamburgers; and more salad, fruits, and vegetables). Menu control in public sector workplaces has been considered, but not widely applied.

Macroeconomic Dynamics of Health: Lags and Variability in Mortality, Employment, and Spending

TE Getzen, International Health Economics Association, Philadelphia, PA, USA

Prologue: Lags Tend to Obscure What is Known

The best known 'facts' about the macroeconomics of health are that rich nations are healthier and spend more on medical care than poor nations, but that additional wealth or spending may not add much to life expectancy after some threshold level has been exceeded (Figure 1(a)–(c)). A fact that receives insufficient attention is that any major macroeconomic change takes time, often quite a long time. An often repeated but generally incorrect 'fact' is that population aging and health risks (obesity and cancer) are major drivers of aggregate spending growth.

Macroeconomists focus on large-scale issues at the national or global level – growth, distribution, business cycles, money, and finances – rather than the micro individual rational choice decisions examined by most health economists. Macroeconomists tend to use time series methods and address dynamics rather than the cross-sectional methods and comparative statics of micro studies. Analyzing when and how change occurs forces more explicit consideration of lags, heterogeneity, and variance – and of the differences between micro and macro processes that might superficially appear to be the same.

Some notable disparities addressed in this article are the contrast between the quick, anticipatory movements of financial markets and the slow inertial flow of complex health care systems (smoothing that renders regular business cycles almost invisible); discrepancies in the determinants of spending between the individual micro level (illness) and the national macro level (per capita gross domestic product (GDP) – with a lag); and divergences in sustainable rates of growth.

Mortality and GDP

During the past 200 years, many parts of the world experienced unprecedented growth in material well being and human health. In the UK, real income per capita rose 10-fold while life expectancy doubled. Demographic transition and the industrial revolution brought similar improvement in the US, France, Germany, Sweden, Japan, and most developed nations. The massive effect of modern economic development on human conditions is well known and beyond dispute. The timing and uneven distribution of such gains is less well recognized. What has become increasingly evident in recent research is that the relationship between 'GDP' and 'Health,' although quite strong and clearly causal, is far from simple.

Long Lags

Any major social change takes time and rests on many preconditions, making a precise dating of a 'starting point' at best imprecise, and possibly misleading. That said, a reasonable consensus among the economic historians and macroeconomists who study growth is that the industrial revolution began around 1775 ($\pm$ 75 years) and was well established by 1850, although wider diffusion and follow-on benefits continued through much of the twentieth century. Therein lies the rub. Although the surge of innovation and economic development was manifestly widespread in nineteenth century Dickensian England, the industrial revolution in 1850 – and for a long time thereafter – is associated with widespread misery and substantial declines in life expectancy. The data presented by Angus Maddison are consistent with the following rather loose and lengthy causal chain: A burst of productivity-enhancing innovations (steam engine and factory work) starting around 1780 allowed rapid growth in population and trade, which eventually (20–50 years later) led to rising average incomes and material well-being of individuals, which in turn (after another 20–50 years) led to a rise in human life expectancy. Some details of timing, paths, and dynamics of this process are discussed in section Growth, Business Cycles, and the Long Run below.

Business Cycles and Employment

Figure 2 compares 'total' and 'health' employment in the US 1990–2010 and reveals two major macro conclusions: The health sector is growing much faster than the rest of the economy (rising share), and that growth is much steadier (lower variance). The jagged seasonal variation very evident in total employment is almost nonexistent in health care. The significant deviations from trend due to recessions in 1990–91, 2001, and 2007–09 readily discernable in total employment are also missing. Instead, health employment shows an almost steady upward incline throughout this 20-year period and for earlier decades as well.

The health sector's lack of response to recession is evident in Figure 2(b). The 'great recession' officially dated as beginning in the fourth quarter of 2007 appears here as a slowdown in rate of job growth starting after a peak (2.1%) in March 2006, which then went below the long-run sustainable rate of increase (0.9%) in November 2007 and turned negative in May 2008, finally reaching a trough in August 2009 when jobs were disappearing at a 5% annual rate. Only after June 2010 did job growth turn positive, and it will still be a number of years before overall US employment again reaches the previous level (139 million) and even longer (perhaps 5–7 years) to compensate for the intervening population growth. In contrast, growth in health employment continued to increase throughout 2007 and decelerated moderately after that. The great recession, to the extent that is visible at all in health care, shows up as a slight dampening in a continuing high rate of growth 2 years after the most massive economic downturn since the depression.

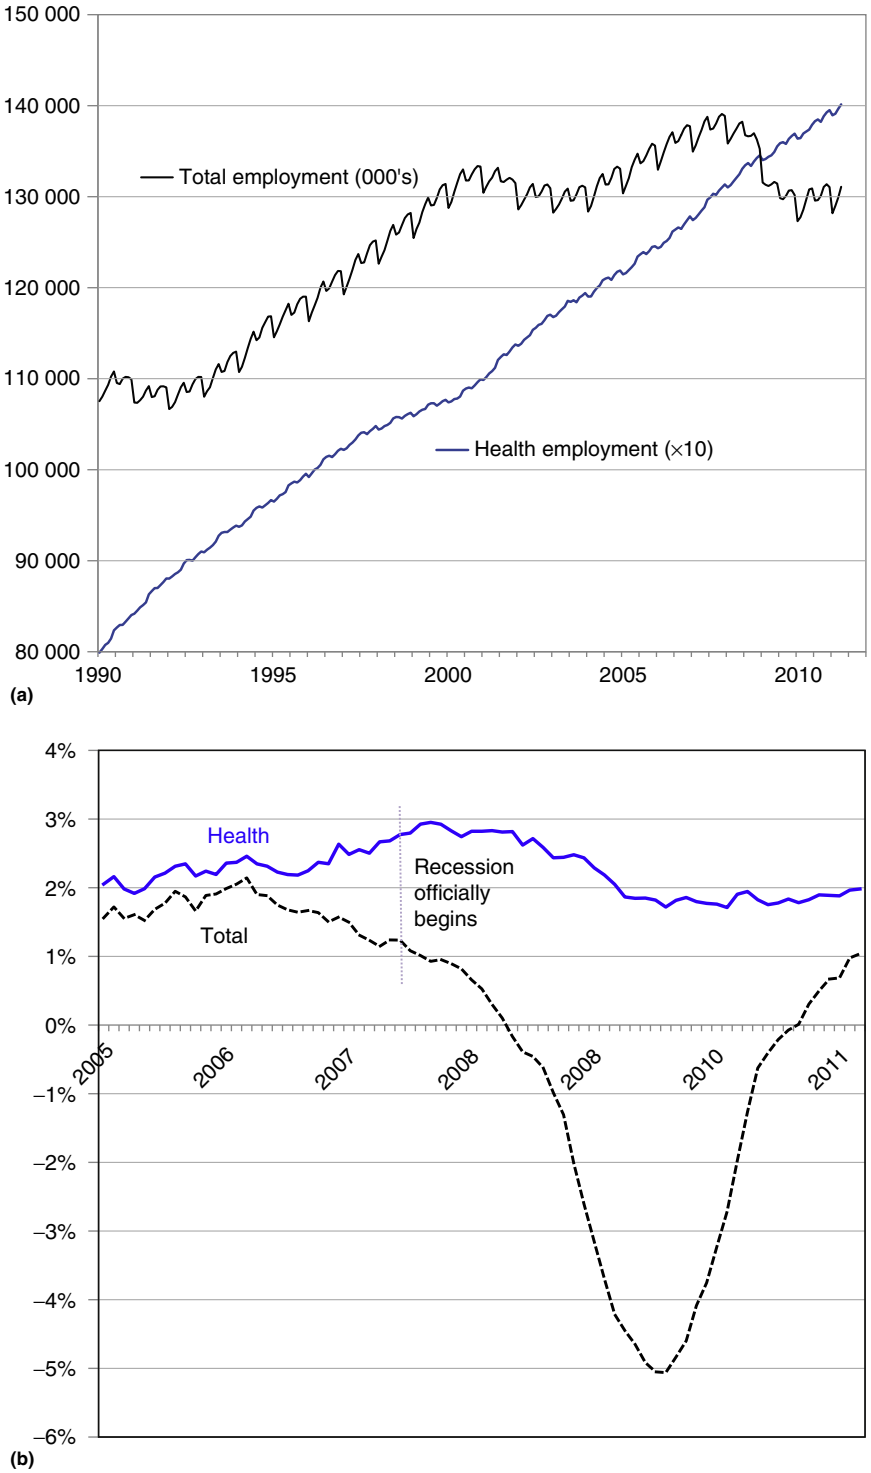

Figure 2 (a) US employment: 1990–2011. (b) Annual % change US in employment: 2005–11.

Unemployment and Mortality

Employment (and its obverse, unemployment) is a main indicator of economic growth. Hence, it seems reasonable that more employment (unemployment) should be associated with higher survival (mortality). Indeed economic historians traced the path of medieval economic fluctuations correlating the price of grain with mortality rates. Twentieth century policy makers often pointed to the adverse effects of unemployment on population health as a justification for countercyclical monetary and fiscal interventions. The research and legislative testimony of M. Harvey Brenner quantifying the

expected number of lives lost for each additional percent of unemployment became so well known that the association of unemployment with mortality was widely referred to as the 'Brenner Hypothesis.' The strong long-run and cross-sectional connection between GDP and mortality made it seem like 'common sense' that a similar short-run relationship should hold. However, Jose Granados, Hugh Gravelle, Audrey Laporte, Jes Sogaard, Adam Wagstaff, and others attempting to empirically verify the Brenner hypothesis reported great difficulty in doing so. In a seminal paper in 2000, Christopher Ruhm reported compelling evidence that recessions were in fact associated with less, rather than greater, mortality – and was able to explain why. Briefly and incompletely put, Ruhm and others have shown that unemployment and the concomitant reduction in general economic activity is associated with changes in behavior and consumption (less driving, more exercise, etc.) that reduce contemporaneous mortality without affecting long-run mortality very much. This is especially true for deaths due to accidents, cardiovascular disease, births, and some other medical conditions, whereas the converse holds for suicide and some other causes of death where acute stress may play a greater role. The conclusion that unemployment lowers mortality rates, although considered counterintuitive 20 years ago, has been so frequently confirmed empirically that most informed researchers would now consider it conventional – even though much of the public still thinks unemployment causes mortality rather than the reverse.

Some of the public confusion arises because these macro results apply to aggregate population mortality rates rather than the typical individual results that people 'see for themselves.' A negative macro correlation between unemployment and mortality does not imply that unemployment is healthy for the individual who loses a job. Indeed, there is compelling research showing that unemployment is highly damaging to the individual who is laid off. Daniel Sullivan and Til von Wachter report that involuntarily unemployed workers suffer a 10–15% increase in annual mortality rates that persists for at least 20 years, reducing average life expectancy by 1–1.5 years. Jason Lindo reports that parental job loss substantially reduces birthweight and child health, while Gerard Van den Berg, Maarten Lindeboom, and France Portrait show that infants born during economic crises in the nineteenth century had reduced life expectancies. These results make it clear that the impact of job loss on individual health (micro effect) is quite different from the macro effect on population rates.

Spending

Expenditures on health care have increased rapidly in all developed (Organization for Economic Co-operation and Development (OECD)) countries over the past five decades, with total spending rising more than 1000% in most countries due to inflation, demography, technology, income, and other factors. However, the relative contribution of each factor is often uncertain, variable over time and across countries, as well as being subject to inertia and lags of varying lengths.

Inflation and 'Real' Expenditures

Differences in the nominal value of money over time and across countries cause large yet presumably unimportant differences in measured spending. If medical transactions were simple spot exchanges and price indexes were perfect, adjustment using deflators and exchange rates would not be an econometric problem. Instead, medical transactions are usually complex, involving group contracts and institutional interactions extending over years or decades. In such a context, inflation and purchasing power parity discrepancies will often distort measures of 'real' health expenditures.

To sidestep real versus nominal issues quantifying resource use within a country, region, township, or household by share of GDP (or of consumption, income, employment, etc.) may sometimes be preferable. However, the inertial response of health care systems to macroeconomic forces means that short-run shifts in shares are more apt to come from delays and measurement errors than substantial changes in real resource use. This is shown below with data from Canada during a spike of inflation in 1974. The measured health share of GDP fell from 0.073 to 0.069, whereas the share of employment in health increased. It is most likely that the real share of economic activity devoted to health was rising rather than falling in 1974.

Year	*1972*	*1973*	*1974*	*1975*
Inflation	5.6%	8.9%	14.4%	9.8%
Nurses	1 52 005	1 59 274	1 68 530	1 77 182
Health share of GDP	7.3	7.0	6.9	7.4
Fraction of employment	0.0180	0.0180	0.0183	0.0189

One way such systematic errors are generated is by delaying wage increases. In a study by Getzen and Kendix, wages of health care workers were estimated to have a secular increase of 0.6% above that of other workers and respond essentially 1:1 to inflation – but with a lag. When inflation goes up (or down), less than half of that change in the rate of inflation is reflected in health care wages in the current year, and even after 2 years, about one-fourth of any shift is still waiting to trickle into the health sector.

$$\text{Wages} = 0.6\% + 1.02\ \text{CPI} - 0.61\Delta\text{CPI}_{0-1} - 0.11\Delta\text{CPI}_{1-2}$$

If it takes 18 or 24 months for changes in the general level of prices to be reflected in the wages of health care workers, significantly longer than for most employees, then measured labor will appear to be significantly below(above) real employment whenever inflation is rising(falling), even though the long-run effect of general price inflation is neutral. Similar distortions arise when purchasing power parities (PPPs) deviate widely from exchange rates. Internationally traded items, such as pharmaceuticals, are priced in international currency units, whereas wages and physician services reflect domestic (PPP) equivalents.

Income Effects

Measurement and estimation of income effects are even more affected by lags and inertial response. In **Figure 3(a)**, the

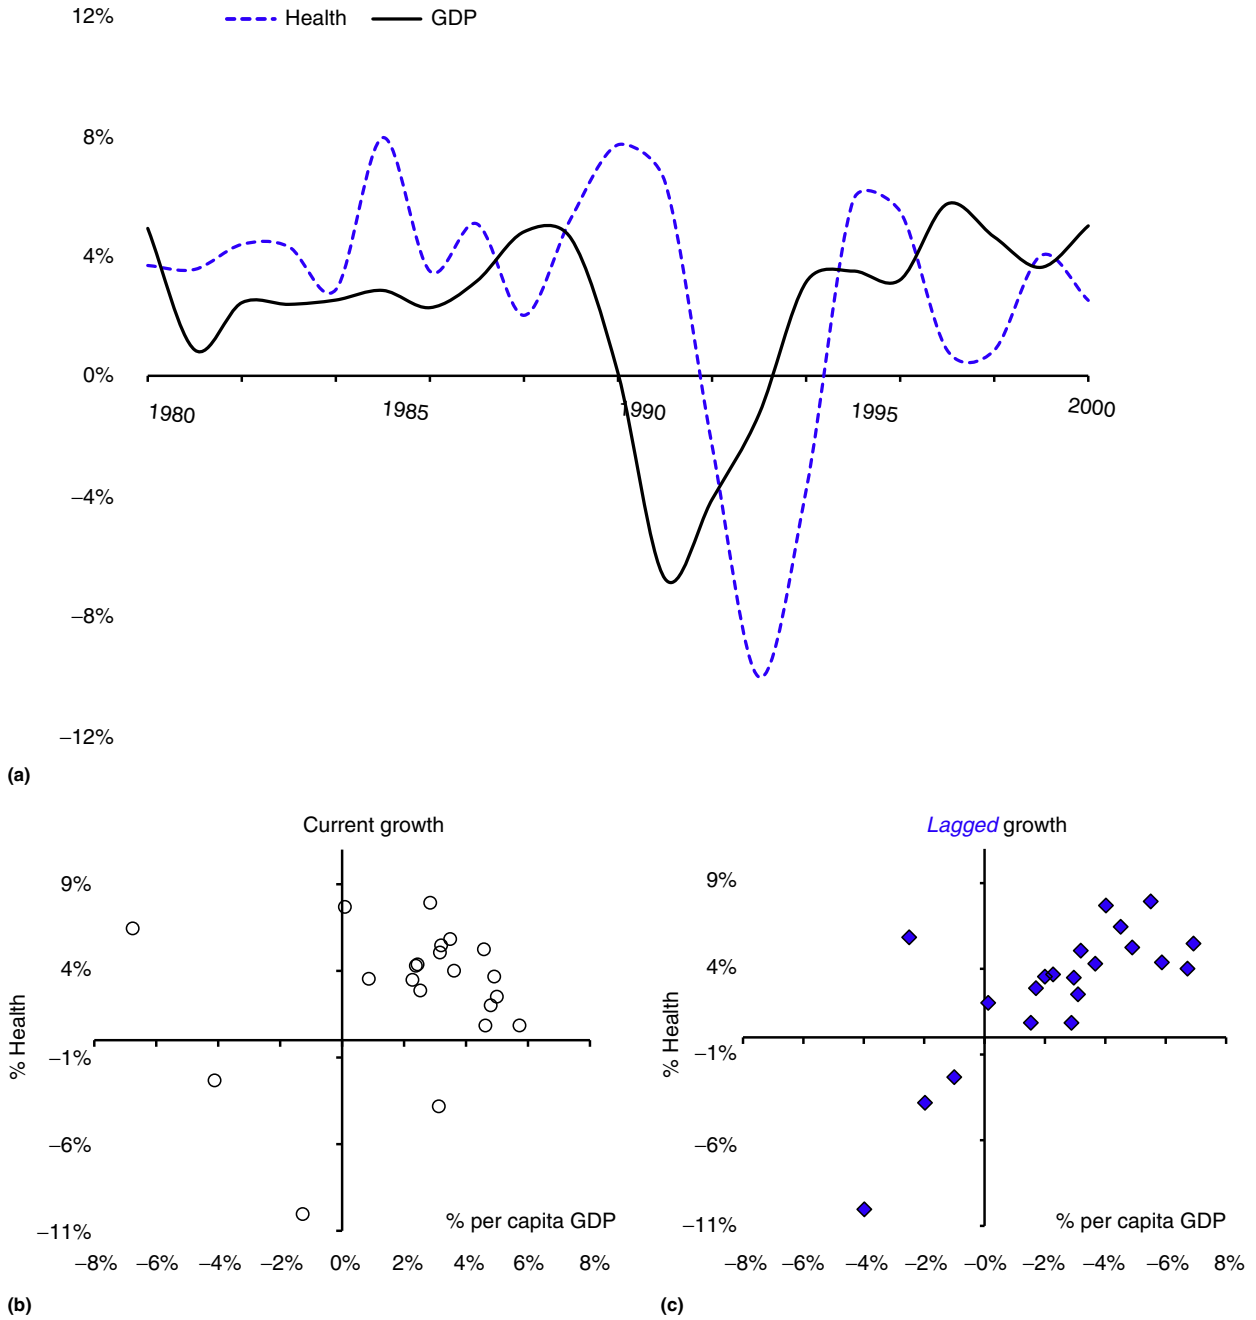

Figure 3 (a) Finland 1980–2000 annual % growth in Income and Health. (b) Current growth. (c) Lagged growth.

1990–93 recession in Finland and the subsequent decline in national health expenditures occurring after a lag of 2 years is clearly visible. Yet when the same data are presented as a scattergram in Figure 3(b), the correlation between GDP growth and health expenditures growth is almost entirely obscured. Only once allowances are made for delayed response spread out over several years does the correlation again become clear, as in Figure 3(c), which plots annual expenditure increases against a lagging 3-year moving average of GDP growth.

Health care spending depends on permanent income, which changes slowly over time. Even after a decision to spend more (or less) has been made, the rigidity of budgets and licensed professions delays implementation. With slowly evolving expectations regarding permanent income and complex institutional inertia, the impact of current changes in GDP are barely apparent in contemporaneous spending. Estimation across a panel of OECD countries from 1961 to 2008 indicates an average lag of 2 or more years before changes in per capita GDP affect health care spending.

$$\%\mathrm{HE} = 0.035 + 0.13\mathrm{GDP}_0 + 0.32\mathrm{GDP}_{-1} + 0.33\mathrm{GDP}_{-2} + 0.15\mathrm{GDP}_{-3} + 0.10\mathrm{GDP}_{-4} + 0.13\mathrm{GDP}_{-5} - 0.26\Delta\mathrm{CPI}_{0-1} - 0.16\Delta\mathrm{CPI}_{1-2}$$

What is not so apparent in this single equation estimate on panel data encompassing 17 countries and 46 years is that the lags between measured current income and changes in spending vary substantially from country to country, by the particular type of health spending (research, physician, hospital, and dental) and even from one time period to the next. Table 1 provides coefficients estimated for several categories of health expenditures within the US for 1960–2009. The average lag for all categories of spending combined is a little over 3 years, but varies from less than 2 years for personal out-of-pocket spending and drugs to more than 4 years for hospitals. Presumably, more detailed accounting would reveal an even greater range, perhaps just a month or two for bandages and over-the-counter medicines but close to a decade or more for construction of new buildings.

500 Observations can robustly establish that lags occur and that they vary, but is hardly able to specify the range and shape of those variations or to identify the many institutional features that cause responses to be delayed. Kenneth Arrow's classic 1963 paper focuses on uncertainty with regard to incidence (risk) and quality (effectiveness) as the cause of special characteristics in the health care market. The first risk, is dealt with primarily through pooled financing. Third party insurance, whether government or private, builds a structural lag into the link between income and expenditure. Premiums are set well in advance and based on expectations – that is, on a form of permanent rather than temporary income.

Although demand side buffering causes some lags, the more significant institutional rigidities that Arrow identifies occur on the supply side – licensure, cost shifting, nonprofit community organization, and other barriers. Adjustment of physician supply is enmeshed in traditional educational institutions that are resistant to change, so much so that any equilibrium must be considered heavily punctuated if not ossified. From 1980 to 2005, US population grew 23% and real health expenditures per capita grew 187%, but just one new medical school was built and the number of US medical graduates rose by only 2% (from 15 632 to 15 962). The shift to produce more graduates carried out in the early 1960s reverberated for more than 30 years (the average length of professional practice), but the grudging and belated accommodation of growth through the professional supply chain indicates how inertial the medical care system can be.

Expectations prevalent during creation tend to get built in, embedded in the processes and organizations by which a medical financing system operates. The Medicare and Medicaid programs in the US were conceived during a period of endless growth and bright technological promise and thus were designed to increase the wages of health workers, to subsidize the construction of hospitals, and to support experimental treatments through generous funding. Enactment in 1965 promoted the rise of Academic Medical Centers, sophisticated subspecialty practice and rapid increases in health spending. Only after the Oil Producing Economies Oil Crisis and recession of 1974 dimmed, the once rosy economic outlook was a serious attempt made to control (rather than expand) the growth of medical spending. Yet grafting cost controls onto an expansionary system has proven difficult. Decades later these two government payment programs, originally just 2% of GDP, are projected to rise above 10% and threaten the entire budget process. Conversely, the UK National Health System was established in a context of postwar austerity in 1948. Although growth in UK spending has been substantial, sometimes more than desired, it has usually been below the OECD average and certainly well below the excessive rates in the US.

Institutional forces are hard to quantify. Empirical estimates of long-run trends (or curvature in trends) are difficult to make and seldom compelling. That said, economic historians and theorists such as Daron Acemoglu, Philippe Aghion, David Landes, Joel Mokyr, Douglass North, Mancur Olson, Dani Rodrik, James Robinson, Paul Romer, Oliver Williamson, and others have concluded that institutions are a primary factor in economic growth and development. In the case of health care, it seems apparent that macroeconomic factors prevalent when the foundations are laid can continue to exert an influence on spending for at least as long as the doctors and politicians then present continue to exist and perhaps as long as the defining institutional structures (licensure, voluntary nonprofit hospitals, and insurance pools) endure.

Population Demographics and Aging

Population can be a neutral denominator by which costs or mortality are scaled. There is little evidence to contradict the simple notion that a group or nation two (or twenty) times the size of another differs in costs or mortality *per person* (or per thousand or per million, holding other factors constant). Growth (or decline) makes the situation more complex, as the

dynamics of changing dependency ratios, disability, aging, and time-to-death come into play. Births and deaths are the basic building blocks of demographics, and both events are expensive. Although now discredited, the impression that population aging itself was the important factor accounting for rising national health expenditures probably arose because: (1) health care spending on the elderly was rising rapidly, (2) health care spending was higher in nations with a more elderly population, and (3) growing fiscal concern regarding how governments could pay for expected increases in pensions and health care services. During the 1970s and 1980s, a number of 'demographic models were constructed that projected future health expenditures using a linear matrix that mimicked the format used for projections of future pension payouts (the '*i*' are 'age–sex' categories or 'age–sex-disease-disability' categories if more detail is desired).

$$\text{Total Cost} = \sum \text{Cost}_i \times \text{pop}_i \times (\text{Total Population Growth} \times \text{Excess Cost Growth})$$

Empirical investigation quickly showed that change in the percentage of population aged 65 years or more or number of elderly accounted for only a small portion of total cost increases, with most attributable to increased cost per person (holding age and sex constant). As government and employer financing of health care expanded, the personal budget constraints that had prevented many people, especially the elderly, from spending considerably on medical care in the 1950s were largely removed during subsequent decades.

The main reason for a rising health share of GDP is secular 'excess cost growth' per person (i.e., medical costs for every age–sex category has grown more rapidly than per capita income). A secondary factor is the extra 'excess' among the elderly (again, holding age and sex constant). In the US, the ratio of spending over:under age of 65 years has moved from 168% in 1953 to 345% in 1970 and above 500% in the 1980s before falling back below 400% after 2001, with similar changes in relative spending ratios occurring in most OECD countries. Governments were spending more, a lot more, on elderly people who had been significantly relieved of the financial burden of doing so. A false impression of causality was created as economic development led to concurrent rises in both average age and per capita spending for most nations. A panel study of OECD data by Getzen demonstrated that the cross-sectional association between age (%65+) and expenditures at a point in time tends to disappear once income effects are accounted for, and also that more rapid growth in the elderly population of a country during the decades 1960–1990 was not correlated with that country's rate of growth in real health spending per capita (illustrated below in **Figures 4(a)** and **(b)**).

Most health economists now agree (even when arguing details, estimation procedures, and causes) that it is more (excess) spending per person, and not population aging, that threatens the fiscal health of nations. Why then were commentators so convinced three and four decades ago that 'aging causes higher health care costs,' – and why was that mistaken impression so persistent when it could so easily be overturned by empirical investigation? Confusion arose from a failure to distinguish between micro and macro phenomena as well as the facile but misleading association of concurrently rising trends. At the individual micro level, older persons do spend more than younger persons because older people are usually sicker and stand to benefit more from therapy. Pooled government financing strengthens the connection between an individual's age and medical expenditures by removing the personal budget constraint. However, the system also disconnects total (and hence average per capita) financing from need. At the national macro level, spending decisions (total funds available) are driven by budgets, not by need or illness. A nation populated only by poor old people suffering from diabetes, dementia, and other illnesses would have to spend less, not more, on health.

Macro (National) and Micro (Individual) Expenditures: Budgets and Allocation

Asked why health care spending is so much higher in Germany than in Ghana, most respondents quickly offer the answer that Germany is much richer. When pressed, they acknowledge that need and potential benefits from medical care are likely to be much higher in Ghana, but 'the funds are not available there.' The connection between purchasing power and spending, so obvious at the national level, is often obscured in microeconomic analyses of aging, disability, or time-to-death. Clarification comes from recognizing that on one hand the use (allocation) of available medical resources is determined by clinicians on the spot immediately responding to the health of the patient, while on the other hand the total amount of national medical resources available (budget) to treat patients is determined through the political process, shaped most strongly by fiscal policies that respond slowly, and with a lag, to changes in GDP (national permanent income).

Finland, like most European countries, is steadily aging. From **Figure 3(a)** above, it is evident that spending on health care was severely restricted in Finland after the deep recession of 1992–94, and also the response was slow, delayed for 2 or 3 years. One searches in vain for evidence that per capita spending for Finland, or any other country rose or fell in response to changes in health status – or that differences in the rates of death, disability, or aging were matched by differences in the rate of growth in spending. Pooling of funds through insurance and tax financing removes the budget constraint from the individual, so that personal income is no longer a major factor determining the amount of care used. However, the budget constraint still applies for the pool as whole (in the case of Finland, the nation), so in aggregate the sum of spending on all individuals is constrained by the average contribution paid in (which, in turn, is usually strongly correlated to per capita GDP). Of course, some medical spending is made by patients from their own budgets or by subnational entities (kin, employee groups, neighborhoods, counties, and provinces) constrained by their own budgets – hence more related to per capita income of that particular group than the nation as a whole.

Spending depends on who makes the decision and how. For food, housing, transportation, and most other consumption, total spending is the sum of many individual decisions. Medical

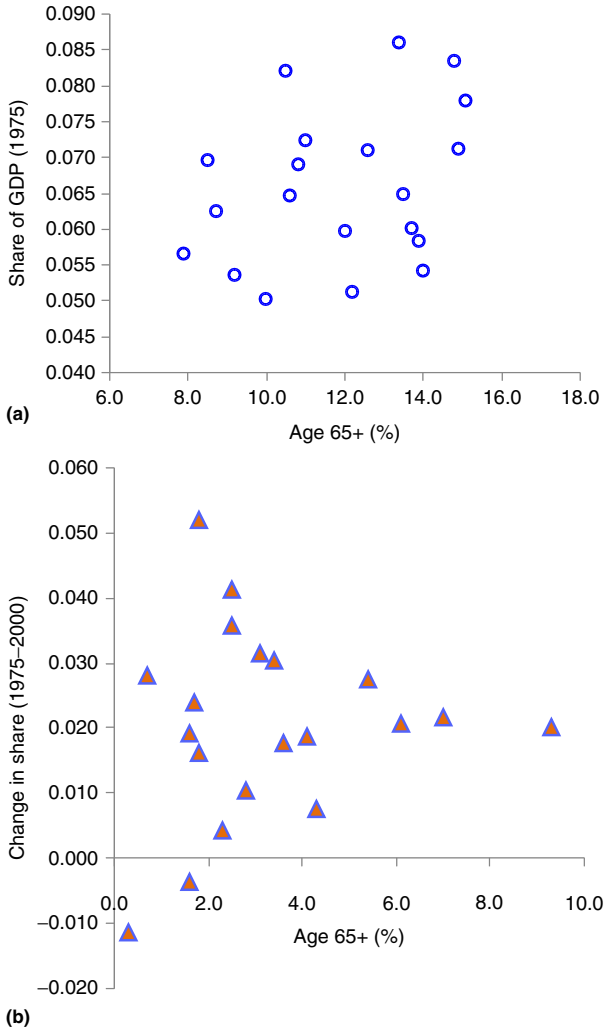

Figure 4 (a) Health share of GDP/ % population of age more than 65 years (twenty OECD countries, 1975). (b) Change in share/change in % population of age more than 65 years (1975–2000).

decisions, conversely, are made by professional agents (physicians) operating within a highly structured system dominated by third-party insurance or tax financing, divorcing spending on an individual from that individual's budget.

Growth, Business Cycles, and the Long Run

A Tale of Two Necessities

Housing and healthcare are both generally considered 'necessities,' although neither conforms to 'Engels law' or meets the technical definition used by most economists (income elasticity <1.0). What they have in common is that both are considered vital and are sufficiently expensive as to require external financing for mass consumption. Housing needs are financed through the mortgage and rental markets, which pool the resources of investors, banks, and other intermediaries. Health care financing needs are met through broad-based taxation and employer insurance pools.

What sharply distinguishes the two sectors is dynamics – different, almost opposing, responses to macroeconomic fluctuations. Housing swings wildly with the business cycle, anticipating and amplifying the ebb and flow of money, employment, and interest rates. Healthcare plods along, an inertial stabilizer that muffles shocks, only belatedly registering the effects of booms and busts, and then with such long and variable lags as to smooth business cycles into near invisibility (Figures 2–4). Differences in financing mechanisms account for much of the differential in dynamics. As pointed out by Robert E. Hall and legions of other macroeconomists, it is the flow of money, which links regions, sectors, and countries – and puts the economy at risk of business cycles, with interest rates as the key transmitter. Slack and contraction make adjustment to financial frictions problematic, sometimes sufficiently so that the equilibrating mechanisms are seriously compromised. The use of money to facilitate transactions, allocate capital, provide credit, and spread risks comes at a cost that rises exponentially during a systemic crisis, with savings, interest rates, and employment unhinged. Housing is

highly leveraged with debt financing and bears the brunt of adjustment. Healthcare is not. It is, in contrast, routinely financed within a pay-as-you-go framework by government or employers. Medicine proceeds with blithe indifference to financial markets. Doctors, nurses, administrators, and even pharmaceutical companies are often unaware of and relatively unaffected by interest rates. Stock markets soar and crash with little more effect on the operation of hospitals than sunspots or tidal waves. The only oscillation that seems to be generated within the healthcare financing system is the 'underwriting cycle' of alternating hard and soft markets for private insurance premiums, pushing quoted rate increases slightly above or below the rise in medical costs. The private health insurance underwriting cycle, however, has a little power and is often offset by countervailing trends in government tax financing. Probably the only way to get a real and significant financial disruption of the medical sector would be to put corporate and government financing under such stress that the entire structure was threatened. Fortunately, this has not yet happened, or at least not with sufficient force as to be evident in the modern national economies and health systems characteristic of most OECD countries since 1960 (although continuing fallout from the 2008 to 2009 recession and subsequent bank collapses in Iceland, Ireland, and Portugal may put that to the test).

Limits to Growth and 'The Great Inflection(s)'

No matter how vital or necessary, there is a limit to the amount of spending on any sector. Expenditures cannot logically exceed 100% of income (at least, not for any extended period of time). Currently, most wealthy OECD economies seem resistant to spending much more than 10% of GDP on health care, with the US at 16% a notable exception. The rise in health spending was very rapid during the 1960s and 1970s, moderated a bit during the 1980s and 1990s before bumping up around the turn of the millennium and then becoming somewhat restrained over the past 5 years (an uptick in share for 2008 and 2009 is mainly because of countries having a temporary decline in GDP rather than a more rapid rise in real health expenditure). Figure 5 was constructed using historical data from the UK and US, but the shape would be similar for other OECD economies – and is remarkably like the typical inflected logistic *S*-curve that characterizes most growth processes. A long period of slow growth (incubation) builds toward an explosive spurt (exponential growth) that is bent back (inflected) as it approaches some constraint that limits growth in the long run (upper bound/stability).

Many aspects of health and economics appear to follow a typical growth process during the nineteenth and twentieth centuries: Medical costs, life expectancy, population, urbanization, industrialization, trade, workforce participation, and GDP all trace recognizable *S-curves*, although each differs somewhat in shape and timing. The growth of per capita income slid along at a very low rate for millennia before rising abruptly after 1850, soaring for a century, and appearing to stabilize (?) near an upper bound of 1–2% within the next century. Life expectancy fluctuated from 20 to 40 years before

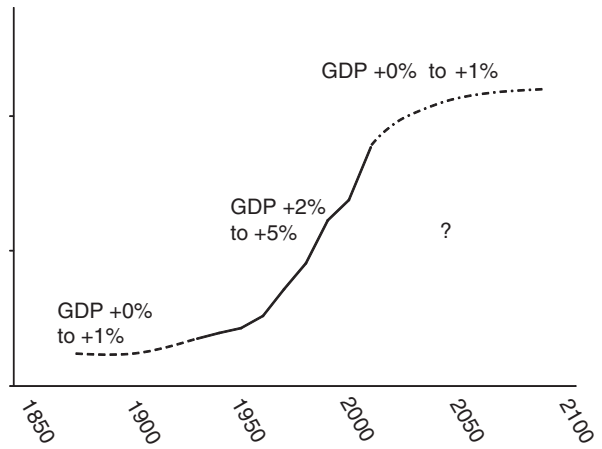

Figure 5 Growth curve: Health share of GDP 1850–2100?

making tremendous gains during the twentieth century and is expected to face diminishing returns as genetic and social factors impose an upper limit (110, 125, or ?). Global population took hundreds or thousands of years for each doubling from prehistoric eons through the middle ages before reaching half a billion around 1550, quickly climbed to one billion by 1820, two billion by 1925, three billion in 1960, six billion in 2000 – and is projected to stabilize after reaching a peak of 10 billion within the foreseeable future. The process of 'demographic transition' traces a similar curve, reversed and displaced in time.

The coincidence of so many dramatic changes in human society could hardly be attributed to chance, yet the causality and order is much debated – and has only recently (and partially) been illuminated with empirical data through the efforts of cliometric economic historians such Gregory Clark, Dora Costa, Robert Fogel, Angus Maddison, and others and placed within a conceptual framework by development theorists and macroeconomists such as Daron Acemoglu, Oded Galor, Chad Jones, Michael Kremer, Rodrigo Soares, and others. The tentative consensus among these scholars is that the gradual increase in knowledge and technology over millennia brought about an end to the Malthusian era, appearing first as a dramatic increase in total population and urbanization, a shift from agriculture to industry, a decline in mortality, and a steady increase in income per capita – transformations that were well underway toward the end of the nineteenth century and clearly before the rise of modern (expensive) scientific medicine or the modern increase in life expectancy beyond the biblical three score and ten. This cluster of transformations by which humanity escaped the era of Malthusian constraints in a burst of exponential growth is variously known as 'development,' 'demographic transition,' 'the industrial revolution,' the 'modern era', or most misleadingly, as 'normal times.'

In 2001, macroeconomists were discussing 'the great moderation,' showcasing compelling results from rational expectation models and financial forecasts based on recent time series data. By 2011, such discussions were supplemented or supplanted by observations on the great depression and financial panic of 1873. The postwar 'normal' should be seen as

an aberration – calm at the eye of a storm that transformed human society and is not yet finished.

Complexities of Measurement and Specification

The reason that business cycles are mostly invisible in health care spending and employment is not that inflation and GDP growth have no effect, but that the relationships are misspecified. To estimate the effect of one variable on another, the units of observation must match the span of action in both time and space. One hundred or even one thousand observations cannot capture the effect of a change in GDP on life expectancy or health expenditures if each observation is one minute long. A minute-by-minute time frame is, however, quite useful for determining the effect of a 10.00 a.m. announcement of clinical results on the price of an exchange-traded biotech stock. Using minute-by-minute, hourly, or even daily measures will tend to increase the signal-to-noise ratio and obscure the long-term low-frequency effects of a recession on health employment or mortality rates. Note also, that observations on the price of a specific biotech stock are neither likely to reveal the broad effects of macroeconomic factors on the market as a whole nor is investigating the determinants of one individual's medical costs during an illness episode likely to reveal the factors that cause national health spending to rise over years or decades.

Inequality and nonlinearity

Not long after Samuel Preston published his analysis in 1975 showing that the positive effect of income on longevity became progressively smaller at higher levels of income, GB Rodgers used a multivariate regression to show that for any given level of per capita GDP, greater income inequality (Gini coefficient) was associated with lower life expectancy. This led to suggestions that inequality and social stress could be an underlying cause of disparities in mortality by ethnicity and occupation status. However, work by Gravelle and others subsequently made it clear that what appeared to be an independent factor was instead an artifact due to nonlinearity: any mean-preserving spread would necessarily cause the estimated coefficient of 'inequality' to be negative – the mortality reduction obtained by the higher income group from gaining $1000 would (diminishing returns) be smaller than the mortality increase imposed on the lower income group losing $1000. Subsequent studies have supported this explanation. An extensive review of the literature by Deaton in 2003 concluded that there is still no compelling evidence that inequality in itself is a major cause of population mortality rates once sufficient care is taken to consider the effects of nonlinearity and other contributing factors.

Income, education, wealth, or socio-economic status (SES)?

Why spending depends on broader measures such as 'permanent' or 'shared' income rather than current individual earnings is fairly evident. Categories and concepts, like temporal boundaries, may also be indistinct. Demographers, sociologists, epidemiologists, and public health researchers examining the connection between income and health at the individual micro level are apt to use a broad concept of resource availability such as 'socioeconomic-status' for which 'household income' is just one aspect or indicator. For macroeconomists, the catchall term is 'level of development' or technology. Occupation, assets, poverty, and malnutrition are all associated with income levels – and with mortality. Ethnicity, education, urbanization, and social status may not be so directly related to income but are rarely independent of it – and are sometimes even stronger predictors of morbidity. The black/white differential appears to be larger in the US than the UK, but UK occupational status disparities seem to be greater. The strength and relative importance of factors varies so much across places and periods that it is unlikely that the determinants of health are constant or fixed, even though almost every region has ethnic (Inuit, Sami, Maori, Romani, etc.) or other groups (widows, orphans, albinos, and refugees) for which health outcomes are persistently worse than average.

Macro models

Measuring income, SES, or economic development is difficult but less problematic than quantifying 'health.' Longevity and mortality rates are clear but crude measures, and neither is applicable to individuals. More detailed, specific, or nuanced assessments (activities of daily living, Euro QoL quality of life measurement-36, quality of life, diabetes prevalence, anti-depressant drug expenditures, disability days, cancer survival, hospital utilization, psychiatric visits, etc.) are all sufficiently incomplete or ambiguous that none can be satisfactorily aggregated to macro measures of 'real' health outcomes. Analysis of system effects is further complicated by reverse causality between health and income – and also by interactions between marital status and occupation, education, and family size, or almost any set of contributory factors. Although each variable has a distinct connotation that is important in certain contexts, they are almost always acting together in related ways that make it difficult, if not impossible, to decompose a compound total network effect into shares, or to reliably estimate an independent coefficient for each variable.

Empirical analysis of macro determinants is often quite limited by the time frame and number of large-scale long-run observations available to discern diffuse and low-frequency responses. Temporal, spatial, and organizational boundaries must be carefully specified to distinguish and reveal micro and macro effects. Changes in coefficients as the unit of observation expands or contracts can be a key for understanding the underlying structure of the process – opening up the institutional black box of a firm, a hospital, the medical profession, or pharmaceutical discovery. The fact that health care employment adjusts quite slowly to inflation tells us something about wage formation within this industry; a mismatch between price indexes and expenditure patterns suggests that little significance should be attached to publicly listed prices; the fact that pharmaceutical research and development is more strongly correlated with prior firm profits than future prospects suggests something about capital allocation within the industry; disparity between individual cross-sectional expenditure estimates and national time series

results may be a useful indicator of the likelihood that a specific policy will be able to 'bend the (national) cost curve.'

Conclusion: Structure and Lags in the Macroeconomics of Health

The health sector is technologically dynamic but fiscally inertial. Major change often takes decades rather than months or years. Responses to macroeconomic shocks are delayed and damped by organizational rigidity so that ordinary business cycles are mostly smoothed away. Price changes, whether physician fees, hospital charges, medical care price index, consumer price index, inflation, or interest rates, can make appropriate measurement difficult but appear to have little effect on aggregate real health resources or outcomes. The process is subject to highly variable lags and complicated by interactions and feedback among variables to such an extent that almost any broadly correct generalization has one or more counter examples that can be named. Coefficients are difficult to estimate with precision and parsing total network effects into a linear combinations or shares for each factor is not very meaningful.

With regard to the current state of the literature, it may be said that since 1960 the development of national health accounting and a host of econometric studies have allowed us to become more precise about what we know and do not know, and considerably more humble about how easy it is to decompose and discern the relative contributions of various factors. Despite the humbling lack of progress in specifying many of the mechanisms and magnitudes involved, several popular hypotheses (aging, unemployment, and inequalities) have been rejected by repeated empirical tests. Some tentative conclusions are probably justified by the extensive research to date:

- The relationship of national GDP to mortality and health expenditures is strong, but not simple or constant.
- Responses are usually delayed, subject to long and variable lags. The inertial smoothing means that most effects of ordinary business cycles are rendered nearly invisible.
- The spatial and temporal boundaries of observations must be matched to the decision process of the phenomena to be estimated. Often the long-run effects are not the same as short run and may even have the opposite sign: for example, unemployment is associated with decreases in short-run mortality but increases decades later. Macro effects on national outcomes and measures are not the same as micro effects on individuals: for example, getting older greatly increases personal risk and individual medical spending, but population aging has little, if any, effect on average per-capita expenditures.
- The main determinants of individual medical costs (illness) have almost no effect on national health expenditures, which are largely shaped by budget and political pressures. Institutional factors (licensure, nonprofit hospitals, and government financing schemes) seem to dominate with prices, including interest rates, playing a much smaller role in health than other sectors.
- Income is intertwined with social organization, ethnicity, education, and other factors in a complex way that precludes any clear decomposition or reliable estimates of independent or relative importance. The magnitudes and interactions of these effects are demonstrably different for different causes of death, for different countries, and for different time periods.
- Nonlinear flattening of the income-mortality curve at the upper end implies that a mean-preserving spread will help the poor more than it harms the rich, thence reducing average mortality, but income inequality *per se* does not have much, if any, independent effect on aggregate mortality rates.
- Demographic transition, industrialization, urbanization, education, life expectancy, increases in health expenditure growth, and other aspects of modern development all appear as typical logistic *S*-shaped growth curves during the twentieth century. This suggests that the postwar span of rapid growth, rather than being a new normal equilibrium, was more like the inflection point in a centuries-long turbulent process of global development that has not yet achieved a long-run steady state.

Macroeconomic Effect of Infectious Disease Outbreaks

MR Keogh-Brown, London School of Hygiene and Tropical Medicine, London, UK

Introduction

Infectious disease outbreaks such as pandemic influenza or severe acute respiratory syndrome (SARS) in 2003 are, thankfully, rare events, but they do occur with some degree of regularity and impose a significant public health burden over a short period of time. For instance, there were three influenza pandemics in the twentieth century: in 1918, 1957, and 1968–69. Each was characterized by the rapid global spread of influenza. In the UK (and many other countries), there were three distinct waves of the 1918 pandemic, each lasting 10–15 weeks, with the largest occurring in the autumn of 1918. The 1957 pandemic occurred in the autumn of that year and comprised a single wave of approximately 15 weeks. The 1968–69 pandemic affected the UK somewhat late in the normal influenza season, resulting in a small first wave in March 1969 and a main wave in mid-winter of 1969–70. Clinical attack rates for the 1918 pandemic are thought to have been approximately 25%, and approximately 2.5% of those infected died. The 1957 and 1968–69 pandemics had higher clinical attack rates, ($>$30% and reaching 45% in some places), but with lower rates of mortality (case fatality ratio approximately 0.04%). The duration of illness is estimated at approximately 5–7 working days per case. In addition, the Swine Flu pandemic of 2009 was a reminder that pandemics seem to occur approximately every 30–40 years, but due to the mildness of the strain, greater population immunity, and the unusual timing of the pandemic there were fewer cases and deaths.

The structure of this article is as follows. First an overview of the link between outbreaks, productive labor supply, and economic effects is provided with reference to morbidity, mortality, and additional absenteeism. A brief discussion of healthcare expenditure related to outbreaks follows this before considering the more weighty issue of behavioral change in response to outbreaks. In the Section Health-Related Expenditure a discussion of the two main methods for macroeconomic assessment, retrospective analysis, and prospective modeling are discussed and selected results are presented and contrasted before conclusions are drawn.

Labor Supply Effects: Morbidity and Mortality

Without entering into a formal analysis of the effects of these outbreaks on productive labor supply, it is evident that, based on the observed 35% clinical attack rates for influenza pandemics, an additional period of absence in a given quarter year by one-third of an economy's labor supply, will have a notable effect on its productive capacity. Simple economic theory teaches us that labor needs to be combined with capital and natural resources in order to produce goods. Although some degree of substitution of labor with capital may mitigate the impact of a reduction in labor supply, such substitution is unlikely to be able to counter the loss of, perhaps, 3–5% of an economy's labor supply in a given quarter. Also, although the value of labor lost from the wage that is assigned to that specific quantity of labor can be estimated, this does not necessarily reflect the loss of productive capacity and the knock-on effects as the decline in one sector reduces the supply of intermediate goods to another and hence just-in-time deliveries are no longer able to meet their tight time targets. Although many of these economic effects are difficult to quantify, it should be evident that productive labor supply is just one element of the full economic cost of an outbreak. Clearly, the morbidity and mortality effects of an infectious disease outbreak vary greatly from perhaps 40 million worldwide deaths (aside from morbidity effects) from Spanish flu to 800 worldwide deaths from SARS. However, research suggests that the economic impacts of SARS were much greater than previous pandemics and much of this may be attributable to globalization and indirect health effects. Therefore, there is some evidence to suggest that direct health effects are not necessarily the only or even the main determinants of economic impact, even if they can be correctly estimated.

Labor Supply Effects: Additional Absenteeism

The loss of productive labor supply through illness and death is not the only factor which could reduce labor inputs to production. During school closure, government policies to mitigate an infectious disease outbreak may also be imposed. In extreme cases, these policies could include advising workers to avoid attending their place of work and, where possible, to work from home. However, a much more likely policy, (and one which the UK implemented in the mild swine flu pandemic in 2009), is a policy of either blanket or reactive school closure. Because children have lower immunity to influenza, mostly attributable to their lack of exposure to previous pandemics, higher clinical attack rates tend to be exhibited in schools than in the population at large. By closing schools, it is intended that the rate of infection amongst children will be reduced and thus will decrease or slow the burden of illness in the population.

However, the closure of schools, particularly primary schools, has an impact on working parents, some of whom may have to take leave from work in order to care for their children. Labor force estimates from the UK suggest that an average of 4.8% of working days will be lost in the quarter of the pandemic due to school closure that lasts 4 weeks, or 15%, if they close for the duration of the outbreak. Some of these estimates may be reduced when informal care arrangements and the ability of some parents to work from home are accounted for. However, the potential for a policy of school closures to result in a greater labor supply loss than the direct health-related effects is evident, and such costs occur in all sectors, not just health. As with the morbidity and mortality effects previously mentioned, these labor force losses will have

ripple effects throughout the economy, which need to be captured from the whole-economy perspective.

Health-Related Expenditure

In addition, many of those who are unwell and absent from work will not visit a hospital or primary-care facility, choosing rather to self-medicate, thus creating another health-related consumption change which may be hidden from healthcare sector expenditure. Some of this consumption may be captured by pharmacies in terms of increased purchase of, for example, pain medication and cold/flu remedies, but other purchases such as face masks and antibacterial hand gels will extend beyond the usual domain of treatment/prevention costs.

Externalities: Behavioral Change

Perhaps the largest potential contributor to the economic cost of infectious disease outbreaks is the externality of behavioral change. Many of the externalities which could potentially affect the economy as a result of an infectious disease outbreak are fear driven and difficult to predict, yet there is evidence to suggest that they do occur. Mention has already been made of the potential changes in shopping behavior which is linked to communicable disease, such as the purchase of self-medication, face masks, and alcohol gel, but more extreme changes in behavior may occur resulting in greater economic effects.

A survey was conducted in the follow up to SARS in eight countries (five European and three Asian), with a sample size of approximately 3500 individuals, to estimate the potential extent of precautionary behavior in order to avoid a pandemic. Although preferences elicited in this way may not reflect real behavior during an outbreak, conducting the survey shortly after the SARS outbreak may be of assistance in improving the validity of the theoretical responses in estimating true practice. The survey results suggest that 70–80% of Europeans would avoid using public transport, avoid entertainment events, and limit their shopping to the essentials. The percentages were similar but slightly smaller for Asian respondents, although Asian respondents were less likely to avoid entertainment events. In response to other questions, approximately one-quarter to one-half of respondents indicated that they would consider taking work absence, remove their children from school, limit social contact, avoid trips to the doctor, and remain indoors.

The evidence of whether such behavioral change is likely to take place in practice will shortly be examined. However, it is anticipated that a significant economic effect would result from any event imposing a substantial change in shopping patterns, attendance at work, and patterns of travel by the public at large, almost all of which would be manifested outside the health sector.

Several potential economic effects of communicable disease have been suggested which cannot be fully (or partly) captured from a partial equilibrium approach focused on the health sector and societal cost, which brings us to consider the evidence that such effects occur and present an alternative approach for their estimation.

Macroeconomic Evidence

In general, two approaches have been used: (1) retrospective estimation from economic statistics and (2) prospective macroeconomic modeling. Owing to their retrospective/prospective directionality, these provide complementary rather than competing evidence.

Retrospective Estimation

Using national economic statistics, it is possible to retrospectively estimate the impact of a significant economic event. Economic series are notoriously variable and therefore the isolation of an event's impact assumes that all other factors remain relatively predictable or consistent. The analysis can take various forms, from a simple comparison of average statistics with those relating to an event of interest to more complicated statistical methods, and such analyses have been performed for infectious disease outbreaks.

The relatively few number of cases and deaths recorded during the SARS outbreak has already been mentioned. These low-level impacts on the productive labor supply would be expected to have little economic effect. However, the economic impacts of SARS have been estimated to be significant.

To capture the economic effect of the SARS outbreak retrospectively, a study was published in 2008 to estimate the economic impacts of SARS from national statistics. Results from that study suggest that Hong Kong suffered an approximate US$3.7 billion loss to gross domestic product (GDP) and China's GDP growth was reduced by approximately 3%. As less than 0.03% of Hong Kong and approximately 0.0004% of China's population were infected with SARS, it seems unlikely that these economic impacts are greatly influenced by healthcare costs and losses of productive labor supply due to illness.

Further retrospective examination of sector-specific effects revealed losses to tourism-related sectors (hotels, restaurants, etc) for several countries amounting to, in particular, approximately US$4.3 billion for Canada and US$3.5 billion for China. In Canada, for example, there were declines in the output of the air transportation and accommodation industry of 14% between March and May 2003 and accommodation output fell by 8%.

These effects present compelling evidence that reasonably large-scale population behavior changes took place at the time of SARS. Some of this behavioral change may have been fear driven in order to avoid infection, and other changes may have been in response to the World Health Organization directive cautioning against travel to infected regions. It is also possible that some effects were attributable to an increased fear of travel at the time of the Gulf War, which highlights the potential uncertainties of retrospective macroeconomic analysis. The pros and cons of this approach are discussed in the following paragraph.

The advantage of retrospective macroeconomic estimation is that it is based on real data and is, therefore, not limited by assumptions as are modeling studies. However, there are three main limitations with this approach. The first, as has already been mentioned, is the confounding influence of other

significant sectoral or macroeconomic effects occurring at the time of the event being analyzed. The second is the limitation imposed by data availability. National statistics data can take time to reach the public domain, often in excess of 3 years, and this imposes considerable delays on effect estimation. Finally, and perhaps most obviously, such analysis cannot be used for prospective estimation and policy analysis, which brings us to consideration of an alternative tool.

Prospective Macroeconomic Modeling

Prospective modeling is very different from retrospective estimation. Macroeconomic models are usually based on real economic data and parameterized using either econometric estimation or calibration. Modeling scenarios are an essential element of macroeconomic modeling. These scenarios are designed to reflect the policy under analysis, including any investment required to accomplish an intervention or policy change, instruments (such as tax changes) to accomplish the policy goal, and, perhaps most importantly from our perspective, the health effects implemented through changes in labor supply to the economy.

Macroeconomic modeling is strong on the issues which are not well addressed by retrospective analysis. It is used for predictive purposes and is able to isolate the specific effects of the policy under analysis. Conversely, it is limited by the scenario design and, as with any modeling exercise, is limited by the validity of the assumptions underlying the scenarios and the model itself. However, most importantly, macroeconomic modeling is able to capture the wider whole-economy effects of communicable disease, particularly those properties of infectious disease outbreaks previously mentioned, which cannot be captured from the microeconomic perspective.

Several macroeconomic studies have been conducted to estimate the cost of infectious disease outbreaks. It is neither possible nor necessary to mention all these results in this brief article, but some results which highlight the importance of the macroeconomic approach to infectious disease impact evaluation will briefly be presented.

Labor Supply Effects

The computable general equilibrium (CGE) method is an important approach to macroeconomic modeling. It consists of a system of equations which specify the behavior of economic 'agents' in an economy and calibrates them on the basis of real economic data for a given country or region. For example, the agents include firms (who combine resource inputs to maximize profits), consumers (who consume and save to maximize their welfare), government, and foreign agents. Using this approach, it is possible to compare the economic impact of counterfactual (do nothing) scenarios with scenarios which reflect changes in health and policy. Several studies have designed scenarios which consider the labor supply effects of pandemic illness alone. In particular, the UK studies use two different models: the COMPACT model of the UK and the CGE approach. The models' scenario designs differ slightly, but estimates of the GDP loss from labor supply reductions due to morbidity and mortality vary between approximately 0.2% for mild disease and up to 1% for severe disease. The scenario designs differ in their assumptions concerning school closure duration and the effect of that school closure in mitigating the outbreak, but all studies highlight that the economic impact of school closure alone is likely to impose equivalent or greater additional economic loss than the disease only effects.

Behavioral Change Effects

There may be many ways in which behavioral change can be mirrored using macroeconomic models. Two examples of this in published studies are work avoidance due to fear of infection relating to the labor supply and changes in consumption. In one article, prophylactic absence from work was modeled as an effect triggered in an individual by the knowledge that someone in their social network has died from the disease. The authors estimated the size of the average social network to be approximately 300 people, and by modeling disease scenarios of differing severity and interventions (vaccination) of differing efficacy, they were able to highlight the potentially much greater economic impact of a fear-induced response to avoid work compared with the disease only effect. The scenarios modeled showed that by avoiding a behavioral response to an outbreak, the potential value of interventions to prevent this harmful economic response might be greater than the value of the health effects alone, and had fear been the driver of behavioral change, the mortality rate of an outbreak might have a more significant effect than the number of people infected.

Changes in consumption based on the survey mentioned earlier have been captured in a macroeconomic modelling study. The modeling scenarios mirrored the postponement of purchasing luxury items: a 50% postponement of clothing purchases and an 80% postponement of goods and services. Some additional purchases were lost rather than postponed: 50% of car and service use and 30% of recreation and culture purchases. These consumption impacts contributed a first-year GDP loss increase of approximately 2% of GDP, which was 10 times the impact of mild disease alone. Although the degree to which this consumption change may take place is questionable, the ability to capture these macroeconomic effects and contrast them with the health effects demonstrates the strengths of macroeconomic modeling in the context of communicable disease.

Accuracy of Macro Models

As has been previously mentioned, the accuracy of macroeconomic models depends crucially on the modeling assumptions used. Furthermore, because macroeconomic models are designed for predictive purposes to isolate the economic effect of an event assuming all other things remain the same, it can be difficult to assess prospectively the validity of such models. However, immediately following the SARS outbreak, two macroeconomic modeling studies were published. One used the results of a CGE model designed to predict the impact of the SARS outbreak based on a 6-month

duration and capturing the changes to consumer demand and confidence in the future (investment implications). This model predicts a 2.63% GDP loss for Hong Kong and a 1.05% loss for China. The China loss, in particular, would be difficult to distinguish in such a rapidly growing economy, but the predicted GDP loss was approximately US$4.15 billion, which is similar to the approximate US$3.7 billion obtained by retrospective estimation from national statistics. Similarly, the other post-SARS study estimated the impact of SARS to vary, depending on its duration, to be between 0.2% and 0.5% for China, which would, again, be difficult to distinguish and which agrees with the retrospective study's suggestion of 'no evidence of a loss.' The estimate for Hong Kong was between 1.8% and 4% or US$3–6.6 billion, which again contains the retrospective estimate. Although this is not proof of the accuracy of macroeconomic models, it provides some evidence of their usefulness in the context of communicable disease modeling.

Conclusion

Evidence suggests that the economic cost of communicable disease, particularly infectious disease outbreaks, is more than the sum of its direct health effects. Interactions between various sectors of the economy, and the processes of combining factors of production and the externalities asociated with communicable disease, indicates that a whole economy, or a macroeconomic approach to economic analysis, is of great importance and is unlikely to equate to the 'societal' cost, which is estimated by scaling up microeconomic data. Therefore, although the detailed health sector or microeconomic approach remains very important for cost-effectiveness and cost-benefit analysis in general, it is important to remember that the health sector and its patients are inextricably linked to the wider economy and those wider economic effects must, therefore, be captured using appropriate tools such as macroeconomic analysis and modeling. By doing so, the wider implications of communicable disease and related policies can be assessed beyond the health sector at a population and economy-wide level.

Glossary

Attenuation It is the reduction in the absolute value of a regression parameter estimate when adding variable to (or otherwise changing) the model.
Bias It is a systematic error in the estimates of an econometric or statistical model.
Confounding factors These are outside factors that are not controlled for but influence the dependent variable.
Dynamics It is the adjustment process when moving from one equilibrium value to another.
Elasticity It is the percentage change in one variable expected due to a 1% change in another variable.
Fixed effect estimate It is a method of estimating parameters in longitudinal data that focuses on deviations from within-group means.
Gross domestic product The total monetary value of all finished goods and services produced in a county in a given year.
Health capital It is the level of health as conceptualized from an investment process resulting from previous flows of health investment and depreciation.
Human capital These are the skills embodied in an individual resulting from training, education, and experience.
Morbidity It is an illness or health condition.
Neonatal mortality These are the deaths within the first 28 days of life.
Nonstationary It is an economic series that has a systematic change (usually over time) in the mean or variance.
Procyclical A condition of moving in the same direction as the overall state of the economy.
Regressors (controls) It is a right-hand side variable in a regression model.
Time price The value of the time required to obtain a good or services.
Time series It is a sequence of data points, measured typically at successive times.

Introduction

The first evidence of mortality being procyclical had been provided by Ogburn and Thomas during the 1920s – procyclical means increasing in good economic times and falling during periods of decline. Additional confirmatory analysis was supplied by Eyer during the 1970s. Nevertheless, until the preceding decade, the conventional wisdom was that health and macroeconomic conditions were positively related. A variety of analyses had been conducted by the strongest adherent of this view, Brenner (1979), who suggested that overall mortality, infant deaths, and fatalities from a variety of sources (including cardiovascular disease, suicide, and homicide) increased during economic downturns, and that morbidity, alcoholism, and admissions to mental hospitals also grew during such periods.

The view that health and economic conditions must be positively related probably rests more on strongly held prior beliefs than convincing evidence. Even a cursory look at the data raises doubts about whether this is necessarily the case. For instance, Figure 1 shows the relationship between detrended age-adjusted total mortality and unemployment rates in the US, from 1980 to 2007 (both transformed to have a mean of zero and a standard deviation of one). The two data series are close to being mirror images of each other. For instance, normalized unemployment rose rapidly during 1980–82, 1989–92, and 2000–04, whereas mortality was declining faster than its long-term trend. Conversely, improvements in economic conditions during 1983–89 and 1992–2000 were accompanied by smaller than usual declines in mortality (or even increases in some years). Such relationships need not be causal but they do suggest that skepticism is warranted with regard to the conventional belief that health improves during good economic times.

Time-Series Analyses

Research conducted before the beginning of the twenty-first century for examining the relationship between macroeconomic conditions and health, typically used a lengthy time series of data aggregated over an entire country. For instance, Brenner's influential research had utilized data from the US or the UK, covering a four-decade period beginning in the 1930s.

The typical model estimated in these types of analyses is some variation of:

$$H_t = \alpha + X_t\beta + E_t\gamma + \varepsilon_t \quad [1]$$

where H is the health or mortality outcome, E is the proxy for macroeconomic conditions, X is a set of supplementary controls, and ε is an error term. More complicated specifications are often estimated including, for example, lags of the macroeconomic variables or detrended values of the dependent and some independent variables. However, this does not change the basic nature of these estimates. The coefficient of key interest $\hat{\gamma}$ will be biased if $\text{cov}(E_t,\varepsilon_t) \neq 0$, which occurs if there are important uncontrolled for confounding factors. This will frequently be a significant problem because any long time series is likely to have omitted factors that affect health and may be spuriously correlated with economic

Figure 1 Unemployment and mortality rates, 1980–2007. Mortality and unemployment rates are detrended (using a linear time trend) and normalized to have a zero mean and standard deviation of one.

conditions. For instance, unemployment declined dramatically after the 1930s, when the Great Depression ended, but mortality decreased at the same time due to improvements in nutrition and in the availability of antibiotics. Failure to control for these causes of better health leads to an overestimate of the detrimental effects of poor macroeconomic conditions.

Presumably because of these issues, time-series studies have arrived at mixed conclusions, with the results being sensitive to the countries, time periods, and proxies for health analyzed. Recent time-series analyses attempt to correct for some inherent in earlier studies, for instance, using statistical rather than ad hoc procedures to model the effect of lags in economic conditions, and correcting for nonstationarity in the data. These innovations do not, however, resolve the basic shortcoming of using a single time series and the results remain ambiguous, although most frequently suggesting that economic downturns are associated with lower mortality.

Estimation Using Pooled Data

One solution to the problem of omitted time-varying confounding factors is to estimate models using pooled data containing time-series information for multiple geographic areas. A key advantage is that, if economic conditions evolve at least somewhat independently (across locations), this geographic heterogeneity can be utilized to control for time-varying confounding factors that have a common influence on health (across locations) at a point in time. An example is the development of widely disseminated new medical technologies for the improvement of health.

These analyses may use aggregate data (such as total or cause-specific mortality rates) or individual-level information, but with the macroeconomic proxies referring to the area and not the person. In the first case, the typical estimation model is some modification of:

$$Y_{jt} = \alpha_j + X_{jt}\beta + E_{jt}\gamma + \lambda_t + \varepsilon_{jt} \quad [2]$$

where Y_{jt} is a health outcome or input in location j at time t, E is the proxy for macroeconomic conditions, X indicates supplementary controls, α is a geographic area-specific fixed effect, λ a general time effect, and ε is the regression error term. The corresponding specification being used with individual data is:

$$Y_{ijt} = \alpha_j + X_{ijt}\beta + E_{jt}\gamma + \lambda_t + \varepsilon_{ijt} \quad [3]$$

where i indexes the individual and some of the X variables may be at the person rather locality level.

In eqns [2] and [3], the location-specific 'fixed effects' (α_j) account for all health determinants that vary across geographic areas but are stable over time. For instance, this could include persistent differences in health behaviors (Victor Fuchs' provides the classic example of disparities in lifestyles between residents of Nevada and Utah), road conditions (that affect traffic fatalities), or medical facilities (e.g., the presence of tertiary-care hospitals). The time effects (λ_t) control for health determinants varying over time uniformly across locations. This includes many innovations in medical technologies, as already mentioned, and also other factors such as national trends in eating habits. Factors that vary within locations over time are not accounted for, but this is often, at least partially, remedied by including controls for location-specific time trends.

The macroeconomic effects are then identified by comparing changes in within-locality health, behaviors, or mortality outcomes, as a function of within-locality changes in macroeconomic conditions (controlling for general time effects). This procedure exploits the fact that local economies are less than perfectly correlated. For example, California's unemployment rate rose much more rapidly from January

of 2007 to January of 2010 (from 5.4% to 13.2%) than that of either Texas (from 4.8% to 8.6%) or New York (from 5% to 9.4%).

A potential shortcoming of this procedure is that national changes in macroeconomic conditions are absorbed in the vector of time variables. Thus, the effects of localized rather than national variations in economic performance are identified and the two need not be exactly the same. Some researchers have addressed this issue by using similar estimation techniques but with data pooled across countries (rather than regions within countries), although this raises questions about generalizability of the results because institutions exhibit substantial cross-national variation.

Researchers have most frequently used unemployment rates as the macroeconomic indicator, although other measures (such as deviations of gross domestic product from trend or the percentage of the prime-age population employed) have sometimes been utilized. However, it is important to realize that these estimates do not measure the effects of an individual becoming unemployed or changing labor market status per se – which is often the focus of epidemiological studies – but instead, these rates are used as a broader marker of economic conditions. It is possible for average health to improve during economic downturns, even when there are negative health effects on those who lose jobs.

Supplementary controls vary but frequently include age, education, and race/ethnicity, with more detailed sets of regressors being generally incorporated into models that are estimated using individual-level (rather than aggregated) data. Incomes are often also included as right-hand side variables but the results must be interpreted with care, because a portion of the macroeconomic effects may operate through changes in incomes. Similar issues arise when controlling for health behaviors (like smoking or physical activity) or medical care utilization, because these may be correlated with health, but partially determined by economic conditions. A variety of methods have been used to examine dynamics of the adjustment process such as, for example, adding lags of the macroeconomic proxies to the model and simulating the effects of either temporary or lasting changes in economic conditions.

Mortality is Procyclical

Research using the longitudinal methods just described in Section Estimation Using Pooled Data has most commonly examined mortality rates. Deaths are of obvious importance because they constitute the most severe negative health shock. They are also objective and well-measured indicators of health that do not require access to the medical system for diagnosis. However, the cause of death may be measured with error, and fatalities do not capture the effects of some health problems (e.g., arthritis) that are either unrelated or only weakly related to mortality.

In a particularly influential study published in the May 2000 issue of the *Quarterly Journal of Economics*, Ruhm had examined how total, age-specific, and cause-specific mortality varied with economic conditions (primarily proxied by unemployment rates) for the 50 US states and District of Columbia over the period 1972–91. Key results, summarized in Table 1, indicate that a one percentage point increase in state unemployment rates was predicted to reduce the total fatality rate by 0.5%, corresponding an unemployment elasticity of mortality equal to −0.04. The strongest responses were for traffic deaths, other accidents, and homicides – declining by 3.0%, 1.7%, and 1.9%, respectively – but significant reduction are also estimated to occur for deaths from cardiovascular disease (0.5%), influenza or pneumonia (0.7%), and liver ailments (0.4%). Infant and neonatal mortality were also expected to fall but there was no change found for cancer deaths, whereas suicides were estimated to increase. Interestingly, although the strongest effects had occurred for relatively young adults (where mortality is predicted to fall by 2.0%), substantial reductions were also predicted for senior citizens, who rarely worked.

Following the publication of Ruhm's article, researchers have used similar methods to examine how economic conditions are related to mortality in various countries and regions of the world. These analyses include studies of 16 German states between 1980 and 2000, 50 Spanish provinces from 1980 to 1997, 96 French departments from 1982 to 2002, 13 EU nations from 1977 to 1996, and 23 Organization for Economic Co-operation and Development (OECD) countries from 1960 to 1997. Virtually, in all of these studies, it has been found that total mortality and motor vehicle fatalities decline when economic conditions worsen, with the estimated elasticities being generally similar in size or larger than those found in the US.

Deaths from cardiovascular disease are also found to fall as the macroeconomy weakens, in most studies examining them, and a procyclical pattern of deaths from influenza or pneumonia is also generally obtained. In contrast, as in the US, cancer fatalities are generally (but not always) unrelated to the state of the economy. These results are plausible. For example,

Table 1 Predicted effect of 1% point increase in state unemployment rate

Type of mortality	*Predicted change (%)*	*Standard error (%)*	*Type of mortality*	*Predicted change (%)*	*Standard error (%)*
All deaths	−0.5	0.1	Heart disease	−0.5	0.1
20–44 year olds	−2.0	0.2	Cancer	0.0	0.1
45–64 year olds	0.0	0.1	Flu/pneumonia	−0.7	0.2
≥65 year olds	−0.3	0.1	Liver disease	−0.4	0.2
Vehicle accidents	−3.0	0.2	Infant deaths	−0.6	0.2
Other accidents	−1.7	0.2	Neonatal deaths	−0.6	0.2
Homicide	−1.9	0.4	Suicide	1.3	0.2

Source: Estimated provided in Ruhm, C. J. (2000). Are recessions good for your health. *Quarterly Journal of Economics* **115**(2), 617–650.

it seems likely that deaths from coronary heart disease will induce more responsive changes in modifiable health behaviors and environmental risks than cancer fatalities. Results have been more mixed when considering mortality due to liver disease, suicide, or homicide – with predicted increases when the economy strengthens in some analyses and decreases in others.

There is some indication that macroeconomic conditions have weaker effects on mortality in countries with strong social safety nets. The results for infant and neonatal mortality also appear to differ across institutional environments, with evidence of strong procyclical variations being obtained for the US, but not for Germany or when OECD countries are the unit of analysis.

Although most research has been for the US or Western European nations, this is starting to change. Recent studies have examined data from eight Pacific Asian nations during 1976–2003 and from 32 Mexican states between 1993 and 2004. The results from Asia largely mimic those obtained for the US, with the prediction of a substantial procyclical variation for total mortality and deaths from traffic accidents or cardiovascular disease, but with (insignificant) countercyclical variation for suicides. The results for Mexico are particularly interesting. The overall findings again indicate that deaths from all causes and most specific causes of mortality (including cancer deaths but not suicides) decline when the economy weakens. However, these patterns pertain to wealthy states only, with mortality in poor states exhibiting a countercyclical fluctuation. Given the wide income disparities between rich and poor Mexican states, such results are consistent with temporary improvements in macroeconomic conditions worsening average health in wealthy areas but improving it in poor ones. The latter finding is anticipated because the marginal benefits of income are likely to be exceedingly high when incomes are very low.

Other Measures of Health

There has been less study of how macroeconomic conditions are related to other measures of health, largely because data useful for examining this issue are harder to come by. Using information from the 1972 to 1981 waves of the National Health Interview Survey (NHIS), one study had found that adult morbidity declined when economic conditions weakened, with larger reductions in acute than in chronic medical conditions. Restricted-activity and bed-days also became less common and there were relatively large reductions in the prevalence of ischemic heart disease and certain back problems. However, this study has provided evidence that nonpsychotic mental disorders increased during such periods which, when combined with prior findings of a procyclical variation in suicides, suggests that mental health may decline during periods of economic deterioration despite the improvement of physical health.

Consistent with the possibility that individuals would become (physically) 'healthier but not happier' during downturns, a study of more recent (1997–2001) NHIS data revealed that the mental health of African-American and less-educated males declined when the economy weakened. Another analyses of 10 years of data (1984–93) from the Panel Study of Income Dynamics had revealed that average self-assessed overall health status fell when local unemployment rates increased and that these effects were largely driven by psychological rather than physical factors.

Changes in Behaviors and Use of Medical Care

There is improvement of physical health during bad economic times because healthier lifestyles are adopted by individuals. Alcohol sales and drunk driving vary procyclically and most research has also indicated that alcohol consumption, dependence, and heavy drinking decline when the economy weakens. However, the evidence from individual-level data is more ambiguous, with one study obtaining the contradictory result that binge drinking increases, whereas overall and heavy drinking fall; another finds an increase in alcohol use among teenagers during such periods. Finally, data for Finland provides some evidence of a countercyclical variation in certain categories of alcohol-related deaths between 1975 and 2001; however, the reverse pattern is observed for the period surrounding the extreme downturn of the 1990s and there is again evidence obtained for a procyclical pattern of overall drinking.

Other behaviors also become healthier when the economy weakens. Analysis of data of the Behavior Risk Factor Surveillance System (BRFSS) from 1987 to 2000 has indicated that severe obesity, tobacco use, and multiple behavioral risk factors decline in bad economic times, whereas physical exercise increases. Further evidence of a procyclical variation of obesity has been obtained from an analysis of the BRFSS during 1984–2002 and in smoking and physical inactivity from a study of 1976–2001 data from the NHIS. There is also an indication that diets become healthier during bad times, although relevant data are inadequate to state this with confidence. Also, less alcohol is consumed by pregnant women during such periods and their sleeping span (which has beneficial impacts on health) increases. However, the lifestyle changes need not be uniform across countries or population groups. For instance, there is some evidence of a countercyclical variation in obesity for African-American men and possibly for Finnish adults.

Better health during downturns is not the result of greater use of medical care – the utilization of most (but not all) types of medical services declines in such periods. Specifically, there is a reduction in routine medical checkups and doctor visits, screening tests, and hospital episodes. This is probably partially due to reductions in employer-provided health insurance, but may also reflect improvements in health itself. Nor are these effects uniform. For instance, there is evidence that advanced treatments for heart disease (like coronary bypass and angioplasty) become more common in bad times and that pregnant women receive earlier and more frequent prenatal care in such periods.

Sources of Countercyclical Variations in Health

As already been mentioned, one reason for health improvement during bad economic times is the adoption of healthier

lifestyles. Some of this change probably occurs because of increased availability of nonwork time during such periods, which is important because activities such as exercising and preparing meals at home are relatively time intensive. Consistent with this is the evidence that higher time prices are correlated with increases in tobacco use and reductions in exercise and socializing. However, there are other reasons why health is being countercyclical. For instance, hazardous working conditions, physical exertion of employment, and job-related stress may all increase during economic expansions, as working hours and pace of jobs rise. Moreover, employment growth during such periods is particularly large in the construction and manufacturing sectors, which have relatively high rates of work-related accidents, and these risks are amplified by the relatively higher presence of inexperienced workers. Incomes also rise during economic booms, which help to explain the rise in risky activities such as drinking and smoking. However, the direct effect of income as estimated for mortality and other health behaviors is often mixed, with a protective impact being often observed for morbidity and functional limitations.

Health may also decline when the economy improves because the former is an input for temporary increases in the output of the latter. As already been mentioned, many individuals will be required to work harder or longer in expansions, and joint products of economic activity – like pollution, driving, and traffic congestion – present further health risks. These latter effects are not limited to persons directly involved in the labor market conditions, but instead, they may frequently be concentrated among those with health vulnerabilities, like senior citizens or infants. Such groups may also be strongly though indirectly affected when care-giving behavior among prime age individuals is modified by increases in the work-hours of their employment or by their geographic migration in search of better employment opportunities.

Relatively strong procyclical fluctuations in mortality for senior citizens were documented and discussed in Section Mortality is Procyclical (**Table 1**), providing evidence of such indirect effects. An in-depth analysis of this same issue has recently been conducted by Miller *et al.* (2009) using data from the Centers for Disease Control and Prevention Multiple Cause of Death Files covering 1978–2004. They have confirmed that there is a strong pattern of procyclical mortality for young adults (18–35 year olds), but have also shown that death rates rise strongly in good times for children (0–17 year olds) and senior citizens, particularly those aged 80 years and above. In contrast, the fatality rates of 35–54 year olds are little affected by macroeconomic conditions. They emphasize the role of factors other than 'own work behavior' (like changes in pollution or the quantity, quality, and nature of health care) as potential mechanisms for explaining these results.

Caveats and Uncertainties

Two important caveats should be kept in mind when interpreting the preceding discussion. First, that the macroeconomic fluctuations so discussed refer to transitory rather than permanent changes in economic conditions. Evidence of physical health improving during transitory downturns should not be taken to imply that permanent economic progress has negative effects. A key distinction is that temporary increases in output can only be obtained by using inputs (including health) more intensively given existing technologies. In contrast, permanent growth results from a combination of technological improvements and expansions in the capital stock (including human capital) that would generally result in higher levels of both economic output and health. For example, there is clear evidence that economic development among previously impoverished countries yields health improvements (although there is less indication of corresponding effects among already industrialized nations).

That said, additional study is needed to determine how long economic growth must be sustained before the initial negative consequences for health turn positive. Previous research permitting such dynamics has generally found that the effects of sustained changes in economic conditions usually accumulate for at least 1 or 2 years, consistent with models where flows of health capital gradually affect overall levels of health, resulting in larger increases in the medium term than initially. Attenuation in the predicted health effects of longer lasting changes in the macroeconomy is observed for some outcomes or studies, but not for others and further investigation of this topic is needed.

Several other uncertainties could be resolved by further research. Generally, one has more understanding of how the macroeconomy affects health than of the mechanisms for these effects. It is particularly important to obtain estimates of the role of environmental risks and other factors (like care giving) that are not directly related to an individual's own labor market experience but may influence health. Data limitations also make it harder to study consequences for mental health and morbidity than it does for mortality, although progress in these areas is being made. How the health effects of macroeconomic conditions vary across institutional environments and levels of economic development are also begun to be learnt, but additional study is required.

Managed Care

JB Christianson, University of Minnesota School of Public Health, Minneapolis, MN, USA

Introduction

This article addresses the general topic of 'managed care,' which Kongstvedt, author of the standard reference on the topic, has characterized as "…..regrettably nebulous" but "… at the very least, … is a system of health care delivery that tries to manage the cost of health care, the quality of that care, and access to care. Common denominators include a panel of contracted providers that is less than the entire universe of available providers, some type of limitations on benefits to subscribers who use non-contracted providers (unless authorized to do so), and some type of authorization or precertification system" (p. 807). He further observes that "Managed health care is actually a spectrum of systems…" (p. 807). To complicate matters, the structure of managed care organizations (MCOs) has evolved over time, reflecting the efforts of MCOs to respond to the demands of employers and public programs that offer health benefits to their employees and participants.

This article describes the evolution of managed care over the past 35 years. To provide a context for that description, it begins with a review of basic findings from agency theory as they apply to MCOs. It then describes the way in which managed care and MCOs have evolved over time, focusing on three different managed care 'eras'. In each era, it reviews the empirical evidence regarding the effect of the financial mechanisms and utilization control techniques being used by MCOs to control costs, as well as the evidence of a 'competitive impact' of MCOs. The article concludes by discussing the current state of managed care. Although elements of managed care are evident in the health care systems of many different countries, this article focuses on the managed care experience in the United States.

Managed Care Organizations: A 'Nexus of Contracts'

In the United States, MCOs contract with private sector employers and government programs to manage the health benefits of their employees or program enrollees. To a lesser degree, MCOs also contract directly with individuals to provide health insurance coverage. As organizations, the revenues of MCOs depend on their ability to satisfy the demands of their purchaser-customers. As long as there are alternative MCOs, unhappy customers can decide not to renew their existing contracts, by seeking alternative MCOs that better meet their demands. In this article, the term 'purchasers' is used to refer to employers and government programs.

Typically, the core services that purchasers contract with MCOs to deliver include (1) establishing and managing a 'provider network' through contracts with providers that specify payment arrangements and provider participation in utilization management activities, (2) paying provider bills for their services, and (3) enforcing coverage limitations. In their contracts with employers, MCOs may assume risk for medical care costs (and purchasers pay 'premiums' to MCOs) or purchasers may retain 'medical risk' (in which case 'self-insured' purchasers pay administrative fees to MCOs for obtaining services). In addition to these 'basic' services, MCOs typically offer other programs to purchasers (e.g. related to utilization management or healthy lifestyle management), with program costs being incorporated in premiums or put up for separate payment by purchasers.

Historically, MCOs have responded to purchaser desires to control their health care costs by (1) applying utilization management techniques that cause network providers to substitute less expensive services or sites of care for more expensive ones, (2) negotiating payment arrangements that contain incentives for network providers to control their costs, and (3) simply using their negotiating power to hold down unit prices in provider contracts. At the market level, purchasers also have expected, or at least hoped, that competition among MCOs for their business, or competition among providers for inclusion in MCO networks, would place downward pressure on medical care costs. Some policy analysts have urged purchasers to adopt specific 'managed competition' strategies to encourage this 'cost conscious' competition on the part of MCOs. However, aggressive pursuit of cost control by MCOs has implications for private sector purchasers. Specifically, depending on how they are carried out, MCOs' cost control efforts have the potential to reduce the value that employees place on their health benefits.

Most employers believe that health benefits are an important part of overall employee compensation, and thus more attractive health benefits can help in employee recruitment and retention, much the same as higher wages. Therefore, in their health benefits strategies, employers attempt to balance the potential benefits of aggressive MCO actions to control costs with the benefits of offering attractive compensation to employees. (Economists generally agree that employees care about overall compensation and thus if employer cost control efforts reduce the value employees place on health benefits, labor market pressures will cause wages to adjust upward in order to compensate for this, with little or no overall gain for employers.) Obviously, conditions in the market for labor affect the importance that employers place on benefit attractiveness versus cost containment; when labor markets are tight, offering attractive benefits becomes more important than when they are soft. In the latter case, employers can support aggressive pursuit of cost containment by MCOs with less risk that any associated reductions in the value of their compensation will cause employees to seek other job opportunities or that the firm will fail to attract new employees. Over time, the types of activities pursued by MCOs, and the aggressiveness with which they are pursued, will reflect the weight that employers place on these two goals for their health benefits programs. And, the most successful MCOs will be ones that can modify their organizational

structures, activities, and products effectively in response to changing purchaser demands.

Agency theory provides one conceptual framework for understanding the pressures faced by MCOs and their options for responding to them. MCOs must contract with multiple providers for the delivery of services to MCO members, besides negotiating contracts with purchasers for management of their health benefits. Historically, many MCO contracts with providers have been of the 'contingent claims' nature in that the MCO agrees to pay the network provider a specified dollar amount for the delivery of an uncertain amount and mix of services in the future. This uncertainty can relate to the types and number of people who will seek services in some future period and the nature of their medical needs. It is very difficult to arrive at contingent contracts that are satisfactory as it is impossible to anticipate all possible future events, and one party to the contract (e.g. the provider in MCO/provider contracts) may be able to characterize the state of the world, for contract purposes, in a manner that serves its interests. For example, providers may argue that patients require extensive courses of treatment if paid on a fee-for-service basis, or very limited treatment if paid on a price per person per time period (capitated) basis. The MCO may not be able to determine if the provider did the right thing given the condition of the patient, especially if there is no consensus regarding the appropriateness and efficacy of different treatment options.

Using the language of agency theory, in negotiations with network providers the MCO (the 'principal') attempts to design contracts with financial incentives that reward the provider (the 'agent') for acting in the principal's best interests. However, typical payment approaches in provider contracts (fee for service, capitation) contain relatively strong incentives for behavior that could, at the extreme, be detrimental to the MCO's interests. For example, fee-for-service reimbursement rewards providers for delivering both necessary and unnecessary services to their patients. This could increase costs unnecessarily as well as expose patients to unwarranted medical risks. This being the case, and depending on the information at their disposal, purchasers might seek out MCOs that are able to negotiate provider contracts that minimize these undesirable outcomes. And, MCOs may attempt to incorporate rules and monitoring mechanisms in the contracts with providers that reduce the likelihood of an overaggressive response of the latter to financial incentives. Also, MCOs may seek to mitigate the incentives in 'pure' payment approaches such as fee for service by employing other financial rewards in contracts, such as payments for meeting care process goals (e.g. periodic testing for blood sugar among diabetic patients, not prescribing antibiotics for treatment of upper respiratory infections or reducing use of magnetic resonance imaging (MRI) in first visits by patients with lower back pain). In practice, there are many different so-called 'blended payment' arrangements accompanying the rules and monitoring mechanisms in the contracts between MCOs and providers.

The type of MCO/provider contract that emerges in any specific situation will depend in part on the competitiveness of the provider market. Where there is relatively little competition among providers (e.g. where provider concentration in a given geographic area is high), they could be expected to negotiate more favorable contractual terms. These could include higher levels of payment for services, an assignment of financial risk that more closely conforms with provider preferences, and/or less obtrusive or objectionable MCO monitoring and oversight of provider activities. In contrast, contracts with terms more favorable to MCOs are more likely where provider markets are competitive, and when excess provider capacity exists. Variations in the contracting environment such as these are likely to lead to a variety of contractual arrangements between MCOs and network providers within the same market as well as across geographic markets. And, contractual arrangements are likely to vary over time as well, being influenced by changes in the structure of the markets for provider services of specific types, the competitiveness of the MCO market, and the preferences of purchasers regarding employee health benefits.

Although MCOs are principals in their contracts with providers, they are agents in their contracts with purchasers. That is, the goal of purchasers is to negotiate contracts with MCOs that lead MCOs to act in the purchaser's best interests. If the actions of MCOs do not promote the interests of purchasers, the MCO risks incurring financial penalties (e.g. the MCO pays for medical care costs above a contract-determined amount) and/or may not have the contract renewed. Different preferences on the part of purchasers in different markets for specific outcomes (e.g. containment of specialist expenditures, avoidance of provider 'never events,' managing care for people with specific chronic illnesses) are likely to be reflected in different terms in MCO contracts with providers. Changes in purchaser preferences are likely to precipitate changes in MCO/provider contracts over time.

Evolution of Managed Care Organizations

MCOs have evolved over four decades from distinct organizations offering a single product is characterized primarily by (1) a restricted, relatively narrow, network of providers with severe penalties for out-of-network use, (2) financial arrangements that shared substantial risk with contracting providers, and (3) aggressive efforts to control utilization, to organizations that offer purchasers a choice of benefit designs for employees, most of which have (1) extensive provider networks and weaker financial incentives discouraging out-of-network use, (2) less financial risk shared with contracting providers, and (3) much more limited, targeted efforts to control utilization. This section describes this evolution of managed care in the United States, focusing on three different periods. In each case, it summarizes evidence on the use and impact of incentives and rules in MCO/provider contracts, and the market-level effects of managed care. The recurring theme in this narrative is how the changing demands of employers and their desires regarding MCO performance have shaped the evolution of managed care. Essentially, this evolution, being wedded to changes in the provider environment, has reduced the potential for MCOs to control purchaser costs through aggressive utilization management and price negotiation with providers. As a result, the role that MCOs are asked to play as agents of purchasers has changed in fundamental ways. Despite still being referred to as MCOs, many of these

organizations arguably no longer conform even to relatively broad definitions of managed care.

Early Stages of Managed Care Organization Development

Before World War II, there were a small number of organizations available to purchasers in some geographic areas that fit the definition of managed care. In particular, these organizations offered limited networks of providers at a lower cost to purchasers than conventional indemnity insurance. MCOs of this type (e.g. consumer cooperative prepaid group practices) had remained a relatively minor, but growing, component of the health insurance market in the United States until the early 1970s, when Congress passed the HMO Act. In addition to introducing the term 'Health Maintenance Organization (HMO)' into the health insurance lexicon, the Act focused employer attention on HMOs as alternatives that offered better benefit coverage at a potentially lower cost than traditional insurance.

The number of MCOs that met the legislative definition of an HMO grew steadily through the 1970s, so that by 1980 there were 236 HMOs with a total enrollment of approximately 9 million people. Over the next 6 years, however, enrollment grew dramatically to 25.7 million members in 626 HMOs. In particular, MCOs with more extensive but less integrated provider panels (IPAs), and often sponsored by local or state medical societies or Blue Cross/Blue Shield plans, emerged as competitive responses to HMOs with more restrictive provider panels. Most new HMOs during the early 1980s were IPA model plans that national HMO firms had established in local markets.

Large employers typically offered one or more HMOs as health benefits options alongside traditional plans, hoping to benefit from HMO presence in two ways: (1) some employees might choose to enroll in lower cost HMOs, accepting a more limited selection of providers and some restrictions on unfettered access in return for better coverage, and (2) the loss of enrollees to HMOs might stimulate other health insurers to more aggressively control their costs. Some policy analysts encouraged purchasers to leverage this new situation by contributing an amount equal to (or proportionate to) the cost of the lowest option toward whatever option the employee chose, with the employee paying the balance. The premise of this 'managed competition' model was that at least some employees would switch to the lower cost options, low cost plans would be rewarded with more revenue, aggressive price competition among HMOs and traditional insurers would ensue, and both employer and employee benefit costs, or at least cost increases, would be moderated.

The argument that HMOs would have lower costs than traditional insurance options rested on three premises. First, they were expected to be able to influence provider use of services because, with relatively limited plan networks, network providers received a substantial portion of their revenues from HMO contracts. Second, again because of the greater reliance of providers on specific HMOs for revenue, HMOs would be able to negotiate contracts that placed providers at risk (to some degree) for costs exceeding expectations, creating incentives for providers themselves to more effectively manage costs. And third, HMOs would be able to exercise their negotiating leverage to hold down provider unit prices.

From the beginning, there was disagreement among policymakers and in published research findings concerning whether lower costs reported for HMO enrollees were entirely the result of more effective utilization management and/or the negotiating power of MCOs. Some studies found that, when employers offered employees a multiple choice of benefit options, relatively healthy employees were more likely to choose HMO options. When offered a choice from among HMOs of different types, healthier enrollees were more likely to choose HMOs with more restrictive networks. Even so, research before 1980 did suggest that HMOs reduced the use of high cost treatment settings, especially hospitals, although more loosely organized HMOs (IPAs) were less effective in doing so. In a widely cited study by the RAND Corporation, hospital admissions in a single HMO were 40% less than in traditional fee-for-service insurance, and costs were 25% less. Research on the impact of specific utilization management techniques used by HMOs during this time period was relatively limited. However, one study reported that utilization review in hospitals reduced hospital expenditures by 12% for a sample of employer groups from 1983 to 1985. Others found similar results for use of inpatient review by BCBS plans.

Not all of the early research evidence supported the ability of MCOs to reduce costs of care or costs incurred by purchasers. For instance, a study of a single HMO found evidence that lower utilization of resources for some procedures was not always reflected in lower overall costs. Other research suggested that how physicians were paid was a key factor in explaining differences in findings for different types of HMOs. An analysis of Illinois HMOs between 1985 and 1987 concluded that providers reimbursed by HMOs using fee for service had higher rates of use of inpatient care and physician visits than those reimbursed by HMOs using other methods, except that the use of individual physician bonus payments resulted in lower utilization. Similarly, other research reported that physicians paid on a capitated basis in IPA type HMOs had service utilization rates which were comparable or lower than in group or staff model plans. This is consistent with general findings from multiple studies, indicating that reimbursement arrangements such as those placing providers at some degree of financial risk can reduce utilization of services.

There was also evidence that competition among HMOs for purchaser contracts occurred during this early period, with several studies describing competitive market dynamics that were stimulated by the development of HMOs in some geographic markets. Other studies sought evidence of an empirical relationship between HMO market presence and premiums of competing insurers, but these efforts were handicapped by the relatively low market penetration of HMOs in most communities.

Notwithstanding evidence of competitive behavior on the part of HMOs, the degree to which any real 'savings' generated by HMOs were passed on to purchasers in the form of lower premiums (for employers that were not self-insured) became a matter of dispute during this early stage of MCO development. HMOs were accused of 'shadow-pricing' traditional insurers, generating profits that were used for expansion. It was argued

that this was possible because most employers did not adopt a 'managed competition' model, choosing instead to cover the entire cost of whichever option the employee chose, or to employ a contribution strategy that substantially subsidized higher cost options. This weakened incentives for HMOs in to compete by offering lower prices to purchasers. Some purchasers may not have adapted a managed competition model because it would result in substantially higher contributions for those opting to retain their traditional insurance, thus resulting in dissatisfaction on the part of these employees with their health benefits.

The Golden Years for Managed Care

By the mid-1980s, HMOs (IPA and closed panel plans) had grown dramatically in number and enrollment. This growth continued from 1985 to 1995, with total HMO enrollment (including point of service (POS) HMOs, see below) increasing from 18 million to 58 million, and the number of HMOs from 381 to 571, peaking at 695 in 1987. From 1985 to 1992, 155 HMO mergers occurred, as well as 152 failures. In an attempt to better understand the changing HMO landscape, several studies examined the causes and impacts of HMO mergers. They found that profit-seeking HMOs seldom absorbed nonprofit HMOs in mergers, and premiums were relatively unaffected by mergers except in very competitive HMO markets, where they were higher, yet only for 1 year postmerger. Mergers did not generally allow HMOs to reach greater scale economies without improved efficiency levels.

Throughout this period, HMOs were offered as options by most large employers and as the only health benefit plan by many smaller employers. The early to mid-1990s marked a period of very low health insurance premium increases; some analysts saw this as the phase of a predictable insurance premium cycle, while others attributed this to the growing enrollment in HMOs and other types of MCOs, as well as their ability to control costs. This generated a significant body of new research on the factors that explained the lower cost of care in HMOs. For instance, a utilization review program instituted by a large national insurer was found to reduce spending on hospital care after 1 year by 8% and total expenditures by 4%. In a study that compared the treatment of heart disease in HMOs and traditional insurance plans from 1993 to 1995, HMOs had 30–40% lower expenditures, with little difference in treatments or health outcomes; the authors attributed the lower expenditures to the lower unit prices paid by HMOs. Trends in the use of outpatient versus inpatient care showed a decline in hospital days per thousand enrollees in HMOs from 1985 to 1995, whereas ambulatory visits per enrollee increased, suggesting that HMOs substituted less expensive for more expensive treatment settings. A review of studies of the use of diagnostic tests in HMOs found that HMO enrollees received fewer diagnostic tests during their inpatient stays than patients enrolled in traditional insurance plans, and did not receive any more tests on an outpatient basis. And, another study found that increases in market share of HMOs were associated with lower MRI availability between 1983 and 1993.

Research conducted during this period found that differences in payment arrangements and practice settings continued to be important in explaining differences in utilization in HMOs. For instance, one study estimated that patients in solo or single specialty group practices, where physicians were reimbursed on a fee-for-service basis, were 41% more likely to be hospitalized than when the group practice received a capitated payment.

A major factor in the growth in MCO enrollment overall (not just HMO enrollment) from 1985 to the mid-1990s was a decision by most large employers to offer Preferred Provider Organizations (PPOs) to their employees. Under this type of MCO, the penalty for seeing a provider outside of the limited network was much less severe than under the traditional HMO (where consumers bore 100% of the cost for services received 'out of network'). Typically, in the PPO model, consumers paid all costs up to a specified deductible level, then continued to pay a share of costs above that level until a specified maximum for consumer expenditures was reached. This design differed from traditional insurance in that the deductible and coinsurance rates were lower if enrollees used 'preferred' providers who agreed in their contracts to be paid set fees and also to participate in the plan's utilization management programs. Providers sought preferred status because they hoped to attract more patients and thereby generate more revenues. Alternatively, they viewed it as a means of protecting themselves against the loss of patients to providers who held preferred provider status. A key to the popularity of PPOs was that consumers could choose between seeing a preferred provider or some other provider at the point of service. By 1995, almost 35 million employees were enrolled in PPOs. HMOs responded to PPO development by devising a plan with similar provider and consumer incentives (the POS HMO), utilizing the HMO network as the preferred providers.

Skeptics doubted the ability of PPOs to effectively control health care costs because they typically reimbursed physicians using a fee-for-service approach, which rewarded provision of more services, and their preferred provider panels were large, presumably making the effective application of MCO utilization management techniques more difficult. However, the relatively modest premium increases of the mid-1990s, which were coincidental with growth in PPO enrollment, seemed to belie those concerns.

The rapid growth during this period in the number of MCOs, the number of national MCOs, and the enrollment in MCOs generated a large body of research addressing the competitive impacts of HMOs. Regarding the relationship between degree of HMO competition and level of HMO premiums, one study found lower premium revenue per HMO enrollee in markets that contained larger numbers of HMOs in combination with a relatively high percentage of the population enrolled in HMOs. Another study found that HMOs had a constraining effect on the premiums of other health insurers at low levels of HMO market penetration despite that premium levels for other insurers were higher at greater levels of HMO penetration. The authors speculated that this could reflect shadow-pricing strategies by HMOs as soon as they had established their market presence.

The impact of HMOs on quality of care was also an important topic of research during this period, that stimulated in part by concerns HMO utilization management policies and payment arrangements shifting risk to providers could have a

negative impact on quality. In general, review articles concluded that there was little support for the concern that HMOs reduced quality. For example, although one study found a negative effect of HMO competition on quality of care indicators relating to treatment of acute myocardial infarction, others found mixed or somewhat positive relationships between measures of HMO competition and quality of care.

As HMO presence grew in some markets, so did the degree of consolidation among hospitals and physician groups, raising concerns of whether HMOs could continue to contain costs by negotiating lower prices for inpatient care for their members. Quantitative analyses found that the increased presence of MCOs in local markets was not a major factor causing hospital mergers, but qualitative evidence suggested that the threat of managed care could have encouraged mergers. Irrespective of the role managed care played in stimulating mergers, quantitative studies found that hospital prices were higher in more consolidated hospital markets. Hospitals in more competitive HMO markets had slower rates of cost growth, but this HMO effect was not significant in highly concentrated hospital markets, suggesting diminished HMO negotiating leverage in consolidated hospital markets.

The Postbacklash Era: Rethinking Managed Care

By the mid-1990s, many large employers had begun to restructure their approaches to health benefits in a way that, arguably, subsequently shaped not just the trajectory of managed care, but the structure of the US health care system as a whole. First, influenced by relatively low premium increases that they attributed to the effective use of financial incentives and utilization controls by MCOs, along with their own savvy health benefits decisions, these employers eliminated their traditional health insurance options, replacing them first by MCOs and, subsequently, by consolidating the number of MCO options offered to employees toward one or two plans. By limiting the number of MCO options, employers hoped that they could reduce their health plan administration costs besides concentrating their purchasing power to achieve more favorable contractual terms with MCOs.

These employer decisions limited employee choice of health benefit options and, in effect, pushed many employees who had valued the flexibility and wide range of provider options offered by traditional health insurance into the more restricted MCO environment featuring both preauthorization for hospital admissions and limitations on referrals to specialists. New MCO members, unfamiliar with these restrictions, had their requests for reimbursement for care from out-of-network providers denied and experienced seemingly arbitrary decisions on the part of MCOs regarding access to care within MCO networks. Their unhappiness was reinforced by growing provider discontent with MCO payments, utilization review and other practice restrictions. The result was 'managed care backlash' that varied in its severity across different markets – less in areas where HMOs were well entrenched with a large market share, and more intense in markets where a large proportion of the population was affected by employer elimination of traditional insurance options.

In effect, purchaser attempts to capture a larger share of the presumed cost savings from enrolling employees in MCOs have resulted in a devaluation of health benefits for some employees. Although much of the anger of consumers was directed at MCOs, the decisions of employers to drop non-MCO plans too were resented by employees. This backlash came at an exceedingly inopportune time for employers, as the mid-to-late 1990s saw significant economic growth and competition to attract and retain employees. In this environment, employers turned to plans with broad provider networks and freedom for employees to access providers of their choice. MCOs responded by expanding their preferred provider networks, seeking to enroll as many providers as feasible in any given community, and by consolidating nationally. Blue Cross/Blue Shield plans held an advantage in this respect, as they already possessed expansive networks, and their enrollment grew, whereas enrollment in HMOs with limited networks declined or remained stagnant.

These changes had important consequences for the structure of MCOs as well as the subsequent shape of the health care delivery system in communities. MCOs sought to become 'one stop shops' to meet employer desires to minimize contracting and health benefits management costs. Those that had started as a product type (e.g. an HMO) now added other options (PPOs and, later, consumer-directed health plans (CDHP)). This allowed employers to make different benefit designs available to employees within a single contractual relationship with an MCO. MCOs, in losing their identification with a single product, became 'health plans' that offered an array of products to employers in different market segments.

At the same time, MCOs were losing the contracting leverage with providers that they had used to restrain rate increases in the past. Because they had to maintain relatively large provider networks to secure contracts with employers, plans could no longer credibly argue that providers would be rewarded with more patients and revenues if they accepted lower fees as preferred providers. Perhaps more important in the view of some analysts was the fact that providers (especially hospitals and specialty groups) merged in order to enhance their negotiating power, as health plans could not withstand significant 'holes' in their provider networks and yet be responsive to employer demands. Although the impact of managed care growth on provider consolidation is not clear, increased provider consolidation has important implications for employers; it makes it very difficult for their agents – the health plans – to hold down rate increases in contract negotiations or implement effective utilization control strategies. In fact, two studies had found that, post managed care backlash, higher HMO penetration in local markets was no longer associated with lower cost growth. And, research based on consumer surveys conducted in 1996–97 found no difference between HMOs and other insurance arrangements in the use of expensive services, but HMO enrollees reported less satisfaction with their care and less trust in physicians. Also, 2002 data pertaining to New York State suggested that a larger number of HMOs in a local health care market was associated with lower quality of care. Taken together, these findings suggest that the changes made by MCOs to meet employer demands had reduced their ability to contain provider prices or control utilization of services, leading some analysts to declare 'the end of managed care.'

Returning to the past by offering 'narrow network' benefit options in contracts with employers, similar in design to early HMOs, would be difficult for health plans, even assuming that employers were inclined to favor such options. In highly consolidated markets, it would be difficult for health plans to exclude any significant provider system and still offer a product that was valued by employees. And, because health plans now offer multiple products, if they exclude a health care system when forming a narrow network product, they risk the withdrawal of that system from other products that rely on having an extensive network for market success.

Faced with tight labor markets, and with the recent managed care backlash firmly in mind, some large employers began advocating for a new health benefits strategy known variously as consumer-centric benefits, or managed consumerism, or facilitated consumerism. At its core, this strategy focuses on creating cost-containing, quality-enhancing competition among providers for consumers, rather than competition among MCOs for enrollees in a situation where employers offer multiple MCO options. In this environment, MCOs compete for contracts with employers by offering new benefit designs that feature greater employee cost sharing, sometimes accompanied by an employer-funded health savings account, besides maintaining substantial freedom of choice among providers. MCOs are charged with providing employees with cost and quality information necessary to make informed choices of providers. Employers contract with MCOs or freestanding vendors to provide disease management programs, intensive care management programs, and 'healthy lifestyle' programs to their employees. To meet these new demands of their employer-customers, MCOs have attempted to 're-invent' themselves as organizations that encourage and facilitate the efforts of employees to more effectively managed their own health besides promoting cost-containing competition at the 'retail' as opposed to the 'wholesale' level.

By 2008, employers and MCOs had made credible inroads in modifying conventional managed care, by introducing elements of a managed consumerism strategy, although not without controversy. Skeptics argued that new 'CDHP' options offered by MCOs, featuring relatively high deductibles (in comparison to earlier benefit designs of HMOs and PPOs) coupled with health savings accounts, were simply mechanisms to facilitate greater cost sharing on the part of employees, and that MCOs were providing limited and not particularly useful information to employees to assist in the choice of providers. They also expressed concerns that CDHPs would be attractive to relatively healthy or higher income employees, but would increase costs disproportionately for sicker employees, and do little to modify employer costs or the growth in health care costs still more generally. In light of these concerns, and the reality that employers make health benefit decisions only once each year, it took several years for CDHPs to become established health benefit options for employers. However, buttressed by federal government actions that conferred tax benefits on the purchase of one type of CDHP (the 'Health Savings Account' plan) along with the experiences of early-adopting employers, 15% of employers were offering CDHP options to employees by 2010, including 34% of firms with more than 1000 employees, and overall 13% of employees were enrolled in these plans.

Research suggests that CDHP enrollees have higher incomes and are in somewhat better health than employees who do not choose to enroll in CDHPs. Employees who switched to CDHPs spent less on health care and used fewer services, but had lower levels of satisfaction with their plans, used less preventive care, and felt that they lacked sufficient information to make informed choices.

The onset of the worldwide recession in 2008 accelerated the implementation of at least one component of the managed consumerism strategy – increased employee cost sharing. Employers facing significant financial challenges focused their attention on the need to take immediate steps to reduce health care costs. Just as unemployment rates rose, employers too became less concerned regarding the possible impact of health care cost containment efforts on their ability to attract and retain employees. Large employers reduced employee compensation by increasing deductibles and coinsurance rates in PPO and CDHP plans as well as by reducing their percent contribution toward premium costs. For many employers, these actions led to year-to-year rates of increase in their health benefits costs of 5% or less.

Large employers also invested in disease management and healthy lifestyle programs to soften the impact of reductions in benefit coverage and, in some cases, because they believed that employee participation in these programs might reduce employer health benefit costs in the longer term. Targeted disease management programs, which include various utilization management components, are now a standard part of MCO offerings to employers, although the evidence that they reduce costs is decidedly mixed. More recently, MCOs have responded aggressively to employer demands to develop healthy lifestyle programs for employees. These programs reward employees for healthy behaviors and, in some cases, include benefit designs that penalize them for unhealthy lifestyles. In a growing number of case studies, programs have been identified that have favorable short-term returns on employer investments. However, other research suggests that there may be wide variation in the ability of such programs to contain costs.

The End of Managed Care?

Clearly, the concept and reality of managed care has changed substantially since the introduction of the HMO Act almost 40 years ago. Large, closed panel MCOs of the type that once exemplified managed care still exist, integrating health insurance with a health care delivery system. However, even these organizations have become 'health plans' in that they offer a variety of products to employers, including CDHPs and other high deductible benefit designs. And, despite the continued success of some limited network plans, the vast majority of employed Americans now are enrolled in health benefit options featuring broad networks, deductibles, coinsurance, and in relatively few intrusive efforts that manage the delivery of care by contracting providers. This would indeed suggest that the concept of 'managed care' has come full circle, reflecting in large part a response to the changing goals of employers for their health benefits offerings. Health plans now generally avoid the label of MCO, preferring to emphasize their evolving

role in supporting consumers both in choosing providers and engaging in healthy lifestyles.

Although some analysts suggest that 'the end of managed care' has occurred with the adoption of 'managed consumerism' by large employers, others refer to 'the changing face of managed care' instead. In fact, there are several reasons to believe that many aspects of the original concept of managed care remain relevant. First, the intensifying pressure on government to contain costs in public programs will continue to make public sector contracts with what now could be called 'traditional MCOs' appealing. At present, approximately two thirds of Medicaid beneficiaries are enrolled in managed care plans with limited provider networks, often aggressive care management, and an emphasis on primary care. (In addition, almost a quarter of Medicare beneficiaries are enrolled in a mixture of different private sector plan types, but these plans generally are less aggressive in managing care of enrollees.)

Second, some MCOs continue to practice utilization management in targeted areas, and some have reintroduced utilization management techniques that they had previously discarded. Perhaps the best example consists of efforts by MCOs to constrain the use of imaging procedures, especially as a first step in the diagnosis of lower back pain. Many MCOs conduct extensive retrospective review, and some require prior authorization and credentialing of imaging facilities and machines. It may be that there will be ongoing opportunities for MCOs to apply traditional managed care techniques to areas where growth in costs and service utilization seems excessive and indicative of poor quality, or where there are clear opportunities to substitute lower with higher cost service venues without jeopardizing quality.

There are also instances where essential aspects of early managed care, albeit controversial at a time, have now become accepted (if not always welcomed) as part of health practice. For instance, the use of data to 'profile' the practices of individual physicians and hospitals, with feedback of findings, was a standard tool employed by early MCOs to challenge provider 'outliers.' This practice continues today at a much more sophisticated and transparent level, with the results made available to some MCOs to their members, published in community reports and/or used to calculate financial rewards for providers. Early MCO support for the development and use of 'practice guidelines' is a second important example. Although providers saw these guidelines as tools used by plans primarily to contain costs, over time guidelines had achieved widespread acceptance as contributing to the practice of high quality evidence-based medicine. In this case, a utilization and quality management tool of the early MCOs has been widely adopted in the support of managed consumerism strategies, and its use will probably continue to expand, as care guidelines are increasingly being incorporated in electronic medical records.

One aspect of managed care that generally has not survived the transition to managed consumerism is the negotiation of capitated and other reimbursement arrangements that place providers at risk for costs exceeding budgeted amounts. However, this could change in the future, as some health plans are now negotiating 'shared gains' contracts with large integrated provider systems. Under these contracts, providers typically must meet quality and/or savings benchmarks in order to share a percentage of savings with health plans. In the United States, the Medicare program is encouraging providers to form Accountable Care Organizations (ACOs) that would contract with Medicare under shared savings arrangements. If a sufficient number of ACOs can be established, it shall accelerate the use of shared savings contracts between MCOs and providers in the private sector as well.

The prospects for MCOs to once again generate savings for purchasers through negotiation of deep discounts in fee-for-service contracts with providers seem to be less promising. In the early years of managed care, the considerable excess capacity in community health care systems was exposed as MCO enrollees used fewer services, especially inpatient care. Providers benefited from offering discounts so long as revenues from new MCO patients were sufficient to cover the fixed costs of unused capacity. Now, hospital occupancy rates are relatively high, and physician shortages are prevailing in many communities, reducing the value of new business to providers. Perhaps more importantly, provider consolidation limits the negotiating leverage of MCOs. It seems unlikely that this situation will change because MCOs will continue to find it difficult to restrain cost increases while negotiating favorable provider payment rates. Provider market power is also likely to inhibit the ability of MCOs to negotiate shared gain contracts that have strong incentives for cost control.

In summary, addressing the question of whether 'the end of managed care' has arrived is complicated. Some of the utilization techniques associated with traditional managed care have survived and may continue, in refined form, into the future. However, the increasing market power of providers, being supported by growing market consolidation, makes it rather unlikely for MCOs to be able to negotiate the sorts of risk sharing and discounted payment arrangements with providers that arguably were key elements to lower utilization of services and reduce costs during the early era of managed care. Interestingly, growing provider consolidation also threatens employers' managed consumerism strategy, which now depends on the willingness of a shrinking number of provider organizations to compete for patients.

Glossary

Adverse selection A situation in which the health insurance market is distorted because individuals are better informed about their probability of needing health care than insurers.

Community rating Regulation of the health insurance market requiring insurers to charge a uniform premium regardless of the state of health.

Libertarian paternalism A policy approach to protect individuals from making decisions against their own interest. Experts design specific arrangements which apply to individuals unless they deliberately opt out.

Open enrollment Regulation of the health insurance market requiring insurers to accept any applicant.

Introduction

A number of countries mandate that individuals purchase health insurance, a policy referred to as mandatory health insurance (MHI). It requires that all or a large part of the population purchase health insurance, which covers a substantial part of healthcare costs. This article reviews the reasons for this policy, considers issues in implementing MHI, and discusses the problems in enforcing the mandate to buy health insurance.

Rationales for Mandatory Health Insurance

Avoiding Free Riding

In most wealthy societies, there is a consensus that life-saving medical care should be made available to citizens in case of need. This creates a free rider problem on part of those with low income who can expect to receive this support when they become ill. By not buying insurance, they save the premium and enjoy a higher level of consumption as long as they remain in good health. However, as soon as sizable payments for medical care occur, these individuals qualify for free treatment. This opportunity to act as a free rider on the rest of the society can mean that *ex ante* individuals do not find it worthwhile to buy health insurance. A possible response would be to deny treatment to individuals who failed to buy health insurance. To a wealthy society, however, this is usually not acceptable or feasible. For instance, if the victim of an accident or a seriously ill person is rushed to hospital, it is unthinkable if not illegal in many countries to refuse to treat the patient because of doubts about the patient's financial means.

Making health insurance mandatory solves this problem. In this sense, it is similar to mandatory car insurance in protecting third parties from being damaged. MHI also has an efficiency advantage in this setting. To receive assistance by others in case of large payments for medical treatment, individuals may refrain from buying any coverage at all. This inefficiently exposes them to smaller risks when they do not qualify for assistance. MHI avoids this inefficiency.

Alternative policies are subsidies for buying insurance, taxes for not buying insurance, or a combination of both. However, high subsidies may be necessary to induce free riders to buy insurance, requiring substantial increases in public expenditure. Taxes have the same effect as MHI provided that they induce all free riders to take up insurance.

Paternalistic Motives

Because data on health risks are often complex, individuals have problems in making informed decisions. In particular, they may underestimate certain risks. Several studies show that individuals tend to have an 'optimistic bias' with respect to their vulnerability to health risks. For instance, individuals typically rate their personal risk with respect to health problems and other hazards between 'average' and 'less than average.'

If risks are underestimated, individuals will tend to buy too little health insurance. As in other branches of insurance, catastrophic risks, illnesses which are very costly, are likely to be insufficiently covered. As a consequence, individuals may suffer financial distress and may not be able to afford adequate treatment. This is unnecessary because insurance to cover these risks can be inexpensive, provided that the probability of getting the illness is low (Nyman, 1999).

A paternalistic response is to mandate individuals to buy health insurance contracts, which provide sufficient coverage, in particular for catastrophic risks. The requirements for these contracts would be based on the opinion of experts who assess health risks. An alternative would be to provide individuals with more information. Given that problems in processing information is the underlying cause for the interference in private decisions, however, this may only help those who have the time and capabilities of assessing in detail the risks they face. As a third way, Sunstein and Thaler (2003) propose 'libertarian paternalism,' a combination of paternalism and free choice. Experts would be consulted for designing a 'default' health insurance contract which would cover individuals unless they decide deliberately for buying alternative or no coverage.

Adverse Selection

Adverse selection in health insurance arises if individuals are better informed about their probability of needing health care

than insurers. A possible implication is market failure in the health insurance market. This argument is based on the famous analysis by Rothschild and Stiglitz (1976). In their model with two risk types, only a separating equilibrium can exist in which high-risk types obtain full insurance, whereas low risks buy partial coverage. Such an equilibrium may not be second-best efficient. Mandatory public health insurance with partial coverage can lead to a Pareto improvement.

The efficiency argument for mandatory public health insurance, however, hinges on the equilibrium specification of the model. In an alternative specification in which insurers anticipate the withdrawal of unprofitable contracts in response to their own actions and can cross-subsidize between contracts, the market equilibrium is second-best efficient, i.e., no Pareto improvement is possible given the self-selection and resource constraints (Crocker and Snow, 1985).

Starting from the premise that health insurance markets are not second-best efficient, Neudeck and Podczeck (1996), Encinosa (2001), and Finkelstein (2004) have examined the effects of MHI which is not tied to public insurance. A general finding is that this policy leads to redistribution from low-risk individuals to high-risk individuals. However, MHI is not able to implement a Pareto improving outcome compared with the unregulated market equilibrium. Whether a second-best outcome can be reached by MHI depends on the specific way of modeling the insurance market.

Enforcing Cross-Subsidies

For individuals with low income, health insurance may not be affordable. This also applies to those with a high risk of needing health care who have to pay high premiums in a market with risk rating. Mandating them to buy coverage usually does not solve this problem. However, in an indirect way, making health insurance mandatory for all can lower the price of health insurance for people with low income or high risks by enforcing cross-subsidies from others. This is the case in a social health insurance system with income-related contributions. In such a scheme, those with high income and low expected health expenditure cross-subsidize the poor and ill.

The problem that the poor cannot afford health insurance can also be solved by paying earmarked transfers for the purchase of health insurance contingent on income. Cross-subsidies between low and high risks, however, are more difficult to implement by transfers. These would need to reflect the risk type in the same way as insurers differentiate their premiums by risk type. This is a demanding task for a government transfer program and has not yet been implemented.

In the absence of a satisfactory transfer solution, MHI can establish transfers to high risks if it is combined with community rating, i.e., the regulation that insurers do not differentiate their premiums by risk type, and open enrollment by insurers. MHI is crucial in this context because otherwise low risks may prefer not to buy any health insurance to avoid cross-subsidizing high risks.

It should be noted that to some extent markets provide cross-subsidies from low- to high-risk individuals. For the individual health insurance market in the US, Pauly and Herring (2007) find that premiums are not proportional to risk, pointing to some risk pooling in the market. This can be partly explained by guaranteed renewable contracts which protect individuals from being reclassified if they turn into a high risk. However, such contracts cannot induce cross-subsidies to individuals who are already high risks at the onset of the contract.

Political Economy Considerations

Making health insurance mandatory increases the demand for health insurance. The private insurance sector may, therefore, have an interest in such a policy and may lobby to bring about such a mandate. Provided that the normative reasons above apply, this is not necessarily against the public interest. However, if competition is low in the health insurance sector, individuals may be forced to buy overpriced health insurance coverage which they do not need.

Implementing Mandatory Health Insurance

Designing Health Insurance Benefit Packages

MHI requires the definition of a minimum benefit package. Otherwise, individuals could bypass MHI by buying a health insurance contract with high deductibles at little cost to meet the mandate. The design of the minimum benefit package should follow the rationales for introducing MHI. To avoid free riding, expensive treatments for which treatment cannot be denied should be included. Paternalistic motives call for coverage of those risks which individuals tend to underestimate. If MHI is introduced to mitigate adverse selection or to enforce cross-subsidies, then the benefit package should conform to the preferences of the insured population.

To what extent these considerations play a role in the actual design of benefit packages in mandated systems has not yet been studied comprehensively. Usually, the health ministry or committees decide about which benefits are included. Sometimes, economic evaluations inform decision makers about the costs and benefits of treatments.

A rare example of an explicit process to determine a minimum benefit package is Chile's introduction of a guaranteed basic uniform benefit package. It applies both to public health insurance and to private health insurers among which individuals can choose (Vargas and Poblete, 2008). Implemented from 2005 to 2007, it is based on an algorithm of prioritization using multiple criteria (burden of disease, inequality, high costs, social preferences, cost-effectiveness, and the rule of rescue, i.e., the imperative to save the life of a person who is at risk of death even if the chances of success are low and costs are high).

Mandatory Health Insurance and Social Health Insurance

MHI on its own does not make health insurance affordable. Further measures need to be taken. MHI often goes along with social health insurance. These systems are characterized by two additional requirements. Open enrollment guarantees that high risks cannot simply be rejected by insurers. Community

rating prohibits insurers from charging risk-based premiums. Frequently, contributions are also income related, making insurance affordable to poor individuals. In Switzerland, by contrast, premiums are uniform. Health insurance is made affordable by premium subsidies that are financed out of tax revenue. Depending on the canton of residence, these subsidies are granted as soon as health insurance costs more than a certain percentage of taxable income of a household.

Mandatory Health Insurance without Social Health Insurance

MHI without social health insurance faces the challenge of making health insurance affordable to those with low income and high expected healthcare expenditure. In particular, this holds true for industrialized countries in which standard health insurance coverage usually includes access to advanced medical technology and is, therefore, expensive. Without social health insurance, health insurance has to be subsidized unless MHI refers only to a very modest benefit package. Several options are available to implement such subsidies. First, access to subsidized public systems like Medicaid in the US or FONASA in Chile can ensure that poor individuals obtain access to affordable health insurance. Second, insurers can receive subsidies if they accept low-income and high-risk individuals. Finally, a policy option is to make individuals eligible for public transfers if their expenditure on health insurance exceeds a certain percentage of their income. Such a system has been introduced as part of the 2006 Massachusetts health reform. It has also been proposed by Zweifel and Breuer (2006), who have made the case for risk-based premiums and wanted to target those with low income and high premiums through premium subsidies.

Problems of Mandatory Health Insurance

Enforcing Benefit Packages

As pointed out in Section 'Designing Benefit Packages,' MHI can only be effective if a minimum benefit package is defined. If MHI refers to a single insurer, there should be no problem in making sure that individuals actually obtain insurance with this coverage. With competing insurers, however, this task becomes more difficult. Given that some individuals do not want to buy insurance, insurers may satisfy this nondemand by selling policies which cover the minimum benefit package only on paper. Insurers, therefore, have to be monitored whether they really provide the benefit package. Furthermore, it is advisable to require insurers to build up sufficient loss reserves to secure that they can meet their obligations. Otherwise, there is the risk that the bill needs to be footed by the public, reintroducing the free rider problem at the insurance level.

Enforcing Mandatory Health Insurance

To what extent MHI can be enforced depends on the institutional context. In an economy where all individuals are employed in the formal sector and are required to spend a certain amount for health insurance, contributions for MHI can be collected via the employer and transferred directly to health insurers. This is typically the case in social health insurance schemes. By contrast, in countries with a large informal sector, MHI can be difficult to enforce. In these countries, subsidized schemes are essential in expanding coverage, because otherwise it will be hard to reach all parts of the population. A tax-financed national health system which covers the entire population may be preferable in such settings (Wagstaff, 2010).

For countries in which contributions are not automatically deducted from the wage bill, the question needs to be addressed how to treat those who do not obtain insurance or refuse to pay premiums. In Massachusetts, individuals face tax penalties if they have access to affordable health insurance and remain uninsured. In Switzerland, those who do not pay their premiums can be denied coverage for nonemergency services. This policy, however, effectively allows individuals to remain uninsured.

Limiting Consumer Choice

An evident drawback of MHI is some limitation of consumer choice. This arises from the need to specify a minimum benefit package which will not always correspond to the benefits individuals would choose according to their preferences. In social health insurance systems, this problem is particularly severe. If there is only one insurance fund, for instance, in Estonia, individuals have no choice at all unless they seek care in the private sector. Even if there are competing funds as in Germany, the Netherlands, or Switzerland, benefit packages are often tightly regulated.

The regulation of the benefits package in a social health insurance scheme with competing insurers can be a response to the incentives for risk selection which arise naturally in such a setting. The requirement to accept any individual at a uniform premium leads to expected losses with high-risk types and expected profits with low-risk types. Insurers, therefore, have an incentive to design their benefit package such that it is attractive for low but not for high risks. Regulation of the benefit package is a possible response (an alternative is risk adjustment which tries to set insurers' budgets according to the risk characteristics of their insured population, Zweifel *et al.*, 2009, Chapter 7). On one hand, minimum benefits can be specified, forcing insurers to offer benefits that are of importance for high risks, such as treatment of chronic diseases. On the other hand, imposing an upper limit on benefits can prevent insurers from including services that are of particular interest to low risks but not essential to health insurance, such as visits to sports centers. These benefits effectively reduce cross-subsidies to high risks (Kifmann, 2002).

Questionable Cross-Subsidies

As discussed in Section Enforcing Cross-Subsidies, MHI can be a means of enforcing cross-subsidies to other members of society. Equity considerations call for subsidies from high- to low-risk types. Also cross-subsidies from high-income to low-income individuals can be justified if these are not implemented through the general tax-transfer system. However, MHI can also lead to cross-subsidies which are difficult to

legitimate. For instance, individuals living in the countryside may have to subsidize those in urban areas with good access to medical care. If premiums are not differentiated according to age, then the young will cross-subsidize the elderly. Given the demographic trends in many countries, this can place a high burden on the young.

Conclusions

MHI can be implemented for several reasons. It can be a policy directed against free riding behavior by those who expect to be covered by others in case of emergency. To the extent that individuals insure too little because they underestimate their health risks, it can be part of a paternalistic intervention by the government. Combined with partial social health insurance, MHI may bring about efficiency improvements in a health insurance market characterized by adverse selection. It can help to enforce cross-subsidies from those with low health risks and high income to high-risk and low-income individuals.

An important point is that MHI by itself usually does not make health insurance affordable. It needs to be combined with social health insurance or with programs which make subsidized health insurance available for those with low income. MHI also requires the definition of a minimum benefit package. Otherwise, individuals could bypass the mandate by buying a health insurance contract with little coverage. When implementing MHI, regulators need to monitor that insurers actually offer the minimum benefit package. Furthermore, measures need to be taken to make sure that individuals actually buy health insurance.

Market for Professional Nurses in the US

PI Buerhaus, Vanderbilt University Medical Center, Nashville, TN, USA
DI Auerbach, RAND, Boston, MA, USA

Introduction

The nursing workforce in the US is comprised of both professional nurses and nonprofessional workers. Professional nurses typically complete nursing education in a hospital-based diploma program, community college or university and are registered and licensed by the state to practice nursing. Professional nurses also include advanced practice nurses (APRNs) who are registered nurses (RNs) that have completed graduate education and practice as nurse practitioners (NPs), certified nurse midwives (CRNMs), clinical nurse specialists (CNS's), and certified nurse anesthetists. Nonprofessional nurses receive their nursing education in technical and vocational programs and are licensed by states as practical or vocational nurses. Supporting professional and nonprofessional nurses are assistive personnel, such as aides, orderlies, and personal care attendants, who have not completed formal education in nursing.

For several reasons, this article focuses on professional nurses. First, there is more complete data on RNs versus either practical or vocational nurses or the various personnel who assist nurses. Because RNs' educational preparation and legal scope of practice enable them to perform more complicated nursing services, RNs have a greater impact on the productivity of the nursing workforce, earn higher wages, and exert a greater effect on healthcare spending, quality of care, and patient safety. And, because APRNs can legally provide many of the services traditionally provided by physicians, these nurses have become a highly visible component of the professional nursing workforce.

The article begins with an overview of the key demographic, educational, and employment characteristics of RNs and then briefly summarizes the forces that affect their demand and supply. Following this, the authors examine the 'cyclical' nature of RN shortages, describe the impact of the recent recessions on hospital RN employment, and identify key issues facing the RN workforce. The article concludes with a discussion of the characteristics and challenges faced by APRNs.

Data for the tables and figures shown in this article are derived from two sources. Data to estimate RN employment growth and the age composition of the nursing workforce were derived from the US Bureau of the Census Current Population Survey (CPS) Outgoing Rotation Group Annual Merged Files. The CPS is a household-based, nationally representative survey of more than 100 000 individuals administered monthly by the Bureau of the Census. This data source is used extensively by the Department of Labor to estimate current trends in unemployment, employment, and earnings and has been used to estimate employment trends for RNs and project the age and supply of RNs and physicians (Auerbach *et al.*, 2007; Staiger *et al.*, 2009). The CPS survey contains information on roughly 3000 RNs employed in nursing each year.

The second source of data comes from the National Sample Survey of RNs (NSSRNs) conducted by the Health Resources and Services Administration (HRSA). The NSSRN is the most well-known and comprehensive source of data on individuals who have active licenses to practice in the US as RNs whether or not they are actually employed in nursing. The surveys have been conducted every 4 years from 1977 to 2008 and provide information on the number of RNs; their educational background and areas of clinical specialty; employment settings; positions; salaries; geographic distribution; and personal characteristics including gender, racial/ethnic background, age, and family status.

Key Characteristics of the Registered Nurse Workforce

Employment and Earnings

As shown in Table 1, RNs are employed in a variety of settings, including hospitals, extended care facilities, ambulatory care clinics, schools, public and community healthcare clinics, insurance companies, and others. Hospitals employ more than 60% of RNs, with the majority working on general medical and surgical care units, critical care and stepdown units, emergency departments, and hospital-based outpatient surgery and ambulatory care centers. Not surprisingly, RNs work in many different clinical and nonclinical positions both in hospitals and nonhospital settings (Table 2). Over the past few decades, data from the CPS (Figure 1) indicate that RN employment on an FTE basis has grown faster in nonhospital settings than in hospitals.

Table 1 Full-time equivalent employment of registered nurses in principal employment settings, 2008

Setting	*Full-time equivalent registered nurse employment*	*Total (%)*
Hospital	1 601 831	62
Nursing home/extended care facility	135 514	5
Academic education program	98 268	4
Home health setting	165 697	6
Community/public health setting	97 210	4

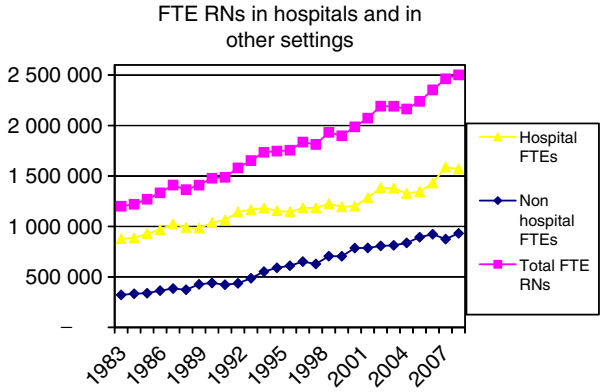

Figure 1 Total full-time equivalent (FTE) RNs by hospital and nonhospital settings, 1983–2010.

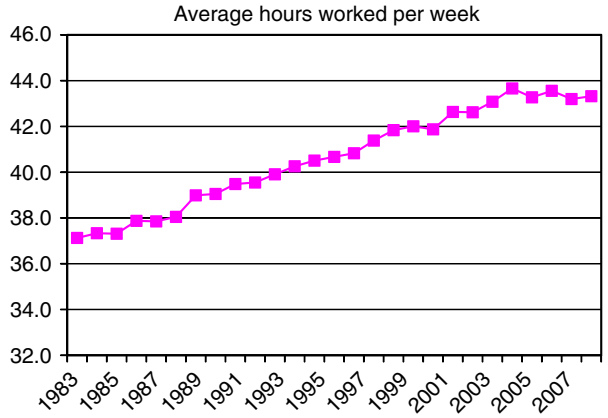

Figure 2 Average hours worked per week by RNs, 1983–2010.

Over the past several decades, the average number of weekly hours worked by RNs has been increasing. According to the CPS, the average number of hours worked by RNs during a given week increased by 2 h from 34.7 h in 1983 to 36.7 h in 2010 (Figure 2).

Using data on hourly earnings from the CPS, real (inflation adjusted) wages, for all RNs, increased 25% from 1983 to 2010. Increases in annual RN earnings were not gradual, however, as most of this increase occurred between 1983 and 1992 (Figure 3). From 1992 to 2000, real earnings stagnated or even dipped in some years, which suggests that excess capacity (too many RNs) may have existed in the nurse labor market during this period, perhaps as a result of the spread of managed care during the 1990s. During the last decade, real earnings among all RNs have increased less remarkably.

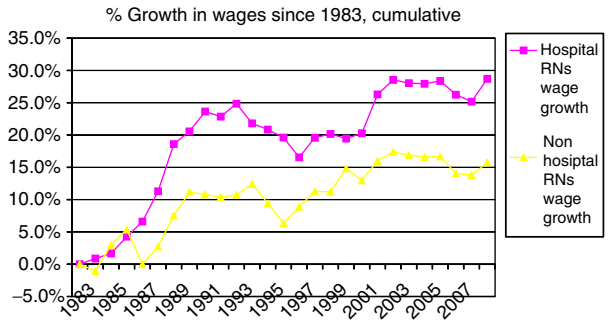

Figure 3 Cumulative percentage growth in RN wages since 1983. Reproduced from Current Population Survey.

Demographics

Although the racial and gender composition of the nursing profession has become gradually more diverse, in 2010 the vast majority of RNs were women (91%) and white (78%). RNs whose initial nursing education took place outside the US or in the US territories also contribute substantially to the RN workforce in the US. According to the HRSA (2010), internationally educated nurses (IENs) have grown as a percent of the US nursing workforce, increasing from 5.1% in 2004 to 8.1% in 2008. The dominant source country of the IEN

workforce is the Philippines (50%), followed by Canada at nearly 12%.

Age

The average age of the RN workforce has been increasing rapidly over the past several decades (Figure 4), from 37.1 in 1983 to 43.2 in 2010. Figure 5 shows the number of RNs participating in the workforce broken into three age groups: under 35 years, between 35 and 49 years, and more than 50 years. Among these groups, the number more than 50 quadrupled from roughly 200 000 in 1983 to nearly 900 000 in 2010. The number of middle-aged RNs (35–49) more than doubled over the same period from 400 000 to nearly 1 000 000, whereas RNs under 35 grew very little and in the present day are just above 600 000. These trends reflect the very large baby boom cohorts who entered nursing in unprecedented numbers in the 1970s and 1980s. In the decades that followed, other professional opportunities opened up for career-oriented women and entry into nursing declined (the groups following the baby boom were also smaller in size due to declining birth rates). Thus, as baby boom RNs have moved through the workforce, the average age has increased. Rapid renewed entry into the nursing profession over the past decade has stabilized the average age and lessened expected future shortages. Nevertheless, as large numbers of RNs of more than 50 years of age retire over the next decade, shortages of RNs may again develop.

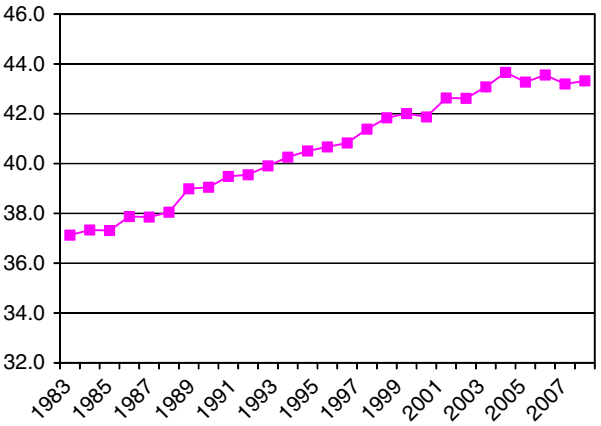

Figure 4 Average age of RNs, 1983–2010. Reproduced from Current Population Survey.

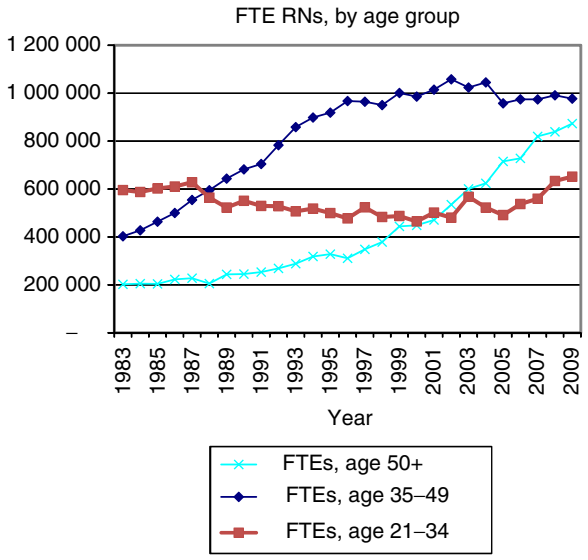

Figure 5 Full-time equivalent RNs by age group, 1983–2010. Reproduced from Current Population Survey.

Education

The educational preparation of RNs in the present day occurs in community colleges or in baccalaureate degree nursing education programs, whereas many of the large number of RNs born in the baby boom generation received their nursing education in hospital-based diploma programs. In 2008, according to the NSSRN, community colleges produced the majority of graduates in 2008 (Figure 6).

Overview of Factors Affecting the Demand and Supply of Registered Nurses

Like any labor market, the performance of the RN labor market as indicated by wages and output (number of RNs or hours worked) is determined largely by forces affecting the demand and supply of RNs. On the demand side of the market, forces arise from factors that determine society's overall demand for healthcare and from a different set of factors that healthcare organizations consider when deciding on the quantity of RNs to employ. The authors will not focus on forces that affect society's overall demand for healthcare, but rather, will focus on areas where that demand may particularly differ for RNs. With regard to the supply side of the market, which is more idiosyncractic to RNs, they distinguish

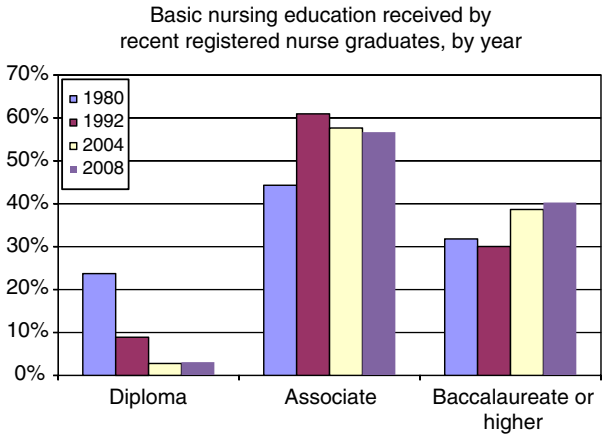

Figure 6 Basic nursing education received by recent RN graduates, 1980–2008. Reproduced from Health Resources and Services Administration (HRSA) (2010). *The registered nurse population: Findings from the 2008 National Sample Survey of Registered Nurses*. Rockville, MD: HRSA.

between forces that determine the long-run supply of RNs (the number of individuals choosing to become an RN) and forces that influence the short-run supply of RNs (participation in the labor market and number of hours worked by existing RNs).

Societal Factors Affecting the Demand for Registered Nurses

Factors that determine society's total demand for healthcare include changes in the health, size, age, and ethnic composition of the population; economic factors; and the organization of the healthcare system. As 60% of RNs work in hospitals, elements that particularly increase demand for hospital care would disproportionally increase the demand for RNs. Changes in the prevalence of diseases requiring hospital care such as congestive heart failure (or needs brought about by old age such as knee and hip replacement) could particularly result in increased need for RNs. The proportion of the US population that is more than 65 years of age will grow from 13% in 2010 to 16% in 2020 to 19% in 2030 – suggesting an increase in the demand for hospital care.

In the near future, the out-of-pocket price of healthcare services will decrease for many of the estimated 32 million Americans that will obtain health insurance in 2014 under the Patient Protection and Affordability Care Act, the health reform legislation passed in 2010, also potentially increasing the demand for healthcare. Although ambulatory care is generally more sensitive to out-of-pocket price than hospital care, it is possible that an increasing proportion of RNs will be employed in ambulatory care in the future if systems devote resources toward patient-centered medical homes and primary care-intensive preventive services (Sochalski and Weinder, 2011).

Organizations' Demand for Registered Nurses

Healthcare delivery organizations are in the business of producing goods and services to satisfy society's demand for healthcare. Because producing many of the goods and services requires RNs (other nursing personnel, other labor, and capital), the number and type of nursing personnel employed at any given time is a function of organizations' demand for nursing services. With respect to RNs, demand is determined by the productivity of RNs relative to nonprofessional nurses, assistive personnel, and capital, the wages and input prices of these other productive factors, and the ability to substitute one type of input for another in the heath production function.

Briefly, the higher (lower) the wages and fringe benefits, it must pay to hire RNs, organizations demand fewer (more) RNs, holding all else constant. The supply of RNs available at the time employers are seeking to hire additional RNs and the quantity of RNs demanded determine the wage RNs can command in the market, and hence the quantity of nurses that employers' can afford to employ. Although RNs command a higher wage than Licensed Practical Nurses, their productivity relative to their wage (marginal product) is greater because they can legally provide a greater number of nursing services. Thus, organizations' demand for RNs is influenced by whether the output organizations are producing requires nursing services that can only be provided by RNs or can be produced by using LPNs or others. For example, long-term care organizations typically provide patient care services that can be provided at less cost by LPNs, whereas the nursing services needed in most acute care hospitals require far more RNs relative to LPNs or nonlicensed personnel.

As the healthcare system has become increasingly focused on improving the quality and safety of care, hospitals have begun to pay more attention to the additional quality and safety that can be obtained by hiring RNs relative to other nursing personnel. Over the past few years, both public and private payers have begun to link hospital payment to patient outcomes that are sensitive to the care provided by RNs; should such incentives be expanded to outpatient and non-hospital settings, then demand for RNs could increase in these settings as well.

Organizations also consider the changing relationship between capital and labor when they determine their overall demand for RNs. Clearly, the combination of resources used to produce healthcare in a hospital a decade ago is not the same as those used to produce health services in the present day. With respect to nursing personnel, the roles and productivity of one type of nurse relative to another (e.g., an LPN versus APRN) have changed markedly over the years due to modifications in state practice acts, innovations in nursing education, changes in institutional policies, emergence of evidence-based practice, collective bargaining agreements that have expanded or restricted the performance of tasks by different types of personnel, and by efforts to mandate patient-to-nurse staffing ratios.

In sum, given the forces affecting society's demand for healthcare and assuming that enough RNs are available and willing to work at the wages and working conditions offered by employers, most healthcare organizations seek to employ the number and mix of RNs and other nursing personnel that can most efficiently produce the treatments and services consistent with the organization's objectives, budget, quality standards, and the ways that other healthcare personnel, capital, and technology can be productively combined.

Forecasts of Registered Nurse Demand

The Bureau of Labor Statistics (BLS) and HRSA have estimated the societal and organizational factors affecting the demand for RNs and both indicate increasing demand for RNs over the near-term future. Based on industry surveys, the BLS estimates overall job opportunities for RNs will increase by 22% from 2008 to 2018, a rate of growth that is much faster than the average of all occupations (averaging between 7% and 13% over the same time period). According to the BLS, growth will be driven by technological advances in patient care, an increase in preventative care and growth in the population of older citizens. Further, the BLS expects that employment growth in hospitals will be slower (17%) than in nursing care facilities (25%), home healthcare services (33%), and offices of physicians (48%).

In 2004, HRSA projected that the future requirement of RNs through 2020 would increase by more than 800 000 FTE

RNs more than 2000 levels. These projections, however, were made before the passage of health reform legislation in 2010, and thus demand is likely to exceed these projections as an estimated 32 million Americans gain greater access to health insurance coverage during the decade.

Factors Affecting the Supply of Registered Nurses

When thinking about the supply of RNs, it is useful to differentiate between the short- and long-run supply of RNs. The short-run supply of RNs refers to the decisions of existing RNs to participate in the labor market and number of hours to spend working. If, for example, we are interested in increasing the supply of RNs to help resolve a nursing shortage, then any increase in RN supply will come initially from stimulating the number of currently available RNs to participate in the workforce or, if they are already working, to increase the number of hours they are willing to work (or both).

Changing the short-run supply of RNs can be accomplished by manipulating factors that existing RNs consider when deciding whether to participate in the nurse labor market and the number of hours they are willing to work. In contrast, because it takes between 2 and 4 years for an individual to complete a basic nursing education program, the long-run supply of RNs refers to the number of RNs that will be available at some point in time in the future. Thus, an expansion in the long-run supply of RNs will not address a shortage of RNs that is being experienced in the present day but may help resolve a future shortage.

Short-Run Supply

RNs' participation and hours decisions are determined by economic and noneconomic factors. Economic factors include the RN's wage (and fringe benefits) and nonwage income (primarily the income of the RN's spouse). In economics, when wages change, both substitution and income effects are elicited. However, because the substitution and income effects exert opposite effects on labor supply decisions, whichever effect dominates will determine RNs employment decisions, holding the effects of other economic and noneconomic factors constant. Many studies of RNs' short-run labor supply show that, on average, increases in wages tend to exert a positive but relatively small impact on the number of hours worked by RNs and a greater impact on the decision of nonparticipants to rejoin the workforce (Sheilds, 2004). With regard to the impact of nonwage income on RNs' labor supply decisions, evidence from labor supply studies indicates that increases in nonwage income exert a negative and substantial impact on participation and hours worked, holding all else constant. Because a majority of RNs are married women, a spouse's income is a significant source of income for many RN households. The effect of spouse income is related to the observed counter-cyclical effect of RN labor supply and the economy as a whole. For example, Buerhaus *et al.* (2009) showed that RN employment tends to grow much faster during and immediately after recessions, with much of employment growth linked to older RNs rejoining the workforce or working more hours. Quantitatively, the authors calculate that a percentage point increase in the unemployment rate is associated with a 1% increase in RN labor supply.

Noneconomic factors also influence RNs' labor market decisions. These factors include: the presence of children (approximately 70% of RNs are married, and studies show that young children at home exert a substantial demand on the RN's time and hence a negative effect on RN participation and hours worked); older adults living in the RNs' household (few studies have examined the impact on the RNs' labor supply decisions, although studies of women in the overall workforce indicate that caring for older adults decreases participation and hours worked substantially); enrollment in education programs (many RNs are obtaining their bachelor's or master's degree and thus have less time available to work in the labor market), demographic characteristics such as age (older RNs work more hours), race (nonwhite RNs have higher participation rates and work more hours) and gender (most studies show that men have higher participation rates and work more hours than women). However, because it is difficult to change the noneconomic factors that affect RNs' decision to work, employers rely on changing wages and fringe benefits to influence the short-run labor supply decisions of existing RNs.

Long-Run Supply of Registered Nurses

In contrast to the short-run supply of RNs that involves the labor market decisions of existing RNs, the long-run supply of RNs concerns the total number of RNs, who will be available in the future. A key factor affecting the long-run supply of RNs is the number of women in the US population between the ages of 20 and 40 years that make up the largest pool of individuals from which nursing education programs draw applicants. As large numbers of women born during the baby boom generation (1946–64) entered their twenties, the size of the pool of women increased in the late 1960s and continued expanding for the next 20 years. Consequently, these pools 'produced' large numbers of RNs. Since 1985, however, the size of the population pool 20–40 has remained relatively stagnant and is projected to change very little over the next 10–15 years.

RN nursing students are drawn into nursing for a variety of personal interests and motivations. However, the growth in new career options for women in the 1980s and 1990s led to a declining propensity of women choosing a nursing career (at the same time that the size of applicant pools were no longer increasing). More recently, enrollments have expanded, suggesting that interest in becoming an RN has increased. Internationally educated RNs, who join the US nursing workforce, have also helped expand the long-run supply of RNs; since the mid-1990s, IENs have been increasing both in number and as a proportion of the nursing workforce in the US.

Economic factors such as tuition, time costs, and prospective earnings also influence the long-run supply of RNs. For some people, the tuition charged by nursing education programs relative to the tuition required by other careers the individual is considering is an important factor in making the decision to become an RN. The less time it takes for an

individual to recoup their investment in a nursing education, given his or her particular skills, the more likely they will become an RN. For individuals who are on the brink of deciding to choose nursing or a different career, RN wages in the nurse labor market can influence their decision, especially if wages are increasing and the individual is aware of the improving economic prospects in nursing.

The capacity of the nursing education system should respond to demand for RNs and interest in becoming an RN in the population – however, that response may be uneven due to institutional or other constraints. Shortages of faculty have been reported since the early 2000s – an oft-cited reason for thousands of qualified applicants being turned away from nursing education programs each year since 2002. That constraint seems to have eased recently, as the past few years have seen strong growth in nursing programs, new graduates and RNs entering the workforce.

Projections of the Long-Run Supply of Registered Nurses

Projections made by the authors in 2000 and HRSA in 2004 suggested that the number of RNs would grow slowly through the current decade, level off for several years, and then decline by 2020 as RNs retire from the workforce. Subsequent projections (Auerbach *et al.*, 2007; Buerhaus *et al.*, 2009) revealed that the future supply of RNs was beginning to grow in response to national initiatives to attract people into nursing. These initiatives appear to have had their desired effect on increasing enrollment into nursing education programs by both young people graduating from high school and by those in their 30s deciding to leave their nonnursing occupation and become an RN.

Registered Nurse Shortages

Perhaps no other topic related to the nursing workforce has dominated the attention of federal and state legislators, workforce planners, nursing organizations, and the media more than hospital shortages of nurses. Shortages have occurred frequently in the US and affect hospitals' (and other care delivery organizations) ability to operate safely and provide access to healthcare. From an economic perspective, a shortage of hospital RNs reflects market disequilibrium in which hospitals' demand for RNs exceeds the existing supply of RNs at the prevailing wage (including nonwage benefits). Thus, a shortage is a market disequilibrium in which labor demanded by hospitals exceeds labor supplied by RNs because the wage lies below the equilibrium wage – the wage level in which demand and supply are in balance. The shortage will not begin to disappear until wages increase to a level that brings about an increase in RNs' short-run labor supply (an increase in participation or hours worked, or both) that satisfies a hospital's demand. If, however, the hospital's demand for nurses continues to expand at the same time that wages are rising, the shortage of RNs will persist.

Figure 7 shows the supply and demand for hospital RNs, with the labor supply curve upward sloping, whereas the labor

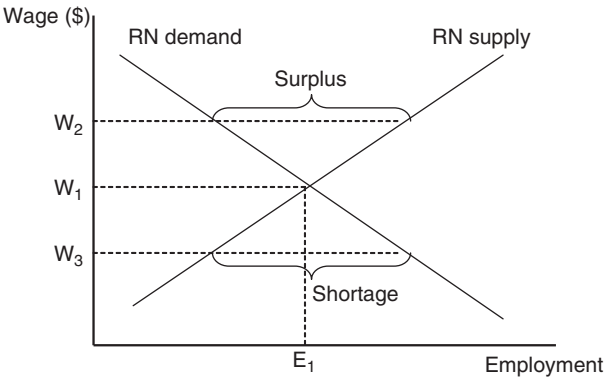

Figure 7 Equilibrium hours and employment in a competitive labor market.

demand curve is downward sloping. At the point where demand and supply intersect, the wage level (W_1) is such that the supply of RN labor is exactly equal to the demand for RN labor at employment level E_1. At any higher wage level, such as W_2, there will be a surplus of RNs seeking jobs because the higher wage increases supply while at the same time reduces hospitals' demand for RNs. In Figure 7, the surplus is reflected in the horizontal distance between the supply and demand curves at wage level W_2. Competition among the surplus RNs to obtain the limited number of hospital jobs will eventually place downward pressure on wages, decreasing wages toward W_1 until the supply and demand intersect W_1, the equilibrium wage.

Similarly, at any wage level below W_1, such as W_3, there will be a shortage of RNs as the lower wage decreases the supply of RNs and increases employers' demand for RNs. The shortage is shown in Figure 7 as the horizontal distance between the demand and supply curves at wage level W_3. Competition among employers to obtain the limited number of RNs will exert upward pressure on wages, pushing wages again back toward W_1. Thus, the point at which labor supply and demand intersect determines the unique equilibrium combination of wage and employment levels (W_1 and E_1) that will result in an equilibrium market. During a shortage, competition among employers to obtain the limited number of RNs will put upward pressure on wages, pushing wages back to their equilibrium level. Thus, shortages should not exist for extended periods, at least in a competitive labor market or in the absence of restrictions that prevent wages from increasing.

If hospitals' demand for RNs increases, the hospitals may find that there are not enough RNs willing to supply their services at the wages they are offering and a new shortage will develop. The development of the shortage is shown in Figure 8 and focuses initially on the long-run equilibrium wage, W_1, at which the short- and long-run supply of RNs are equal to the demand for RNs. In the short run, the outward shift in RN demand from D_1 to D_2 results in a shortage of RNs. The shortage develops because not enough RNs are willing to supply their time to hospitals at this prevailing wage rate, W_1. However, as soon as RN wages increase and reach a new equilibrium at the point where the new labor demand curve (D_2) crosses the short-run labor supply curve, the shortage will disappear. This movement along the short-run labor supply curve results in much higher wages and somewhat higher

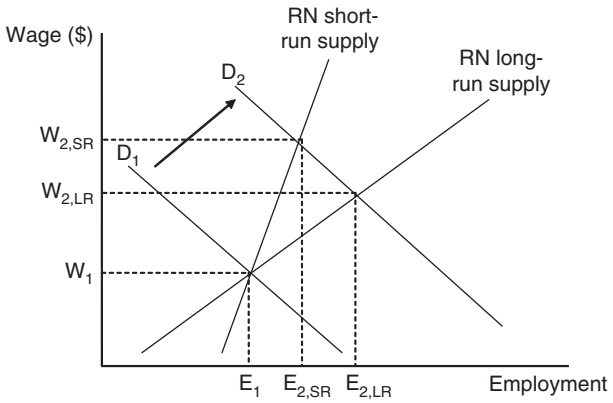

Figure 8 Impact of outward shift in labor demand on short- and long-run competitive equilibrium.

employment in the short run (increased participation and hours worked by existing RNs) from E_1 to $E_{2,SR}$. In other words, the increase in RN wages will first stimulate some existing RNs to respond in the short run by rejoining the workforce, moving from nonhospital settings into hospitals or by working additional hours (switching from a part- to full-time basis, working overtime or even working a second job). Eventually, in the long run new individuals will choose to become RNs drawn to nursing by the wage increase, thus multiplying the effect of the initial short-run response to the wage increase. Thus, over time, the new equilibrium will move to the point where the new labor demand curve (D_2) crosses the long-run labor supply curve at $W_{2,LR}$, in Figure 8. Thus, outward shifts in the labor demand curve tend to primarily increase wages in the short run, whereas having more of an impact on employment (and less on wages) in the longer run.

As noted above, shortages of RNs tend to be transitory and corrected by increases in the wage rate unless hospitals do not increase RN wages or for some reason are blocked from raising them. Unless demand is continuing to expand at the same time, the increased long-run supply of RNs will, in turn, exert downward pressure on wages. As the wage rate decreases, employers will be willing to hire additional RNs until they reach the point depicted by $E_{2,LR}$ and the labor market for RNs will once again adjust to a new long-run equilibrium wage and employment level of RNs.

If a hospital's demand for RNs should increase again, the hospital may find that there are not enough RNs willing to supply their services at the prevailing wage it is offering and consequently a new shortage will develop. The series of short- and long-run adjustments will begin a new, and eventually a new market wage will be reached where the long-run demand and supply of RNs are in balance and employment levels are higher. The repetition of this cycle of demand, supply, and wage adjustments is often referred to as the 'cyclical' shortage of nurses.

The speed with which shortages are resolved depends on several factors including: how high and quickly a hospital increases RN wages; how sensitive RNs are to the wage increase (the RN wage elasticity of supply); and how sensitive is hospitals' demand for RNs over the range of wage increases they are considering offering RNs (the employers' wage elasticity of demand for RNs).

History of Hospital Registered Nurse Shortages

Surprisingly, although hospitals have reported shortages of RNs in every decade since the 1960s, there is no agreement about how to define and measure shortages. One common indicator of shortages is the job vacancy rates reported by hospitals (the percentage of vacant FTE RN positions that hospitals are actively trying to fill). In general, reports of hospital shortages typically occur when FTE RN vacancy rates exceed 4%. Most, but not all, reported hospital RN shortages since the mid-1960s were driven by increases in the demand for RNs and were resolved after hospitals' increased real wages.

For several years before the creation of the Medicare and Medicaid programs in 1965, hospital RN vacancy rates were very high, exceeding 15%. The new financial resources provided by the Medicare program enabled hospitals to increase RN wages, which subsequently brought about an end to the shortage by the end of the decade. During the 1970s, demand for RNs continued to grow, but wage controls imposed by the federal government via the Nixon administration's Economic Stabilization Program combined with high inflation rates restricted the increase in RN wages from rising fast enough to bring hospitals' demand and supply of RNs into equilibrium. Consequently, hospitals reported double-digit RN vacancy rates and shortages of RNs during most of the 1970s.

Following large increases in real wages in the early 1980s, hospital RN vacancy rates began decreasing and the shortage ended quickly. However, with the beginning of the Medicare prospective payment system in 1983, hospitals faced new incentives to become more efficient and, among other adjustments, shifted less acutely ill patients to lower cost outpatient departments. Because RNs are more productive than LPNs at the prevailing wages, hospitals' demand for RNs increased. Throughout the decade, hospitals' demand for RNs increased approximately 3% annually and despite increases in real wages, the supply of RNs was unable to catch up to the significant growth in demand, resulting in hospitals once again reporting RN shortages during much of the latter part of the 1980s.

During the 1990s, the growth in the hospitals' demand for RNs slowed to approximately 2% per year as managed care developed rapidly. Both RN hospital vacancy rates and real wages soon decreased, bringing the shortage of RNs to an end. The increased number of RNs joining the RN workforce that were being supplied by nursing education programs resulted in an apparent surplus of RNs during the mid-1990s and real earnings and vacancy rates both decreased. However, by the end of the decade, yet another RN shortage was reported by hospitals but, in this case, the shortage was concentrated in intensive care units (ICUs) and operating rooms.

When data on RNs were analyzed by age categories, hospital unit, and educational background, it was discovered that the shortage broke out in these units because they were the first to experience the implications of underlying changes in the age and education composition of the RN workforce that resulted in a decrease supply of certain types of RNs. Shortages reported by ICUs and stepdown units resulted from a decrease in the number of younger RNs entering the workforce who have a greater propensity than older RNs to work in critical care units. Shortages in operating rooms resulted from the

decline in the number of older diploma-educated graduates who had a greater propensity to work in this setting, as they began to retire from the workforce. This analysis demonstrated that unlike the earlier shortages that were driven by increases in demand, the shortage that developed in 1998 was driven by supply-side factors reflected by the changing age composition of the RN workforce.

Impact of Recent Recessions on Hospital Registered Nurse Shortages

By the early 2000s, the hospital RN shortage spread throughout other nursing units as demand for hospital care began to increase. In 2001, hospital FTE RN vacancy rates exceeded double-digit levels. However, during 2001 a recession developed, and though it lasted only 8 months, unemployment rates remained high over the next 2 years (Table 3). Because the majority of RNs are married, increases in overall unemployment meant that many RN spouses either lost their job or feared that they could be laid off. To ensure the economic welfare of their households, many RNs who were not working at the time, particularly married RNs, rejoined the nursing workforce. During 2002 and 2003, hospital RN employment increased dramatically, shooting up by an estimated 185 000 FTEs. This burst in RN employment decreased the impact of the nursing shortage and reduced vacancy rates to approximately 8% by the end of 2006. As the shortage continued into 2007, it became the longest lasting shortage of hospital RNs in the past 50 years.

The second recession of the past decade began in December 2007 and lasted through June 2009, even though monthly unemployment rates continued to increase before peaking at 10.1% in October. Once again, hospital RN employment increased as nonparticipating RNs rejoined the hospital workforce and other RNs, who were already working increased their work hours. During 2007 and 2008, hospital RN employment surged, adding nearly one-quarter million FTE RNs. Moreover, more than 100 000 of this increased employment occurred among RNs older than 50 years of age, suggesting that some RNs who had retired rejoined the workforce. Another 50 000 RNs left their positions in nonhospital settings for higher paying hospital jobs, which also offered richer benefits (particularly health insurance coverage) and flexible work hours. Although national estimates of hospital RN vacancy rates are not available to assess the effect of this employment increase, anecdotal reports suggest that the national shortage of RNs that had begun a decade earlier in 1998 had finally come to an end for many hospitals (Auerbach *et al.*, 2011).

The Future of the Registered Nurse Workforce

Over the decade, the RN workforce will be dominated by older RNs in their 50s. Because the number of RNs in their 50s is so large (approximately 900 000), it will be very difficult to replace these RNs with new entrants, and thus new shortages are expected. These shortages could be larger than previous shortages of RNs experienced since the 1960s and could take an extended period of time for the labor market to adjust and establish a new equilibrium in which the shortage disappears.

Currently, the looming threat of large retirements from the workforce is masked by the lingering effects of the recent recession on the labor supply decisions of the current workforce. Average monthly unemployment rates remain above 8% and appear to be continuing to stimulate record high participation in the labor market by the existing stock of RNs. Reports of new graduates of nursing education programs having substantial difficulty finding jobs suggest that the hospital labor market may be in equilibrium. However, once the economy strengthens and there is a strong jobs recovery, many currently employed RNs, particularly older RNs, may retire from the workforce. If large numbers of RNs exit and if they withdraw from the workforce rapidly, then a new shortage is likely to develop. However, the stock of new graduates waiting for new jobs to develop may be large enough to enter the labor market and replace those exiting and thereby decrease the risk of new shortages developing.

Beyond these uncertainties, the nursing profession faces other challenges, particularly in an era of health reform. Many of these challenges are described in a recent report by the Institute of Medicine (IOM), The Future of Nursing: Leading Change, Advancing Health. The IOM report offered four key messages and eight recommendations aimed at strengthening the nursing workforce (Table 4). Several of these were aimed at strengthening patient centered, high quality, coordinated, primary care that is expected to be in great demand as the number of the insured grow while physicians increasingly move toward specialization. Although it is beyond the scope of this article to discuss these messages and recommendations

Table 3 Changes in national unemployment rates and full-time equivalent (FTE) registered nurse (RN) employment in the US, 2001–10

Year	*National unemployment rate (%)*	*FTE RN employment and change from prior year hospitals*	*FTE RN employment and change from prior year nonhospital*
2001	4.7	1 201 003	786 387
2002	5.8	1 285 718 (84 715)	787 564 (1177)
2003	6.0	1 384 482 (98 764)	807 498 (19 934)
2004	5.5	1 378 116 (– 6366)	813 317 (5819)
2005	5.1	1 326 914 (– 51 202)	837 269 (23 952)
2006	4.6	1 345 711 (18 797)	894 162 (56 893)
2007	4.6	1 429 989 (84 278)	923 165 (29 003)
2008	5.8	1 588 226 (158 237)	875 260 (– 47 905)
2009	9.3	1 569 496 (– 18 730)	932 406 (57 146)
2010	9.6	1 608 453 (38 957)	926 907 (5499)

in detail, one recommendation calling for removing barriers restricting NPs' scope of practice has received considerable attention from the media, health policy makers, and many in the medical profession. Therefore, the authors conclude the discussion of the professional nursing workforce by providing a brief overview of APRNs.

The Advanced Practice Nurse Workforce

The term APRN refers to four types of nurses who have received advanced education and training beyond that required to become an RN and include NPs, certified RN anesthetists (CRNAs), CNS's, and CRNMs. Most states require APRNs to complete a master's degree in nursing, and the vast majority of state legislature have delegated to state boards of nursing the authority to establish requirements for certification examinations in each type of APRN and in the various advanced practice subspecialties. In a few cases, the state board of medicine holds this authority (Cuningham, 2010). Data from the NSSRN indicate that approximately 8% of RNs or 220 000 of 2.6 million RNs employed in nursing in 2008 were APRNs. Below, the authors briefly describe the roles and key characteristics of each type of APRN (see Table 5).

Table 4 Key messages and recommendations

Key messages

1. Nurses should practice to the full extent of their education and training
2. Nurses should achieve higher levels of education and training through an improved education system that promotes seamless academic progression
3. Nurses should be full partners, with physicians and other health professionals, in redesigning healthcare in the US
4. Effective workforce planning and policy making require better data collection and an improved information infrastructure

Recommendations

1. Remove scope-of-practice barriers
2. Expand opportunities for nurses to lead and diffuse collaborative improvement efforts
3. Implement nurse residency programs
4. Increase the proportion of nurses with a baccalaureate degree to 80% by 2020
5. Double the number of nurses with a doctorate by 2020
6. Ensure that nurses engage in lifelong learning
7. Prepare and enable nurses to lead change to advance health
8. Build an infrastructure for the collection and analysis of interprofessional healthcare workforce data

Source: Reproduced from Institute of Medicine (2011). *The future of nursing: leading change, advancing health*. Washington, DC: The National Academies Press.

Nurse Practitioners

NPs are the largest and most rapidly growing APRN. According to the HRSA (2010), an estimated 130 000 NPs were working in nursing in 2008, double the number estimated a decade earlier. The role of NPs was established in the mid-1960s and focused on serving women and children in rural and underserved inner city areas where physicians were scarce. In the present day, NPs work across many populations and geographic regions and their focus have expanded to include family care, pediatrics, geriatrics, adult health, women's health, psychiatry, neonatology, and acute hospital care of adults and children. Currently, 39% of NPs work in hospital settings, particularly in specialized inpatient care units and hospital-affiliated primary care clinics, approximately 36% provide primary care in traditional ambulatory care settings (including retail clinics), and 12% work in public and community healthcare agencies and in schools. In 2008, full-time NPs earned $83 000 on average in 2008, compared to $67 000 for all RNs HRSA (2010).

Clinical Nurse Specialists

Although the number of CNS's has declined recently, CNS's are the second-largest type of APRN and are estimated to number approximately 45 000 in 2008. The role of a CNS is to improve clinical care, primarily in hospitals and extended care facilities, by providing advanced clinical nursing expertise to help coordinate care for individuals, educate nursing personnel who provided direct care, and help identify and improve aspects of the health system organization that affect patients and nursing staff. CNS's have expertise in one or more clinical areas such as oncology, pediatrics, geriatrics, psychiatric/mental health, adult health, obstetrics, acute/critical care, and community health. Although about half of CNS's are employed in hospital settings, often in administrative or supervisory roles, CNS's also work in ambulatory care, public health, and academic settings. Nearly 64% are over the age of 50 years, making them the oldest group of APRNs. Average earnings for a full-time CNS were $86 000 in 2008.

Table 5 Number and characteristics of advanced practice registered nurses, 2008

	Nurse practitioners	*Certified nurse midwives*	*Certified nurse anesthetists*	*Clinical nurse specialists*
Number employed in nursing, 2008	132 000	15 000	30 000	45 000
Number employed in nursing, 2004	118 000	11 000	28 000	57 000
% More than age 50 years	50%	54%	50%	64%
Average salary (full time)	$83 000	$75 000	$135 000	$84 000
Physician type with most overlap	Family or general practitioner	Obstetrician/gynecologist	Anesthesiologist	N/A
Main setting of work	Primary care settings	Hospitals	Hospitals	Hospitals

Certified Registered Nurse Anesthetists

Nurses have been providing anesthesia since the Civil War and in the present day provide approximately 32 million anesthetics annually in the US and represent two-thirds of anesthetists in rural hospitals (American Association of Nurse Anesthetists, 2011). Most (82%) CRNAs not only work in a hospital operating room, but they also deliver anesthetics in birthing centers/obstetrics departments, dental offices, emergency rooms, plastic surgery centers, and outpatient surgery facilities. CRNAs play a particularly important role providing anesthesia in the military and the Veterans Administration and in hospitals located in rural areas. There were roughly 30 000 CRNAs working in 2008, a 16% increase from 2000. On average, CRNAs are younger and more likely to be male (more than 40%) than other APRNs. In 2008, CRNAs reported average earnings of $136 000, which is much higher than all other groups of RNs or other APRNs HRSA (2010). Unlike anesthesiologists, CRNAs are more likely to work in rural rather than urban areas.

Certified Nurse Midwives

CNMs care for women before, during, and after childbirth. Their role began in the nineteenth century to fill a particular need in impoverished urban and rural areas with limited access to physicians. Nurse midwifery arose both in New York City and Kentucky in the late nineteenth and early twentieth centuries. The earliest US nurse midwifery programs were designed to meet the needs of special populations in urban, rural, and impoverished populations with limited access to physicians HRSA (2010). Most CNMs work in hospitals, with 42% specializing in labor and delivery, 34% in obstetrics, and 14% in gynecology or women's health. One-fourth worked in ambulatory care settings in 2008. There were approximately 15 000 CNMs employed in nursing in 2008, making them the smallest group of APRNs, although their numbers have grown since 2004. CNMs earned $75 000 on average in 2008, and 55% were more than age 50 years.

Overlap with Physicians

CNMs, CRNAs, and particularly NPs perform roles throughout the healthcare delivery system and provide many services that overlap considerably with those of physicians (respectively, obstetricians/gynecologists, anesthesiologists, and physicians proving primary care such as internists, pediatricians, and family practitioners). That overlap has several implications. First, areas of the country that have difficulty attracting physicians (particularly rural or inner city areas) have relied on APRNs to fill workforce gaps. Consequently, APRNs are more likely to work in rural and inner city areas and serve patients that are less likely to have private insurance. Second, the degree to which APRNs can substitute for physicians has resulted in a growing literature and policy debate about whether APRNs provide care of comparable quality to their physician counterparts. Most studies find that NPs can successfully handle up to 80% of primary care visits, and that the care received by patients seeing either an NP or a primary care physician is comparable in terms of quality or resource use (Newhouse *et al.*, 2011). Some studies have employed randomized clinical trials, for example, assigning patients to either NPs or primary care physicians (Laurant *et al.*, 2004). In light of projections of shortages of primary care physicians by 2020 (Association of American Medical Colleges, 2011) and because provisions in the Patient Protection and Affordable Care Act will expand the insured population and demand for primary care (Ku *et al.*, 2011), the demand for NPs is likely to grow as will the controversy surrounding policies that call for expanding the NP workforce to make up the gap in primary care (Naylor and Kurtzman, 2010; Pohl *et al.*, 2010). Similar debates over quality and practice restrictions also involve CRNAs (Dulisse and Cromwell, 2010).

All states regulate the boundaries of practice governing the services each type of APRN is permitted to perform. Particularly in the case of NPs, 'scope of practice' laws regulate aspects of practice such as the required level of physician supervision and collaboration and the ability to prescribe medications. Critics of these laws assert that they reduce access and increase the cost of care by forcing patients to seek care from physicians who typically charge higher prices than NPs. Defenders argue that they are necessary to protect patients from low-quality care and unsafe practice. Currently, such laws vary widely from state to state and this variation is viewed by some as hampering reimbursement by private insurers to NPs in certain states (Tine-Hanson-Turton *et al.*, 2006).

An analysis of state scope of practice laws that governed NPs and CNMs from 1992 to 2000 suggested that the state laws were becoming less restrictive during this period (HRSA, 2000). Considerable variation and restrictions remain, however, as illustrated in Missouri where new patients who had an initial visit with an NP had to be seen by a physician within 2 weeks or in South Carolina that requires a supervising physician be available at all times for consultation. Some states only permit NPs to prescribe certain medications or to refer patients for laboratory tests on an approved list (Lugo *et al.*, 2007; HRSA, 2000). As of 2010, 16 states allowed NPs to practice independently from a physician (Fairman *et al.*, 2011).

Scope of practice issues for CNMs are similar to those of NPs, with states varying on the degree of prescriptive authority, supervision by physicians, and the extent to which CNMs can be reimbursed directly (HRSA, 2000). Yet, despite extensive state variation in scope of practice for NPs and CNMs, there is little research or evidence as to the effects of the laws on processes and outcomes of care.

Summary

Much of the production and distribution of personal healthcare services in the US depends on professional nurses, RNs and APRNs, who are employed in wide variety of clinical and nonclinical positions in countless organizations. Professional nurses deliver basic and advanced nursing care services, practice nursing independently, and function as both complements and substitutes to physicians. The RN workforce is dominated by the large and aging baby boom cohorts who are expected to retire in large numbers over the decade, threatening to create a new nurse shortage in hospitals and other

settings, particularly as the demand for healthcare expands due to the implementation of health reform, the aging of the baby boom generation, and other factors. How long it will take for a new equilibrium to be reached in the nurse labor market will depend on how many RNs retire, whether there will be enough new RNs to replace them, how much demand grows, and how effectively organizations adjust to these changes. Increasing demand for healthcare also affects physicians, particularly primary care physicians whose supply is projected to fall below the estimated demand by the end of the decade. Because NPs are viewed as being good substitutes for the majority of primary care services provided by physicians, healthcare policy makers are focusing on efforts to allow NPs and other APRNs to practice to the full extent of their education and training by reforming restrictive state laws and nurse practice acts.

Markets in Health Care

P Pita Barros, Universidade Nova de Lisboa, Campus de Campolide, Lisboa, Portugal
P Olivella, Universitat Autonoma de Barcelona and Barcelona GSE, Cerdanyola del Valles (Barcelona), Spain

Glossary

Capitation A payment from a third-party payer such as a health authority or an insurer to a supplier such as a health plan or a health-service provider that is made per enrollee (in the case of health plans) or per individual in the population residing in the catchment area (in the case of paying for specific healthcare services).

Complementary (or supplementary) private health insurance (PHI) Private health insurance cover for copayments in the public sector.

Copayment If both a patient and a third-party payer share the payment of some service, the part that the patient bears.

Duplicate PHI In the presence of a national health service that covers part or the whole population and a (large) portfolio of services, private insurers offer insurance covering a similar portfolio of services.

Health plan Usually an insurer that receives its premium from a third-party payer rather than from (or on top of) the individual's out of pocket premium.

National Health System or National Health Service (NHS) In an NHS, health insurance and healthcare services are integrated into a single health authority, which either owns its own network of final providers or subcontracts with (usually) nonprofit private hospitals. The whole system provides a large portfolio of services and is financed trough general taxation and limited copayments.

Premium The price of an insurance contract. Also used to describe a third party's payment to a health plan for each of its enrollees, in this case sometimes also referred to as capitation or capitation rate.

Supplementary PHI The Organization for Economic Co-operation and Development is proposing to relegate the term supplementary to PHI that covers services that are not covered by the national health system, some dentistry services being a usual example (see Complementary PHI).

Yardstick competition In health care, the use of comparative performance indicators, usually by a health authority, to design payment mechanisms for providers.

Introduction

The first question one should ask when addressing healthcare markets is whether health care is any different from other goods. If it is not, economic theory states that, as with apples and pears, the unfettered competitive market will lead to efficient outcomes and that equity can be reached by appropriately redistributing purchasing power *ex ante*. This brings the question of why in some countries healthcare markets do not even exist or are severely restricted. In national health services (NHSs) like those in the UK or Spain, a single door provides access to most health goods and services (pharmaceutical products usually being an exception), and market forces may disappear or be relegated to the stage where the health authority subcontracts with providers (doctors and hospitals). Less extremely, why is regulation of healthcare markets desirable?

Before answering these questions, let the reader be first warned that a broad interpretation of what a market is has been taken here. For instance, in the market for prepaid health plans, the individual may not pay a price either when enrolling a plan of her choice nor when she uses the services this plan provides. Even farther away from the usual idea of a market, in a NHS, the health authorities may base the remuneration of the hospitals they own or subcontract with on relative performance evaluations (RPEs). In this case, a hospital's revenue depends on how its performance compares to the average. For those who want to read more, their web search should include the terms 'yardstick competition' and 'contests.' Even an individual's choice between seeking treatment in his or her NHS or resort to a private hospital can be seen as a market. There, the 'price' in the public provider may be the time the individual has to wait. All the examples given have one thing in common: as a provider, your revenues fall if your performance (the combination of price and quality) falls as compared with your rivals or to any other existing outside option (e.g., an alternative treatment). The broad term 'market forces' is used to refer to this effect.

Now, the questions posited above can be readily answered. Health care is either publicly provided or its market severely regulated because society does not believe that free markets do such a good job. The differences between health and other goods, as well as the differences between health care and other services, can be traced back to the work of Arrow (1963). Since then, the role of markets in the allocation of resources in the health sector has been scrutinized from many angles. The role of ethics and societal judgments was, and is, widely discussed. The societal value of health care is not necessarily restricted to the standard notion of economic welfare (measured by the difference between an agent's willingness to pay for a service and the costs the agent bears, the so called 'agents' surplus'). Other considerations like happiness, freedom to choose, and absence of pain, for example, are often included as relevant for assessment of resources allocation, in addition to the mere utility from consumption of health and health care. Health in itself, by its nature, does not have a market for transaction. The role of markets in determining welfare (and the proper meaning of welfare) is distinct in the health sector. For an introduction to the discussion, see the essays contained in Cookson and Claxton (2012).

Still, markets are one mechanism that allocates resources in the health care in many ways. There are several reasons why

 doi:10.1016/B978-0-12-375678-7.01301-8

markets may behave differently in this sector, irrespective of the social judgment one makes about the adequateness of the resulting allocation. The focus is on the particular features of the market mechanism (without discussing here the welfare reasoning associated with each of those features) and the resulting reasons for government intervention.

The first reason – and the one that is best understood – is that some healthcare goods have external effects. That is, their consumption affects (positively or negatively) other individuals. The first example that comes into mind is vaccines. It is well known that markets for vaccines will not work well because individuals often ignore their beneficial external effect on everybody else's well-being. A free market will lead to under vaccination. Note that this does not directly apply to a hip replacement. One could say that taking care at home of a family member who can hardly walk puts lots of strain on the other family members. However, this is a type of externality that is likely to be internalized by the individuals themselves, because they probably care as much about the well-being of their family as for themselves.

The second reason – also well understood for a long time – is that providers could hold some degree of the so-called 'market power.' The idea is that if very few providers are available then they will be able to restrict supply in a way that price will be too high as compared to its optimum value: the cost of providing the unit that is least valued by society. This brings two effects. One is on equity, as consumers are worse-off whereas suppliers are better-off. The other is on efficiency; too few units are enjoyed by society. Why are healthcare goods prone to such a situation? The obvious reason is the existence of patents in some areas, which restrict the number of providers to one. Now patents are there for other reason that would take it too far. The other is that there exist some treatments that imply extremely large fixed costs. It does not make any sense to have two CT-scan machines in a small village. Such issues are taken up in Chapter 9.14 Health-Insurer Market Power: Theory and Evidence (00914). The existence of insurance coverage by making the patient (buyer) less sensitive to price induces the providers (sellers) to increase the price at the expense of the third-party payer.

The third reason involves the presence of privileged information (or asymmetric information) in one or both sides of the market. Health care is plagued with examples of this. On the consumer side, he or she may be more knowledgeable about his or her own health risks and needs (say intensity of pain). On the supplier side, healthcare goods are usually expert goods, meaning that providers are more informed of the true benefits (or long run side effects) of certain treatments. Again, markets perform quite poorly under these circumstances.

The fourth reason is the presence of risk. However, risk *per se* is not really problem for markets. It only implies that the notion of a good becomes a little more sophisticated. Given a single service, say a hip replacement, there are two or more goods, one for each possible circumstance that the individual may encounter. A hip replacement when the individual is perfectly healthy is not the same good as a hip replacement when the individual is under excruciating arthritis pain. The solution is to create an insurance market. In such a market firms (now called insurers) offer to exchange goods (in this case money and hip replacement) between these circumstances. The provider offers a hip replacement for free in case of severe arthritis pain (and only in that case) for free in exchange for x monetary units *ex ante*. One refers to x as the insurance premium. The market for insurance should perform well if none of the aforementioned problems is present. However, what does *ex ante* mean? What if an individual has privileged information of the likelihood of needing a hip replacement? Individuals who expect to need a hip replacement are more willing to pay the insurance premium. This leads to all sorts of problems. One of the solutions to these problems is quite drastic: get rid of insurance markets altogether and have a monolithic (vertically integrated) public-health system, perhaps financed with taxes or the like.

The fifth reason, intimately linked with the previous one, is the presence of moral hazard in either or both the consumer and the provider's side. On the demand side, the idea is that the individual, once insured, bears the consequences of a bad event less than fully and keeps a behavior that is detrimental to his/her health. Let this be illustrated with two very simple and very practical examples. If an insured individual becomes severely arthritic, he or she will obtain a hip replacement at a low price, perhaps even for free. Hence he or she will keep practicing vigorous sports. The same goes for stomach reduction and eating in a disorderly manner. These are of course rather extreme examples, but there seems to be some evidence that such behavioral decisions are present. Note that a real issue only exists if these behaviors cannot be contracted on because they are not publicly observable. Hence some researchers include moral hazard under the umbrella of asymmetric information, but they are not the same thing and require different cures. (See **Box 1** for a taxonomy of informational problems and market/government responses to them.) In the supply side, moral hazard refers to situations where the actual actions of the provider (be it a doctor's diagnose effort or care in treating a patient, be it the manager of a hospital who fails to contain costs) are unobservable. Again the idea is that the decision maker (doctor, manager, and nurse) may not bear the full impact of his or her actions. This is the case for example if the doctor receives a fixed monthly remuneration (independent of health outcomes) and medical errors go unpunished. It is worth mentioning here that the term moral hazard is also used to describe the phenomenon by which an individual who faces a low or zero price due to insurance may overuse the services. To distinguish both phenomena the literature (not unanimously) uses the terms *ex ante* moral hazard, which refers to the change of behavior that may lead to greater needs, and *ex post* moral hazard, which refers to the increase in service usage for a given need. It is easy to see that empirically identifying which is the source of higher usage is a complex question. On this, see Chapter 9.16 Moral Hazard (00916).

The last reason is the presence of the so-called bounded rationality. In this concept, misperceptions of one's own health status, lack of the mathematical capability to appraise extreme probabilities, intertemporally inconsistent behavior, or purely irrational behavior are included (perhaps too broadly). Since individuals are unable to make proper choices, the government (or a delegate of the government) makes them for them.

Box 1 A taxonomy of informational problems and market/government responses, with health-care examples

Informational problems

1. *Asymmetric information:* Some party in a relationship has privileged information on the environment.
   1.1. *Adverse selection:* The uninformed party is the first to make a decision or take some action, to which the informed agent responds. Synonym: *Hidden type.*
   1.2. *Signaling:* The informed party is the first to make a decision or take some action, to which the uninformed party responds.
2. *Imperfect information:* Once the relationship between two parties has already been established, i.e., through a contract, one of the parties takes an action that is unobservable to the other or which cannot be contracted on either for legal reasons or because a judge cannot enforce the contract. Synonyms: *moral hazard; unobservable action.*

Responses

0. General
   0.1. Uninformed party gathers more information
      0.1.1. Monitoring and auditing
      0.1.2. Prompt informed party to report his or her private information
      0.1.3. Prompt the informed party to show unfalsifable information
      Note: the two last procedures may lead to a signaling problem, since both reporting and providing information are subject to strategic/opportunistic behavior.
1. To adverse selection
   1.1. Offer a menu of contracts (screening)
   1.2. Public provision
2. To signaling
   2.1. Forbid information disclosure (difficult to implement)
   2.2. Public provision
3. To moral hazard
   3.1. Risk sharing: make undesired actions more costly
   3.2. Risk equalization and risk adjustment: so that all actions lead to the same benefits

Examples of adverse selection

Informed party	*Uninformed party*	*Information*	*Decision by uninformed party*	*Decision by informed party*	*References*
Potential insuree	Insurer	Current health status	Price and coverage to offer	Purchase insurance and from whom	Rothschild and Stiglitz (1976)
Doctor	Patient	True health benefits/long run side effects of some treatment	Prescribe A or B /refer to specialist or not	Accept/reject; change doctor	Garcia-Mariñoso and Jelovac (2003)
Manager of the hospital	Hospital board/owners/government	Risk mix in the catchment area	Allot a budget/Set P4P incentive scheme	Accept/reject	

Examples of signaling

Informed party	*Uninformed party*	*Information*	*Decision by informed party*	*Decision by uninformed party*	*References*
Potential insuree	Insurer	Current health status	Choose an expensive full coverage contract or a cheap partial coverage contract	Reject/accept the agent	Grossman (1979)
Potential insuree	Insurer	Results of a blood test	Refuse to show results of genetic test	Premium and coverage	Hoy and Polborn (2000)
Doctor	Patient	Doctor's altruism	Time spent in diagnosis	Change doctor	Jack (2005)

Examples of imperfect information

Informed party	*Uninformed party*	*Decision by informed party*	*References*
Potential insuree	Insurer	Engage in some risky behavior	Zeckhauser (1970)
Doctor	Patient	Diagnostic effort to be exerted	Dranove (1988)
Manager of the hospital	Hospital board/owners/government	Managerial effort (e.g., cost containment); Personal interest purchases	Ma (1994)
Owner of a n HMO offering a health plan	Government paying a premium for each enrollee	Distort the quality of some services upwards or downwards in order to avoid high risks/attract low risks	Frank *et al.* (2000)

These are not the only reasons for government intervention. For example, social valuation of market outcomes may lead to government action as well. Generally speaking, dominance of one resource allocation mechanism over the other cannot be presumed (market vs. state). How the markets operate is of concern here.

Having said this, the next question is whether regulation or public provision do indeed palliate any of these problems present in healthcare markets. In doing so, a guide throughout the most related entries in the encyclopedia will be offered. Section Introducing Market Forces in a NHS briefly addresses the introduction of competitive forces in a national health system. Section Market Regulation addresses the regulation of private health insurance and provision markets, Section Duplicate Systems discusses the interaction between public and private insurance. Section A Closer Look at the Provision of Goods and Services in Health takes a closer look at the delivery of health goods and services. Section A Teachers' Guide offers a teacher's guide to these issues. Section Concluding Remarks offers some concluding remarks.

Introducing Market Forces in a NHS

Market forces in NHSs have been implemented basically trough two different policies. On one hand, in some national health systems like that in England, Denmark, Sweden, and Norway, patients are allowed to choose between a set of hospitals in case of needing specialized care. (*see* Chapter 13.10 The Impact of Competition on the Hospital Sector (01310) for an empirical appraisal of the effects of such policy.) On the other hand, some national health systems are remunerating hospitals according to the results of RPE. (*see* Chapter 13.13 Comparative Performance Evaluation: Information on Quality (01313)).

In the first case, the idea is that increasing patients' choice where patients face no copayment would foster competition in quality, as long as quality is observable by patients (or by doctors, but then patients and doctors incentives should be aligned). However, this depends in turn on how the chosen hospital is remunerated. If the remuneration is per episode and is fixed (like in a diagnosis-related group system) and quality is observable, theory predicts an increase in quality, since hospitals offering lower qualities would lose market share. However, it is not so clear that this assumption is satisfied to a sufficient degree. Moreover, even if a specific episode is reimbursed at a fixed fee, a hospital could be in financial trouble if it faces a catchment area where individuals bring higher costs for the same ailment. Things are even worse if hospitals are allowed to set their fees, since in that case they could raise a given service fee without compromising demand (recall that the patient obtains the service for free).

As for the effects of RPE-based remuneration systems under public provision, the Chapter 13.13 Comparative Performance Evaluation: Information on Quality (01313) and Chapter 13.14 Heterogeneity Across Hospitals (01314) review, respectively, issues related to obtaining information on quality of care and on hospital performance at large. The main problem is the asymmetry of information between patients and payers, on one hand, and providers, on the other hand, on provider's effort to deliver the adequate amount of care at the right cost. Asking the providers information faces evident problems related to truth telling and monitoring. Comparing across providers is, in this setting, a natural way to obtain information as long as performance of different providers is correlated. Fichera *et al*. discuss the instruments for quality comparison. One important decision is to which type of quality measurement is more informative, and whether attention should be put in quality of outcomes, in quality of processes, or in quality of inputs. It is not surprising that instead of a single quality indicator, a set is used. Using a set of indicators, however, poses the question of how to aggregate these indicators into a single variable. Without such aggregation it may be impossible to obtain a clear ordering of hospitals according to quality, as some hospitals may fare above the average in some services and worse in others.

On a different but related line, Chapter 13.14 Heterogeneity Across Hospitals (01314) addresses the question of how to structure payments to providers (hospitals) in a way that accounts for their performance and heterogeneity. A prospective payment equal for all providers may induce incentives for selection and for lower unobservable quality. Although in Chapter 13.13 Comparative Performance Evaluation: Information on Quality (01313) the focus in on instruments that may help to measure quality, Chapter 13.14 Heterogeneity Across Hospitals (01314) uses the distinction between long-term and short-term sources of cost heterogeneity, and uses the payment system to not pay for short-term inefficiencies and to keep efficiency incentives. The control of performance in unobservable characteristics is made implicitly through the payment rule.

Market Regulation

Every market is characterized by demand, supply, and a 'mechanism' that connects both to each other. In the standard textbook treatment of markets, that mechanism is the price of the good. Markets included in the health sector often deviate from this simple framework. Market analysis applied to health care or health insurance has to adjust for particular features involved.

First of all, the health sector involves several types of markets. Three of them are highlighted: the market for labor inputs, the market for goods and services, and the market for health insurance. Each of them has their own specific set of issues. Indeed, several entries in the encyclopedia are devoted to pharmaceutical and medical equipment industries.

Take a healthcare good or service. As mentioned above, the uncertainty about the moment and intensity of need for health care leads to the existence of insurance mechanisms (public, private, or both). Such insurance implies markets for healthcare goods and services have a third agent, the insurer, who decouples the price received by the provider from the price paid by the consumer. This third agent may take a passive role, as in traditional reimbursement models, or may take an active role. The active role can range from establishing conditions under which demand can exert (eventually limited) choice of providers, to contracting and paying directly providers or even integrating vertically insurance and

provision. Of course, if a single enterprise implements such integration it is got back to NHS (Figure 1).

The Private Health Insurance Market

Even in a basic private health insurance system, like the one present in Switzerland or in the US for those not covered by Medicare or Medicaid, the market incorporates a vertical dimension that is depicted in Figure 2. In the final stage of the vertical relationship, doctors and hospitals are contracted by insurers in order to provide healthcare goods and services. In the intermediate stage, consumers seek insurance contracts from insurers. Each of these stages is in itself a market, and often researchers have concentrated attention in one of them either by taking the outcomes in the other as given or by assuming that the other performs efficiently. In other words, in studying the insurance market, all the problems listed above are often assumed away in the relation between insurer and provider. Conversely, the insurers' revenue is taken as given when one studies the contracting phase between providers and insurers.

This is not to say that the lessons learned in studying one market are not useful in studying the other. Indeed, in both markets, a major issue is how to set the payments given that each firm (be it an insurer or a final provider) faces a heterogeneous set of consumers. Indeed, an individual may have a high or a low probability of falling ill, which matters for the insurer, and the same individual, once ill and hence requiring a specific treatment, may bring high or low costs, which matters for the service provider. In the first instance and if the insurer is able to choose and collect premia from the individual, the issue is whether and how does the insurer charge (or is allowed to charge) different premia to individuals presenting different characteristics (age or gender for instance). This practice is usually termed risk classification or risk categorization (see Section Risk classification). If the insurer instead receives the premium from a third-party payer (like in Medicare or in the Netherlands), the same issue is termed risk equalization or risk adjustment. In the relationship between the insurer and the provider, one speaks of designing patient classification systems and their use to set risk-adjusted payments.

The overall idea is that premium should fit the expected cost for every individual and that health treatment price should fit its cost. Otherwise, the supplier (again, insurer, or provider) will have an interest in attracting the individuals or serving the treatments where payment exceeds cost (cream skimming or cherry picking) and avoid the individuals or treatments where the inequality is reversed (dumping or skimping). Both opportunistic behaviors fall under the term risk selection.

The importance of these mechanisms in the working of healthcare markets is today clear. Chapters 13.3 Risk Adjustment, the European Perspective (01303), 13.7 Risk Adjustment as Mechanism Design (01307), and 9.18 Risk Selection

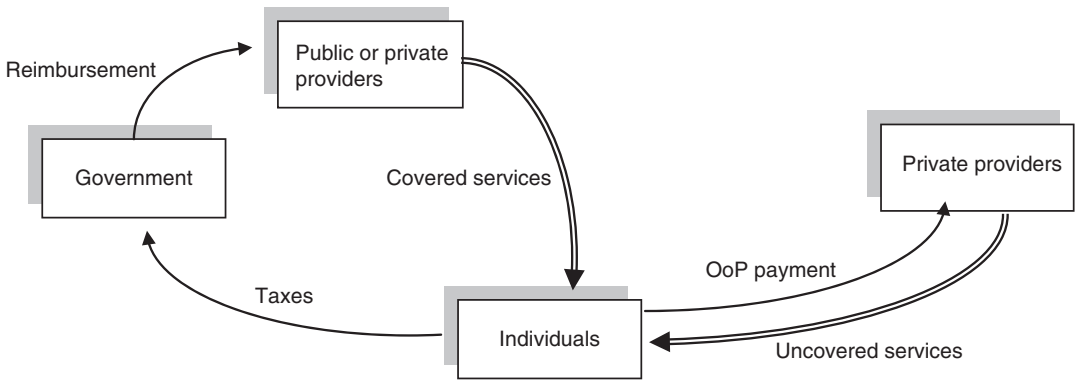

Figure 1 A pure NHS system. **OoP** stands for out-of-pocket payment.

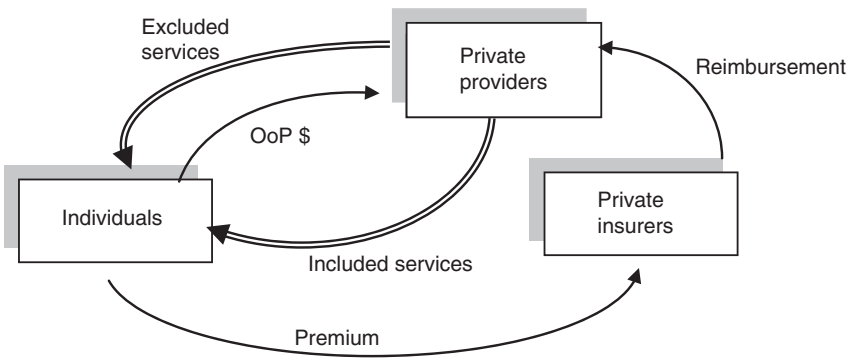

Figure 2 A pure private health system.

and Risk Adjustment (00918) address the role and characteristics of risk adjustment/risk equalization, while Chapter 13.16 Risk Classification and Health Insurance (01316) discusses risk classification. The latter issue is addressed first.

Risk classification

Important issues arise from information asymmetries between agents. A natural intervention is the demand for further information to be incorporated in decisions. In this vein, risk classification aims at reducing informational asymmetries between health insurers and individuals.

Under perfect risk classification, an insurer conditions its contracts on so many individual characteristics that the individual and the insurer have the same information (and therefore the same expectations) about future costs. In this case an individualized premium fitting these expected costs can be set. Such elimination of asymmetric information will lead to an efficient market allocation. However, high risks will face higher premia than low risks. The government can then set appropriate taxes and transfers to improve the welfare of the former at the expense of the latter. Voluntary participation by the low risks may put a limit to such cross subsidization, unless the government makes purchasing insurance mandatory. Incidentally, equalizing premia by the government is not to be confused with some naive 'community rating' where the insurer is not allowed to set different premia to different individuals. Such a policy might either lead to risk selection or to the self-exclusion of the low risks (the so called 'spiral of death').

The problem is that risk classification can only be performed on the basis of observable characteristics of the population. Moreover, collecting data on such characteristics may be quite costly. In any case, only a small set of variables is actually used to design contracts, and this implies that these variables fall very short of being perfect predictors of health risk. As a consequence, the market usually reacts by implementing self-sorting menus of contracts (be at the industry or at the firm level). By this it is meant that individuals, who now have privileged information on their true health risks, reveal this information by choosing one contract instead of another. Such self-sorting menus can only be constructed, however, by reducing the coverage and premia of the contracts aimed at attracting the low risks. Better risk classification could reduce these distortions according to some authors.

Note that the importance of improving – or limiting – risk classification depends on the extent of asymmetric information existing at the outset. This needs to be tested empirically. Current empirical work has progressed but is still far from a definite answer to the question of how significant and pervasive are the asymmetric information problems. Some studies found effects of relevant magnitude whereas others found less impressive implications. A well-recognized problem in testing for asymmetric information is that individuals may have privileged information on dimensions other than risk, and that differences in one dimension could be countervailed by differences in another. For instance, more risk-averse individuals (in principle more willing to pay for coverage) may at the same time have safer habits or lifestyles, which reduces their willingness to pay for coverage.

Switching costs

Whenever more than one possibility of health insurance coverage exists, patients will typically face trade-offs in choosing one health insurer over the other, and issues of switching across health insurers cannot be neglected. Chapter 13.12 Switching Costs in Competitive Health Insurance Markets (01312) details the knowledge in this particular point, individuals' switching across health insurance plans. Taking the Swiss long-lasting experience with health plans' competition, a review of it is of interest to the countries promoting choice of insurance contract. As for consumers' choice and consequently for switching behavior, several issues are particularly relevant: choice overload, the resistance to change (status quo bias); and the existence of risk selection.

Preferred providers

It is stated above that the vertical structure Individuals–insurers–providers is seldom studied as a whole. Some exceptions exist, however. An important issue is with which provider each insurer decides to work. The selection of providers by insurers will also determine how demand for health services is directed toward providers. Chapter 13.15 The Preferred Provider Market (01315) takes up the implications of this market relationship. The main issue is how insurers define the size of the network of providers they use, and how that size depends on the specific rules used to define which providers belong to the network. Selecting a subset of market providers as preferential providers (insiders henceforth) changes the strategic incentives of providers to compete in the market. More specifically, by being included in the network of a health insurance plan (public or private), insiders gain a competitive advantage vis-à-vis the outsiders. To see this, notice that patients will pay less (or even not pay at all) when choosing to be treated by an insider than when selecting an outsider. Hence insiders will face a demand for health care with lower price elasticity, bringing higher prices in equilibrium. This harms the insurer since it must bear higher prices herself. Providers will compete to become members of the preferred network of providers in order to obtain this competitive advantage. Equilibrium may have most or even all providers as preferred ones.

In this context, the payment rules set to providers gain importance as a way to induce competitive pressure. Indeed, the third-party payer can reintroduce competitive pressure by having the patient pay less for the outsider treatment the higher the price of the insider treatment is. In other words, if the insider sets a higher price, the reimbursement received by the patient when choosing an outsider is also larger. Some demand is then diverted from the insider to the outsider. Provider networks are also a form of competition between insurers as well. Patients may opt for one or the other networks based on the list of providers in each network. Competitive forces will be present both across providers and across insurers.

Demand-side issues

The demand side of health care is also characterized by information problems. Patients are not fully knowledgeable about their own health condition, and they are not completely informed about treatment options. Patients rely on physicians to guide them through the healthcare system in order to

restore their health condition. This agency relationship is taken up in Chapter 13.11 Primary Care, Gatekeeping and Incentives (01311), where the interaction of the referencing of patients to other providers (hospitals and specialists) and incentives is discussed. Gatekeeping receives particular attention. In itself, gatekeeping is a constraint on freedom of choice by patients, in the context of a trade-off between free choice and more informed choice. The advantage of using a gatekeeping organization does depend on the incentives of physicians acting as gatekeepers, which raises the issue of incentives faced by gatekeepers to perform their role. Primary care concentrates several roles (health promotion and prevention, diagnosis and treatment, referral, and long-term care). By restricting freedom of choice, gatekeeping is expected to be associated with lower patient satisfaction but also with lower (unnecessary) use of health services and lower expenditures. The empirical evidence on this trade-off has not yet produced results that account for confounding factors introduced by financial incentives faced by physicians (systems with freedom of choice use, generally, fee for service payments, whereas systems with gatekeeping use capitation).

The Role of Risk Adjustment in Market Competition among Health Plans

Countries with competition in health insurance want to ensure, at the same time, affordability of health care to all citizens and nondiscrimination of contribution based on individual risk. Health insurers, however, for the same value of contribution, prefer to contract with the better risks. This led to a role for risk adjustment in market competition among health plans. The solution adopted was to set a two-steps system (Figure 3). First, contributions not based on individual risk are used to build a pool. Second, risk-adjusted payments from the pool to health insurers (or health plans) aim at the double objective of providing enough funds and avoiding incentives for selection of good risks. In most cases these payments are made on a capitative basis, that is, per enrollee in the health plan, hence the term capitation rates. Risk adjustment is an essential element of market competition but its accurate definition is a difficult task. This system is in place, with some variations, in the Medicare sector in the US, the Dutch, Belgian, and German systems, as well as the system in place for public servants in Spain. The European approach to it has been mainly data driven (hence term statistical risk adjustment), attempting to find the more adequate system of risk adjustment based on observables like age, gender, and even prior use of healthcare services. The intricacies of this way to adjust payments are discussed in Chapters 13.3 Risk Adjustment, the European Perspective (01303) and 9.18 Risk Selection and Risk Adjustment, the latter from a US perspective.

A different approach is discussed in Chapter 13.7 Risk Adjustment as Mechanism Design (01307). Although statistical risk adjustment takes it for granted that an insurer will not engage in risk selection if expected costs (calculated *ex ante*) are close enough to the capitation rate, the latter entry admits the possibility that even in this case individuals may make use of their privileged information on their true health risks. Equivalently, there may be observables that are correlated with expected costs but cannot be used in the risk adjustment formula (either due to non discriminatory laws or inherent uncontractability). This implies that both individuals' choices and insurers' behavior must be taken into account when designing the capitation system. This leads these authors to seek an adequate distortion in weights of the risk adjustment model to provide the correct incentives to providers. This approach requires empirical work in understanding how providers (or health insurers) react to risk adjustment rules in order to design these rules taking into consideration such reactions. The empirical challenge is not to find the best statistical fit, but to measure reactions in behavior of health plans (or providers).

Duplicate Systems

In countries with a NHS, the main insurance protection is Government provided. Private (voluntary) health insurance has then a duplicate role of coverage (see Figure 4). Chapter 13.17 The Interaction Public and Private Providers of Health Services (01317) looks into the rationale and implications of such duplicate health insurance coverage in countries with NHS. Duplicate health insurance coverage means private health insurance to cover for the same risks as the NHS. The reasons suggested include promotion of population health, containing health expenditures, increased population choice, and health system 'responsiveness,' whenever the NHS fails to deliver health care to the extent desired by the population. The empirical support for the reasons behind duplicate private health insurance is not fully conclusive.

A different set of questions is related to the impact of double coverage on use of services, and whether it adds, or substitutes for, NHS expenditures. On this aspect, no conclusive evidence is available. Double coverage seems to be associated with higher use of healthcare services, though some of it can be diverted from the NHS. Overall, there is no evidence or

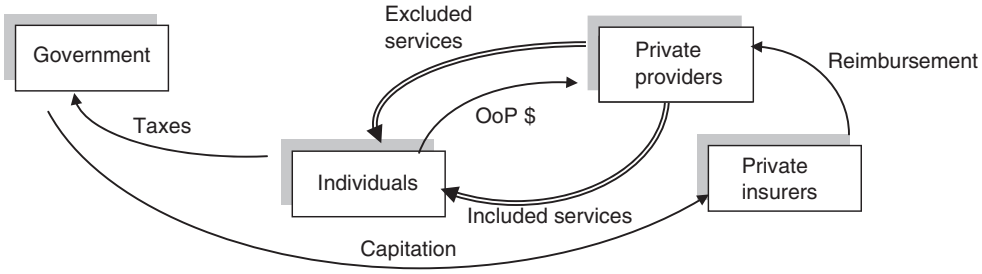

Figure 3 Competition among prepaid health plans.

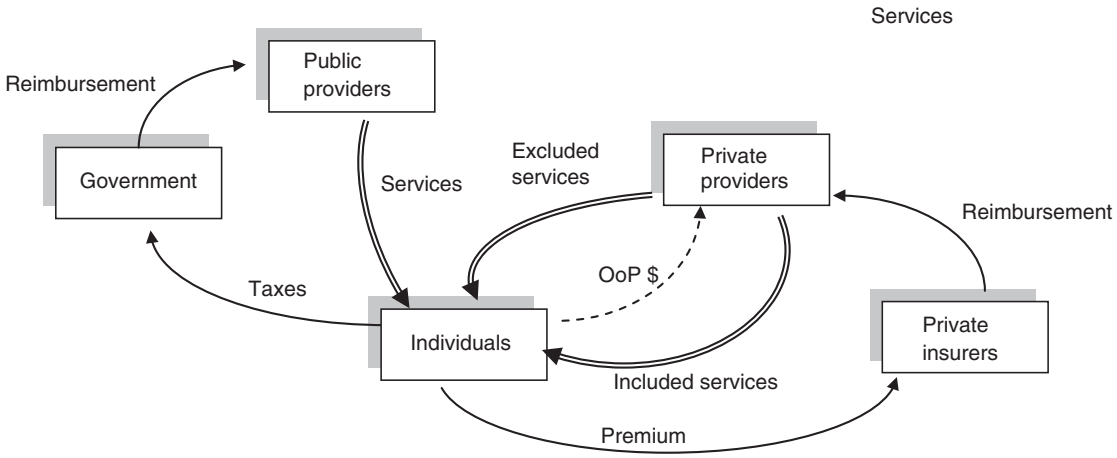

Figure 4 A duplicate system.

theory justifying a strong presumption of more efficient (less costly) healthcare provision through the duplicate coverage than under the NHS. That the private and public systems implicitly compete for patients brings two other issues that are discussed in Sections Waiting Lists and Specialists: the possibility that a physician works for both sectors and the role of waiting as a rationing device.

A Closer Look at the Provision of Goods and Services in Health

On the supply side of healthcare markets, many different providers exist, according to the particular good or service. The main ones are hospitals, primary-care services, imaging services, and pharmacies. Firms operating in other markets have several instruments to compete and attract demand: price, quality, and advertising are the main ones. Their use in health care is often restricted by regulation. Three nonprice competition variables are addressed below, namely, advertising, waiting time, and quality; and two specific providers, Pharmacies and Specialists. Other providers are dealt with in the encyclopedia: *see* Chapters 11.2 The Market for Professional Nurses in the US (01102) and 11.4 Nursing Unions (01104) for nurses, and Chapter 11.11 Dentistry (01111) for dentists.

Advertising

The role of advertising in healthcare markets is discussed in Chapter 13.9 Advertising (01309). Advertising from healthcare providers is often subject to strong restrictions if not banned at all. Advertising has long-been recognized has having two different roles, information and persuasion. Both types of advertising direct demand to the product or service being advertised. Although the informative advertising is usually taken to produce positive effects (as it reduces information asymmetries), persuasive advertising is considered socially wasteful, as it distorts preferences. An important aspect is the ambiguous impact of advertising on unobserved quality of health care, both in theory and in empirical evidence. Advertising seems to matter for competition between healthcare providers, as when bans on advertising are lifted, the later increases. But again the nature of advertising matters, as persuasive advertising may soften competition (and lead to high prices) whereas informative advertising increases price competition.

Waiting Lists

In some healthcare markets, price is not the only instrument to match supply and demand. Owing to random demand and random treatment times, setting demand to equal supply in each moment in time leads to excess capacity and idle resources. In private markets, these random elements are diversified across the several existing providers. In the presence of NHSs (or integration of insurance and provision), the diversification role of random arrivals for treatment and random treatment times cannot be done by choosing available providers. Instead, waiting lists and waiting times are used as an alternative mechanism to balance the system. Determining access to health care based on the price paid is often considered unfair and undesirable, and using time is preferred. Discriminating time to access based on clinical need (prioritization) is acceptable whereas doing it on the basis of ability to pay the price usually is not. Chapter 13.4 Waiting Times (01304) takes up this issue, discussing the role of competition in reducing waiting times in a context where waiting times work as a rationing device to allocate patients across providers. Waiting times are common in NHSs. Waiting times perform several roles. Waiting time works as a variable that balances demand and supply as a substitute to price, as health insurance protection and equity considerations entail prices having a much smaller role. Waiting times lead patients to make a trade-off between faster treatment and price paid when a private sector having no waiting times is available. The use of waiting times and waiting lists can also be seen as an alternative device to redistribute resources, as patients resorting to the private sector to skip waiting lists pay twice.

Quality

In many health systems, prices of health of health care are regulated, either by decision of a NHS or by agreement set

with health insurers. Providers, nonetheless, would like to guide demand toward their own services and products. When price is not available, other competition instruments have to be found. One of these instruments is quality, as long as quality is observable by the key choice maker (which in some cases is the patient and in other cases is the medical doctor, acting as agent of the patient). A main concern is whether competition will lead to lower quality, as providers attempt to save costs, or in higher quality, as providers look at ways to increase demand. According to Chapter 13.10 The Impact of Competition on the Hospital Sector (01310), the second force seems to be stronger.

Pharmacies

Pharmaceuticals are probably the most diffused type of good. Pharmaceutical products can be used by patients during treatment episodes, during admission for treatment (e.g., at hospitals), but are also widely used in ambulatory care. Many chronic conditions are treated on a daily basis with pharmaceutical products. Physicians prescribe the treatment and patients will buy the product from specialized retail outlets, pharmacies. The retail distribution of pharmaceutical products is, therefore, one more aspect of competition in the health sector. There are often constraints on price (regulation of pharmaceutical prices) and margins (distribution margins may be regulated), as well as constraints on entry. In some countries only pharmacists can own pharmacies. In some countries, a new pharmacy can only open on authorization from a regulatory body. In some countries, opening of a new pharmacy needs to obey rules related to population size and distribution as well as distance to competing pharmacies. Chapter 13.5 Pharmacies (01305) presents a thorough and extensive review of how different countries regulate pharmaceutical retail distribution, and they treat the implications of the different regulatory regimes. Price regulation and entry regulation interact strategically and getting it right requires careful analysis.

Specialists

Healthcare services are intensive in labor. Several dedicated professions exist, like physicians, nurses, and pharmacists, for example. The working of labor markets is therefore of importance. This is particularly true for physicians. They have the ability to 'guide' demand (patients) across services and providers. Chapter 13.2 Dual Practice in Duplicate Private-Public System (01302) addresses the positive and normative aspects of how the working of physicians' labor market affects market equilibria. Chapter 13.6 Specialists (01306) looks into the role of physicians as experts acting as agents of patients and of other healthcare providers. Physicians direct demand, which, under public or private health insurance arrangements, is often insensitive to prices. Then, the incentives faced by physicians will be a crucial element in determining how they allocate demand to providers. Gonzalez takes aim at a particular setup for doctors' decisions. In this setup, physicians may work in both a public and a private healthcare provider. Their decisions will define how demand splits across the two sectors. Physicians' decisions are again sensitive to the incentives they face. Possible policies include bans to working in a second job. Theoretical treatments of dual practice provide ambiguous effects on efficiency and quality of care. This ambiguity is not solved by empirical research, leaving room for further work. Although at first inspection a ban on dual practice would be welfare enhancing as it reduces the incentives for physicians to shift patients from public to private healthcare providers, there are other effects at play. Allowing dual practice has the benefit to the public sector of a lower cost to retain highly qualified professionals. Thus, a careful analysis of each institutional setting is called for.

A Teachers' Guide

For a focus on funding and payment in health care that pays special attention to insurance mechanisms, Chapters 13.16 Risk Classification and Health Insurance (01316), 13.17 The Interaction Public and Private Providers of Health Services (01317), 13.12 Switching Costs in Competitive Health Insurance Markets (01312), 13.3 Risk Adjustment, the European Perspective (01303), and 13.7 Risk Adjustment as Mechanism Design (01307) provide an overall view of issues related to market competition and instruments used by health insurance institutions. These readings complement chapters from other parts on health insurance, especially Chapters 9.17 Supplementary Private Insurance in National Systems in the USA (00917) and 9.24 Supplementary Private Health Insurance in National Health Insurance Systems (00924) on supplementary private health insurance and Chapter 9.18 Risk Selection and Risk Adjustment (00918) on the US experience with risk adjustment.

Demand and supply side issues related to health care are dealt within stand-alone entries and therefore some basic knowledge of the microeconomics of consumer behavior would be recommended to fully benefit from these entries.

When the interest lies in vertical market interactions, concentration should be put on Chapters 13.5 Pharmacies (01305) and 13.15 The Preferred Provider Market (01315). As for horizontal competition Chapters 13.6 Specialists (01306) and 13.4 Waiting Times (01304) are of interest.

Concluding Remarks

Since the seminal work of Arrow (1963) the application of economic theory to health care has evolved tremendously. The application of the usual apparatus of demand and supply to healthcare markets has been questioned in many aspects including how society assesses allocations of resources. Both demand and supply side features received attention. Markets of health insurance, healthcare goods and services, and health professions were and are today explored in detail.

Since early the asymmetric information aspects of demand and supply of health insurance were explored. Inefficiencies of market allocations and the issue of existence of market equilibrium were identified. It is now understood to some extent how health insurance markets work, what motives there are

for regulation, but challenges remain. Two of the main ones, deserving both theory and applied research, are risk categorization and risk adjustment and consumers' switching behavior. Market equilibrium is often determined by freedom of choice of consumers, and competitive pressure for efficient supply comes from consumers' exerting choice. Therefore, reducing information asymmetries and understanding how choice of consumers occurs is likely to originate further research. Regulation in health insurance markets is often intertwined with reducing impact of information asymmetries (here the risk pooling funds in certain countries, the mandates for health insurance in other countries and the existence of NHSs as mandatory insurance can be named) and with promotion of consumers' choice of health plans (e.g., such as rules and periods of switching health plans).

The markets for provision of health care also deviate from standard textbook analysis, as patients, the final consumers, often use the services of experts (doctors) to guide their demand of health care. They often have health insurance (either public or private), which makes them less (or even totally) insensitive to price at the moment of use. As a result, consumption decisions are distorted and market prices, if left totally unregulated, too high. Consequently, third-party payers (health insurers, sickness funds, and NHSs) over time moved into a more active role, in both the demand and the supply side. Market equilibrium then becomes the result of the interaction of demand, supply, and third-party payers. The continued growth of healthcare costs leads to interest in how the market allocates resources and how such allocation can be influenced. The role of nonprice market equilibrium mechanisms also ranks high in the agenda. Waiting lists can be named, where time is the rationing device, but also supply-side management such as medical guidelines and protocols, procedure authorizations, and so on. Advertising restrictions in healthcare markets are common, and competition in quality often substitutes for price competition. Bringing together these different aspects into the analysis of market equilibrium and its properties has resulted in a large stream of research in specific topics.

The development of new products and services, innovation, is another area of interest, not the least because technology is considered one of the main drivers of rising healthcare costs. The so-called 'bending the cost curve' in health care will certainly be related to the rate of growth and costs of delivering innovation.

Society's values have an impact on the way market equilibria in healthcare markets are looked at and consequently on the regulation imposed. Access to health care is a major concern. Ensuring access implies the development of networks of providers. The network can be centrally defined and built, as it is the case in NHSs, or can result from decisions of health insurers. Defining networks of providers of health care affects market equilibrium and competition both in health insurance markets and in healthcare provision markets. As third-party payers are increasingly active in managing demand and supply, this area is likely to receive further research attention.
