A classical generation system operation optimization problem is the combined scheduling of hydroelectric and thermal power plants. Specifically, ineffective use of hydropower will increase the use of high operating cost thermal plants. The power system operator's problem is, therefore, to minimize the total cost of generation system operations for a given time period with uncertainties in load requirement and water availability.

Generation System Expansion Planning

In a simplified form, the generation system expansion planning problem for a time horizon [0, T], may be expressed as follows (Anderson 1972):

$$\text{Minimize} \quad c_f(x_1, x_2, \ldots, x_n) + c_v[y_1(t),\ y_2(t),\ \ldots,\ y_n(t)]$$

$$\text{such that} \quad \sum_i y_i(t) \geq L(t) \quad \text{for } t \text{ in } [0, T]$$

$$0 \leq y_i(t) \leq d_i x_i$$

x_i	is the capacity of plant i;
$y_i(t)$	is the capacity of plant i used at time t;
$L(t)$	is the load at time t;
d_i	is the derating of plant i because of random forced outages;
c_f	is the present worth of the fixed costs; and
c_v	is the present worth of the variable costs.

In a more sophisticated formulation, the random nature of plant outage is taken into account by replacing the first constraint with:

$$\Pr\left\{\sum_i y_i(t) < L(t)\right\} \leq p \quad \text{for } t \text{ in } [0, T]$$

Probabilistic simulation models have been used to determine the optimal dispatch schedule accurately (Stremel et al. 1980; Sidenblad and Lee 1981). With the solution of the production costing subproblem, a number of OR/MS techniques, including linear and nonlinear programming, can be used to solve the overall generation system planning problem.

Another level of sophistication is to require x_i to be integer-valued. In this case, either mixed integer programming (Benders 1962) or dynamic programming (Jenkins and Joy 1974) can be used for generation system planning solutions.

A comprehensive application of OR/MS and other engineering-economic analysis techniques to generation system expansion planning has been the Electric Generation Expansion Analysis System (EGEAS) developed by the Electric Power Research Institute (EPRI 1983).

Optimal Maintenance Scheduling of Generating Units

Another optimization problem in generation system operations is unit maintenance scheduling. Each generating unit has a set period each year for preventive maintenance. The objective of optimal maintenance scheduling is to minimize the overall production cost while meeting the generation system reliability standards throughout the year. The problem is somewhat similar to the knapsack problem in OR/MS. Because utility business requirements vary, often a heuristic approach is required to find a solution for maintenance scheduling for a specific power system (Yu and Freddo 1978).

Fuel Inventory Planning

One other area in generation system planning amenable to OR/MS application is fuel inventory planning. Chao et al. (1989) have developed an optimization computer program that performs formal cost-benefit analysis of the following problems:

- uncertain fuel deliveries and fuel burn;
- seasonality in fuel use and fuel supply;
- supply disruption of varying severity, warning times, and duration; and
- nonlinear shortage costs.

Utility Resource Planning

Over the past years, there have been major changes in the electric utility industry in the United States. As a result, utility resource planning objectives have also evolved (Yu and Chao 1989).

In the 1970s, growing environmentalism imposed an additional tradeoff between environmental control cost and generation system reliability. A major application of OR/MS techniques was the development of the Over/Under Capacity Expansion Model funded by the Electric Power Research Institute (EPRI 1987).

In the 1980s, prevailing energy conservation ethics has given rise to the widespread adoption of the Least Cost Planning concept, also referred to as Integrated Resource Planning. Under this planning concept, in addition to an economic comparison among themselves, electric supply alternatives are to be further compared with demand-side management options, that include energy conservation and load management. As the research management arm of the U.S. electric utility industry, EPRI has also funded the development of a number of major optimization tools in this area (EPRI 1988), including the Multi-objective Integrated Decision Analysis and Simulation (MIDAS) model and the Utility Planning Model (UPM).

Trends and Challenges

There has been a fundamental changing trend in the electricity industry worldwide. This trend is largely driven by the ideological popularity of market economy and the development of low-cost high-efficiency gas turbine combined cycle generation technology. In this changing trend, the traditionally vertically integrated electricity industry is disintegrated and restructured so that electricity generation and retailing become competitive businesses while transmission and distribution systems remain regional monopolies.

In this restructured electricity industry, the applications of OR/MS tools become more important than ever to effectively manage the complexity and uncertainty in the competitive business environment and ensure the fairness of the market and the profitability of the investors. The following are a few major examples of these applications.

Transmission System Congestion Charge Allocation

In the restructured industry, a transmission system becomes a common carrier for all generating units. In addition to transmission charges, these units also need to pay a charge for the right to ship power under congestion. How to accurately estimate and properly allocate the congestion charge is a complex task that requires a systematic and quantitative approach. One such an approach that has received increased acceptance has been proposed by Chao and Peck (1996). Their idea is to allocate a fixed and finite set of transmission capacity rights to electricity suppliers according to a trading rule for the short-term leasing of these rights. The holders will set a price that maximizes its profit, while the rights are assigned to market participants that value them the most highly. As a result, this approach is efficient and involves a series of optimization analysis.

Game Theory Applications in Generation Competition

In the competitive generation market, there are many opportunities for game theory applications. In this market, a common bidding rule is the so-called second price bidding rule. By this rule, electricity suppliers bid on an hourly basis the amounts and the prices they would be willing to supply power. These prices are staggered from low to high together with their respective amount to form a electricity supply curve of that hour. At the same time, the power purchasers would bid the amounts and prices they would be willing to pay at the given hour. Their prices are staggered from high to low together with their respective amounts to form the electricity demand curve for the hour. The price at which supply and demand curves meet is the market clearing price, that will be paid to all suppliers and paid by all purchasers. With game theory, market participants can develop bidding strategies by anticipating the actions and reactions of the competitors. On the other hand, regulators who are responsible for the fairness and effectiveness of the market can also use game theory to detect potential dominance of the market by a small number of participants and possible collusive behavior among

participants. Several technical papers about these applications have collected by the Institute for Electrical and Electronics Engineers (IEEE 1999).

Risk Management through Option Theory

In the competitive market, investments in generation plants entail unprecedented risks, because they are no longer protected by economic regulation for guaranteed returns. Similarly, there are considerable risks as well as profitability in the retailing of electricity based on a combination of long-term contract and short-term market trading. As a result, both investors and retailers need to effectively manage their risks while maximize profitability. In addition to the usual decision and risk analysis techniques, a new approach for these investment and portfolio strategies, called real option has been developed through the extension of option theory from the financial field. In this approach, to provide flexibility in a highly uncertainty business environment, investors will make small initial investments to secure the rights for future large-scale investment options and retailers will negotiate option contracts to manage uncertainty and hedge against risks. This area is rapidly expanding, see Trigeorgis (1996) for an introduction and review. In addition, Smith and Nau (1995) provides an insightful comparison between option pricing theory and decision analysis.

The Smart Grid

Electric power system has always been information intensive. Because electricity generally cannot be stored, the operation center of a power system must continuously monitor changes in electricity demand and matches it by increasing or decreasing power supply in accordance with the merit order of the marginal cost of generation. In the meantime, the center also needs to constantly maintain the reliability of the system by stabilizing the system voltage and frequency and re-routing electricity in response to breakdowns and outages in the system. These functions require large-scale information acquisition, data analysis, and system control functions, which are the basis of the Supervisory Control and Data Acquisition/Energy Management System (SCADA/EMS) of modern power systems.

With the rapid advances in information technology (IT), it has been envisioned that such SCADA/EMS can be expanded far beyond the existing power delivery network that supplies electricity to an uncontrolled demand. Instead, advanced IT—so-called Smart IT because of its ability to actively acquire, process, communicate, analyze, and display information to provide interactive and adaptive control of both the system inputs and responses—will enable the power system to optimally manage both electricity supply and demand through real-time electricity pricing signals; interactive end-use sensors, communications, and controls; and environmentally based energy-trading mechanisms, as well as to effectively integrate distributed energy resources, including renewable, energy storages, and electric vehicles. Through advanced data analysis by the Smart IT, the power system can further anticipate future changes and develop appropriate responses, including self-healing in case of system breakdown and emergency control in case of natural or man-made disasters. In other words, Smart IT can provide constant information acquisition, processing, analysis, communication, and control to create a Smart Grid that simultaneously optimizes all generation, transmission, distribution, and end uses to continuously adapt to changing supply conditions, customer demands, and environmental and other policy requirements. This is a vision that has caught the imagination of both researchers and business people and gained the popularity among technical professionals and government officials alike throughout the world.

However, as IT continues its revolutionary changes, the Smart Grid vision also continues to evolve. To develop a Smart Grid based on a given set of Smart IT would not only be a long and expensive undertaking, but the results could also become technically obsolete as soon as it is completed. (A prominent example was the development of a Customer Information System by a major U.S. electric utility in the 1990s, which took 5 years at a cost of over 300 million dollars, but became outdated as soon as it was completed.) Therefore, in all countries in the world, Smart Grid concepts have been partially implemented in various segments of the power system, such as smart end-use management, two-way communications and interactions between utilities and customers, utility asset management with smart substations, and smart regular and emergency operation centers.

At the same time, these concepts have been also implemented more comprehensively in a smaller-scale local power grid, called the microgrid, in which there are often many independent power generators with renewable energy sources. Both these incremental developments of large-scale smart grid and the interactions between the more fully developed microgrids with the main power grid pose great challenges, but at the same time provide enormous opportunities for research in OR/MS in the optimization of resource allocation and system operation, see (Chakrabortty and Ilić 2011; Vasant et al. 2011) for some initial summaries.

Electronic Commerce

Edgar H. Sibley[1] and Abeer A. Al-Hassan[2]
[1]George Mason University, Fairfax, VA, USA
[2]Kuwait University, Kuwait City, Kuwait

Introduction

Electronic Commerce (EC) has become a significant way of selling products and services because of the major improvements in electronic and Information Systems (IS) technology. This technology, however,

can only be exploited effectively by specialized business structures and organizational practices. At the same time, new laws, treaties, and international standards were enacted to respond to the worldwide changes needed to control and yet ease the movement of goods and data over borders. Because of its effectiveness, the term electronic commerce has been expanded to encompass types of systems that use similar technology, but have only marginal commercial aspects, such as governmental systems that interface with citizens. For example, the Internal Revenue Service (IRS) has a site that provides electronic forms for income tax submission and social systems that provide interfaces to members of social or professional organizations.

The definition of EC may be derived from that of normal commerce, which is as follows:

Commerce *(noun): the exchange or buying and selling of commodities on a large scale involving transportation from place to place* (*Merriam-Webster*).

Electronic Commerce is thus the use of information technology (IT) to provide an infrastructure with interfaces that allow communication between people and organizations for business or commercial purposes. It is buying, selling, or exchanging of products, services and information via an electronic network (generally the Internet, Intranet, and its extensions) (Efraim et al. 2010).

As a result of Information Technology (IT), most large stores include a pure brick (physical) operation and an on-line presence. The combination is termed "brick and click" and allows a seller to reach more customers and a world-wide audience, as well as compete with other businesses. Today, there are also stores that reside purely online (e.g., selling digital media, such as books, music, or operating systems) and rely completely on the Internet as its interface with customers. More businesses are expected to move online in order to stay competitive.

Using the Internet model, the process of buying goods and services becomes more transparent. EC allows the buyer to browse vendor offerings and prices.

Some History of Electronic Commerce

In the United States, starting in the 1960s major organizations used computers to automate previously manual operations, thereby improving the speed and accuracy of business computations. By 1970, most large enterprises had automated their simple manual business functions, such as payroll, and some early database management systems facilitated data sharing. Soon after this, the first internal networks were implemented by large firms. Additionally well-informed managers started interconnecting their geographically distributed computer systems via phone lines. Within years, the Internet was born and by the mid-1980s, there had been major adoption of network technology. Moreover, the advantage of communicating between consumers and suppliers (business to business or B2B) had led to the idea of electronic data interchange (EDI) where orders could be placed electronically, according to nationally defined and contractually approved methods. Electronically controlling inventory significantly reduced the costs of supply chain management. Because of the advent of gateways between networks and countries, the World Wide Web became a reality. The Internet had therefore joined phones and fax machines as a medium for commerce at a distance. All seemed well until the 1990s when the EC industry suddenly faced loss of public confidence. Banks and investors became doubtful of EC as a profitable venture and stopped funding EC startups. Consequently, the so-called dot com bubble burst. In the following years, however, EC sites gradually recovered from this setback and some e-businesses returned profits. As a result, today, most large US stores and businesses have effective Web sites with personal and corporate customers accessing them. This confirmed EC as an effective way of doing business.

Fields Associated with Electronic Commerce

EC technology changes the way that merchants conduct business; manufacturers develop relationships with other merchants; and consumers access information and obtain goods and services. Their IS must be adapted to take advantage of the opportunities of EC, as well as satisfy the expectations of those who establish a relationship with or purchase goods and services from the organization. This online medium redefines the ways in which companies and customers communicate.

As EC becomes a new source of customers and a means for the expansion and creation of business opportunities, many business and related disciplines become, directly or indirectly, an important part of the business model. Some affected business related areas are:

- Law and Policy: Legislators have passed new laws and are finding it necessary to modify or reinterpret old ones to deal with EC. The hierarchy of laws and regulations includes control over all transactions between governments, organizations, and people, thus incorporating international, national, and local laws. Major organizations must also negotiate for special considerations with various regulatory bodies throughout the world. Governments must also influence business processes to gain taxation and other revenue, protect national values and culture, and maintain relevance, while regulatory bodies have to deal with the effect of case law. Such issues of governance must be solved; within the firm, policy makers must therefore react by creating new rules and procedures that deal with the effect of the new modes of business.
- Finance and Accounting: This discipline must deal with new means of payment worldwide, therefore understanding the many different taxes (e.g., purchase tax, value added tax, etc.), currencies, and accounting requirements are important.
- Managerial: Corporate management must understand the cultural and political issues that affect the profitability and general operation of their organization around the world. The new way of conducting business must cope with many cultures and religions, whose members may find some content offensive or even blasphemous. The opportunity for illegal activities or even mischief also has increased; thus, ethical behavior plays a major role in the development of the EC Web site and also of the care of the information passing into and out of the Web site. Of course, this also implies a need for businesslike behavior within the Web site.
- Information Technology: The chief information officer, who is in charge of the IT systems and their maintenance, must deal with many issues including development of the Web site and its database and their maintenance. The Web site must be protected against the depredations of the cyber criminal or hacker.
- Psychology/Organizational Behavior: The system designers must be aware of the behavior of a customer while shopping online. Attention to this can aid in customer retention; navigation within a site, searching for products, and ensuring general ease of operation. Analyzing the differences between the feel or playfulness of Web sites are important to the customer who has the site as his or her major interface with the store.
- Marketing: This discipline must adapt to a new type of customer or face potential loss of market share. There is seldom any salesperson available on the site and thus the designer or architect of the site should provide a surrogate to aid the customer in navigating the site and learning of other people's feelings about the goods. The marketing consultant should, therefore, use new techniques such as data mining to find how to attract customers and implement new advertising techniques.
- Economics and Operations Research: Economists study markets, products, and commodities. As the Internet becomes an integral part of today's economy, supply and demand, as altered by EC, become important. Supply chain management is a particular example of the application of operations research (OR) principles to EC systems.

The Classification of Electronic Commerce

EC can be characterized by the types of entities that are communicating; these include Businesses (B), Consumer or Citizens (C), Governments (G) and Employee or Exchange (E). Obviously, these are paired and thus are referenced Business to Consumer (B2C) implying the use of specific types of transactions between Bs and Cs. The most important in terms of volume and financial commitments is B2B, where linked transactions take place between two or more companies resulting in supply chains. Some other classifications discussed by Efraim et al. (2010) include:

- Consumer-to-Consumer (C2C) – transactions between customers. Examples of such a site would be in person to person sale of artwork or second hand equipment;
- Business-to-Employee (B2E) – transactions within an organization, e.g., a business allowing its employees to perform transactions such as submitting time sheets online;

- Government-to-Citizen (G2C) – transactions where citizens make payments or apply for forms online;
- Mobile Commerce (M-COMMERCE), transactions that take place via a network, possibly using a phone or personal digital assistant (PDA) as the input device;
- Location Commerce (L-COMMERCE) – transactions that locate the user and solicit attention, such as the use of global positioning satellites (GPS) data in mashups on the PDA or cell phone or by sending a text message to a potential customer near a restaurant.

The Process of Electronic Commerce

Customers using an EC site experience a similar procedure to that when shopping at a traditional store. The normal steps are:

Step 1. Search for the Store of Interest
Similar to using a phone book's business directory, a potential buyer will often browse, or surf, the World Wide Web (WWW) to window shop or find a product. This surfer may use a search engine to locate stores, expand the search to worldwide, and establish conversation/dialogue with stores. One particularly important aspect of operation in the WWW is in the use of intelligent autonomous software agents or bots. These may be spawned by a site as a means of gathering information about possible suppliers or competitors. The bots are able to search the Web (mimicking real person inquiries) via search engines and visiting possible sites of interest, and may determine which sites offer the best prices or service. This can help the purchaser make a choice based on their criteria.

Step 2. Navigation and Selection
Similar to walking within a store, a surfer moves within a Web site to find items of interest. This may result in a customer selecting a particular item because of its price, the site's terms and conditions, and the seller's overall reputation. For chosen items, a selection is made by moving the product or service into a so-called shopping cart. A transaction may also depend on negotiating a price between the buyer and seller in some medium of exchange or barter. The seller may thus present the product or service for sale and reduce the asking price until a sale occurs, particularly in retail situations where the costs of maintaining inventory may erode the profit margin at the asking price or when the inventory has a limited lifetime (like fruit and vegetables or seasonal material). This devaluation is usually hidden from the customer except at discount outlets.

Step 3. Checkout (Payment)
Similar to payment via a checkout counter, payment within an EC site involves forms of electronic payment, including ways of submitting e-cash or billing systems. The actual exchange of money may occur either before or after delivery, with intermediaries (such as credit and debit card companies or banks) aiding in the exchange. For EC to work, efficient and paperless settlement processes must exist; each charges the merchant a relatively small transaction cost.

Step 4. Delivery
Similar to a traditional buying technique, once the sale has been completed, the parties must agree on the time and method of delivery of the product or service. For products, online merchants sometimes maintain small inventories of the most popular products and coordinate with suppliers for the delivery of the remainder. This coordination is contracted in advance and the consumer is unaware of the inventory of the merchant. Since business consist of moving quantities of inventory from the manufacturer to the consumer, lowering inventory costs at each step is important. Just-in-time (JIT) operations can reduce inventory cost to zero (if the EC site is merely acting as an intermediary in the transaction) or close to zero. The vendor will often send a confirmation that includes information so that the buyer can track the process of delivery.

The Elements of an Electronic Commerce Site

Any business with an online Web site should consider how certain important elements are to be implemented. The most common sections/elements on EC sites (Efraim et al. 2010) are:

- About Us section – this contains information about the business. Some include the history of the company, its vision, mission, and objectives, while others include management team and major hierarchies (departments, etc.) of the company and even a message from its Chief Executive Officer (CEO).
- Terms of Use – in which the company provides information on its overall policies, especially its

view of and care in ensuring security and thus how it stores and preserves private information provided by its customers when making a purchase.
- Customer Database/Customer Account – almost every company creates an account for its customers. The customer account normally allows the user to give a username and password for selecting and tracking purchases. However, if a customer is only window shopping or navigating an electronic catalog, this is seldom required, though the EC business could use such information in future promotion campaigns.
- Electronic Catalog – an electronic catalog offers information about the products or services provided. They can be displayed in the form of text, pictures, or even videos. A customer can be sent a customized catalog compiled from knowledge stored in the Web site database about the customer's prior purchases.
- Search Engine – for large companies, a special search engine is often provided to customers to help them narrow and speed up their Web site navigation by typing in keywords that should help them find information on possible products or services that appear to suit their needs.
- Shopping Cart – a shopping cart or shopping bag where shoppers can accumulate items that they are considering or intend buying.
- Payment Gateway – a check out process where a customer pays for products and services on the Web site.
- Contact Us – a section that usually gives information on ways that a customer may contact the company: toll-free numbers, email addresses, and even live chats are available on most sites, thereby providing a surrogate for the missing salesperson in an automated site.

Non Traditional Business Models and EC

Social Networking and EC

Social networks are analogous to traditional town meetings; they can be viewed from two revenue perspectives:

1. Through their Business Model, where their revenue was mainly achieved by assessing an annual or shorter term fee or subscription from participants.
2. As an electronic billboard, displaying advertisements, such as pop-up, banners, or sidebars that provide income.

They provide regular meeting space where members can create groups or sell products simply by posting them, the electronic equivalent of classified ads in a C2C format.

Auctions and EC

Alternatives to traditional auction houses may be found in EC form. English (forward) or Dutch (reverse) auctions, for example, may be completed online.

Bartering and EC

Some EC sites now use pure bartering methods or pass merchant money (scrip) as a way of charging and paying for goods or services. The site revenue is then obtained from traditional advertising methods or the income of the Web site developer from users purchasing the scrip at a slight cost from the site owner for use in exchanging or bartering. One advantage to barter participants is the lack of a trail showing any equivalent to a monetary transaction; this makes such transactions difficult to track by local or governmental authorities who find it difficult to impose taxation.

Revenue Models

Revenue models in EC describe "how the firm will earn revenues, produce profits, and produce a superior return on invested capital" (Laudon and Traver 2010). The most common revenue models are:

- Advertising – receiving revenue from companies advertising on the site.
- Subscription – a fee charged for offering content or service to members of a special site, such as a professional organization or social club.
- Transaction fee – charging a fee for a particular transaction on a site, similar to charging for a newspaper classified advertisement.
- Sales – revenue based on the profit from selling goods, services, or information.
- Affiliate – revenue from a referral fee resulting from redirecting a consumer to another site at which he or she made a purchase.

Web Economics

The area of economics is somewhat expanded by adding commerce over a network. The term Webonomics was coined to show a difference and underline new effects. It can be considered as the study of the effect of the WWW on production, distribution, and consumption of goods and services. The world is now dealing with an information-based economy and this redefines the way that the network can be exploited.

At least four major groups profit from using a Web:

- Consumers – The buyer and the individual or group wishing to trade something of value. The consumer will be interested in an online product or service only if it is the best, cheapest, or most convenient alternative and is from a trustworthy source; lack of safety and privacy standards hamper growth.
- Content Creators – The providers of raw materials and manufacturers. They are vying to attract consumers and often maintain their own Web sites, which must be as attractive and as up-to-date as possible; they are hoping to build their image among the millions of surfers.
- Marketeers – The marketers of products, facilitating the barter, trade, and purchasing processes bringing content creators to consumers and vice versa.
- Infrastructure companies – The engineers of the Web who build and sell computing and communication hardware, such as Web servers, routers, etc., as well as the software for building and maintaining sites.

Internet Marketing and Electronic Commerce

The use of EC allows the vendor to utilize new methods for marketing with no immediate relationship to non-EC marketing. Four of these are:

- Banner advertising – This is often found on pages regularly read by buyers, including the header page of a search engine, news service, or local news site.
- Preference profiles – By using tracking mechanisms, such as cookies, a vendor can determine the likes and dislikes of prior customers and target them for future special offers. Cookies are text files placed on the user's computer hard drive when visiting some Web sites; they contain data that was collected from a purchase and stored for future use. During subsequent visits, these text files are retrieved by the site software and used to personalize advertising. Thus, the user has to enter less data when making a new purchase and sellers can tailor marketing efforts via data mining.
- Leveraging information about a community – The seller can use push technologies, based on market assessment data, such as expected income or sociological characteristics of an area. These allow the seller to provide unsolicited information about a product or service that may be attractive such as winter cruises to warm climates for retired people living in relatively high priced localities; the buyers provide (sometimes unwittingly) a profile of their interests. For example, a book seller will send e-mail to customers when a previously purchased author has had a new book published.
- Broadcast desired product requirements – These provide a virtual tradingfloor where the buyer presents requirements and solicits bids from vendors. The buyer can then contact the most promising vendor and initiate a purchase. This is comparable to newspaper classified ads.

Technological Aspects

All EC sites can be considered to consist of two layers: the connectivity layer and the modules.

The Connectivity Layer

- EC has, as its base, a communication network, which is the way that organizations and people communicate. The medium for the network may vary in complexity from:
- Direct Connection – similar to a phone line between organizations or parts of an organization. This was the original way that early B2B systems were implemented and it is still in use. EC for some vending machines and modern parking meters, which use cash or credit card as a method of payment (micropayments); these transactions are for less than $10.00. However, more locations such as airports and shopping malls have vending machines that sell electronic devices such as cameras worth $200.00 or more. And

- Internet Connections – through a public network, like the Internet, with a need for some way of protecting the transmission of data from interception, corruption, or altering, such as encryption of the data on and off the network.

Direct Connection Networks were originally built and maintained by large manufacturing corporations primarily to support their supply chains. These were effective, but the cost of building and maintaining private networks can seldom be justified, except when the security needs of the organization are very high. Some examples of such special needs are in national security systems (the Department of Defense, etc.) or industries with extremely high competitive environments. These may require substantial protection over technology or process and thus need internal data retention with limited sharing of data with members of its supply chain (such as leading members of the aircraft and electronics industries). Most commercial systems and private users find it sensible to use an external, public service that provides an interface to the internet (an so-called Internet Service Provider or ISP). The speed of access and transmission of ISP services has risen markedly through the years due to the demand of users and the availability of faster network components. The economies of scale make the large systems provided by ISPs much cheaper and, thus, few organizations can no longer afford the luxury of a private network. Virtual Private Networks (VPN), however, are becoming popular and new architectures, such as cloud computing, seem to be viable.

The VPN is a special service of an ISP that provides high security by encrypting and authenticating technology to protect data entering and leaving the storage facilities. Thus, its users can experience a similar effect to that of a private network except that there is some delay due to the time spent in encrypting and decrypting the data. The security can be tailored to the organization, group (such as branches or divisions), or individual at the cost of servicing sets of encryption keys.

Cloud computing involves the use of the Internet as a massive, but inexpensive, storage device provided by an ISP. While it has little security (unless encryption is added in much the same way as in a VPN), the economies of scale again make this architecture very cheap. Many social networks are therefore using a cloud for storing their data, but with little or no expectation of security on the part of their users.

The Modules

- There are four modules that interface with the connectivity layer. They communicate through the layer and to the Internet. The modules are:
- Customer Information – This contains all customer related data such as name, address, and credit card information, possible interests, latest purchases, etc.
- Product and Services Information – This contains information about all products and services that are currently available for sale, including their prices and discount, detailed description of the product, and possible graphics. This module presents the information to customers in an easy to read and pleasing format.
- Payment Information – This module interfaces with the seller's financial institution so that it can authenticate the buyer's solvency prior to completing a sale.
- Shipping Information – This contains information about the various shipping methods available and their costs. The information is sent to customers who then select their preferred method and the consequent price is added to their payment information.

Trust in Electronic Commerce

Without trust no one will purchase from a store; the customer must believe that the product is well made and the seller must believe that the payment is not fraudulent. Similarly, in EC there must be trust between the parties, except that they are usually separated by some geographic distance and are potentially unknown to one another. Consequently, the primary challenge to the proliferation of EC has been in bolstering trust in the site and ensuring trust in the payment. The first entails assuring the customer of the security of the site and the vendor's intent to exclude hackers and crackers, while the second is provided by the banking system by authenticating the payment. Thus, security requires mechanisms that ensure non release and safe retention of data while privacy ensures that personal and other important data is not released to other people or organizations without the customer's explicit permission that the vendor may do so.

A lost credit card can result in significant loss to its owner or the credit card company. If someone steals

a card and publishes its number on the Web, there is likely to be a very rapid loss of cash, more than that from a single criminal who holds one stolen credit card.

When a direct link is established between a private network and the Internet, a company's internal network and all company resources are extremely vulnerable to hackers. Thus, the more a company allows access to its sites (describing products, services, and processes), the more vulnerable the enterprise is to information loss (stealing). For this reason, most systems use one of the many forms of encryption, which allows them to provide the necessary services of:

- Non-Repudiation – proof that the person or organization really participated in an electronic exchange of information resulting in a financial commitment;
- Confidentiality – mechanisms to ensure that any message cannot be read by unauthorized individuals;
- Authorization – internal functions to ensure that the internal staff are assigned access based on their role in the organization;
- Integrity – mechanisms to make sure that data are not modified by unauthorized persons during their storage or transmittal; and
- Authentication – Because an Internet transaction does not involve face-to-face interaction, this must guarantee that the person participating is not a fraud. The authentication function verifies that the offer of goods or services is from a registered provider and validates the identity of the purchaser, while ensuring and monitoring that each party is adhering to the terms of agreement. There are two basic models for authentication: digital signatures, and certificates.

"Web site owners are using a terms of use/terms of service agreement posted at their Web site to allocate, limit, reduce, mitigate, avoid, and otherwise manage potential risks in cyberspace," (Westermeier et al. 2007). Almost all Web sites contain a Terms of Use section. Such service agreements add to the confidence in or trust that a customer feels for a Web site.

Furthermore, some users and vendors are concerned with (i) transaction or credit card details stolen in transit, (ii) customers' credit card details stolen from a merchant's service, or (iii) merchants or customers masquerading as legitimate buyers or sellers (Chaffey et al. 2007). Thus the Terms of Use section explains how the site will provide security for concerned users by discussing how it deals with authentication, unauthorized access, and hardware and software used to provide security (e.g., its use of firewalls). Similarly the section provides Web site users information on how the site deals with their privacy by stating that the customer information will be kept confidential, that there are a restricted set of operations allowed on the data (such as data mining for customer interests), the use of cookies, and any third party to whom data maybe released, such as a bank.

Validation in Electronic Commerce Research and Development

Research on EC Web site effectiveness generally involves the collection of customer feelings about a specific aspect of a Web site and its consequent use. As such, the research tends to be psychological in nature, requiring the development of a model of the process being investigated, determining the variables that interact in that process, and using this model to help in positing hypotheses. It is then necessary to examine the variables for any overlap or interactivity between them and decide how to measure them. This leads to the construction and validation of survey instruments that measure the feelings or perceptions of customers about the Web site or its architecture.

Thus, the research requires the development of validated methods of measuring the customer's reaction to the Web site followed by collection of data from a relevant population of Web site users. The data from the survey must then be analyzed utilizing one of the many statistical methods, such as Structural Equation Modeling (SEM), to derive relationships between the data and thus prove or disprove the hypotheses.

Elementary Elimination Matrix

A square nonsingular matrix obtained by replacing a column of the identity matrix by some vector. Every pivot operation on a system of linear equations is equivalent to multiplication of the system from the left by an elementary elimination matrix. In the simplex method, such a pivot matrix is called an eta-matrix.

Ellipsoid Algorithm

The first polynomial-time algorithm for linear programming. The ellipsoid algorithm was originally developed by Shor, Udin and Nemirovsky as a method for solving convex programming, but it was Khachian who showed that this method can be adapted to give a polynomial-bounded algorithm for linear programming. The basis of the ellipsoid algorithm is a method for finding a feasible solution to a set of linear equalities. This method constructs a sequence of ellipsoids of shrinking volume, each of which contains a feasible point (if one exists). If the center of one of these ellipsoids is feasible to the system of inequalities, the algorithm terminates. If not, then after a known (polynomial) number of iterations the volume of the ellipsoid will be too small to contain a feasible point, and hence the system is infeasible. This method for solving inequalities can be used to solve linear-programming problems in polynomial time, by writing the primal and dual feasibility constraints and the equality of the primal and dual objectives as a system of inequalities. Despite its tremendous theoretical importance, the ellipsoid algorithm appears to have little practical significance, since its computational performance has been very poor.

Emergency Services

Kenneth Chelst
Wayne State University, Detroit, MI, USA

Introduction

Emergencies range in scope from the routine—situations involving limited police, fire, and/or medical personnel—to the catastrophic—such as large-scale natural or man-made disasters. The latter category includes Hurricane Andrew and Hurricane Katrina, the Exxon Valdez and Deepwater Horizon oil spills, nuclear power plant meltdowns in Chernobyl and northeast Japan, earthquakes in Haiti and New Zealand, and tsunamis in Indonesia and Japan.

Whether emergencies occur hundreds of times each day, once a decade, or once in a lifetime, the planning and management of emergency services are complicated by various uncertainties:

1. The time and location of the emergency
2. The scope of the emergency
3. The type of call and the personnel and equipment needed to handle the initial emergency
4. The type of call and the personnel and equipment needed to handle the aftereffects of the initial emergency

Because of the differences in frequency and scope between the more routine basic emergency and the rare large-scale disaster, different strategic, tactical, and operational planning approaches are required.

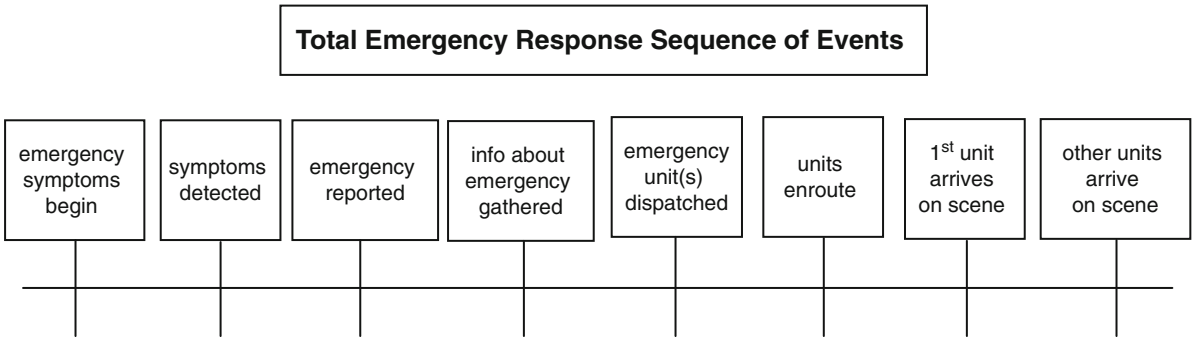
Common Emergencies: Police, Fire, and Emergency Medical Services

Police, fire, and emergency medical services (EMS) all operate in a complex, unpredictable year-round 24-7 environment. Typically, managers of these emergency services function within severely constrained budgets and face two common complex operational questions:

1. How many emergency service vehicles should be staffed each hour of the day?
2. Where should these vehicles and personnel be located?

In an ideal world, decision makers would focus on their ultimate goals when addressing these questions. Police officials would evaluate strategies in terms of their relative effectiveness in reducing crime and the fear of crime. Fire service administrators would allocate equipment and personnel so as to reduce fire damage. EMS managers would compare alternatives with regard to lives saved and disabilities avoided. Unfortunately, the relationship between many decisions and their ultimate impact are not fully understood. For example, the impact of a 10% increase in patrol cars on crime levels cannot be predicted. Similarly, the number of lives saved as result of building an additional fire station cannot be estimated. And, further, the impact of ambulance service on survival rates following automobile accidents is not fully understood. In contrast, there has been significant progress in understanding the relationship between the number and type of emergency medical units in a community and the likelihood that ambulance service will save the life of a person in full cardiac arrest (Erkut et al. 2008).

As a result, operations research (OR) models designed to assist emergency service decision makers use the surrogate measure of response time, as well as workloads, when structuring resource allocation decisions. Figure 1 illustrates the total response pattern to an emergency. It begins with the onset of symptoms of an emergency (e.g., chest pains, smoke, suspicious persons). There is a delay until the symptoms are recognized as an emergency and a further delay until the emergency is reported. The dispatcher must process the call and find an emergency unit to dispatch. It may take time for the unit with its personnel to leave its location and begin traveling to the emergency. The final response time delay is the travel time to the scene of the call. For fire services and ambulance services housed at stations, there could be an additional delay between the time the station is notified of the call and the time it takes for the vehicle to be in motion on the street. If multiple units are dispatched to the same call, there will be multiple arrival times. OR models focus on two components of



Emergency Services, Fig. 1 Total emergency response sequence of events

response time: (1) the queueing delay, the time from call receipt until an emergency unit is available for dispatch, and (2) the travel time to the scene of an emergency.

In the 1970s, faculty at M.I.T. and researchers at the New York City RAND Corporation (a joint venture between New York City's government and the RAND Corporation) developed models that address these two basic deployment questions, with funding from the National Science Foundation and the Department of Housing and Urban Development (Larson 1972; Walker et al. 1979). One specific relationship that developed from this research was the square-root law that estimates the average travel distance to a random call:

$$\text{Average Travel Distance} = c^*\{A/[N(1-b)]\}^{1/2}$$

where A = area, N = the number of emergency service stations or vehicles, b = the proportion of time an emergency service unit is busy, and c = a constant of proportionality (usually between 0.6 and 0.7) calibrated from real-world data. The parameters a and b are city-specific, while N represents the key decision: the number of units to deploy. This simple square-root formula is utilized to make aggregate decisions on deployment. It predicts that quadrupling the number of available emergency units reduces average travel distance by only 50%. The estimated travel distance is converted into travel time by either assuming an average speed or by using regression analysis to define a nonlinear relationship between distance and time. Police deployment models use average speed, while fire models tend to use regression analysis.

A major problem in planning emergency services is that the number of calls per hour is a random variable. Thus, decision makers use the Poisson process, a probabilistic model for forecasting the number of calls in a designated period of time. These forecasts are the input into simulation or queueing models that estimate the average delay between the arrival of a call and the dispatch of an emergency unit. The average queueing delay is added to average travel time to determine total average response time.

Police Services: The allocation of police patrol resources is complicated by a number of factors. First, the number of police patrol units on the street is usually much larger than the number of fire stations or ambulances. Second, these police units respond to a wide variety of calls with different levels of urgency (e.g., armed robbery in progress versus loud music next door). In small and medium-size cities and suburbs, quality-of-life calls and traffic enforcement are often the bulk of the police workload. Lastly, police call rates vary significantly by time of day and day of week. Because of this added complexity, planning in a large city might proceed in three phases.

In the first phase, police officials use aggregate data and a model such as PCAM (Patrol Car Allocation Model) to determine the number of patrol units to assign to different parts of the city for different periods during the week. Next, police commanders use a descriptive model such as the hypercube or simulation model to design patrol beats for individual patrol units (Larson 1974). These models forecast response times for different priorities of calls, as well as workloads of patrol units. Police managers can then apply a mathematical- programming model to design a work schedule for personnel to ensure that there is enough manpower on duty to staff the proposed street personnel plan (Green and Kolesar 2004).

In all decision making regarding emergency services, there is a tension between efficiency and equity. A deployment plan that minimizes average response time will tend to concentrate resources in high-risk areas, leaving other areas with response times significantly longer than average. This conflict has been addressed in a variety of ways. To achieve equity, PCAM allows the decision maker to establish minimum response time standards for each region of the city. Once enough patrol units have been assigned to each region to achieve these minimum standards, PCAM can allocate excess patrol resources to minimize citywide average response time (Chaiken and Dormont 1978). Alternatively, concepts of multi-attribute utility and group-decision making can be used to assist decision makers in exploring tradeoffs between equitable deployment plans and efficient ones.

The police are responsible for more than simply responding to emergencies. One goal of routine or directed patrol is to deter crimes. In addition, police patrol units are often the first investigators at a crime scene. (See the entry "► Crime and Justice" to explore the link between police and crime).

Local Fire Services: Fire service deployment is the least complex of the three services to analyze. Fire call rates are typically low; firemen spend less than an hour a day responding to calls. Response times are generally affected by the number of fire stations and whether firefighters are awake or asleep, rather than variations in the average call rate over the course of a day. Consequently, most municipalities tend to staff their fire stations at the same manpower levels around the clock to provide a constant level of fire protection. Some locales, such as Loudon County, Virginia, vary the mix of volunteers and full-timers by time of day and day of week. This is more a function of the availability of volunteers than a reflection of varying call rates.

The low workload simplifies the analysis of fire station locations. Fire station planning models make the reasonable assumption that the nearest fire unit will be available to dispatch immediately when a need arises. Among deterministic optimal location models that are used to situate fire stations, coverage and *p*-median models stand out. A coverage model locates fire stations so as to maximize the number of people or houses situated within, for example, four minutes' travel time of the nearest station. This is consistent with International Association of Fire Fighters (IAFF) standards that are reported in terms of coverage. The *p*-median model locates stations so as to minimize the average response time to a target population at risk.

In some complex environments, such as New York City, operations researchers have used a descriptive model that allows the decision maker to add or delete fire stations and then assess the impact (Walker et al. 1979). The descriptive model provides a wider range of performance statistics than the coverage and *p*-median models, and predicts response times for the arrival of a second and third fire engine; it also differentiates between equipment with different roles (e.g., engine trucks and ladder trucks).

As a result of the 2007–2009 recession, many cities have seriously considered substantial cutbacks in fire services. Such cuts are only possible because city officials generally staff for relatively rare events in emergency services. For example, the International City/County Management Association (ICMA) found that in one city of 300,000, there were still five units available for immediate response even during the busiest hour of the year.

Thus the reduction of staff without compromise in service has been an area of close inquiry. Although the IAFF standard is four men per engine, a National Institute of Standards and Technology (NIST) study found that four men were only 5% more effective than three, using standard equipment and water (Averill et al. 2010). Furthermore, fire hoses that operate with compressed air foam rather than water are much lighter and easier to handle, thus requiring fewer personnel than calculated in the IAFF standard. Models for staffing and overtime related to providing coverage for vacations, unscheduled absences, and retirements have also been studied.

Emergency Medical Services: In cities and densely populated counties, ambulance services operate at higher workloads than fire services. Often they are included as part of the fire service. In those instances, EMS calls often account for more than 80% of the total call volume of the fire/EMS. Utilization rates of 15% to 30% are not uncommon, and, in busy periods during the week, workloads exceed 50%. Consequently, ambulance location models that assume the nearest stationed ambulance will not be busy when a call comes in are oversimplifying reality. This has led to the development of more

complex coverage models that incorporate concepts such as backup coverage and workload adjustment factors. By doing so, these models approximate probabilistic concepts while maintaining the capability of using a deterministic optimal location model to place ambulances. An alternative to these optimal location models is the hypercube queuing model. This model is primarily descriptive and can be used to evaluate ambulance placement plans. Heuristic search algorithms have been appended to the hypercube model to facilitate the search for better solutions (Morabito et al. 2008).

Unlike fire equipment, ambulances and other EMS vehicles may be stationed on the street and easily relocated. State-of-the art dispatch systems facilitate the dynamic relocation of these vehicles. The relocation may be triggered by an overload in one area that has tied up the local ambulances, leaving a region uncovered. Alternatively, these vehicles may be redeployed as a result of established patterns of demand according to area, time of day, and day of the week. Both integer-programming and dynamic-programming models have been developed to assist in this redeployment (Maxwell et al. 2010).

The final stage of emergency medical treatment occurs in an emergency room. Simulation is frequently used to study alternative emergency room designs, staffing levels, and triage policies within this department (Wang et al. 2009).

Policy Questions: The models described above focus on developing plans to improve day-to-day operation of emergency services. OR models have also played an important role in exploring a number of policy questions with regard to cost benefits. For example: (1) which is more cost-effective, to spend public dollars on more fire stations to reduce response time or to subsidize the placement and maintenance of smoke detectors to reduce the delay until the detection of the fire? (2) Which is more cost-effective, more but less costly basic life support ambulances or fewer but more expensive advanced life-support ambulances? (3) What is the cost-benefit ratio for automatic defibrillators? (4) What are the relative benefits of one- and two-officer patrol units? (Chelst 1981).

Cities with populations as large as 70,000 have trained public safety officers to handle both police and fire emergencies. This has proven cost-effective in some locales but not in others. OR models have been used to study such mergers of emergency services, thus enabling decision makers to assess the potential impact on fire and police response times and cost (Matarese and Chelst 1991).

Despite the success of OR models in key operational and policy questions, relatively few cities employ them on a regular basis in their decision making regarding emergency services. Success stories from various cities still appear periodically in the literature, but there is no critical mass of researchers or operations research analysts dedicated to improving the performance of these types of emergency services. Instead, the typical local study involves one or more faculty members working with a local area emergency service to solve a particular problem. Such work generally entails no more than minor variations on existing research.

Operations researchers whose area of specialization is location theory continue to enhance their models. This has included expansion of the definition of coverage models, incorporation of multiple objectives, and inclusion of probabilistic issues that relax the assumption that the nearest emergency service responder is available when a call comes in. These enhancements, however, have not generated any greater practical interest from administrators. One interesting development is a software system, ALIAS, that was designed to assist ambulance location decisions. Its strength is that it integrates geographic information system (GIS) technology into a descriptive decision-support system. The system enables a decision maker to consider multiple objectives while making specific location decisions.

The recession that started in 2007 and the subsequent housing collapse have led to serious shortfalls in financing emergency services. City managers around the U.S. are taking unprecedented steps in requesting substantial cuts in emergency service personnel. In 2007, ICMA began providing city officials with a clear assessment of the workload of their police and fire departments, as well as an analysis of response time. A typical police report overlays workloads of all types against deployment levels. In one instance, a city council decided to reduce its patrol force by 30%, returning it to a level last seen in the late 1970s.

The most important change in policing since 1990 involves descriptive analytics. New York City pioneered the use of timely crime data to focus police resources. These data were used in regularly

scheduled, wide-ranging meetings in which precinct commanders accepted responsibility and were held accountable for implementing strategies to reduce crime. This concept was called COMPSTAT and copied in a number of major cities (McDonald 2001). With the spread of computerized mapping, even smaller cities can routinely produce crime maps to identify hot spots. Researchers have now moved beyond mapping and developed predictive models of crime patterns (Gorr et al. 2003). In Great Britain, researchers are making progress in estimating the likelihood of an arrest for a burglary reported in progress as a function of response time.

Disaster Planning and Management

In contrast to police, fire, and emergency medical services, disaster planning, in terms of both frequency and scope, is at the extreme end of the spectrum of emergency planning and management. Disasters of limited scope, such as commercial airplane crashes, may occur once a year. Calamities on the scale of the Exxon Valdez oil spill, Hurricane Andrew, the Bhopal-Union Carbide disaster, or the Chernobyl nuclear accident were thought to occur no more frequently than once a decade. However, perceptions may be changing as four major disasters occurred in just one ten year period between 2002 and 2011. In any case, when they do occur, they can affect the lives of millions of people and despoil millions of square miles of the environment. As a result of a series of massive disasters, research in disaster planning and management has gained added urgency, and decision-support systems to help plan for and manage disasters are a growing area of research and software development (Altay and Green 2006).

This growth has been driven in part by regulatory requirements that mandate disaster plans, as well as recognition that prevention and planning are cost-effective. The International Emergency Management and Engineering Society (TIEMES) was formed in 1994, and, in 1998, a special issue of IEEE Transaction on Engineering Management was dedicated to this topic. The most visible U.S. governmental agency in this area is the Federal Emergency Management Agency (FEMA). With respect to past disasters, there is also increasing global cooperation in developing early warning systems. A global warning system for tsunamis was developed in reaction to the 2004 massive tsunami that led to catastrophic loss of life in multiple countries in South Asia. In addition, national public health agencies cooperate in tracking the spread of epidemics.

Emergency Services, Table 1 Disaster categories

Category 1	Category 2	Category 3
Locally contained disasters	Localized disasters with potential for spread	Massive disasters
Aircraft or shuttle disaster	Forest fire	Hurricane
Mine explosion	Toxic chemical leak (train wreck or tanker overturn)	Tsunami
Disaster at sea (ship or ferry)	Hazardous oil spill	Major snow or ice storm – large-scale power outages
Major terrorist attack	Nuclear power plant accident	Floods
Mudslides or avalanche		Earthquake
High-rise fire		Volcanic eruption

Locally Contained Disasters: Disasters can be grouped into three categories that reflect their scope and duration (see Table 1). The first category covers disasters of limited duration, such as an airplane crash, space shuttle explosion, mine explosion, cave-in, or bombing. These disasters involve a single short-lived catastrophic event. The impact is usually limited to the individuals in the vicinity of the disaster, though it may, like that of 9/11, affect life far beyond the immediate focus of the terrorist attacks. The primary opportunity for risk mitigation in Category 1 disasters is in disaster prevention. Another strategy is to contain or dissipate the initial force of the disaster and work to increase the possibility of survival. Rapid evacuation may also be important if there is a risk of secondary explosions or continuing collapse, as in the case of a mine or building explosion.

Operations research has played a significant role in understanding and avoiding the risks associated with air transportation (Machol 1995). Collision-risk models have been used to establish safe and efficient separation standards. Simulation models have been used to design better runway configurations to avoid takeoff and landing disasters, while maximizing the efficiency of airports. In the case of the space shuttle, probabilistic models were used to identify the greatest sources of potential catastrophic failure, and

organizational pressures were identified that also contributed to increased risk of failure.

Evacuation has been an area of modeling at every level of disaster (Yi and Özdamar 2007). Simulation has been used to study mine-fire escapes and as a training tool to prepare miners to make the right decisions in an emergency (Cole et al. 1998). Evacuation of buildings is the subject of a number of papers that model the escape routes as a network. If probabilistic issues are factored in, a queueing network model can be used to study evacuation capacity. Early warning systems increase the potential effectiveness of evacuation procedures. Florida has developed effective strategies for evacuating large areas when a hurricane is forecast. In addition, Florida counties have plans to locate disaster recovery centers to assist victims of a local disaster. Unfortunately, there was no effective evacuation strategy or assistance for the New Orleans area as Hurricane Katrina approached. (See the entry "► Fire Safety Modeling and Applications" where evacuations are discussed in more detail).

Localized Disasters with Potential for Spread: The second category involves disasters of longer duration with potential to spread. This category includes forest fires, oil spills, hazardous waste leaks, and nuclear power plant accidents. Forest fires have drawn significant attention from operations researchers in large part because the USDA Forest Service has used analytic models in a wide range of areas. Decision analysis has been used to study different strategies and tactics to clear away underbrush so as to limit the scope of fires. A simulation model known as FARSITE calculates how a fire will spread under specific prevailing weather and environmental conditions (Finney 2004). Understanding and planning for forest fire spread is a continuing area of critical research. The USDA Forest Service developed the National Fire Management Analysis System (NFMAS) to assist in planning attacks on forest fires (Donovan et al. 1999). The system is a simulation that is used iteratively to determine the effect of different decisions designed to reduce the economic impact of a specific forest fire.

With regard to hazardous waste, the focus has been on models to route shipments of hazardous materials so as to reduce the risk in transit and to determine where to locate unpopular facilities (List and Turnquist 1998). The Hazardous Materials Transportation Uniform Safety Act of 1990 has improved the routing of shipments of hazardous materials and the planning for emergency response. Because there are different stakeholders affected by the routing decisions, the models are generally multi-objective. One set of OR models integrate the routing decision with the siting of emergency response teams.

Planning for massive oil spills begins with broad systemic assessment of risk so as to reduce its likelihood. This is followed by developing a plan to pre-position appropriate containment and cleanup equipment. Mathematical programming has been the modeling technique of choice. Once an accident has occurred, the key task is to forecast damage spread as a function of weather and environmental conditions. The challenge then is to rapidly assemble needed people and equipment resources so as contain the accident as soon as possible. A mathematical-programming model was developed to model the dispatch of cleanup equipment (Iakovou et al. 1996).

If the forecast indicates that there are people in harm's way, they have to be evacuated as rapidly as possible. The Nuclear Regulatory Commission requires utilities to develop and update evacuation plans. MASSVAC is a software package that models traffic movement during evacuation and has a user equilibrium assignment algorithm to improve evacuation time. Once evacuation has been accomplished, the next responsibility is to clean up the mess or repair the damage. The goal is to either return the environment to its original state or, more likely, to bring it to an equivalent state of environmental health. OR's role in the long-term problem of restoring the environment has been limited to waste water contamination problems.

Massive Disasters: The third category involves massive disasters that can encompass a region, a state, or even a whole country, such as Haiti. These include hurricanes, major snow and ice storms, massive earthquakes, large volcanic eruptions, or extensive flooding. These massive natural events may not be preventable, but governmental strategies that encourage better planning can reduce the impact of the disaster. In 2011 a number of cities along the Mississippi River benefited from this type of planning. They were saved from being deluged by floods when overflows were diverted to less populated areas. Also, cities and individuals can be encouraged to build away from a flood plain or construct buildings and structures more resistant to earthquakes and hurricanes. One of the earliest public sector applications of decision analysis

with imperfect information involved seeding hurricanes to reduce their impact.

Improvements in forecasting have helped people carry out short-term tactics, such as boarding up windows, evacuating from the area of an impending disaster, and stockpiling emergency supplies. One decision support system (but without OR models) is designed simply to convert National Weather Service forecasts into forecasts of specific emergency hazards (Subramanian and Kerpedjiev 1998). The first major application of this system was the Basin Rainfall Monitoring System, intended to predict in simplified and useful fashion the risk of flash flooding.

Once the immediate disaster is over, local, state, and national agencies must cooperate to address short-term, day-to-day needs, to create and implement stop-gap solutions such as temporary roads and bridges, and then to work to help a region rebuild its housing and industrial infrastructure (Beresford and Pettit 2009). Rebuilding should be implemented with an eye toward reducing the chance of a future similar disaster. One integrated application of OR techniques involved managing emergency repair logistics for an electric utility (Zografos et al. 1998). The integrated framework included: (1) a data management module with GIS to track service restoration by geography, (2) an information system module to monitor vehicles and communications, and (3) an analytic module to optimize the division of the region into districts and a simulation to study and improve dispatch operations.

Operations research models in this domain tend to emphasize centralized and integrated planning. This planning would include dispatching vehicles around a transportation infrastructure that has been compromised and locating facilities to assist people in need. Often, however, these massive events seriously undermine communications, making it difficult to implement a comprehensive plan. It has been proposed that a more flexible localized effort be the key element of any strategy.

Saint Louis University, St. Louis, MO, USA

Introduction

Different engineering disciplines have unique characteristics and problems. Operations research (OR) is a field made up of many conceptually different methods and algorithms, each suited to a specific environment. Thus, some specific OR methods and algorithms are better suited to the solution of certain types of engineering problems than others. Applications of OR methods and algorithms to problems in those engineering disciplines best suited to such applications are described below.

Communication Systems Engineering

Operations research methods are widely used in various aspects of communication system planning, design, manufacturing, and implementation (Daigle and Langford 1988). Examples that illustrate the diversity of applications of OR methods to communication systems include a filter design which uses game theory (Kazakos 1983) and the use of Markov chains to model a synchronous time division multiplexing frame synchronization algorithm (Liu and Hammond 1980). The use of OR methods in the design and analysis of computer communication networks has attracted significant attention in the literature, since the design and analysis of these networks depends almost entirely on OR methods. Sauer and McNair (1983) used simulation to analyze computer communication systems. Queueing theory and stochastic processes were used by Hayes (1984) and by Stuck and Arthurs (1985) to analyze such systems. Marcus and Papatoni-Kazakos (1983) analyzed a multi-access protocols problem via dynamic programming. Self-healing communication networks that allow re-routing of demands through switching processes at designated nodes have been designed using a node-path linear-programming approximation to the multi-commodity network formulation (Saniee 1996). Luna et al. (2008) used a grid-based generic algorithm to solve automatic frequency planning problems. These problems occur in global systems for mobile communications networks. Several evolutionary algorithms applied to a class of communication network design problems were evaluated by Nesmachnow et al. (2007). A brief description of two of the most important problems in the design of contemporary communication systems follows.

Statistical Multiplexing — The design of a communication system based on high-speed links

that transmit information generated by many users generally has an economic advantage over a design based on separate links between pairs of users (Daigle and Langford 1988). Multiplexing and concentration are terms used to characterize methods of assigning the capacity of a link among many users. Multiplexing represents the case where the capacity of a link is divided into frequency bands and each user is assigned to a specific band. Concentration represents the case where the capacity of a link is smaller than that needed to accommodate simultaneous requests by all users, and, thus, a line sharing approach is necessary. In that case, a queueing system is used to control the traffic of user requests for communication.

Statistical multiplexing, also called asynchronous time-division multiplexing, is an approach for link sharing that combines characteristics of both multiplexing and concentration (Daigle and Langford 1988). The users' messages need to be transmitted over a communication link. While a users' message is divided in some systems into packets, the message remains intact in others. When statistical multiplexing is implemented, the users' messages are kept in a queue before being transmitted over the communication link. Depending on the volume of messages, queueing delays may occur. The delays obviously present an inconvenience to the users, and should be considered in evaluating the appropriateness of statistical multiplexing for a particular environment.

Statistical multiplexing systems have been designed and analyzed using queueing theory, Markov-chain models and renewal theory. Poisson arrivals are assumed in many cases to simplify the analysis. The Poisson-arrivals-see-time-averages (PASTA) property is often used to obtain analytical results (e.g., see Wolff 1982). The Chapman-Kolmogorov equation is generally used to analyze discrete-time systems, while equilibrium balance equations are frequently used to analyze continuous-time systems (Daigle and Langford 1988).

Topological Design of Local Distribution Networks — The problem of designing the topological aspects of local distributed networks is composed of five subproblems (Gavish 1982). The subproblems include determination of: the number of concentrators; the location of concentrators; the method of connecting the concentrators to the switch; the assignment of terminals to concentrators; and the interconnection between terminals and concentrators. The subproblems can be solved simultaneously (Daigle and Langford 1988).

In the terminal layout problem, a tree structure is sought that minimizes the total cost of connecting all the terminals to the packet switch, that is, terminal or node 1 (Daigle and Langford 1988). It is assumed that the number of terminals or nodes is $n - 1$, and are numbered 2 through n. The cost c_{ij} of connecting terminal i to terminal j for $1 \leq j \leq n$ and $1 \leq i \leq n$ is assumed to be given. It is also assumed that c_{ij} is infinite for $i = j$. It is further assumed that the measure of traffic associated with each terminal identifies the communication flow between the terminal and the switch. Daigle and Langford (1988) discussed solution methodologies that have been applied under the following conditions: when trees are unconstrained, degree-constrained, capacity-constrained or both capacity and degree constrained.

Structural Engineering

Mathematical programming (MP) has been extensively used to determine the optimal structural design of various engineering systems. Applications of MP to the design of civil engineering structures are surveyed below. MP has also been used to design structures undergoing free or forced vibrations. An overview of this subject is also provided below.

Designing Civil Engineering Structures — While many feasible designs that satisfy functional requirements often exist, a trial-and-error procedure may be needed to obtain the optimal solution (Kirsch 1988). The efficiency of the structural design process can be improved by automating portions of the design process. Such automation is possible because of the progress made in computer technology, structural analysis, and optimization methods (Atrek et al. 1984; Soares 1986).

Kirsch (1988) suggested that an automated design process be considered an iterative process. The iterative cycle, in this process, is composed of two main steps: (1) analysis of the current structural design, and (2) redesign, that is, modification of the design by optimizing an objective function subject to the pertinent constraints.

Some of the parameters characterizing a structure are fixed during the automated design process.

The parameters that are not fixed are the design variables. The design variables represent the following characteristics of the structure:

1. Physical properties of the materials
2. Topology
3. Configuration or geometric layout
4. Cross-sectional dimensions.

The design of the structure is defined once the value of the design variables are obtained. From analyzing the structure, one can determine the forces and displacements. Structural optimization problems often deal with cross-sectional design variables. These variables are usually assumed to be continuous despite the fact that they actually can obtain only discrete values (Kirsch 1988).

Truss structure is the subject of most structural optimization studies. An illustrative example of such optimization was given by Kirsch (1988). Grillage is a flexural system composed of beam elements. Moses and Onoda (1969) illustrated that grillages introduce significant design difficulties, in addition to those usually encountered in the optimal design of any indeterminate structure. The design difficulties typical to grillages include multiple local optima and internal forces sensitive to changes in the design variables. Kirsch (1988) provided an example that illustrates the possibility of multiple optimal topologies in flexural systems. The optimal design of reinforced-concrete structures was formulated by Kirsch (1988) as a four-level MP problem. Krishnamoorthy and Murno (1973) formulated a linear-programming (LP) model to satisfy compatibility and limited ductility, equilibrium and serviceability conditions as constraints. The model has a linearized objective function for the total volume of steel reinforcement. Kirsch (1988) formulated a typical prestressed system design problem using MP.

Designing Optimal Vibrating Structures — The objective functions used in designing structures that are subject to dynamic loads include both maximization of eigen-frequencies and minimization of dynamic deflection and/or stress (Adali 1988). The resonance range of structures undergoing free vibrations are increased by maximizing either the fundamental or higher-order frequencies. Dynamic deflections and/or stresses are minimized for structures undergoing forced vibration to improve the structure's service performance. Structures may be subject to both free and forced vibrations during operational life. For this reason, lower bounds are generally imposed on the eigen-frequencies and upper bounds are imposed on the dynamic deflection and stresses (Adali 1988). In this case, the resulting design problem is a constrained optimization problem. Such problems are routinely solved using penalty function methods. The problems, however, can also be formulated as multicriteria optimization problems.

Beam design problems for the case of continuously vibrating structures were formulated by Adali (1988) using MP. The objective function in such problems is maximization of the fundamental frequency. The use of MP in formulating beam design problems for discrete structures like frames and trusses is fairly obvious.

Some structures may be subject to forced vibrations caused by environmental forces such as wind, waves, and earthquakes. The objective in designing such structures is to minimize the deflection and/or stresses caused by dynamic loads (Adali 1988). Structures under dynamic loads can be effectively designed using MP (Khot et al. 1986).

The penalty-function method is an effective optimization method used to design structures when there are constraints on stress, deflection, and maximum frequency. Several penalty-function techniques useful in designing structures having constrained beams and frames are discussed by Adali (1988).

MP has been successfully used to optimally design composite, lightweight structures like those typically used in the aerospace industry. After studying the designs of laminated plates and shells undergoing free vibrations, Adali (1988) demonstrated how to use MP in designing such optimal composite structures.

Results of sensitivity analysis were used by Hsieh and Arora (1986) for satisfying state-variable constraints. Sensitivity results for eigen-frequencies were obtained for frames and composite plates. Their use was illustrated by Adali (1988) via specific examples. Evolution strategies were applied by Hasanceb (2007) to optimize the design of truss bridges. This optimization problem involves identification of the bridge's shape and topology configurations, as well as sizing of the structural members for minimum weight. Cagdas and Adali (2007) developed optimum designs for

clamped-clamped columns under concentrated and distributed axial loads. The design objective was the maximization of the buckling load subject to volume and stress constraints. Barreled cylinders and domes of generalized elliptical profile were optimized by Blachut and Smith (2007) for their buckling resistance when loaded by static external pressure. The optimum shells were found using either a static or adaptive tabu search method.

Chemical Engineering

Many applications of OR techniques can be found in the design and operation of chemical plants. These application include refinery planning, equipment design optimization, and optimization of equipment networks. Solutions to the complex nonlinear optimization problems typical of chemical engineering have been gradually improved due to the continuous progress made in nonlinear programming (NLP), mixed integer-linear programming (MILP), scheduling, and simulation techniques, as well as to the improvement made in related software (Biegler et al. 1988).

Many chemical engineering optimization problems are much too large and complex to be solved by direct application of generic OR algorithms (Biegler et al. 1988). By examining both the unique physical characteristics of each system and the unique structure of each optimization problem, however, it is possible to reduce very large and often highly combinatorial problems to manageable size (Biegler et al. 1988).

Biegler et al. (1988) demonstrated that when addressing the optimal design/operation problem of continuous processes, an understanding of model construction and execution must precede algorithm selection and tuning. Modeling is typically done using process simulation. By taking advantage of the unique composition of the system being modeled, one is in a better position to successfully optimize system design. The NLP applications from optimizing design/operation problems dealing with continuous processes are discussed by Biegler et al. (1988), and illustrate the advantages of both the unique analysis of each problem and the intelligent application of generic optimization algorithms.

The combinatorially complex problem for synthesis of process structures was discussed by Biegler et al. (1988). Problems related to utility systems, energy recovery systems, and total processing systems were considered. The problems related to utility systems can be formulated as MILP. The binary variables in such problems are the structural choice variables. It is possible to significantly reduce the number of binary variables by taking advantage of the uniqueness of constraints and problem structure (Biegler et al. 1988). A reduction in the number of binary variables makes it possible to use software for MILP. Biegler et al. (1988) showed that a complex mixed integer-nonlinear programming (MINLP) can be broken down into a series of subproblems having well-structured solutions. This decomposition is accomplished through use of thermodynamic insights and the system's structural features. Beigler et al. (1988) applied these ideas to a total processing system that consisted of a utility plant, a heat-recovery network, and the chemical plant itself.

The design and scheduling of noncontinuous processes generally involves multi-products. Noncontinuous processes involving multi-products are typical to some high-value-added chemical and biochemical products. Problems in these areas are discussed by Biegler et al. (1988). Two types of facilities were considered: the network flow shop configuration and the multi-purpose plant. These facilities can be modeled using MINLP. Because of the complexity of the models, approximation and decomposition methods are necessary to solve them (Biegler et al. 1988). Design problems in a multipurpose plant involve some aspects of scheduling and therefore add to the complexity. While some portions of these design problems can be formulated and solved as MILP scheduling and sequencing problems, most portions require the development of specialized approximation algorithms. The application of combined continuous-discrete simulation concepts to modeling and analysis of continuous batch chemical processes was presented by Biegler et al. (1988).

Churi and Achenie (1997) developed an MINLP model for single component refrigerant design . The design objective is to build a refrigerant molecule that has desired physical properties and performance characteristics. Scheduling of chemical batches using stochastic integer programming was reported by Urselmann et al. (2007). The scheduling algorithm combined evolutionary algorithm and mixed-integer programming into two-stage stochastic programming problem.

Aerospace Engineering

The design of an aerospace vehicle is a multidisciplinary project that involves the following disciplines: control theory, solid mechanics, fluid mechanics, dynamics, electronics, and computer engineering. Optimization theory has a significant role in aerospace engineering since it is extremely important to achieve optimal design in every aerospace project.

Aerospace Structures — The motivation for applications of optimization methods to the design of aerospace structures is the need for efficient light-weight structures. The decision variables of a typical problem involved in optimizing an aerospace structure are the structural member dimensions. The objective of such a problem is to minimize structural weight subject to constraints on limit stresses in members-nodal displacements, on natural frequencies of the structure, and on the stability of the eigenvalues (Hajela 1988).

One way of formulating and solving optimization problems related to aerospace structures is to first define an optimality criterion and then attempt to satisfy the criterion via a numerical algorithm (Berke and Khot 1974). This approach, however, is very restrictive as the definition of optimality criterion is problem dependent (Hajela 1988).

The application of NLP methods to the design of aerospace structures is more flexible than application of optimality criterion. NLP methods, however, are computationally inefficient for design problems involving large numbers of variables and constraints (Hajela 1988). A more practical way of achieving an optimum aerospace structural design is by using numerical optimization.

Sobieski (1988) showed how numerical optimization could be used in aerospace structural design. He also described the role of decision variables, objective function, constraints, and the design space in numerical optimization. Sobieski (1988) illustrated how a search procedure composed of modules (e.g., search algorithms, approximate analysis, and sensitivity analysis) could improve the design of aerospace structures. He also elaborated on several ways of combining modules into an effective comprehensive optimization procedure. Sobieski (1988) described ways of dealing with the unique difficulties involved in large-scale aerospace structural design problems.

Aerodynamic Characteristics — The geometry of the airfoil (that is, wing cross-section) affects configuration lift and drag characteristics. Design variables of an airfoil include thickness, distribution over the chord-wise dimension, radius of curvature of the airfoil's nose, and the camber or arch of the airfoil chord (Hajela 1988). The values of these variables determine the lift and drag of the aerospace vehicle given the characteristics of the flow in which the airfoil is expected to operate. Flow can range from low subsonic speeds to high supersonic speeds. Atmospheric re-entry vehicles can experience hypersonic flow. The entire spectrum of airfoil shapes and their respective lift and drag for low speed flow have been documented (Hajela 1988). Simulated flow conditions in a wind tunnel can be useful in designing new shapes for airfoils that must operate under changing flight conditions. The use of wind tunnels is expensive, however, because it calls for the development of a model and because delays are inevitable in scheduling the use of a wind tunnel. Furthermore, only a limited number of design alternatives can realistically be examined in a wind tunnel.

Airfoil shapes can be designed using numerical computation techniques for fluid flow such as the finite-difference method or the finite-element method (Hajela 1988). Aidala (1988) developed the concept of obtaining optimum airfoil shape by using a weighted sum of standard airfoil shapes. The weight constants, in that case, are the decision variables. Their values must be selected to optimize desired aerodynamic characteristics. Aidala (1988) also elaborated on another design approach in which airfoil geometry was refined to obtain desired pressure distribution over the airfoil. Variable-complexity methods were applied by Thokala et al. (2007) to aerodynamic shape design problems. The objective was to reduce the total computational cost of the optimization process. Transonic airfoil design problems considering inviscid and viscous flow solvers were solved by Shahrokhi and Jahangirian (2010). They used a surrogate assisted evolutionary optimization method to solve the problems.

The aerodynamic design of an aircraft must allow for a mechanically and aero-elastically acceptable wing and must also satisfy several different performance requirements (Aidala 1988). The Lagrange multipliers method can be used to achieve

an optimal aerodynamic design when linear theories are sufficient to characterize the design problem (Aidala 1988). The typical approach in the more general nonlinear case has been to integrate analysis codes with a general nonlinear optimization method (Aidala 1988). A general nonlinear optimization approach to aerodynamic design is the most frequently used in such optimization problems and described by Aidala (1988). To obtain computationally efficient results, however, numerical optimization must be used.

Aerospace Vehicle Performance — A unique characteristic of aerospace vehicles is that there are no external forces like buoyant (static) lift or ground reaction forces that can support a vehicle (Kidwell 1988). Thus, an aerospace vehicle must be designed to generate the forces needed for longitudinal, lateral, and vertical translation (Kidwell 1988). The forces must be proportional to the vehicle's mass and to the requirements for acceleration. Growth factor (Kidwell 1988) is a measure of the overall increase in the aircraft gross weight caused by adding one pound of weight (from payload, fuel, structural weight, etc.). The growth factor indicates the compounding effect of weight. Any increase in the requirement for weight necessitates increase in one or more of the following: wing area to provide the necessary additional lift; engine size to compensate for the increase in drag; and fuel requirements that are a consequence of the greater engine thrust needed to counter drag (Kidwell 1988). Every component of an aerospace vehicle must be designed with minimal weight in mind, as any change in the weight of a particular component has a significant effect on the performance of the entire vehicle. Kidwell (1988) discussed several methods useful in designing aircraft that meet desired performance criteria. He also showed how numerical optimization could be use to achieve an optimal aircraft design having acceptable computational effort.

Optimal locations of dual trailing-edge flaps was determined by Viswamurthy and Ganguli (2007). The objective was to achieve minimum hub vibration levels in helicopters. Chang, et al. (2008) developed a deductive top-down estimation methodology for assessing the reliability of aircrafts propulsion system.

Electrical Circuit Design

The filter design problem was formulated by Lasdon and Waren (1966) as a nonlinear program. Optimal filters were obtained using an interior penalty function in a problem formulation having a minimax type of objective function. Lasdon, Waren et al. used NLP in designing optimal antenna arrays, cascade crystal-realizable lattice filters, and optimal filters (Waren et al. 1977).

The use of optimization methods in the design of filters and in the modeling of active electrical devices is reviewed by Temes and Calaham (1967). Temes and Zai (1969) designed active equalizers based on least pth approximation. The theory of generalized least pth approximation was developed by Bandler and Charalambous (1972). This approach allows one to use any value of p while solving several minimax problems.

Madsen et al. (1975) developed a minimax electrical network optimization algorithm based on successive linear approximation of a nonlinear objective function. Applications of their algorithm include the design of transmission-line transformers and the design of microwave filters (Bandler and Rizk 1979).

Optimization methods have been routinely used in the design of digital filters (Bandler and Rizk 1979). Optimization methods such as LP, NLP and integer programming (IP) were used in the design of a nonrecursive filter based on minimax responses (Helms 1971). Steiglitz (1970) showed how optimization methods could be used to design recursive digital filters. Recursive digital filters with optimum word length were designed by Bandler et al. (1975).

Optimization methods have been used extensively in the design and operation of power networks (Bandler and Rizk 1979). The problem of minimizing the cost of fuel for thermal power plants, for example, is solved on-line every few minutes. The solution to this problem is periodically used to adjust the output of the power plant (Bandler and Rizk 1979). The problems of optimizing hydroelectric systems are generally much larger than those of thermal power plants. Gagnon et al. (1974) developed an NLP model for solving such problems.

Computer System Design

Several different aspects of computer system design are described below.

Selecting an Optimum Network Configuration — To optimize the configuration of a computer system, the system can be modeled as a closed queueing network. Consider, for example, the problem of configuring a batch-oriented, nonpaged, multiprogramming system (Trivedi and Kinicki 1980). The central server queueing network given in Sarma et al. (1988) can be used to model such systems. The system characteristics that are considered include variables related to both the size of the main memory and the speed of a fixed number of secondary storage devices. $m + 1$ service facilities (i.e., facility 0,. . ., facility m) in a closed queueing system represent active resources of the system such as the CPU and I/O channels. Each service facility is composed of a single server when the ith facility has a processing capability of b_i work units per unit of time. The degree of multiprogramming is denoted by n. The network is composed of n stochastically equivalent programs that switch back and forth between service at the CPU and service at the I/O channels. After processing by the CPU is complete, service from the ith I/O channel is requested by a program with probability p_i ($i = 1, 2, \ldots, m$).

The device speed vector $\boldsymbol{b} = (b_0, b_1, \ldots, b_m)$ in this design example (see Sarma et al. 1988) is considered to be the decision variable. The branching probabilities p_i ($i = 1, \ldots, m$) are assumed to be parameters. The design problem is formulated as follows:

$$\begin{aligned} &\text{Maximize } T(\boldsymbol{b}) \\ &\text{subject to } F(\boldsymbol{b}) + M(n) \le B \\ &\qquad\qquad b_i \ge 0, \quad i = 0,\ 1,\ 2,\ \ldots,\ m \end{aligned}$$

where $T(\boldsymbol{b})$ is the system throughput; $F(\boldsymbol{b})$ is the cost of $m + 1$ service facilities; $M(n)$ is the cost of the main memory; and B is the budget available for the purchase of the necessary hardware. For the method of solving such a problem, see Sarma et al. (1988).

Design of Fault-Tolerant Computer Systems — The design optimization problem under consideration includes measures of system dependability, performance and cost. More specifically, a shared and replicated resources architecture designed for high reliability applications is considered. Real-time control typifies an application that necessitates high reliability. The modular multi-processor system (MMPS) (Pedar and Sarma 1983) is an example of this architecture.

One characteristic of the MMPS is that the system's computational capability, as well as the corresponding memory contention, change when the processor and the memory unit fail (Sarma et al. 1988). Trivedi (1982) showed that system reliability can be analyzed using Markov models if the failure rates of the processors and of the memory modules are assumed to be constant. The state, in this case, represents the number of operational processors and the number of operational modules at a given time. It is assumed that the program memory is divided into several stages. The decision variables include the number of stages, the number of modules in each stage, the replication factor in a give stage, and the number of processors. The problem faced by the computer design engineer is to minimize the total cost of the system subject to constraints on unreliability of the system's computations.

Task Allocation in Distributed Computer Systems — Given a program composed of several modules, the problem under consideration is the allocation of the modules to the individual processing elements of a multiprocessor system. This problem can be formulated as a constrained optimization problem (Sarma et al. 1988). The objective of such problems is to minimize the cost function that depends on the specific allocations. The constraints include restrictions on the speed of the processors and the limits on memory capacity. Allocation problems are generally computationally intensive (i.e., NP-complete). The three most widely used approaches for solving these problems are graph theoretic, integer programming, and approximation algorithms. Graph theoretic algorithms are practical in solving only problems involving a small number of processors. While integer programming is more widely used in solving allocation problems, it is difficult to predict the amount of computations necessary to obtain the needed accuracy. Approximation algorithms are generally considered the most practical method for solving allocation problems since they can provide acceptable solutions at low computational cost

(Sarma et al. 1988). OR methods have been applied to other aspects of computer systems design. One example is the use of optimization algorithms for motion recovery in computer vision (Lee and Park 2008).

Mechanical Engineering

OR methods have been successfully applied to various mechanical engineering design problems. A few examples follow.

Engine design–Aittokoski and Miettinen (2008) applied a simulation-based optimization to the design of a two-stroke combustion engine. The optimization approach involves interactive multiobjective optimization. A hybrid evolutionary algorithm consisting of a generic algorithm and particle swarm optimization was applied by Jeong et al. (2008) to the geometry design of diesel engine combustion chamber. The new design resulted in reducing exhaust emissions.

Yixian et al. (2009) developed a topology optimization approach for the design of compliant actuators using mesh-free methods in which the thermo-mechanical multi-physics modeling and geometrically non-linear analysis were included. The optimization problem was formulated as a nonlinear programming-problem to which a sequential convex programming method was applied. The mechanical structure of a five-bar parallel robot was designed by Villarreal-Cervantes et al. (2010) using a constraint-handling differential evolution algorithm to solve the nonlinear dynamic optimization problem.

Environmental Systems Analysis

Charles ReVelle
The Johns Hopkins University, Baltimore, MD, USA

Introduction

Within a decade after the emergence of operations research at the end of World War II, civil and environmental engineers were already adapting the remarkable mathematical tools that had evolved in the defense sector during the war. They quickly applied these tools to the solution of important societal problems relating to environmental protection. Applications of operations research to urban and regional water management began in the late 1950s primarily under the leadership of Lynn and Charnes. Solid wastes management using the tools of OR began in the mid-1960s led by Liebman and engineers at Berkeley. The development of air pollution management models followed not long after. Parallel to these engineering-based investigations of environmental issues were applications in forestry/timber management/recreation as well as game and fisheries management. The three engineering-based areas of environmental OR application will be reviewed.

Urban Water Management

First, in historical sequence of environmental applications of operations research, was urban and regional water management. Urban and regional water management encompasses many activities, some of which have been approached with OR tools and others which have seen very little application activity. Water resources management, a parallel activity to urban and regional water management, focuses on the operation of reservoirs and systems of reservoirs for purposes of water supply, recreation, flood control, irrigation, hydropower, and navigation. It also deals with aquifer management, conjunctive use of ground and surface waters, and interbasin transfers. The activities of urban and regional water management, in contrast, are principally concerned with the local delivery of water, with treatment of water, with disposal of wastewater, and with the quality of receiving waters, although quantity and quality intersect in a number of problem settings. Water resources management is discussed in this encyclopedia under its own heading.

Here, water is followed (1) out of the reservoir to the water treatment plant that produces drinking water, (2) through the distribution system to the consumer, (3) from the consumer through the sewer system (4) to the wastewater treatment plant (sewage treatment plant), and (5) into the receiving water body, where the pollution content of the treated wastewaters of many communities interact with stream dissolved oxygen resources.

The water treatment plant is designed to produce drinking water that is free of disease-causing bacteria, viruses and protozoa. The water should be attractive (clear) and palatable with little in the way of objectionable tastes, odors, or color. The processes in a typical water treatment plant are designed to achieve these criteria. The design and arrangement of the component processes are probably susceptible to a cost optimization in which constraints are placed on the final concentrations of various contaminants. The design would constitute the first stage of applications of systems analysis to urban water management. However, very little in the way of OR/systems analysis has been done in water treatment plant design.

From the water treatment plant, the water enters a distribution system for delivery to customers. In this second stage of systems applications, linear programming and nonlinear programming have been applied to the design of water distribution systems although the nonlinearity in the equations has generally been approached by iterative application of linear programming to approximate an unknown multiplicative term. Decisions include which links of the system to build, the diameters of the pipes, the water flows in each link of the system, and the pressure heads at junctions of the system. A series of papers have appeared on this topic beginning in the late 1960s. A major difficulty in this design problem is the tradeoff between cost and redundancy (needed for reliability) and the lack of a good operational measure of redundancy. A unique article that explicitly compares a number of the approaches to this problem was jointly prepared by many of the researchers in the area of pipe network optimization and appears under the title "Battle of the Network Models," (Walski et al. 1987).

Residential consumers, as well as industry and commerce, receive the water from the distribution system, use it and abuse it for washing, bathing, lawn watering, irrigation and manufacturing processes. As a consequence of the use, the quality of the water is degraded, principally by the presence of organic contaminants, but also with micro-organisms and inorganic chemicals. Treatment at a sewage treatment plant is required to restore the water to a level of quality that will not impair the water in the receiving body.

To reach the sewage treatment plant, the wastes from residences, commerce and industry enter a wastewater collection system, the sewer system, which conveys them to the plant. The design of the sewer system represents a third stage of application of systems analysis to urban water management. A number of optimization models have been built to determine which links to build, diameters of individual sewer lines, the depth at which each line is placed and the slopes of each line. A representative work in this field is that of Walters (1985).

The sewers transport the wastes from their origins to the treatment plant which itself requires design. The design of the wastewater treatment plant represents a fourth stage of application of systems analysis to urban water management. The treatment plant typically consists of ordinary biological processes which remove organic wastes that are in solid form as well as organic wastes that are dissolved in the waste stream. Organic wastes are removed from wastewater because they will otherwise be degraded by microbes when they reach a lake or river and that biodegradation would remove dissolved oxygen from the water. Because fish and other stream aquatic organisms require adequate levels of oxygen to survive, it is imperative that sufficient amounts of organics be removed from wastewater to protect the dissolved oxygen resource that sustains the fish and other aquatic life. Depending on the requirement of the receiving water, the treatment plant could also include physical-chemical processes to remove not only nitrates and phosphates, but also the small fraction of organics which is resistant to biological treatment. The design of treatment processes using optimization methodology was begun in the early 1970s. A research paper on the subject which usefully refers to past works is that of Tang et al. (1987).

From the treatment plant (where the removal of organics takes place), the restored wastewater may enter a river or lake where it mixes with receiving waters. The concentration of organic wastes ultimately discharged into the receiving waters will decrease as the degree of treatment/level of removal at the wastewater treatment plant increases. Without much treatment, the amount of dissolved oxygen in the lake or river consumed by oxidation of the organic wastes will be relatively large, making the water environment inhospitable to fish and other desirable aquatic organisms. Predictive models for the removal of the oxygen resource and biological decay of organic wastes were first developed in the 1910s and have become increasingly descriptive and encompassing since that time. A text reference that clearly describes these numerous models is Thomann and Mueller (1987). These differential and difference equation models describe the response of the receiving waters to inputs of organic and other wastes.

While the response of the receiving water to the input of a single stream of organic wastes had been largely modeled by the late 1950s, the response of a river or lake to a number of spatially separated waste streams had not been described analytically. If wastes from multiple treatment plants are entering a river, then an optimization problem arises in which one seeks the least cost set of treatment plant efficiencies (level of treatment or degree of removal)

that can ensure the dissolved oxygen concentration everywhere in the river remains above a desired level or standard. The desired level or standard reflects the uses of the water body whether for fishing, swimming, boating, etc. Of course, it is possible and desirable to develop the tradeoff between the system cost of wastewater treatment and the dissolved oxygen standard. The dissolved oxygen standard represents the value of the lowest level of dissolved oxygen that occurs anywhere along the length of the river. Linear and dynamic programming models have been developed for this optimization problem which is really a problem in linear optimal control — in the sense that the dissolved oxygen responses are governed by differential equations.

After manipulation, which can be extensive, of the governing equations that describe the system and the constraints on performance, these models can be converted to the optimization form

$$\textit{Water Pollution Abatement Model}:$$

$$\text{Minimize} \quad \sum_{i=1}^{n} c_i e_i$$

$$\text{s.t.} \quad \sum_{i \in I} a_{ij} e_i \geq S \quad \forall j \in J$$

$$0 \leq e_i \leq 1 \quad \forall i \in I$$

i, I = the sources and set of sources from which organic pollutants are discharged;

j, J = the points and set of points at which the dissolved oxygen standard must be met;

c_i = cost per unit of removal efficiency at source i;

e_i = the removal efficiency at source i;

a_{ij} = the amount of dissolved oxygen that is protected or is allowed to be present in the stream at point j per unit of removal efficiency at point i; and

S = the dissolved oxygen standard that must be met at all monitoring points in the river.

In an estuarine situation where tidal movements cause pollutants to mix upstream and downstream of their point of discharge, all a_{ij} coefficients are non-zero and positive. In contrast, in a non-tidal river, only those a_{ij} are nonzero and positive for which the point j is downriver from source i. That is, in a non-tidal river, pollution from a source i has negligible effect on a point of measurement upstream from that source.

It is useful to develop the multi-objective tradeoff curve between total treatment cost and the dissolved oxygen standard because costs may increase rapidly in some portion of the curve, suggesting that further gains in quality can be obtained only at considerable expense. The river basin optimization model that chooses treatment efficiencies for each of many waste sources is a fifth stage in the application of systems analysis to urban water management (see ReVelle and Ellis 1994; McGarity 1997).

While realistic and relatively complex, the treatment plant/river basin optimization models do not completely describe the options for designing a pollution abatement program for the waste sources on a river. Their lack centers around the assumption that each discharge of treated wastewater enters the receiving water body at a known and prespecified point somewhere along the river, usually at its point of origination. Thus, another fundamental problem, and a sixth stage of application, is the siting of wastewater treatment plants along a river. That is, the previous model selected removal efficiencies but assumed that the flows from each of the wastewater treatment plants entered the river at the same geographical position as the community or industry that generated the flow. In contrast, the problem of siting wastewater treatment plants assumes a single prespecified and high removal efficiency for all the plants on the river, but seeks the positions for discharges which minimize the total treatment cost. The single treatment level is presumed to be sufficiently high that dissolved oxygen standards are not violated along the river. At one extreme, discharges may still occur at each community or industry along the river. At the other extreme, discharges may be consolidated into a single regional wastewater treatment plant. Most likely, however, is the partial consolidation of wastewater flows with some at-source discharges and some flows merging at regional plants for treatment and discharge.

The motivation of this problem setting is that economies of scale in treatment may be captured when wastewater flows are combined and treated together. Working against this cost advantage in consolidating flows are the additional costs of piping and pumping that are incurred when wastewater flows are merged at central points. Thus, the objective of the regional wastewater treatment plant problem is to minimize the sum of treatment costs and piping/pumping costs. The more dispersed that communities are along a river, the less likely will be consolidation in regional plants. Much work has been done on this

problem since the early 1970s, most of it focusing on a fixed charge approximation of the concave costs of treatment. Zhu and ReVelle (1988) provided an efficient and exact solution to siting regional treatment plants along an essentially linear river via integer programming and refer to most previous published research on the problem. Whitlatch (1997) provides a review of the literature of regional treatment plant siting.

A variation of and combination of the two previous problems has not been well studied; this is the problem which seeks the least cost set of treatment efficiencies and the sites for regional wastewater treatment plants given that a dissolved oxygen standard is honored along the length of the river. Multiplicative nonlinearities and concave or fixed charge cost functions make the problem especially challenging.

A final and seventh stage of application of systems analysis to urban and regional water management is the problem of cost or burden sharing. The notion here is that a regional authority has been created whose goal is to stimulate cooperation in the solution of environmental problems. Cooperation takes the form of joint activities, e.g. regional wastewater plants vs. separate plants for each community — if the regional solution saves money. Since the authority is assumed to be unable to coerce the communities to cooperate, it must find the means to induce cooperation; the goal is to find an effective and attractive way to distribute the savings from joint undertakings. Such a distribution should be chosen in a way that makes every participating community better off than it would be if it were to treat its waste flow alone or to join some other non-optimal coalition. An article that refers to prior work in allocation of costs for regional environmental facilities is Zhu and ReVelle (1990), but a more expansive treatment of cost allocation across the many areas of water resources and water quality is given in Heaney (1997).

Solid Wastes Management

Management of the operation and of the design of urban and regional solid wastes systems constitutes an important environmental area for the application of optimization. Although the level of research activity in urban solid waste systems has decreased since the middle 1970s, challenging problems remain and would surely be addressed if research funding were to flow to this sector as it did twenty years ago. Regional solid waste management, especially with regard to hazardous wastes routing and siting, has been thriving.

The field of urban waste management may be roughly divided into two sectors: a collection/routing sector and a siting sector. In the first category, collection/routing, are two related classes of problem: routing within a district and the creation of districts. Routing within a prespecified district means either visiting at least once every link within the district with the least total length route (minimal retracing of links) or visiting each link twice (corresponding to collection on both sides of the street) with the least total length route (no triple tracing required). The principle of a routing that includes every link at least once is minimal retracing, a property that is achieved by minimal length matching of odd nodes (nodes with an odd number of incident links). In the routing that covers each arc twice (two-sided collection) there are no odd nodes so that matching is not required and the route can be completed with a total length equal exactly to two times the total length of links in the district. Alternatively, the best routing might be the one with the least total cost, where time is a major factor in the determination of cost. As a consequence, a route that included many left turns against a high volume of oncoming traffic might be inferior to a longer route with mostly right turns. Route design with consideration of cost, time and left turns remains a challenging problem.

The creation of collection districts from a large network of streets, however, requires a prior step in which links are assigned to each district in such a way that the total collection distance/time (and possibly volume or weight loading) in each district is within a preset bound. Once each district is created, the routing step would be undertaken next. However, the district creation step and the routing within a district step influence one another. That is, the length of the minimal length routing within the district is only finally determined by routing so that in theory the assignment of links to a district cannot be completed without knowing the length of the minimal route within the district. Heuristics have been used to resolve this problem (Liebman 1975).

In the second sector are siting problems. At least four types of siting problems can be identified: the central siting of collection vehicles, the siting of a central incinerator, the siting of sanitary landfills (of which there may be a number), and the siting of transfer stations (the stations where smaller trucks

offload to larger vehicles for more distant hauling). All of these siting problems have been studied, but not all are well solved.

A review of solid waste operations management is given in Liebman (1975), and a review of the siting of processing facilities and landfill sites is given in Gottinger (1988). Liebman (1997) revisited routing and siting in solid wastes management.

Regional solid waste management has received inspiration from the mounting problems of disposing of hazardous wastes. Issues of routing, scheduling and siting abound — with conflicting objectives. On the one hand, routes and sites should be chosen to minimize cost. On the other hand, routes and sites should be chosen to decrease risk and population exposure. A special issue of *Transportation Science*, edited by Turnquist and Zografos (1991), took up the issues in hazardous materials transportation in five articles. A review of the logistics of hazardous waste management is given in Turnquist and Nozick (1997).

Control of Air Pollution

The application of systems analysis to the control of air pollution dates from the late 1960s. Modeling efforts drawn from air pollution meteorology were then applied for the first time to develop predictive equations that could be applied in constraint form for air pollutant concentrations downwind from emission sources. From these predictive equations, transfer coefficients could be derived. Each such transfer coefficient provides the unit increment of pollutant concentration downwind (in say milligrams/cubic meter) at a particular point of measurement for each unit of emission (say tons per day) at each pollutant source. Thus, each ton/day of sulfur dioxide emitted from a specified source has a quantifiable impact on the atmospheric sulfur dioxide concentration at each of a number of downwind sites. With such transfer coefficients, as well as costs of abatement at the sources, and, with an atmospheric concentration standard to be met, it is possible to structure an optimization model. This air pollution management model chooses the least cost set of removal efficiencies, one removal level for every source, that achieves atmospheric concentrations of the pollutant at all specified points of concern at or below the standard.

A basic model that has been proposed for the management of acid rain is described next. The model follows the same form as the water pollution abatement optimization model described earlier. It should be noted that this model presumes no chemical reactions of pollutants, but only gradual dissipation of the pollutant.

The optimization problem is given as

$$\begin{aligned} &\textit{Acid Rain Management Model}: \\ &\text{Minimize} \quad z = \sum_{i \in I} c_i R_i \\ &\text{s.t.} \quad \sum_{i \in I} t_{ij} E_i R_i \geq \sum_{i \in I} t_{ij} E_i - S_j \quad (j \in J) \\ &0 \leq R_i \leq 1 \quad \forall\, i \in I. \end{aligned}$$

I, I = index and set of sources;

J,J = index and set of points at which concentrations are monitored;

R_i = fractional removal efficiency at source i;

E_i = tons per unit time of emissions at source i without any removal;

t_{ij} = transfer coefficients (mg/m^3/ton/day); the increment to the atmospheric concentration at j per unit of emissions at i;

S_j = atmospheric standard at receptor point j for the pollutant; and

c_i = cost per unit of pollutant removal.

This basic acid rain management problem can be manipulated in many ways. The transfer coefficients can be a single set of known numbers. They can also be random variables, and the constraints can then be either expected value constraints or chance constraints. Many possible sets of transfer coefficients can also be considered, leading to models that minimize maximum regret subject to investment in pollutant removal. Developments in air pollution management models, in general, and acid rain, in particular, were surveyed in reviews of water and air quality management by ReVelle and Ellis (1994) and Ellis (1997).

Concluding Remarks

The environmental models discussed here have much in common. Air and water pollution control models both have the equivalent of transfer coefficients which

translate upstream and upwind discharges and emissions into downstream and downwind concentrations. Water pollution control facilities as well as landfills and incinerators require siting and regionalization to minimize costs. Where power plant air emissions are part of the control equations, siting of power plants also becomes an issue in air quality management. Finally, burden sharing and cost allocation issues are common to all these areas of environmental management. An annotated bibliographic treatment of applications of mathematical programming to the many areas of environmental quality management is provided by Greenberg (1995). The problem set in environmental systems analysis is rich, diverse, challenging and important.

- ▶ Markov Processes
- ▶ Queueing Theory

Erlang

The unit of traffic load used in congestion analysis of telecommunication networks. The traffic load is the expected number of arrivals during an average service time. This quantity is dimensionless, but is refered to as the number of *erlangs* offered to the system. Named after the Danish mathematician/engineer A. K. Erlang, who founded modern queueing theory with his work on telephony in the early 1900s.

See

- ▶ Offered Load
- ▶ Queueing Theory

Erlang B Formula

The probability that all servers are busy in the multiserver queueing system M/M/c with Poisson input, exponential service and no waiting space, and thus that an arriving customer will be unable to enter the system (i.e., is blocked).

See

- ▶ Queueing Theory

Erlang C Formula

The probability that all servers are busy in the multiserver queueing system M/M/c with Poisson input, exponential service and infinite capacity.

See

- ▶ Queueing Theory

Erlang Delay Model

The multiserver queueing system M/M/c with Poisson input and identical exponential service for each server.

See

- ▶ Queueing Theory

Erlang Distribution

A continuous random variable is said to have an Erlang distribution if its probability density may be written in the form $f(t) = a(at)^{k-1}\ e^{-at}/(k-1)!$ where k is a positive integer and a is a positive real number. The constant k is called the shape parameter, while a (or various equivalents) is called the scale parameter. The Erlang distribution is a special case of the gamma distribution with integral shape parameter.

See

- ▶ Gamma Distribution

Erlang Loss Model

The multiple-server queueing system M/M/c with Poisson arrivals, exponential service times, c servers, but no additional space for holding customers.

Ethics in the Practice of Operations Research

Joseph H. Engel
Bethesda, MD, USA

Introduction

Ethics in the practice of operations research is the set of moral standards to which a practitioner of OR/MS should adhere in doing his or her work, so that the analyst can do relevant work responsibly and objectively, and be perceived as doing so.

The OR/MS worker must apply the basic principles of scientific methodology in such a way as to be transparent in the way the work is reported. A technically qualified but disinterested party should be able to verify that the work has been carried out in a valid manner, based on data that have been gathered and analyzed correctly.

Operations research, as distinguished from the physical sciences in general, deals with interactions between people and the systems they operate. With this in mind, the discussion here concerns the OR/MS analyst's ethical requirements operationally, in terms of beginning, conducting, and reporting a study (as covered in Caywood et al. 1971, 1129–1130).

In Beginning a Study

The OR/MS analyst should discuss thoroughly with the client the nature of the problem to be solved, and should become familiar with the system, so that the analyst and the client can reach agreement on the client's objectives in operating the system to be studied, measures of effectiveness in achieving the system objectives, and the boundaries of the system. Both parties need to "agree on what *will* and *will not* be done" (Caywood et al. 1971).

The careful delineation of the objectives of a system in planning how to begin a study is important in all cases, particularly where there are multiple objectives. All component objectives and measures of performance must be carefully defined.

Of comparable ethical importance in the formulation of the problem is the determination of

the extent of the system to be studied. This means that analyst and client should agree on which portions of the system can be affected by the operation of the system and what phenomena affected by the operation of the system are of concern to the client. Then, properly relevant analysis of possible operation of the system can lead to recommendations which should lead to the desired improvement.

It also is important for the analyst to understand the general nature of all of the effects that the system can have on the total environment, regardless of whether or not the system operator is directly interested in some of these effects. Uncovering unexpected effects may make it possible for the system operator to acquire a better understanding of the overall relationship of the system to its surrounding. This, perhaps, may lead to more useful results than might have otherwise been possible.

In Conducting a Study

Having selected measures of performance and having defined the system boundaries, the analyst must plan for data collection to ensure its maximum accuracy and relevance to the problem at hand, without interfering unduly with what the operating personnel are doing.

As in other people-oriented sciences, the OR/MS scientist often cannot conduct controlled experiments (because they inflict an undue burden of cost or damage on the operating personnel). The analyst may have to be content with observing a series of operational trials under what are hoped to be relevant field conditions. But, to the maximum extent possible, the number and nature of specific data collecting trials should be stipulated by the analyst, with the concurrence of the client, so as to ensure that a statistically valid amount of data covering all relevant facets of the operation will be collected.

This depends to a great degree on the nature of the mathematical model being used to describe the system being studied and how its performance is affected by factors under the control of the system operator, as well as by uncontrollable environmental factors. The time, personnel and equipment available and costs of conducting trials must also be taken into account in planning the quantity and extent of data collection.

The analyst should assure that qualified operators are trained in using appropriate data recording equipment and that they do record the data from the proper number of trials under the desired range of conditions that are to be recorded, or that they tell the analyst how many trials were really conducted, and under what conditions. Wherever possible, the analyst should observe the data collecting trials directly to determine whether they are conducted under true field conditions and to become aware of possible sources of error or inaccuracy in the data collection.

The analyst should not operate equipment being evaluated during data collection trials, because the analyst is not part of the operating system, and such participation can bias the results of the trials unexpectedly. This need not preclude the analyst from operating or observing the system on other convenient occasions to help build a good understanding of how the system is supposed to operate. It is generally preferable for the client's operating personnel rather than the analyst to collect the data. This is most desirable if the collection of such data is or ought to be part of the normal operating process (because such procedures are often valuable to the operators for training and self evaluation purposes).

Once the data are collected, the analyst must study it together with the mathematical model being used to describe system performance. The analyst must not arbitrarily omit data or add new or nonexistent data to develop results that are more to the liking of the analyst (or the client), and should make proper statistical, mathematical, and logical use of the data to derive valid conclusions. The analyst should try to reach an understanding of the nature of the conclusions, and why they agree (or fail to agree) with any prior opinions that may exist concerning the system being studied. The analyst should conduct sensitivity analyses of the effects of variations in key parameters or assumptions and should deal with possible limitations on the accuracy of observed data values and the effect of these limitations on the conclusions.

In studying a single objective system, the analyst uses a mathematical model appropriately to determine what combination of control variables will yield maximum performance effectiveness. Multi-objective systems are more difficult.

In the comparatively simple case of a single type of cost versus a single measure of performance, the analyst can treat the problem by first discovering how to maximize performance for a given cost, or, alternatively, by discovering the least expensive way to achieve a specified level of performance.

The decision maker (usually the client rather than the analyst) must decide on the maximum amount of money he or she wishes to spend, or the minimum level of performance desired. Then the analyst can solve the problem by recommending how to get the best performance at the desired expenditure level, or, alternatively, by recommending the smallest expenditure to achieve the desired level of performance.

The general solution in multi-objective systems is often difficult because there does not exist a mathematically rigorous method to find how to optimize the operation of any such system. In the special case when it can be shown that each of the objectives can be achieved more effectively when the system is operated in one certain way rather than in any other way, that way is a unique and dominating optimum solution to the problem. Similarly, multiple dominating solutions (each of them identically effective to all other dominating solutions with respect to each of the corresponding values of the component measures, and at least as effective in all of their components and more effective than some of the corresponding components of the non-dominated solutions) can be found. But dominating solutions do not always exist.

In such cases, it is necessary to consider possibly conflicting objectives in order to develop balanced procedures that deal with all important factors affecting performance. Such a problem might arise, for example, in optimizing the design of a military aircraft in terms of its range, cruising altitude, speed, payload weight, delivery accuracy, defensive ability, procurement and operating costs.

In general, a multi-objective index is used together with a sensibly designed mathematical model to be used to find out how to select values of control variables to maximize the value of the index. Such an index is usually structured to increase in value in a balanced way whenever any component measure indicates an improvement within an acceptable range (for example, the index might be a positively weighted sum of positive powers of each positive component measure). This is often hard to accomplish. If, for example, a system must be designed to optimize a time stream of expected short-run and long-term future costs and benefits, it is difficult to decide how to discount and balance long-term future costs and benefits against the short term. These long-range planning problems are not always dealt with properly, as witness frequent emphasis on ending each fiscal year in the black without paying enough attention to long-term profitability.

In Reporting a Study

Having performed the analysis and drawn conclusions, the analyst must report the findings and their possible limitations to the client in as complete and understandable a manner as possible.

It is well worth reviewing the mechanics, as well as the ethics of reporting a study. All aspects of the analysis, the data collection procedures, the fundamental assumptions and mathematical model used, including the values of any multi-objective index and each of its components, conclusions, recommendations and their limitations, should be reported and explained to the client. When an analysis is conducted using a multi-objective index, the analyst should explain to the client how the values of the coefficients and exponents used in the index have been chosen, including a thorough discussion of the implications inherent in their selection. At all costs, the analyst must avoid conducting and then reporting the analysis in such a way as to warp results intentionally so as to validate the analyst's own or anyone else's prior conclusions. Further, the analyst reports only to the client and nobody else without prior permission from the client. Leaks are unethical (Caywood et al. 1971).

The ethical problems connected with the reporting process revolve around the need to analyze and report relevantly, honestly, completely, clearly, and exclusively, so the client will understand what has been done as well as what has not been done. Failure to do so is an ethical failure, because the analyst will have failed to deliver what was contracted.

Concluding Remarks

Beyond the ethical requirement's of beginning, conducting, and reporting an OR study, as discussed above, there are a number of other ethical issues that analysts encounter in their research and applied activities. Many of these issues are similar to ones faced by all professionals, for example, data availability and computational reproducibility, peer review procedures, the handling of conflicts of interest. The book edited by Wallace (1994) covers the full range of such ethical issues. Further ethical concerns are discussed in the special issue on ethics and operations research of the journal *OMEGA* (37, 6, 2009); in particular, see the papers Gass (2009), Le Menestrel and Van Wassenhove (2009), and Walker (2009). Caywood et al. (1971) offers a valuable discussion of the concept and ethical issues of the analyst as an advocate. Brams (2002) discusses a multicriteria decision aid, the PROMETHEE–GAIA procedure, and shows how it could provide well-balanced solutions between rationality, subjectivity, and ethics.

Event-Driven Simulation

A computer simulation paradigm in which each simulated event is contained in a (logical) module of code (subroutine). Each module is executed when and only when other code determines that event should occur. Generally, event-driven simulations have stochastic (random) decisions that determine if and when (in model time) an event will occur.

Evolutionary Algorithms

Zbigniew Michalewicz[1] and Marc Schoenauer[2]
[1]The University of Adelaide, Adelaide, South Australia, Australia
[2]INRIA Saclay – Île-de-France, Orsay cedex, France

Introduction

The Evolutionary Computation (EC) techniques are stochastic algorithms whose search methods model some natural phenomena: genetic inheritance and Darwinian strife for survival. The idea behind Evolutionary Algorithms (EAs) is to do what nature does. Consider rabbits as an example: at any given time there is a population of rabbits. Some of them are faster and smarter than other rabbits. These faster, smarter rabbits are less likely to be eaten by foxes, and therefore more of them survive to do what rabbits do best: make more rabbits. Of course, some of the slower, dumber rabbits will survive just because they are lucky. This surviving population of rabbits starts breeding. The breeding results in a good mixture of rabbit genetic material: some slow rabbits breed with fast rabbits, some fast with fast, some smart rabbits with dumb rabbits, and so on. And on the top of that, nature throws in a "wild hare" every once in a while by mutating some of the rabbit genetic material. The resulting baby rabbits will (on average) be faster and smarter than these in the original population because more faster, smarter parents survived the foxes. (It is a good thing that the foxes are undergoing similar process — otherwise the rabbits might become too fast and smart for the foxes to catch any of them). So the metaphor underlying evolutionary algorithms is that of natural evolution. In evolution, the problem each species faces is one of searching for beneficial adaptations to a complicated and changing environment. The "knowledge" that each species has gained is embodied in the makeup of the chromosomes of its members. From the point of view of optimization, EC is a powerful stochastic zeroth order method (i.e., requiring only values of the function to optimize) that can find the global optimum of very rough functions. This allows EC to tackle optimization problems for which standard optimization methods (e.g., gradient-based algorithms requiring the existence and computation of derivatives) are not applicable. Moreover, most traditional methods are local in scope, thus they identify only the local optimum closest to their starting point.

An Algorithm

A general framework is introduced, which accounts for most existing Evolutionary Algorithms.

Let the search space be a metric space E, and let F be a function $E \to \mathbb{R}$ called the objective function. The task of evolutionary optimization is to find the maximum of F on E (the case of minimization is easily handled by considering $-F$).

A population of size $P \in \mathbb{N}$ is a set of P individuals (points of E) not necessarily distinct. This population is generally initialized randomly (at time $t = 0$) and uniformly on E. Then the fitness of each individual is computed (on the basis of the values of the objective function); a fitness value is represented as a positive real number—the higher the number, the better the individual. The population then undergoes a succession of generations; the process is illustrated in Fig. 1.

Several aspects of the evolutionary procedure require additional comments:

- **Statistics and stopping criterion**: The simplest stopping criterion is based on the generation counter t (or on the number of function evaluations). However, it is possible to use more complex stopping criteria which depends either on the evolution of the best fitness in the population along generations (i.e., measurements of the gradient of the gains over some number of generations), or on some measure of the diversity of the population.
- **Parental selection**: Choice of some individuals that will generate offspring. Numerous selection processes can be used, either deterministic or stochastic. All are based on the fitness of the individuals. Depending on the selection scheme used, some individuals can be selected more than once. At that point, selected individuals give birth to copies of themselves (clones).
- **Application of variation operators**: To each one of these copies some operator(s) are applied, giving birth to one or more offspring. The choice among possible operators is stochastic, according to

```
procedure evolutionary algorithm
begin
    t ← 0
    initialize population
    evaluate population
    while (not termination-condition) do
    begin
        t ← t + 1
        select individuals for reproduction
        apply variation operators
        evaluate newborn offspring
        select individuals for survival
    end
end
```

Evolutionary Algorithms, Fig. 1 The structure of an evolutionary algorithm

user-supplied probabilities. These operators are always stochastic operators; it is common to distinguish between crossover (or recombination) and mutation operators:

- Crossover operators are operators from E^k into E, i.e., some parents exchange genetic material to build up one offspring. In most cases, crossover involves two parents ($k = 2$), though more parents can be used.
- Mutation operators are stochastic operators from E into E.

– **Evaluation**: Computation of the fitnesses of all newborn offspring. As mentioned earlier, the fitness measure of an individual is directly related to its objective function value.
– **Survival selection**: Choice of which individuals will be part of next generation. The choice can be made either from the offspring only (in which case all parents die) or from both the offspring and the parents. In either case, this survival selection procedure can be deterministic or stochastic.

Sometimes the variation operators are defined on the same space as the objective function (called phenotype space or behavioral space); in other cases, an intermediate space is introduced (called genotype space or representation space). The mapping from the phenotype space in the genotype space is termed coding. The inverse mapping from the genotype space in the phenotype space is termed decoding. Genotypes undergo variation operators, and their fitness is evaluated on the corresponding phenotype. The properties of the coding mappings can greatly modify the global behavior of the evolutionary algorithm. For more (implementational) details related to the structure outlined in Fig. 1 and further discussion on the above aspects of the evolutionary procedure, see (Michalewicz and Fogel 2004).

An Example

The following example based on an example given in chapter 2 of (Michalewicz 1996) presents the action-steps of a standard genetic algorithm — the best-known paradigm within evolutionary algorithms — for a numerical optimization problem. These action-steps illustrate general structure of evolutionary algorithms given in Fig. 1. Here, without loss of generality, consider a maximization problem where the objective function f takes positive values on its domain.

Consider the maximization of a function of k variables, $f(x_1, \ldots, x_k) : \mathbb{R}^k \rightarrow \mathbb{R}$. Suppose further that each variable x_i can take values from a domain $D_i = [a_i, b_i] \subseteq \mathbb{R}$ and $f(x_1, \ldots, x_k) > 0$ for all $x_i \in D_i$. Assume the optimization specifies some required precision: suppose six decimal places for the variables' values is desirable.

It is clear that to achieve such precision each domain D_i should be cut into $(b_i - a_i) \cdot 10^6$ equal size ranges. Denote by m_i the smallest integer such that $(b_i - a_i) \cdot 10^6 \leq 2^{m_i} - 1$. Then, a representation having each variable x_i coded as a binary string of length m_i clearly satisfies the precision requirement. Additionally, the following formula interprets each such string:

$$x_i = a_i + decimal(1001...001_2) \cdot \frac{b_i - a_i}{2^{m_i} - 1},$$

where $decimal(string_2)$ represents the decimal value of that binary string.

Now, each individual (in genetic algorithms terminology, individuals are often called chromosomes) is represented by a binary string of length $m = \sum_{i=1}^{k} m_i$; the first m_1 bits map into a value from the range $[a_1, b_1]$, the next group of m_2 bits map into a value from the range $[a_2, b_2]$, and so on; the last group of m_k bits map into a value from the range $[a_k, b_k]$. A chromosome represents a potential solution to the problem.

To initialize the population, simply set some *pop_size* number of chromosomes randomly in

a bitwise fashion. However, if there is some knowledge about the distribution of potential optima, such information may be used in arranging the set of initial (potential) solutions.

At each generation (while loop, see Fig. 1), evaluate each chromosome (using the function f on the decoded sequences of variables), select new population with respect to the probability distribution based on fitness values, and alter the chromosomes in the new population by mutation and crossover operators. After some number of generations, when no further improvement is observed, the best chromosome represents an (possibly the global) optimal solution. Often the algorithm is stopped after a fixed number of iterations depending on speed and resource criteria. For the selection process (selection of a new population with respect to the probability distribution based on fitness values), a *roulette wheel* with slots sized according to fitness is used here; such a roulette wheel is constructed as follows:

- Calculate the fitness value $eval(v_i)$ for each chromosome v_i $(i = 1, \ldots, pop\_size)$.
- Find the total fitness of the population

$$F = \sum_{i=1}^{pop\_size} eval(v_i).$$

- Calculate the probability of a selection p_i for each chromosome v_i $(i = 1, \ldots, pop\_size)$:

$$p_i = eval(v_i)/F.$$

- Calculate a cumulative probability q_i for each chromosome v_i $(i = 1, \ldots, pop\_size)$:

$$q_i = \sum_{j=1}^{i} p_j.$$

The selection process is based on spinning the roulette wheel pop_size times; each time select a single chromosome for a new population in the following way:

- Generate a random (float) number r from the range [0..1].
- If $r < q_1$ then select the first chromosome (v_1); otherwise select the i-th chromosome v_i $(2 \le i \le pop\_size)$ such that $q_{i-1} < r \le q_i$.

Obviously, some chromosomes would be selected more than once. This is in accordance with the Schema Theorem (see Comparison section): the best chromosomes get more copies, the average stay even, and the worst die off.

Now, apply the recombination operator, crossover, to the individuals in the new population. As mentioned earlier, one of the parameters of a genetic system is probability of crossover p_c. This probability gives us the expected number $p_c \cdot pop\_size$ of chromosomes which undergo the crossover operation. Proceed as follows:

For each chromosome in the (new) population:

- Generate a random (float) number r from the range [0..1];
- If $r < p_c$, select given chromosome for crossover.

Now, mate selected chromosomes randomly: for each pair of coupled chromosomes generate a random integer number pos from the range $[1..m-1]$ (m is the total length — number of bits — in a chromosome). The number pos indicates the position of the crossing point. Two chromosomes

$$(b_1 b_2 \ldots b_{pos} b_{pos+1} \ldots b_m) \text{ and}$$
$$(c_1 c_2 \ldots c_{pos} c_{pos+1} \ldots c_m)$$

are replaced by a pair of their offspring:

$$(b_1 b_2 \ldots b_{pos} c_{pos+1} \ldots c_m) \text{ and}$$
$$(c_1 c_2 \ldots c_{pos} b_{pos+1} \ldots b_m).$$

The next operator, mutation, is performed on a bit-by-bit basis. Another parameter of the genetic system, probability of mutation p_m, gives us the expected number of mutated bits $p_m \cdot m \cdot pop\_size$. Every bit (in all chromosomes in the whole population) has an equal chance to undergo mutation, i.e., change from 0 to 1 or vice versa. So proceed as follows:

For each chromosome in the current (i.e., after crossover) population and for each bit within the chromosome:

- Generate a random (float) number r from the range [0..1];
- If $r < p_m$, mutate the bit.

Following selection, crossover, and mutation, the new population is ready for its next evaluation.

This evaluation is used to build the probability distribution (for the next selection process), i.e., for a construction of a roulette wheel with slots sized according to current fitness values. The rest of the evolution is just cyclic repetition of the above steps.

It is relatively easy to keep track of the best individual in the evolution process. It is customary (in genetic algorithm implementations) to store "the best ever" individual at a separate location; in that way, the algorithm would report the best value found during the whole process (as opposed to the best value in the final population) — this approach illustrates so-called elitist strategy.

Historical Paradigms

This section introduces the four historical paradigms that build what is today known as Evolutionary Computation.

Genetic Algorithms

In the canonical genetic algorithm (GA) (Holland 1975; Goldberg 1989), the genotype space is $\{0,1\}^n$. Note that the phenotype space can be any space, as long as it can be coded into bitstring genotypes. The parental selection is proportional selection (the best-known being the roulette wheel selection as discussed in the previous section): P random choices are made in the whole population, each individual having a probability proportional to its fitness of being selected. The crossover operators replace a segment of bits in the first parent string by the corresponding segment of bits from the second parent, and the mutation operator randomly flips the bits of the parent according to a fixed user-supplied probability. In the survival selection phase, all P offspring replace all parents (aka generational survival). The best fitness in the population can thus decrease: the original GA strategy is not elitist.

However, it rapidly became clear that the genotype space can be almost any space, as long as some crossover and mutation operators are provided (Radcliffe 1991; Michalewicz 1996). Moreover, proportional selection has been gradually replaced by comparison-based selections, from ranking (the selection is performed on the rank of the individuals rather than on their actual fitness), or tournament selection (one selects the best individual among a uniform choice of T individuals, T ranging from 2 to some small proportion of the population size) – see, e.g., (Chakraborty et al. 1996) for a discussion on these selection methods. Finally, most users use the elitist variant of survival selection, in which the best individual of generation t is included in generation $t+1$, whenever the best fitness value in the population decreases.

Evolution Strategies

Evolution Strategies (ESs) (Rechenberg 1972; Schwefel 1981) have been designed as parametric optimization algorithms, i.e., optimizing functions of floating-point variables. The original ES handles a population made of a single individual given as a real-valued vector. This individual undergoes a Gaussian mutation: addition of zero-mean Gaussian variable of standard deviation σ to each of the real variables. The fittest from the parent and the offspring becomes the parent of next generation. The critical feature is the choice of parameter σ: Originally, the so-called $1/5$ thumb rule (i.e., when more than $1/5$ mutation are successful (respectively unsuccessful), increase (respectively decrease) σ (Rechenberg 1972).

ES then evolved into population-based algorithms (Bäck and Schwefel 1993), termed $(\mu,\lambda)-$ES or $(\mu+\lambda)-$ES: μ parents generate λ offspring. (There is no parental selection, i.e., every parent produces λ/μ offspring on average). Moreover, the survival selection is deterministic, i.e., the best μ individuals become the parents of the next generation, chosen among the $\mu+\lambda$ parents plus offspring in the elitist $(\mu+\lambda)-$ES scheme, or among the λ offspring in the non-elitist $(\mu,\lambda)-$ES scheme (with $\lambda \geq \mu$).

The main operator remains mutation, generalized into multi-variate Gaussian mutation, i.e., defined by a full covariance matrix C and a scaling factor σ, also called the step-size mutation. In the 90s, the powerful paradigm of self-adaptive mutation was the rule: C and σ were added to the description of the individuals, and undergo mutation as well. The recent trend is to adapt C and σ based on the history of the evolution, leading to the state-of-the-art algorithm of Covariance Matrix Adaptation – Evolution Strategy, CMA-ES (Hansen and Ostermeier 2001; Auger and Hansen 2005). CMA-ES is almost parameter-free: it uses a $(\lambda/2,\lambda)-$ES survival selection, where the parameter λ is chosen as $4+\lfloor 3\log(n)\rfloor$ (Hansen and Ostermeier 2001), and increased in case of highly-multi-modal functions (Auger and Hansen 2005).

Evolutionary Programming

Evolutionary Programming (EP) is one of the oldest EAs, originally proposed to evolve finite state machines [27]. As in ESs, there is no parental selection, and every individual in the population generates one offspring. Moreover, the only evolution operator is mutation. Survival selection is what is today called a $(P + P)$-ES, i.e. the best P individuals among parents and offspring become the parents of the next generation.

As in the field of GAs, further works rapidly generalized the approach to handle any search space, still emphasizing the use of mutation as the only operator (Fogel 1995). Several variants were then introduced, from stochastic survival selection to self-adaptive mutations (similar to the ones from Evolution Strategies, though discovered completely independently (Saravanan et al. 1995)).

Genetic Programming

Genetic Programming (GP) as a method for evolving computer programs first appeared as an application of GAs to tree-like structures (Koza 1992). Original GP evolves tree structures representing LISP-like S-expressions. The strength of this representation is that a closed crossover operator can easily be defined: by swapping sub-trees between two valid S-expressions, one always gets a valid S-expression. Koza's original work used a steady state genetic algorithm evolutionary mechanism (Syswerda 1991): a parent is selected by tournament (of size 2 to 7 typically), and generates an offspring by crossover only. The offspring is then put back in the population using a reverse-tournament: T individuals are uniformly chosen, and the one with the worst fitness gets replaced by the newborn offspring.

Since then, most published work considered also mutation. Further, several variants of tree-based GP have been proposed (e.g., linear GP (Nordin 1997), Cartesian GP (Miller and Smith 2006), push-GP (Spector and Robinson 2002)). At present, Genetic Programming is viewed more generally as program evolution (Banzhaf et al. 1998).

Modern Trends: Hybrid Methods

Many researchers further modified evolutionary algorithms by adding some problem-specific knowledge to the algorithm. Several papers have discussed initialization techniques, different representations, decoding techniques (mapping from genetic representations to phenotypic representations), and the use of heuristics for variation operators. Davis [20] wrote (in the context of classical, binary GAs):

> It has seemed true to me for some time that we cannot handle most real-world problems with binary representations and an operator set consisting only of binary crossover and binary mutation. One reason for this is that nearly every real-world domain has associated domain knowledge that is of use when one is considering a transformation of a solution in the domain [. . .]. I believe that genetic algorithms are the appropriate algorithms to use in a great many real-world applications. I also believe that one should incorporate real-world knowledge in one's algorithm by adding it to one's decoder or by expanding one's operator set.

Such hybrid/nonstandard systems enjoy a significant popularity in the evolutionary computation community. Very often these systems, extended by the problem-specific knowledge, outperform other classical evolutionary methods as well as other standard techniques. For example, a system Genetic-2 N (Michalewicz 1996) constructed for the nonlinear transportation problem used a matrix representation for its chromosomes, a problem-specific mutation (main operator, used with probability 0.4) and arithmetical crossover (background operator, used with probability 0.05). It is hard to classify this system: it is not really a genetic algorithm, since it can run with a mutation operator only without any significant decrease of the quality of results. Moreover, all matrix entries are floating-point numbers. It is not an evolution strategy, since it did not use Gaussian mutation, nor did it encode any control parameters in its chromosomal structures. Clearly, it has nothing to do with genetic programming and very little (just matrix representation) with evolutionary programming approaches. It is just an evolutionary computation technique aimed at a particular class of problems.

Comparison

Many papers have been written on the similarities and differences between these approaches (Bäck and Schwefel 1993; Fogel 1995; Bäck 1995). Clearly, these similarities and differences can be discussed from different perspectives.

- **The representation issue**
  Original GAs, ESs and EP address only bitstrings, real numbers and finite state machines, respectively. However, recent tendencies indicate that this is not a major difference. Moreover, it is still far from trivial to select appropriate variation operators for the chosen representation and the objective function, aka the *fitness landscape* (Radcliffe 1991; Michalewicz 1996).
- **The usefulness of crossover**
  According to the Schema Theorem (Holland 1975; Goldberg 1989), GAs main strength comes from the crossover operator: better and better solutions are built by exchanging building blocks from partially good solutions previously built, in a bottom-up approach. The mutation operator is then considered as a background operator. On the other hand, the philosophy behind EP and ESs is that such building blocks might not exist, at least for most real-world problems. Also some experimental results contradict the building block hypothesis; for example, uniform crossover (Syswerda 1989) is very disruptive of short schemata whereas one and two-point crossover are more likely to conserve short schemata and combine their defining bits in offspring. This top-down view considers that selective pressure plus genotypic variability brought by mutation are sufficient. This discussion on significance of the crossover has been going on for a long time. However, even when crossover is experimentally demonstrated beneficial to evolution, it could be because it acts like a large mutation (Jones 1995). Yet another example of the duality between crossover and mutation comes from GP's history: the original GP algorithm (Koza 1992) used only crossover, with no mutation at all, with very large population size: the rationale is that all building blocks that are necessary to represent at least one sufficiently good solution are already present in the initial population, and only need to be recombined.
- **Mutation operators**
  Whereas the usefulness of crossover has been heavily discussed, that of mutation is acknowledged by all trends (with the historical exception of Koza's work in GP – Genetic Programming section). Indeed, mutation is the only operator that ca re-introduce diversity in the population, as crossover is de facto limited by the current population. From a theoretical point of view, only mutation can guarantee the ergodocity of the stochastic process (i.e. that all points of the search space can be reached whatever the current population). However, the way mutation operators are applied differ from one paradigm to another, and should be closely linked to the types of selection that are used. Traditional GAs use a low mutation rate, i.e. the average number of bits that are flipped remains small (though it can take large values, with very small probabilities). Because all offspring replace all parents without competition, high mutation rates would totally prevent any convergence to any optimal solution, as mutation gets more and more destructive as the population contains better and better solutions. Within ESs, on the other hand, all individuals undergo mutation, and only the strength of the mutation is varied (e.g., the standard deviation of the Gaussian mutation, in one dimension). Together with the fact that several offspring are generated from each parent, this nevertheless still allows the algorithm to converge. Furthermore, it can converge to any arbitrary precision provided the mutation strength is decreased accordingly: this was first demonstrated by self-adaptive ES (Schwefel 1981; Beyer 2001), and proved right for CMA-ES as well (Hansen and Ostermeier 2001). Indeed, adaptive and self-adaptive mutations can have a significant impact only when all individuals undergo mutation. Furthermore, it also requires some property of the mutation with respect to the fitness function called the strong causality principle emphasized in Rechenberg (1972): mutation should be parameterized in such a way that small mutations have small effects on the fitness. This property is not specific to floating-point optimization, and should be kept in mind when designing mutation operators for a particular representation. In particular, this property is not true when floating-point numbers are encoded into binary strings (as is the case in traditional-syle GAs).
- **The selection mechanisms**
  They range from the totally stochastic fitness proportional parental selection of GAs with generational survival, to the deterministic (μ, λ) survival selection of ES, through the stochastic, but elitist (i.e. preserving the best), tournament-based survival step of EP and the steady-state scheme used

in GP. Though some studies have been devoted to selection mechanisms (see e.g., (Chakraborty et al. 1996)), the choice of both selection steps for a given problem (fitness-representation-operators) is still an open question (and is very likely to be problem-dependent).

The current trend in the EC community is to mix up all these features on a very pragmatic basis, trying to best fit the application at hand: some ESs applications deal with discrete or mixed real-integer spaces (Bäck 1995), the early arguments (Antonisse 1989) against the dogma "binary is the best" have diffused in the community, and the Schema Theorem has been extended to any representation (Radcliffe 1991). Moreover, most ESs (including CMA-ES) use some crossover operator, mutation has been added to GP, etc. And the different selection operators are more and more being used now by the whole community.

On the other hand, such hybrid algorithms, by getting away from the simple original algorithms, also escape the few available theoretical results, and EAs can today only rely on successful applications (see Application Areas section) to demonstrate their usefulness as general-purpose optimization algorithms.

Theoretical Results

Theoretical studies of Evolutionary Algorithms can be roughly categorized into three different types.

- An Evolutionary Algorithm can be viewed as a Markov chain in the space of populations, as the population at time $t+1$ only depends on the population at time t. The full theory of Markov chains can then be applied. Some asymptotic results were obtained for general EAs (Eiben et al. 1991), and for more focused algorithms (Rudolph 1997), but for very specific and simple functions. Stronger results (convergence in finite time) were obtained using the powerful Friedlin-Wentzell theory (Cerf 1996), for very general functions, but a specific algorithm. However, those results have limited practical consequences as the real-world environment often requires short response times.
- The specific characteristics of Evolution Strategies allowed precise theoretical studies on the sphere function, i.e. the quadratic function. Early theoretical studies by the ES pioneers resulted in Rechenberg's 1/5th rule (Rechenberg 1972), and in Schwefel's first self-adaptive ES (Schwefel 1981). Those works were later pursued in Schwefel's group in Dortmund, with the precise study of the so-called progress rate, i.e. the improvement from one step of the algorithm to the next, by Beyer (2001). Finally, those results that had been obtained asymptotically for very high dimensions, have been rigorously justified in any dimension. In particular, all numerical values for optimal settings have been shown to actually be optimal, with the help of the theory of irreducible Harris recurrent Markov chains (Auger 2005; Auger and Hansen 2006).
- Last, but not least, classical Algorithm Complexity Theory has been used to study EAs on discrete spaces. The pioneer of this approach was Ingo Wegener, and most works in this area come from his group in Dortmund (and some spin-offs groups led by former Wegener PhD students). Here the algorithms under study are simple but actual algorithms (and they get less and less "simple" every year), while the fitness functions are simple functions or classes of functions. Results range from effective complexity for hitting the optimum of linear boolean functions with a (1 + 1)-ES (Droste et al. 1998) to general bounds for stochastic search algorithm in generic black-box scenarios (Droste et al. 2006).

However, one should keep in mind that all the above theoretical analyses address some simple models of Evolutionary Algorithms. As stated earlier, the modern trends of EC gave birth to algorithms working on poorly structured search spaces (see next section), or hybrid algorithms, for which no theory is applicable at the moment.

Application Areas

It is widely acknowledged that in Evolutionary Computation theory lags far behind practice. Indeed, lessons from successful applications are one of the main driving forces of EA research today. Several edited books are devoted to applications of EAs (e.g., see the recent (Yu et al. 2008)), and almost every event related to EAs has its own special session dedicated to applied works, and their proceedings provide a wide overview of actual applications (e.g., see several

special sessions of the annual IEEE Congress on Evolutionary Computation – CEC, and the Real-World Application track run every year during the ACM Genetic and Evolutionary Computation Conference – GECCO).

This section will quickly survey the preferred domains of application of EAs, and the different sub-domains will be distinguished according to the type of search space they involve.

Combinatorial Optimization

Hard combinatorial optimization problems (NP-hard, NP-complete) involve huge discrete search spaces, and have been studied extensively by the Operational Research community. Two different situations should be considered: academic benchmark problems and large real-world problems.

As far as benchmark problems are concerned, it is now commonly acknowledged that pure EAs alone cannot compete with OR methods (see all papers about combinatorial optimization in (Bäck et al. 1997) for instance). However, in the last decade, hybrid algorithms termed Genetic Local Search, or Memetic Algorithms where the EA searches the space of local optima with respect to some OR heuristic, have obtained the best-so-far results on a number of such benchmark problems (e.g., from (Merz and Freisleben 1999) to (Merz and Huhse 2009)).

The situation is slightly different for real-world problems: pure OR heuristics generally don't directly apply, and OR methods have to take into account problem specificities. This is true of course for EAs, and there are many success stories where EAs, carefully tuned to the problem at hand, have been very successful, as for instance in the broad area of scheduling (Paechter et al. 1998; Semet and Schoenauer 2006). A few commercial applications of EAs were also reported; some of them resulted in a significant return on investment (Michalewicz et al. 2005). However, these applications required also forecasting components, resulting in hybrid adaptive business intelligence systems (Michalewicz et al. 2006).

Parametric Optimization

The optimization of functions with floating-point variables has been thoroughly studied by practitioners, and many very powerful methods exists. Though the most well-known methods address linear convex problems, there are many other cases that can be handled successfully (Bonnans et al. 1997). However, the recently appeared CMA-ES (Covariance Matrix Adaptation Evolution Strategy) (Hansen and Ostermeier 2001; Auger and Hansen 2005) can be viewed as the leading Evolutionary Algorithms in the continuous domain, outperforming the best methods from both deterministic and stochastic domains for highly multi-modal, irregular, ill-conditioned and non-separable functions. An impressive list of applications of CMA-ES is maintained on its inventor's web page (Hansen 2009).

The situation is different when dealing with multi-objective problems: Multi-Objective Evolutionary Algorithms (MOEAs) are the only ones that can produce a set of best possible compromise (the Pareto set), and have recently received increased attention. MOEAs use the same variation operators than standard EAs, but the Darwinian components are modified to take into account the multi-valued fitness (Deb 2001; Coello et al. 2002). Note that MOEAs are discussed in the Parametric Optimization section because prominent application results have been obtained in that area (see e.g., (Obayashi 1997)), but apply on any search space, as only the Darwinian part of the algorithm is different from that of a single-objective EA.

Mixed Search Spaces

Mixed search spaces involve different types of variables, generally both continuous and discrete, and EAs are flexible enough to handle such search spaces easily. Once variation operators are known for continuous and discrete variables, constructing variation operators for mixed individuals is straightforward: crossover for instance can either exchange values of corresponding variables, or use the variable-level crossover operator. Many problem have been easily handled that way, like the optical filter optimization (Bäck and Schütz 1995; Martin et al. 1995), where one is looking for a number of layers, the unknown being the layer thickness (continuous variable) and the material the layer is made of (discrete variable). Furthermore, some platforms now exist that help the non-EC expert to implement generic EAs for a given problem involving different types of mixed search spaces, requiring only a structured description of potential solutions – and of course a routine to compute the fitness of those candidate solutions (Costa and Schoenauer 2009).

Artificial Creativity

A very promising area of application of EAs, where EAs can be much more than yet another optimization method, is that of design, where the ability of EAs to handle almost any search space allows programmers (and artists!) to unveil their wildest ideas. The idea of component-based representations can boost innovation in structural design (Gero 1998; Hamda and Schoenauer 2002), architecture (Rosenman 1999), as well as in many other areas including art (Bentley 1999). But the most original idea in that direction is that of emrbyogenies: the genotype is a program, and the phenotype is the result of applying that program to "grow an embryo"; the fitness of the genotype (the program) is obtained by testing that phenotype in a real situation. Such approach already lead to astonishing results in analog circuit design for instance (Koza et al. 1999) – though exploring a huge search space (a space of programs) implies a heavy computational cost. Note that those results were achieved using Genetic Programming, using both crossover and mutation, and a huge (distributed) population as well.

Concluding Remarks

Natural evolution can be considered as a powerful problem solver achieving Homo Sapiens from chaos in only a couple of billion years. Computer-based evolutionary processes can also be used as efficient problem solvers for optimization, constraint handling, machine learning and modeling tasks. Furthermore, many real-world phenomena from the study of life, economy, and society can be investigated by simulations based on evolving systems. Last but not least, evolutionary art and design form an emerging field of applications of the Darwinian ideas.

An interesting question asks for guidance on the types of problems for which evolutionary methods are more appropriate than, say, standard operations research methods. Real-world problems are usually difficult to solve for several reasons; these include (Michalewicz and Fogel 2004):

- The number of possible solutions is so large as to forbid an exhaustive search for the best answer.
- The evaluation function that describes the quality of any proposed solution is noisy or varies with time, thereby requiring not just a single solution but an entire series of solutions.
- The possible solutions are so heavily constrained that constructing even one feasible answer is difficult, let alone searching for an optimum solution.

Naturally, this list could be extended to include many other possible obstacles. For example, one could include noise associated with our observations and measurements, uncertainly about given information, and the difficulties posed by problems that have multiple and possibly conflicting objectives (which may require a set of solutions rather than a single solution). All these reasons are just various aspects of the complexity of the problem.

Note that every time a problem is solved, one is only finding the solution to a *model* of the problem. All models are a simplification of the real world — otherwise they would be as complex and unwieldy as the natural setting itself. Thus the process of problem solving consists of two separate general steps: (1) creating a model of the problem, and (2) using that model to generate a solution:

Problem $\Rightarrow$ Model $\Rightarrow$ Solution.

Note that the "solution" is only a solution in terms of the model. If the model has a high degree of fidelity, there is more confidence that the solution will be meaningful. In contrast, if the model has too many unfulfilled assumptions and rough approximations, the solution may be meaningless, or worse.

So in solving real-world problem there are at least two ways to proceed:

1. Try to simplify the model so that traditional methods might return better answers.
2. Keep the model with all its complexities, and use nontraditional approaches, to find a near-optimum solution.

In other words, the more complexity in the problem (e.g., size of the search space, evaluation function, noise, constraints), the more appropriate it is to use a nontraditional method, like Evolutionary Algorithms. One often has to choose between approximating a model or approximating the solution. And a large volume of experimental evidence shows that this latter approach can often be used to practical advantage.

One can also look at Evolutionary Algorithms from a broader perspective of population-based methods, where a set of potential solutions is being processed

in parallel. Apart from Evolutionary Algorithms, there are other population-based approaches that have been proposed over the last 20 years; these include Differential Evolution (Price et al. 2005), Artificial Immune Systems (Dasgupta and Niño 2009), Particle Swarm Optimization (Clerc 2006), Ant Colony Optimization (Dorigo and Stutzle 2004), and Cultural Algorithms (Cowan and Reynolds 2004).

Introduction

Devising computer-based systems that can solve problems by reasoning about facts and assertions has been a central, ongoing quest in the artificial intelligence field. By the early 1970s, research into these reasoning systems had begun to focus on systems that could solve difficult problems in narrow problem domains such as diagnosing diseases, assessing chemical structures of unknown molecules, determining ore deposits in geological sites, and solving applied mathematical problems. These systems came to be known as expert systems, because they solve problems that would otherwise require services of experts in their respective problem areas. Perhaps the best known of these early expert systems is MYCIN, whose approach to diagnosing blood infections is documented in Buchanan and Shortliffe (1984). Descriptions of other pioneering expert systems such as DENDRAL, MACSYMA, and PROSPECTOR can be found in Barr and Feigenbaum (1982).

By the early 1980s, the focus in expert system (ES) research had shifted from demonstrating the feasibility and efficacy of such systems to the identification of tools and methods that could facilitate their development. Each of the pioneering expert systems was custom-built, requiring considerable expense and years of development by specialists in artificial intelligence. If expert systems were to come into widespread use, it was clear that faster and less costly means for creating them had to be found. This search has been largely successful, spawning a host of commercially available, computer-based tools for ES development and leading to the creation of specific methods for guiding the process of ES development. These tools and methods have been instrumental in the growing number of expert systems used in such application areas as engineering, manufacturing, finance, and business administration (Blanning 1984; Mockler 1989; Tyran and George 1993; Liebowitz 1998; Liao 2005). When the result of expert system execution is used in decision making, which is very often the case, the expert system functions as an artificially intelligent decision support system (Holsapple and Whinston 1986, 1996).

Specific examples of expert system applications range widely from agricultural loan evaluation (Bryant 2001), to prioritizing sewer inspections (Hahn 2002), to production system advising (Wagner et al. 2003), to architectural design modification (Bachman 2004), to analysis of disturbances in the quality of power systems (Reaz et al. 2007), to machine vibration analysis (Ebersbach and Peng 2008), to interpreting ECG readings (Mahesh et al. 2009), and so forth. Expert systems have come to be very widely used on the Web (Duan et al. 2005). Being routinely embedded into Web-based applications, they are rarely thought about as being expert systems. To the extent they are even named at all, terms such as recommenders or advisors are much more common.

Two prerequisites for assessing ES possibilities are an understanding of the nature of expert systems and an appreciation of how they can be developed. The general nature of expert systems is described first, including characterizations of ES functions, architecture, and operation. Then, ES development is examined in terms of methodological issues and classes of available tools.

General Nature of an Expert System

An expert system functions as a readily available substitute for some source of expertise that cannot always be consulted in a facile, timely, and affordable manner. For instance, consider the case of a person who is an expert in some problem domain, such as financial planning. This human source of

expertise about financial planning is able to accept requests for advice about specific problems in the domain, reason with the expertise to produce recommendations, communicate the resultant advice, and explain the rationale underlying that advice. A computer-based system that can perform these same functions, giving recommendations and explanations comparable to those of the expert, is called an expert system. Not all ESs substitute for an individual human expert. An ES can also be a surrogate for a group of experts, multiple individual experts, the expertise embodied in a set of historical data, or expertise revealed in the behavior of some non-human system.

Expert systems offer many potential advantages over relying on the original source of expertise for advice (Holsapple and Whinston 1986, 1996). Unlike a human expert, an ES does not sleep, become ill, take vacations, have a bad day, forget, require compensation, become tied up with more important matters, or retire. From an organization's viewpoint, the exercise of building an ES results in a formalization and preservation of expertise. It yields an advice giver that can be readily replicated for simultaneous use at geographically diverse sites, ensuring consistency of recommendations. Holsapple and Whinston (1990) argue that ESs can be instrumental in implementing competitive strategies.

The functioning of an ES is based on three major components: a user interface (having two parts: a language system and a presentation system), an inference engine, and a body of stored knowledge that forms the basis for reasoning about problems in some domain of interest. The user interface is that part of an ES that its user (e.g., a person seeking advice) directly experiences. It accepts a user's characterization of a specific problem. It asks for clarifications of that characterization, as needed. It presents the ES's advice to the user about treating the problem. The user interface also accepts user requests for justifying advice and presents those justifications to a user. Expert systems can vary widely in terms of the style and sophistication of their user interfaces, even when the other two architectural components are fixed.

A second component of ES architecture is the knowledge store it possesses. In ES parlance, this is often called a knowledge base . It typically holds two distinct kinds of knowledge: descriptive and reasoning. Descriptive knowledge is concerned with describing states of the world (e.g., that revenue was $10 million last year or is expected to be $15 million next year). Reasoning knowledge is concerned with specifying what conclusion is valid when a particular situation is known to exist (e.g., that an unemployment rate of over 8% warrants a certain reduction in revenue expectations). Additional types of knowledge can be found in the knowledge bases of some ESs (Holsapple and Whinston 1996).

There is more than one way to represent each type of knowledge stored in an ES. Descriptive knowledge may be simply represented as values of state variables, often called attribute-value pairs (e.g., the revenue attribute or variable has a value of $10 million). Or, such pieces of descriptive knowledge may be structured into database records, frames, semantic nets, arrays, spreadsheet cells, and other computer-based organizations. Similarly, pieces of reasoning knowledge are subject to multiple representation modes. One commonly used approach involves the use of rules. Each rule has a premise, characterizing some situation, and a conclusion, indicating what actions can be taken (e.g., what changes can be made to state variable values) if the situation is determined to exist. A variety of rule representation languages exist. They differ in terms of style, flexibility, and power of representation. Some such differences are surveyed in Mockler (1989).

Inference Engine

At the heart of general ES architecture is an inference engine. This is a software component that reasons with the stored knowledge of an ES to derive advice corresponding a user's problem statement. It also tracks the flow of reasoning about the problem, as a basis for justifications presented via the user interface. Clearly, an ES's inference engine must be compatible with a) the particular representation language used to specify stored descriptive and reasoning knowledge, b) the user interface's interpretations of user requests, and c) the user interface's ability to package inference engine results. From one ES to another, inference engines vary not only to ensure compatibility with different user

interface and knowledge representation conventions, but also with respect to how they reason.

Two prominent kinds of reasoning approaches are forward chaining and backward chaining. In either case, the inference engine uses rules to establish values for variables whose states are unknown at the outset of a consultation. These values constitute the raw form of the advice that is ultimately packaged for presentation to a user. The main difference between the two kinds of reasoning is the progression of processing whereby unknown variables become known. In either case, if an ES holds insufficient knowledge to solve a problem, the inference engine will fail in its attempt to establish values for unknown variables.

In the forward chaining case, an inference engine examines the premise of each rule. If the premise is true, then the actions specified in the rule's conclusion are performed (i.e., the rule is fired). Thus, firing a rule can result in changes to values of variables, including the assignment of values to previously unknown variables. After every rule has been examined in this way, the inference engine makes a second pass through the rules. If additional rules are fired in this pass, the process continues with a third pass, and so forth. Processing stops when no further rules are fired in a pass or when some other terminal condition is satisfied (e.g., a value has been established for some designated unknown variable).

In contrast, backward chaining is a more goal-directed approach to reasoning. It considers a rule's conclusion before trying to evaluate the premise. Establishing a value for a specific unknown variable is the inference engine's overall goal. In its effort to meet that goal, the inference engine identifies the subset of rules whose conclusions could affect the goal variable's value. These are called candidate rules. In considering a candidate rule, the inference engine attempts to evaluate the premise. If this evaluation is impossible because the premise involves unknown variables, then each of those variables successively becomes the new current goal. The inference engine performs backward chaining for the current goal variable, identifying its candidate rules and attempting to evaluate their premises. When a rule's premise is found to be true, the rule is fired. When a premise is found to be false, the inference engine proceeds to another candidate rule. This basic processing pattern continues recursively until a value is established for the consultation's overall goal variable or until that variable's candidate rules are exhausted (possibly without reaching a solution).

There are many variations to each of these two reasoning approaches, affecting both the speed and the results of inference engine operation. One kind of variation involves the degree of reasoning rigor. These are variations in how exhaustive inference engines are in making passes through a rule set or in considering candidate rules. Another variation concerns rule selection order. That is, in what sequence does an inference engine process rules within a pass or within a candidate rule subset? There is also considerable room for variation in the strategies inference engines use for evaluating a premise (e.g., the order for considering conditions in a compound premise). Inference engines can vary greatly in their treatments of uncertainties about variable values and rule efficacy. Some ignore the possibility of uncertainties, while others use specific algebras to combine certainty factors in an effort to qualify the resultant advice. Holsapple and Whinston (1986, 1996) present an extensive discussion of such variations.

Expert System Development

Tools for building expert systems fall into three major categories: programming languages, shells, and integrated environments. In using the former, an ES developer (often called a knowledge engineer) designs and programs the inference engine and the user interface. Also, storage structures for holding reasoning and descriptive knowledge must be designed so their contents are accessible to the inference engine. Appropriate knowledge must then be stored in such structures. A shell removes much of this work from an ES developer, but also reduces the developer's flexibility. With a shell, the developer has a ready-made inference engine, user interface, and knowledge storage structure. Thus, the main development task consists of putting the appropriate knowledge into that structure. Shells also commonly give developers some facilities for customizing the user interface inputs and outputs. Some give developers a modicum of control over the inference engine's reasoning behavior (e.g., over the degree of rigor, selection order, treatment of uncertainty). Shell inference engines can often interface to other pieces of software (e.g., use spreadsheet data).

An integrated environment for ES development has all the facilities of a shell, plus other computing

capabilities normally found in separate software tools. That is, the inference engine is enhanced to accomplish kinds of processing other than reasoning: database management, spreadsheet processing, model management, forms handling, graph generation, and so forth. Such capabilities can be exercised in the course of rule processing. Conversely, consultation can occur in the context of one of these other kinds of processing. Such tools allow the creation of ESs that more closely approximate human experts, who are not limited to reasoning about a problem, but can also do data retrieval, extensive calculations, fancy presentation, and so on. A checklist for tool selection, plus an in-depth examination of an integrated environment, can be found in Holsapple and Whinston (1986). Mockler (1989) provides a comparative feature survey of representative commercial expert system development tools.

Regardless of the tool used, a developer faces the task of managing the ES development project. The books of Buchanan and Shortliffe (1984), Hayes-Roth, et al. (1983), and Liebowitz (1998) contain valuable insights into the methodology of ES development. The ES development cycle introduced by Holsapple and Whinston (1986, 1996) is typical of several that appear in the literature. One aspect of development that has received considerable attention is the phenomenon of knowledge acquisition (KA). This is concerned with the activity of eliciting reasoning knowledge from a source (e.g., human expert), perhaps structuring/analyzing it, and representing it in a form that can be directly stored in the knowledge base of an ES for later use in making inferences about specific problems posed by a user.

A representative overview of KA issues, methods, and tools was provided by Kidd (1987). The methods include such techniques as structured interviewing and protocol analysis. The KA tools are primarily induction mechanisms that attempt to acquire general domain knowledge from sets of specific examples of expert behavior. Dhaliwahl and Benbasat (1990) introduced a variable-oriented framework for guiding empirical research that evaluates performance of such methods and tools. Holsapple et al. (1993) provide a summary of basic theoretical and empirical KA developments.

Expert System Extensions

Over the years, various extensions to the basic idea of rule-based expert systems have arisen. Some of these involve alternative approaches to representing and processing reasoning knowledge, such as the use of case-based reasoning (Waston 1995; Bergmann et al. 2003). Other extensions imbue reasoning systems with learning capabilities, by using such techniques as skill refinement (Deng et al. 1990), neural networks (Gallant 1993; Im and Park 2007), or genetic algorithms (Holland 1992; Dehuri and Mall 2006). Beyond certainty factors, other methods to deal with uncertainties in the course of reasoning include Dempster-Shafer techniques of evidence (Yager 2008). In a somewhat related vein, expert systems can be developed to accommodate representation and reasoning for non-discrete descriptive knowledge in the form of fuzzy variables (Siler and Buckley 2005). Another extension is concerned with the coordination of multiple expert systems, each having reasoning knowledge that could be relevant to solving a problem at hand. Holsapple et al. (1997) have advanced a market-based mechanism to do this coordination in a way that causes the community of expert systems to learn (i.e., improve its performance) over time.

Further Reading

Aside from the growing number of books dealing with expert systems, there are several scholarly journals emphasizing ES topics. These include *Expert Systems*; *Expert Systems with Applications*; *IEEE Intelligent Systems*; *and Intelligent Systems in Accounting, Finance, and Management*. ES topics are also covered in more general journals of artificial intelligence (e.g., *Artificial Intelligence*), as well as journals concerned with computer systems for business (e.g., *Decision Support Systems*) and engineering (e.g., *IEEE Transactions on Data and Knowledge Engineering*). Links to numerous World Wide Web sites dealing with expert systems and artificial intelligence can be found.

Exploratory Modeling and Analysis

Steve Bankes[1], Warren E. Walker[2] and Jan H. Kwakkel[2]

[1]BAE Systems, Arlington, VA, USA

[2]Delft University of Technology, Delft, The Netherlands

Introduction

Exploratory Modeling and Analysis (EMA) is a research methodology that uses computational experiments to analyze complex and uncertain systems (Bankes 1993, 1994). EMA can be understood as searching or sampling over an ensemble of models that are plausible given a priori knowledge, or are otherwise of interest. This ensemble

may often be large or infinite in size. Consequently, the central challenge of exploratory modeling is the design of search or sampling strategies that support valid conclusions or reliable insights based on a limited number of computational experiments.

EMA can be contrasted with the use of models to predict system behavior, where models are built by consolidating known facts into a single package (Hodges 1991). When experimentally validated, this single model can be used for analysis as a surrogate for the actual system. Examples of this approach include the engineering models that are used in computer-aided design systems. Where applicable, this consolidative methodology is a powerful technique for understanding the behavior of complex systems. Unfortunately, for many systems of interest, the construction of models that may be validly used as surrogates is simply not a possibility. This may be due to a variety of factors, including the infeasibility of critical experiments, impossibility of accurate measurements or observations, immaturity of theory, openness of the system to unpredictable outside perturbations, or nonlinearity of system behavior, but is fundamentally a matter of not knowing enough to make predictions (Campbell et al. 1985; Hodges and Dewar 1992; Pilkey and Pilkey-Jarvis 2007). For such systems, a methodology based on consolidating all known information into a single model and using it to make best estimate predictions can be highly misleading.

EMA can be useful when relevant information exists that can be exploited by building models, but where this information is insufficient to specify a single model that accurately describes system behavior. In this circumstance, models can be constructed that are consistent with the available information, but such models are not unique. Rather than specifying a single model and falsely treating it as a reliable image of the target system, the available information is consistent with a set of models, whose implications for potential decisions may be quite diverse. A single model run drawn from this potentially infinite set of plausible models is not a prediction; rather, it provides a computational experiment that reveals how the world would behave if the various guesses any particular model makes about the various unresolvable uncertainties were correct. EMA is the explicit representation of the set of plausible models, the process of exploiting the information contained in such a set through a large number of computational experiments, and the analysis of the results of these experiments.

A set, universe, or ensemble of models that are plausible or interesting in the context of the research or analysis being conducted is generated by the uncertainties associated with the problem of interest, and is constrained by available data and knowledge. EMA can be viewed as a means for inference from the constraint information that specifies this set or ensemble. Selecting a particular model out of an ensemble of plausible ones requires making suppositions about factors that are uncertain or unknown. One such computational experiment is typically not that informative (beyond suggesting the plausibility of its outcomes). Instead, EMA supports reasoning about general conclusions through the examination of the results of numerous such experiments. Thus, EMA can be understood as search or sampling over the ensemble of models that are plausible given a priori knowledge.

Central Problems and Solutions

Inferring global properties of a large or infinite set from a finite sample is not a deductive process but requires some combination of inductive and abductive inference along with effective data mining and visualization tools. Consequently, EMA is computationally a more difficult problem than any specific question of deductive inference, and produces results that are more contextual and provisional. How to cleverly select the finite sample of models and cases to examine from the large or infinite set of possibilities is one of the major issues to be addressed in any EMA application. A wide range of research strategies are possible, including structured case generation by Monte Carlo, Latin Hypercube, or factorial experimental design methods, search for extremal points of cost functions, sampling methods that search for regions of "model space" with qualitatively different behavior, or combining human insight and reasoning with formal sampling mechanisms. Computational experiments can be used to examine ranges of possible outcomes, to suggest hypotheses to explain puzzling data, to discover significant phases, classes, or thresholds among the ensemble of plausible models, or to support reasoning based upon an analysis of risks, opportunities, or

scenarios. Exploration can be over both real-valued parameters and non-parametric uncertainty, such as that involving different graph structures, functions, problem formulations, or model formulations.

In making policy decisions about complex and uncertain problems, EMA can provide new knowledge, even where validated models cannot be constructed. A simple example is the use of models as existence proofs or hypothesis generators. Demonstrating a single plausible model/case with counterintuitive properties can beneficially change the nature of a policy discussion. Another example is the use of multiple models that capture different framings of the same policy problem. Instead of debating which is the right model, the policy debate can shift to the identification of policies that produce satisfying results across the different models. Another simple example of potentially credible inductive inference from model exploration is provided by situations where risk aversion is prudent. Here, an exploration that develops an assortment of plausible worst case failure modes can be very useful for designing hedging strategies. This is true even if models are not validated and sensitivities are unknown. Other examples of useful research strategies include the search for special cases where small investments could (plausibly) produce large dividends, or extremal cases (either best or worst) where the uncertainties are all one sided and a fortiori arguments can be used. All these examples depend on the fact that partial information can inform policy even when prediction and optimization are not possible. The space of models and associated computational experiments can be searched for examples with characteristics that are useful in choosing among alternative policies. The search for information of use in answering policy questions can often be served by the discovery of thresholds, boundaries, or envelopes in a space of models that decompose the entire space into sub-spaces with different properties. For example, EMA could seek to discover which models or initial states have stable or chaotic dynamics, or the search could have the goal of discovering which regions in model space favor either of two alternative policies.

EMA will typically result in a very large number of model runs. The resulting outputs must be analyzed, and displays need to be made to communicate the results to analysts and decision makers. The EMA practitioner is not interested in finding a single best policy given a validated predictive system model, but wants to display the pattern of policy performance over the entire uncertainty space of possible system models. Successfully applied algorithms in the context of EMA include the Patient Rule Induction Method (PRIM) and Classification and Regression Trees (CART) (Breiman et al. 1984; Friedman and Fisher 1999; Lempert et al. 2008; Agusdinata 2008). Advances in machine learning and data mining have generated many more algorithms that can support EMA, such as Self Organizing Maps (Kohonen 2001), (t-distributed) Stochastic Nearest Neighbor Embedding (van der Maaten and Hinton 2008), and Support Vector Machines (Vapnik 1995). Increasingly, such algorithms are available in standard statistical data analysis software packages (e.g. SPSS). The Evolving Logic company produced a software environment called the Computer Assisted Reasoning system (CARs), which supports the generation of the EMA cases to be run and the manipulation and display of the results of the runs.

EMA has proven to be a very powerful approach to the discovery of robust decisions and the development of adaptive policies. Adaptive policies are based on explicit recognition that accurate prediction is impossible in light of the many uncertainties that are present. The goal of adaptive policies is to allow implementation to begin prior to the resolution of all major uncertainties, with the policy being adapted over time based on new knowledge. Adaptive policies combine actions that are time urgent with those that make important commitments to shape the future, preserve needed flexibility for the future, and protect the policy from failure (Walker et al. 2001). EMA can support the development of adaptive policies by using the set of plausible models or plausible futures as a challenge set. Through searching for conditions under which given policies fail, these policies can iteratively be improved, resulting in adaptive policies that are robust against the full range of foreseeable future situations (Lempert et al. 2003; Agusdinata 2008). In such applications, EMA provides an important alternative to specifying policies through optimization. There is a close relationship between these computational approaches and emerging adaptive business practices, such as discovery driven planning (McGrath and MacMillan 1995; McGrath and MacMillan 2009) and real options (Amram and Kulatilaka 1999).

EMA has also been used successfully for scenario discovery. Scenario discovery is a model driven approach that builds on the intuitive logic school in scenario planning (Bryant and Lempert 2010). The aim of scenario discovery is to analyze the results from a series of computational experiments in order to reveal which combinations of hypotheses and guesses were responsible for generating the results of interest. Results of interest can be identified based on the performance of candidate policies, but other criteria can also be used. One common use of scenario discovery is to identify combinations of external events that would lead to the failure of the policy being investigated. For discovering the combinations of hypotheses and guesses responsible for the results of interest, both CART and PRIM can be used (Lempert et al. 2008). Scenario discovery has been used in the context of water resource management in California (Groves and Lempert 2007) for evaluating alternative policies considered by the U.S. Congress while debating reauthorization of the Terrorism Risk Insurance Act (Dixon et al. 2007), and for assessing the impact of a renewable energy requirement in the U.S. (Groves and Lempert 2007).

Applications of EMA

Exploratory modeling can be driven by data, a question or decision, or by the needs of model development. Data-driven exploration can be used to support model specification — exploring alternative model structures that might be used to explain a dataset. Or, it can provide an alternative to maximal likelihood or maximal entropy approaches to model estimation by supporting, for example, the visualization of level sets in likelihood surfaces. Question driven exploration begins with a question to answer (e.g., what policy should the government pursue regarding global warming?) and addresses this question by searching over an ensemble of models and cases believed to be plausible in order to inform the answer. Question driven exploration provides an alternative to supporting decision making through forecasting or prediction. EMA also provides a strong alternative approach to model development in allowing guesses and disagreements about uncertain modeling details to be avoided during the process of programming and delayed until the process of model use where these guesses can be motivated by the actual strategy of model based problem solving.

Although the practice of EMA is under continuing, it has been used on variety of decision-making problems. Lempert et al. (2003) applied it to climate change problems in an effort to identify policy options that are, on the one hand, acceptable to a wide variety of countries, depending on their state of development and their belief about climate change, and, on the other hand, are robust across a wide variety of different plausible future climate change developments. In this study, a system dynamics model was used to generate a wide variety of futures. Each future arose out of a set of beliefs about the different factors and their relative magnitudes that contribute to climate change. Next, a variety of policy options was identified, and the performance of these policies in the different futures was calculated. Using the decision-theoretic minimax criterion, the robustness of the different policies can be assessed, and improved, in order to come to a policy that is robust across as many futures as possible. Or, as is often the case when different uncertainties and risks are being considered, no policy may be dominant. In that case, a priori assignments of values can be avoided by presenting decision makers with sets of non-dominated policies and providing analytic support for understanding how choices among them trade off among risk categories.

Another EMA application is from the field of energy generation. Agusdinata (2008) studied how CO2 emissions could be reduced in the Dutch household sector. The Dutch national government wants to reduce carbon emissions from Dutch households by 80% in 2050 compared to 1990. The extent to which that goal can be realized depends on a wide range of factors and actors. For example, the energy generation depends on the layout of the electricity and gas networks. Depending on how these networks evolve, certain options become available or are excluded. Agusdinata (2008) used a 'system of systems' approach to model these complex interdependencies. He made 100,000 model runs across a variety of uncertainties and analyzed them using a CART Tree. This allowed decision makers to see the different routes by which they could reach their goal, depending on how, for example, population would evolve.

A third area in which EMA has been applied is transport planning. Agusdinata et al. (2009) report a case study related to intelligent speed limiters, which is similar in approach to Agusdinata's (2008) household energy case. The field of airport strategic planning has

been investigated by Kwakkel et al. (2010). In this study, several tools from the U.S. Federal Aviation Administration for calculating airport performance were integrated into a single fast model that calculates airport performance in terms of noise, emissions, external safety, and capacity. This component is complemented with a variety components that model different exogenous developments, such as demand, technological development, and demographics. For each type of exogenous development, a set of representations are available. Depending on how these are combined, 48 structurally different models can be specified. Kwakkel, et al. explored the performance of adaptive strategies versus static Master Plans across these 48 structures and their associated parametric uncertainties. It was shown that dynamic adaptive strategies outperformed static Master Plans in practically all plausible situations.

Other EMA applications are reported in Bankes and Margoliash (1993), Bankes (1994), Park and Lempert (1998), Brooks et al. (1999), Lempert et al. (2003), Pruyt and Hamarat (2010a, b), and Hamarat and Pruyt (2011a, b).

Exponential Arrivals

When customers interarrival times to a queueing system are defined by a sequence of independent and identically distributed exponential random variables. If a system has exponential interarrival times with distribution function $A(t) = 1 - \exp(-\lambda t)$, then the number of arrivals to the system in any period of time t has the Poisson distribution with probability function $p_n(t) = \exp(-\lambda t)(\lambda t)^n/n!$.

Exponential Smoothing

Robert G. Brown
Materials Management Systems, Thetford Center, VT, USA

Introduction

Exponential smoothing is a technique for revising an estimate of the average of a time series to extrapolate as a forecast. It was first formalized by R.G. Brown (about 1944) with continuous variables in the analysis of a ball-disc integrator used in a naval fire control device. It was later applied, also by R.G. Brown (1959), with discrete observations in the early 1950s.

Exponential smoothing with discrete (usually monthly) observations of demand had considerable appeal for inventory control because it was possible to revise the forecasts for all products in an inventory in less than 30 days with unit record (punched card) equipment. The formula for revising the estimate of the average is

$$\begin{aligned} new\,forecast &= old\,forecast + \alpha \times (error) \\ &= old\,forecast + \alpha \times (latest\,observation \\ &\quad - old\,forecast) \\ &= (1-\alpha) \times old\,forecast + \alpha \\ &\quad \times (latest\,observation). \end{aligned}$$

The smoothing constant α was originally set to 0.1, not from any theoretical considerations, but because one can multiply on unit-record equipment merely by moving the wires on the plug board one place to the left and adding. But, clearly, better approaches for estimating a good value to use for α would come over time.

Later, Weiner (1949) showed that an estimate of the average of a time series gave the minimum squared error when one uses some optimum set of weights. Box and Jenkins (1970) demonstrated a rigorous procedure for finding that optimum set of weights. The optimum weights often decline more or less geometrically with age. Indeed, for short series the wholly empirical technique of exponential smoothing was usually indistinguishable from the optimum weights.

In the late 1950s, Brown (1963) extended the model to include a secular trend. The first model used single smoothing and double smoothing. Brown (1967) showed that this was equivalent to smoothing the values of the coefficients in a polynomial of any degree. This led to the generalization to include complex polynomials that could be interpreted as Fourier series to approximate repeatable seasonal variation.

Winters (1962) developed an elaborate simulation to find the best value of three smoothing constants, for level, trend, and seasonal profile respectively. Simulations with different models and different smoothing constants are usually misleading because the sampling error with short series is larger than the effect being sought. Since exponential smoothing learns, several implementers let the coefficients in the

model start from arbitrary values. There is a problem in that the rate of learning takes much longer than the normal span of patience of people who need a good forecast now.

The initial values of the coefficients should be estimated by regression on available history. (For new products there will be other products in the inventory that serve the same market which can be used as analogs). Since the Fourier series is an orthogonal basis, one can fit all the terms up to the Nyquist frequency (at least two observations per cycle for the highest frequency) and reject harmonics that are not significant under a chi-square test with two degrees of freedom.

Decisions based on a forecast need information about the probability distribution of forecast errors. The form of the distribution may be Gaussian, but there are not infrequent cases where the errors are bounded below, with a long upper tail. Therefore it is advisable to check the distribution form that is appropriate to the actual data. Usually one parameter, the variance, is sufficient to develop the model of probabilities.

Brown (1959) proposed the use of the Mean Absolute Deviation (MAD) as a measure of dispersion. On unit-record equipment, it is simple to measure the absolute deviation — leave out the wire that carries sign. If the form of the distribution is exactly normal the standard deviation is 1.25 times the MAD. However in actual data the ratio has been observed to be anywhere from 1 to 1.7. Thus it is prudent to measure the Mean Squared Error (MSE). The MSE can be revised with each new observation by applying exponential smoothing to the square of the error in the most recent forecast.

A theoretical model of a time series often is seriously different from actual data. Sales are distorted by promotions, federal regulations, competition, weather, and errors in recording. During the process of revising the forecast it is advisable to produce exception reports. The demand filter reports data that are more than K standard deviations from the most recent forecast. The tracking signal reports significant bias in the forecast.

The head of forecasting should take these exception reports seriously. First find the assignable cause for the exception, and then take appropriate action. Do not wait until the exception is reported to start thinking about the assignable cause. Be aware of events in the operating environment that could cause exceptions and use the reports to confirm or deny hypotheses about the problems actually occurring. Look for patterns, where several series seem to show the same anomalies.

Several techniques have been proposed for the tracking signal. Brown (1959) originally used the cumulative sum of forecast errors. However, the expected value of that sum in the future is the current sum. A large error can bias the signal so that a very small error later could cause an exception.

The next technique was the smoothed error tracking signal (SETS) which applied exponential smoothing to the error with sign. This technique is slow to react to a real change in the underlying process which generates the data. Trigg (1966) proposed using the SETS to modify the smoothing constant(s) — make the forecasts more responsive when they are wrong and more stable when they are close to the data. They failed to show that the feedback system is critically damped in all regions where it may be applied.

Gardner (1985) has done a study of the comparative effectiveness of a variety of tracking signal techniques. Barnard (1959) proposed the V-mask based on Wald's sequential analysis for quality control (Wald 1947). Brown (1971) used a parabolic mask as the envelope of these V-masks with a range of likelihood ratios. The technique has been extended to monitor the MSE as well as the forecast, based on analogy with Shewhart's (1931) X-bar and R charts for statistical quality control.

During the course of fitting the initial model outliers are the analogs of demand filter exceptions. Brown (1990) used the term "significant event" to refer to history where there is evidence that not all the history came from a process that can be described by the same model. Significant serial correlation with a lag of one observation may be caused by such a significant event (there are other causes). Brown (1990) has evolved a method with cumulative sums for estimating the time when that event occurred, so that the model can be fitted only to observations since that time.

The whole idea of forecasting from a description of history is on the way out. It will be common to pass point-of-sale data quickly and accurately to each operation in the logistics chain, rather than to forecast what one enterprise will order from another enterprise.

Extremal

Maximum or minimum.

Extremal Column

In the Dantzig-Wolfe Decomposition Algorithm, the extremal columns are the columns of the extremal (master) problem.

See

- ▶ Dantzig-Wolfe Decomposition Algorithm

Extremal Problem

In the Dantzig-Wolfe Decomposition Algorithm, the extremal column is the original linear-programming problem expressed in terms of its extreme point solutions.

See

- ▶ Dantzig-Wolfe Decomposition Algorithm

Extreme Direction

A point in a convex set that cannot be expressed as a convex combination of two other directions of the set.

Extreme Point

A point in a convex set that cannot be expressed as a convex combination of two other distinct points in the set. Extreme points are also known as corner points or vertices. The extreme points of a rectangle are its four vertices, while the extreme points of a circular disc are the points on its circumference. For a linear programming problem, the extreme points of its convex set of solutions correspond to basic feasible solutions, and it can be shown that, if the problem has a finite optimal solution, then one of the extreme points is optimal.

Extreme Point Solution

A solution to a linear-programming problem that is an extreme-point of its convex set of solutions. Such solutions correspond to basic feasible solutions.

Extreme Ray

A ray in a convex set whose direction is an extreme solution.

Facilities Layout

Bharat K. Kaku
Georgetown University, Washington, DC, USA

Introduction

In both manufacturing and service operations, the relative location of facilities is a critical decision affecting costs and efficiency of operations. The facility layout problem (FLP) deals with the design of layouts wherein a given number of discrete entities are to be located in a given space. The definitions of entities and spaces can vary considerably, making solution techniques applicable in a wide variety of settings, as can be seen from the examples given below.

Entities	Space
Departments	Office building
Departments	Factory floor
Departments	Hospital
Interdependent plants	Geographical market
Indicators and controls	Control panel
Components	Electronic boards
Keys	Typewriter keyboard

In what follows, approaches used to model the FLP are discussed first, followed by optimal algorithms and heuristic approaches for solving these problems, and ending with some remarks concerning directions for future research.

The Quadratic Assignment Formulation

The FLP is most often treated in the OR/MS literature as the Quadratic Assignment Problem (QAP), which is a special case requiring identical area and shape requirements for the locations of all facilities. This allows pre-definition of the locations and calculation of the distances between them (typically center-to-center, either rectilinear or Euclidean). Suppose there are N facilities to be assigned to N locations. Define four $N \times N$ matrices whose elements are, respectively:

$c_{ij} =$	fixed cost of assigning facility i to location j
$F_{ij} =$	level of interaction between facilities i and j
$d_{ij} =$	cost of one unit of interaction (e.g., the distance) between locations i and j
$x_{ij} =$	1 if facility i is assigned to location j, and 0 otherwise.

Then the QAP is to

$$\text{Minimize} \quad \sum_{i,j} c_{ij}x_{ij} + \sum_{i,p}\sum_{j,q} f_{ip}\, d_{jq}x_{ij}x_{pq} \qquad (1)$$

$$\text{subject to} \quad \sum_{j} x_{ij} = 1 \quad \forall\, i \qquad (2)$$

$$\sum_{i} x_{ij} = 1 \quad \forall\, j$$
$$x_{ij} \in \{0,\ 1\} \quad \forall\, i,j \qquad (3)$$

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

Alternatively, $\rho(i)$ can be defined as the location to which facility i is assigned, leading to an equivalent but more compact statement of the problem. The QAP is then to find a mapping of the set of facilities into the set of locations so as to

$$\text{Minimize} \quad \sum_i c_{i,\rho(i)} + \sum_{i,p} d_{\rho(i),\rho(p)}. \qquad (4)$$

Objective
Minimize cost of interactions
Minimize cost of material handling
Minimize movement of patients and medical staff
Maximize profit
Minimize eye/hand movement
Minimize cost of connections
Minimize typing time

The quadratic assignment problem was first formulated by Koopmans and Beckmann (1957) in the context of the location of interdependent plants. The c_{ij} elements represent the expected revenue of operating plant i at location j independent of other plant locations, the f_{ij} elements represent the required commodity flows from plant i to plant j, and the d_{ij} elements represent the transportation costs per unit between location i and location j. The objective function maximizes the net revenue, that is, the excess of expected revenue over the transportation costs.

It is the interdependence of facilities due to interactions between them that leads to the quadratic term in the objective function and makes the problem a difficult one. If the departments are independent of each other (i.e., all $f_{ij} = 0$), the QAP reduces to the familiar linear assignment problem, for which efficient solution techniques exist. Further, the traveling salesman problem is a special case of the QAP. To see this, consider the interaction matrix to be a cyclic permutation matrix with the following interpretation: A flow of one unit (the salesman) travels from the first city in the tour to the second city in the tour to the third city, and so on, finally returning to the first city in the tour. The distance matrix is simply the matrix of distances between cities, and the fixed costs are zero. A solution to this QAP can be interpreted as follows. If $x_{ij} = 1$, then city i is in the jth location in the tour. This shows that the QAP belongs to the class of NP-hard problems.

The Adjacency Requirements Formulation

This approach is based on adjacency requirements and closeness ratings. The former stipulate the set of pairs of facilities that must be adjacent, or must not be adjacent, in any feasible solution, whereas the latter are measures of the desirability of locating a pair of facilities in adjacent locations, generally based on the interaction between them. The adjacency requirements must permit at least one feasible solution. If there is more than one feasible solution, then the closeness ratings are used to choose the optimal solution. In evaluating a solution, the closeness ratings are added only for facility pairs that are adjacent.

The QAP has received most of the attention in the literature for the following two reasons. First, it considers interaction costs for all pairs of facilities, whereas the adjacency requirements formulation maximizes the sum of closeness ratings for adjacent facilities only, while satisfying the adjacency requirements. Second, the adjacency requirements formulation does not consider fixed costs which can be important, especially when a layout is being redesigned, which is more common than design of a brand-new facility. In the rest of this article, the discussion is restricted the QAP. Further information on the adjacency requirements approach can be found in Foulds (1983) and a more extensive list of references for the QAP can be found in the review by Kusiak and Heragu (1987). The book by Heragu (2008) offers a comprehensive look at applications of the QAP model in different settings.

Optimal Algorithms for the QAP

Algorithms for obtaining exact solutions to the QAP can be classified under the categories of linearization and implicit enumeration.

Linearization — Several linearizations have been proposed for the QAP. The first one was by Lawler (1963) who linearized the problem by defining variables $y_{ijpq} = x_{ij}\, x_{pq}$. Compared to the original QAP, the resulting integer programming problem has N^4 additional binary variables and $N^4 + 1$ additional constraints. A linearization proposed by Kaufman and Broeckx (1978) is the most compact,

adding only N^2 new continuous variables and N^2 new constraints. Bazaraa and Sherali (1980) suggested another linearization to which they applied Benders decomposition. None of these approaches has proved to be computationally effective. More details can be found in the survey paper by Kusiak and Heragu (1987).

Implicit Enumeration — Branch-and-bound algorithms have been the most successful in solving the QAP to optimality; problems with as many as 15 or 16 facilities can be solved in reasonable time. Some earlier implicit enumeration methods were pair-assignment algorithms where a node in the branch-and-bound tree corresponds to the assignment of a pair of facilities to a pair of locations (Land 1963; Gavett and Plyter 1966). These did not prove to be competitive with single-assignment algorithms which assign one facility to one location at each node.

Gilmore (1962) and Lawler (1963) independently developed a lower bound for use in a single-assignment branch-and-bound procedure. This lower bound forms the basis for the most successful implicit enumeration algorithms published (Bazaraa and Kirca 1983; Burkard and Derigs 1980). How the Gilmore-Lawler lower bound is calculated is described next.

Suppose $\mathcal{F}$ is the set of facilities (possibly empty) that have already been assigned, and $\mathcal{L}$ is the set of locations to which these facilities have been assigned. Using the alternate formulation (4), a lower bound on completions of this partial assignment is given by

$$\begin{aligned}\text{Min}\quad & \sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip}\, d_{\rho(i),\rho(p)} \\ & + \sum_{i\in\mathcal{F}}\sum_{p\notin\mathcal{F}} [f_{ip}\, d_{\rho(i),\rho(p)} + f_{pi} d_{\rho(p),\rho(i)}] \\ & + \sum_{i\notin\mathcal{F}} c_{i,\rho(i)} + \sum_{i\notin\mathcal{F}}\sum_{p\notin\mathcal{F}} f_{ip}\, d_{\rho(i),\rho(p)}. \end{aligned} \tag{5}$$

The first two terms in the expression (5) are the known fixed and interaction costs of assignments already made; the third term captures the interaction costs between assigned facilities and those yet to be assigned; and the last two terms represent the fixed and interaction costs of assignments not yet made. A minimum can be calculated for the last three terms as follows. Consider the assignment of any unassigned facility $i \notin \mathcal{F}$ to a free location $j \notin \mathcal{L}$. The incremental cost due to this assignment is

$$\sum_{p\in\mathcal{F}} [f_{ip}\, d_{j,\rho(p)} + f_{pi} d_{\rho(p),j}] + c_{ij} + \sum_{p\notin\mathcal{F}} f_{ip} d_{j,\rho(p)}. \tag{6}$$

Now the first two terms of (6) are known, and the third term needs to be minimized. Form a vector of flows consisting of the ith row of the flow matrix minus the diagonal element minus the elements corresponding to assigned facilities ($i \in \mathcal{F}$). Arrange the elements of this vector in decreasing order. Form a similar vector of distances consisting of the jth row of the distance matrix minus the diagonal element minus the elements corresponding to filled locations ($j \in \mathcal{L}$), and arrange it in increasing order. The scalar product of these vectors provides the necessary minimum cost. Essentially, the largest interaction with i incurs the lowest per unit cost, the second largest interaction incurs the second lowest cost, and so on. Repeat for all pairs (i, j) such that $i \notin \mathcal{F}$ and $j \notin \mathcal{L}$. A solution to the linear assignment problem (LAP) with these incremental costs as cost coefficients provides a lower bound on the three unknown terms of (5).

Let the value of this solution be z^*. The Gilmore-Lawler lower bound is then obtained as

$$LB = \sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip} d_{\rho(i),\rho(p)} + z^*. \tag{7}$$

Any node at which the lower bound is greater-than-or-equal-to the upper bound can be fathomed in the usual way. However, an attractive feature of this lower bound is the fact that additional information is available to be used in the search process. Consider the solution to the LAP solved to obtain the lower bound, with facility $i \notin \mathcal{F}$ assigned to location $\rho(i)$. The dual variables of the optimal solution can be used to reduce the cost matrix so that every $(i, \rho(i))$ element is zero. Adding together the next smallest element in that row and in that column gives the regret or minimum additional cost if assignment $(i, \rho(i))$ is not made. The lower bound plus regret gives the alternate cost of this assignment. Using this cost as a branching rule, the next assignment is chosen with the maximum alternate cost. Further, while backtracking, if the

alternate cost at a node is greater than the upper bound, no more nodes need to be evaluated at that level on the present branch.

Heuristic Solution Methods for the QAP

Given the limited size of problems that can be solved to optimality (smaller than most practical problems), there has been considerable interest in developing heuristic procedures for the QAP. Heuristics for the QAP can be classified as limited enumeration, construction methods, improvement methods, and hybrid methods.

Limited Enumeration — It has often been observed that an optimal solution is found fairly early in a branch-and-bound procedure, with the majority of the solution time then being spent in proving optimality. A heuristic based on limited enumeration takes advantage of this feature by setting a cut-off time to truncate the search process. The search can either be shortened or allowed to cover more of the search space in a fixed amount of time by fathoming a node at which the gap between the lower and upper bounds is sufficiently small. This gap can be set based on empirical evidence about the behavior of bounds, for example, in the QAP the lower bound rises rapidly at higher levels of the branch-and-bound tree and then more gradually. Thus a dynamic gap could be used, larger at higher levels and decreasing at lower levels of the tree.

Construction Methods — A constructive procedure starts with an empty assignment and adds assignments one at a time until a complete solution is obtained. The rule used to choose the next assignment can be a simple one such as assign the facility with the maximum interaction with a facility already assigned and place it as close as possible to that facility. Alternatively, a rule may be employed that takes into account assignments already made, as well as future assignments to be made, which is likely to lead to better solutions. Examples of the latter type of rule would be the use of alternate costs obtained in the process of calculating lower bounds (see above) or the use of an evaluation function such as that devised by Graves and Whinston (1970). The Graves-Whinston method uses statistical properties to compute an expected value for the completion of any partial assignment using only basic arithmetic operations. The computation time is very reasonable, thus making it a good choice as a constructive heuristic. In addition to the notation defined earlier, define $\mathcal{L}$ as the set of locations that have been assigned facilities. Suppose also that k assignments have already been made. The expected value of a complete assignment is given by expression (8) whose terms are analogous to those in (5):

$$EV = \sum_{i\in\mathcal{F}} c_{i,\rho(i)} + \sum_{i\in\mathcal{F}}\sum_{p\in\mathcal{F}} f_{ip} d_{\rho(i),\rho(p)} + \frac{\sum_{i\in\mathcal{F}}\sum_{p\notin\mathcal{F}}\sum_{j\notin\mathcal{L}} [f_{ip} d_{\rho(i),j} + f_{pi} d_{j,\rho(i)}]}{n-k} + \frac{\sum_{i\notin\mathcal{F}}\sum_{j\notin\mathcal{L}} c_{ij}}{n-k} + \frac{\sum_{i,p\notin\mathcal{F}} f_{ip}\left(\sum_{j,q\notin\mathcal{L}} d_{jq}\right)}{(n-k)(n-k-1)}. \tag{8}$$

Improvement Methods — Improvement procedures start with some sub-optimal solution and attempt to improve it through partial changes in the assignments. The design of an improvement routine requires decisions concerning the following: type of exchange — pairwise, triple, or some higher order; number of exchanges to consider — should all possible exchanges be considered or a limited set; choice of exchange actually made — first improvement or best improvement; order of evaluation — random or predetermined. An effective strategy is to use pair-wise exchanges in fixed order of decreasing interactions, considering all possible exchanges, and accepting the first improvement. Higher order exchanges are best used sparingly. Other improvement techniques, such as simulated annealing (Connolly 1990) and tabu search (Skorin-Kapov 1990), that avoid the trap of local optima have been applied with success to the QAP.

Hybrid Methods — Some of the most successful heuristic solution methods for the QAP can be termed hybrid methods because they combine the power of improvement methods with some method for obtaining solutions to be improved, for example, construction methods (Ligett 1981), limited enumeration (Bazaraa and Kirca 1983), or cutting planes (Burkard and Bonniger 1983). Kaku et al. (1991) successfully combined constructed solutions with exchange improvement by systematically

constructing solutions that were different from each other. This forces different areas of the search space to be examined.

Concluding Remarks

The QAP formulation suffers from two drawbacks. First, it assumes identical area and shape requirements for all facilities. Unequal areas could be dealt with by dividing all facilities into equal-area modules which could be kept together in a solution by introducing very high artificial flows between them. However, this increases the size of the problem. Improvement methods can employ such a strategy since the number of facilities is less of a concern, however, exchanges are then limited to either equal-sized facilities or to adjacent facilities. Work by Bozer et al. (1994) incorporating the use of space-filling curves in facility layout overcomes this handicap for improvement methods. Second, the QAP deals exclusively with interaction costs, generally material handling costs. This is not likely to be the only concern in facility layout. For this reason, the general practice is to allow a human designer to evaluate and fine tune a solution before implementation. For example, Fu and Kaku (1997) examined the effect of layout design on work-in-process (WIP) levels in a factory, an issue of great interest when considering lean manufacturing. They found that good QAP solutions generally reduce the levels of WIP, but there are exceptions which the QAP approach cannot discern. The following are some of the features that are desirable in a heuristic solution procedure for the FLP: The ability to handle different area requirements; the ability to produce good solutions with reasonable computational requirements; and the ability to either consider multiple criteria or present the decision maker with good layout alternatives to choose from.

Introduction

Location problems that can be quantified as optimization problems are natural candidates for operations research approaches, and many such problems have been studied using mathematical-programming methodology. This article gives an overview of some of this activity. Models of these location problems are classified as planar, network, and mixed integer-programming models, and methodology for solving such types of models is outlined. There is little doubt that the contributions to facility location consist principally of algorithms — well-defined computational procedures for solving quantifiable problems.

A location problem must be quantifiable for there to be any hope of solving it with an algorithm: there must be a well-defined objective to be optimized, for example, cost to be minimized, or profit to be maximized. Likewise there are usually well-defined constraints, for example, budget constraints, which limit the scope of the optimization. Location problems which are highly subjective or political in nature are thus usually not very good candidates for operations research approaches, although even for such problems there may be results which can help to reduce the scope of the problem under consideration, or identify basic tradeoffs of interest.

In what follows, some basic location models are considered. For further reading, see the texts by Handler and Mirchandani (1979); Love et al. (1988) and Francis et al. (1992).

Selected Models

This section describes some of the basic but popular and useful models of location theory, along with brief discussions of their solution approaches. Note that demand points are referred to as existing facilities and the facilities to be located as new facilities. In developing the models, the following notation is used:

p: number of new facilities. The value of p may be a decision variable or may be fixed;
m: number of existing facilities;
w_i : weight associated with existing facility i;
X: location of a single new facility;
$\boldsymbol{X} = (X_1, \ldots, X_p)$: locations of p new facilities; and
$D_i(X)$: the distance between existing facility i and the *nearest* new facility.

Model 1, P-Center Problem

The objective in this model is to locate p new facilities to minimize the maximum distance to an existing facility. Let $g(\boldsymbol{X}) = \max_{i = 1,\ldots,m} \{w_i D_i(\boldsymbol{X})\}$ represent the maximum (weighted) distance any person has to travel; then the problem can be posed as

$$\underset{x}{\text{Minimize}} \; g(X).$$

This problem is known as the p-center problem and, besides other applications, has been used to model locations of emergency medical facilities such as the location of a helicopter to minimize the maximum time to respond to an emergency, and the location of a transmitter to maximize the lowest signal level received.

Model 2, Covering Problem

In this problem, the number of facilities to be located is not fixed a priori. Each existing facility should be within a specified weighted distance from at least one new facility. The objective is to find the number of new facilities, p, and their locations, $\boldsymbol{X}$, to minimize the cost of the new facilities.

The version of the covering problem with a finite set of candidate facility locations can be modeled as a set-covering problem. With S as the set of n candidate sites for facilities, denote the sites by $j = 1, \ldots, n$. Define variables y_j which take on a value 1 if a new facility is opened at site j and 0 otherwise. Let f_j represent the cost of locating (opening) a facility at j. Customers (existing facilities) are indexed

by $i =; 1,\ldots, m$. Let $a_{ij} = 1$ if a new facility located at site j can cover existing facility i, 0 otherwise, $i = 1,\ldots, m$ and $j = 1,\ldots, n$. Note that the a_{ij} values are constants and are determined prior to the formulation. An integer-programming formulation of the set-covering problem can be written as:

$$\min \sum_{j \in S} f_i y_i$$

$$\text{subject to :} \quad \sum_{j \in S} a_{ij} y_i \geq 1, \qquad \forall i = 1, ..., m$$

$$yi \in \{0, 1\} \qquad \forall i = 1, ..., n.$$

The objective function sums up the fixed costs of locating the new facilities. When each $f_j = 1$, the objective function minimizes the number of new facilities to be located. The first constraint ensures that each existing facility is covered while the second constraint restricts the variables to be binary.

Model 3, Simple Plant Location Problem

In the simple plant location problem (SPLP), a number of new facilities need to be opened (the actual number is a decision variable) to serve a given set of customers. There is a fixed cost of opening each facility. The objective is to minimize the sum of the fixed and variable costs of serving the demand points, and to determine the optimal allocation pattern for all customers.

The SPLP can be formulated as a mixed-integer program as follows. In addition to S, f_j and y_j defined earlier, let $c_{ij} = 0$, $i \not\in 1,\ldots, m$ and $j = 1,\ldots, n$, be the unit cost of servicing customer i from a new facility located at j. Letting x_{ij} denote the fraction of customer i's service provided by site j, a formulation of the SPLP is:

$$\min \quad \sum_{j \in S} f_i y_i + \sum_{i=1}^{m} \sum_{j \in S} c_{ij} x_{ij} \qquad (1)$$

$$\text{subject to :} \quad \sum_{j \in S} x_{ij} = 1, \quad i = 1, ..., m \qquad (2)$$

$$y_j \in \{0, 1\}, \quad j = 1, ..., n \qquad (3)$$

$$x_{ij} \geq 0, \quad i = 1, ..., m, \quad j = 1, ..., n \qquad (4)$$

and

$$x_{ij} \leq y_j, \quad i = 1, ..., m, \quad j = 1, ..., n \qquad (5)$$

Expression (1) totals site costs and service costs. The requirement that each customer be completely served is assured by (2). Expression (3) prevents a fractional opening of a site, and (4) assures nonnegative service. The condition that service cannot be provided from an unopened facility is guaranteed by (5).

If there are no facility related cost terms in the objective function (i.e., $f_j = 0$ for all j) and the number of facilities is restricted to exactly p, then the resulting problem is known as the p-median problem.

Solving the Models

In order to describe selected contributions that operations research has made towards providing solution procedures for the above problems, the problem space is divided into three classes: planar models, network models, and discrete models. Many of the above models can be posed on any one of the three spaces with some slight modifications, and almost all models can be put into one of the three classes.

The main difference in these three classes of models is the manner in which the distance between two points is defined. In planar models, the distance function $d(\cdot)$ is a norm, often Euclidean, rectilinear, or some other norm, and the number of possible locations for new facilities is infinite. This renders the corresponding problems as continuous. If (a_i, b_i) are the coordinates of a point i, then the Euclidean distance between points i and j is given by $\sqrt{(a_i - a_j)^2 + (b_i - b_j)^2}$, while the rectilinear distance is given by $|a_i + a_j| - |b_i - b_j|$, where $|\cdot|$ is the absolute value function.

Many of the best known OR algorithms for solving location problems involve choosing best locations from a finite collection of possible sites. Since a site either is chosen or is not, such problems are intrinsically discrete in nature and are candidates for being solved as integer-programming problems. For example, a banking corporation might be uncertain as to how many branch banks there should be. The corporation would realize that the more banks it

locates, the more convenient the branches would be to its customers in terms of travel time or travel cost. On the other hand, the more branches there are, the higher would be the operating expenses and fixed costs. Thus there is a trade-off between convenience and operating costs, which it would be important to analyze. Such trade-offs often occur in solving location problems.

In discrete models, the number of existing facilities and the number of potential sites for new facilities is finite. Distances may be derived from planar or network distances, or some more general type of transport cost which is proportional to distance. Discrete problems, modeled as mixed integer programs, are often more difficult to solve. On the other hand, many realistic assumptions can be incorporated in discrete models which cannot be included in planar or network models.

When a location problem has substantial transport costs, and the fixed site costs are relatively independent of location, there are several other approaches to modeling it. Often it is assumed that transport costs are directly proportional to transport distances. When these distances are incurred on a transport network, such as a road network, the result is often a network model. Such models usually employ shortest path algorithms to compute travel distances. The focus of network model research has been principally upon two topics: 1) algorithms to solve the problems, and 2) localization results, such as vertex-optimality results, which reduce to a finite collection the set of locations which must be considered to obtain an optimal solution (Hooker et al. 1991) Once such a finite set is obtained, the resulting remaining problem may well be modeled as an integer- or mixed- integer programming problem.

Distances are often more accurately represented in network models than in planar models, but the need for data is also higher in network models since the length of each segment is needed. For many models it becomes advantageous to work directly with the network, exploiting its properties in developing a solution procedure. The existing facilities are located on the network, and the new facilities are to be located at points on the network. An additional advantage of network models is that they make problem visualization easier. Thus, even if the problem is not solved as a network problem, a solution presented in network form may assist the decision maker in understanding the problem and the issues involved.

It is possible, for a network location problem, that it may be prohibitively expensive to obtain, or to work with, the necessary network data. In such cases, network distances may well be approximated using planar distances, for example, Euclidean or rectilinear distances. This results in what is called a planar model. The related problems are often easier to analyze, and can be helpful for providing insight. Often results from nonlinear programming can be employed to help solve such problems.

Real-world location problems which occur in urban contexts may well have millions of demand points when each private residence is a demand point. It is common to use some means of aggregating demand points. The aggregation reduces the problem size, but introduces error into the model. There is evidence that aggregation errors decrease with the number of aggregate demand points at a decreasing rate. For a small number of aggregate demand points, the error may be quite high; for a larger number it may be quite low, and increasing the number even more will give little additional decrease in the error, see Francis et al. (1999).

As concerns algorithms/solution approaches to the three classes of problems, planar problems are usually solved using linear or nonlinear programming methods; network problems are usually solved using network and graph-theoretic methods; discrete problems are usually solved using integer-programming methods. More information on these methods can be found in the references. In addition, many artificial intelligence based heuristic approaches, such as genetic algorithms, tabu search, and simulated annealing, can be used to solve location problems.

Factorable Programming

Richard H. F. Jackson
National Institute of Standards and Technology, Gaithersburg, MA, USA

Factorable programming problems are mathematical programming problems of the form

$$\underset{x \in R^n}{\text{minimize}}\, f(x),$$
$$\text{subject to } g_i(x) > 0,$$

for $i = 1,\ldots, m$, in which all the functions involved are factorable. Loosely, a factorable function is a multivariate function that can be written as the last of a finite sequence of functions, in which the first n functions in the sequence are just the coordinate variables, and each function beyond the nth is a sum, a product, or a single-variable transformation of previous functions in the sequence. More rigorously, let $[f_1(x), f_2(x),\ldots, f_L(x)]$ be a finite sequence of functions such that $f_i : R^n \to R$ where each $f_i(x)$ is defined according to one of the following rules:

Rule 1: For $i = 1,\ldots, n, f_i(x)$ is defined to be the ith Euclidean coordinate, or $f_i(x) = x_i$.

Rule 2: For $i = n + 1,\ldots, L, f_1(x)$ is formed using *one* of the following compositions:

a. $f_i(x) = f_{j(i)}(x) + f_{k(i)}(x)$; or
b. $f_i(x) = f_{j(i)}(x) \cdot f_{k(i)}(x)$; or
c. $f_i(x) = T_i[f_{j(i)}(x)]$;

where $j(i) < i$, $k(i) < i$, and T_i is a function of a single variable. Then $f(x) = f_L(x)$ is a factorable function and $[f_1(x), f_2(x),\ldots, f_L(x)]$ is a factored sequence. Thus a function, $f(x)$, will be called factorable if it can be formed according to Rules 1 and 2, and the resulting sequence of functions will be called a factored sequence, or at times the function written in factored form.

Although it is not always immediately grasped, the concept of a factorable function is actually a very natural one. In fact it is just a formalization of the natural procedure one follows in evaluating a complicated function. Consider for example the function

$$f(\boldsymbol{x}) = [\boldsymbol{a}^T\boldsymbol{x}]\ \sin[\boldsymbol{b}^T\boldsymbol{x}]\ \exp[\boldsymbol{c}^T\boldsymbol{x}],$$

where $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, and $\boldsymbol{x}$ are (2×1) vectors. The natural approach to evaluating this function for specified values $\boldsymbol{x}_1^0$ and $\boldsymbol{x}_2^0$ is first to compute the quantities within the brackets then to apply the sine and exponential functions, and finally to multiply the three resulting quantities. This might be done in stages as follows:

$$\begin{aligned}
f_1 &= \boldsymbol{x}_1^0 & f_9 &= \boldsymbol{c}_1 f_1\\
f_2 &= \boldsymbol{x}_2^0 & f_{10} &= \boldsymbol{c}_2 f_2\\
f_3 &= \boldsymbol{a}_1 f_1 & f_{11} &= f_9 + f_{10}\\
f_4 &= \boldsymbol{a}_2 f_2 & f_{12} &= \sin(f_8)\\
f_5 &= f_3 + f_4 & f_{13} &= \exp(f_{11})\\
f_6 &= \boldsymbol{b}_1 f_1 & f_{14} &= f_5 \cdot f_{12}\\
f_7 &= \boldsymbol{b}_2 f_2 & f_{15} &= f_{13} \cdot f_{14}\\
f_8 &= f_6 + f_7
\end{aligned}$$

This is one possible factored sequence for $f(\boldsymbol{x})$.

To understand what follows, the concept of an outer product matrix must be introduced. An $(m \times n)$ matrix $\boldsymbol{A}$ is called an outer product matrix if there exists a scalar α, an $(m \times 1)$ vector $\boldsymbol{a}$, and an $(n \times 1)$ vector $\boldsymbol{b}$ such that

$$\boldsymbol{A} = \boldsymbol{a}\,\alpha\boldsymbol{b}^T.$$

The expression $\boldsymbol{a}\,\alpha\boldsymbol{b}^T$ is called an outer product or a dyad. Note that a dyad is conformable since the

dimensions of the product are $(m \times 1)(1 \times 1)(1 \times n)$, which yields the $(m \times n)$ outer product matrix $\boldsymbol{A}$ as desired. A useful property of outer product matrices is that, if kept as dyads, matrix multiplication is simplified to inner products alone, saving the computations required to form the matrices involved. For example,

$$\begin{aligned} \boldsymbol{Ac} &= \boldsymbol{a}\ \alpha[\boldsymbol{b}^T\boldsymbol{c}], \\ \boldsymbol{d}^T\boldsymbol{A} &= [\boldsymbol{d}^T\boldsymbol{a}]\ \alpha\boldsymbol{b}^T, \quad \text{and} \\ \boldsymbol{AF} &= \boldsymbol{a}\ \alpha[\boldsymbol{b}^T F], \end{aligned}$$

where $\boldsymbol{c}$ is $(n \times 1)$, $\boldsymbol{d}$ is $(m \times 1)$ and F is $(n \times m)$.

It is well-known (McCormick 1983) that factorable functions possess two very special properties that can be exploited to produce efficient (fast and accurate) algorithms: i) once written in factorable form, their gradients and Hessians may be computed exactly, automatically, and efficiently; and ii) their Hessians occur naturally as sums of dyads whose vector factors are gradients of terms in the factored sequence. The first of these properties eases the task of providing the derivatives of a nonlinear programming problem to a computer software solution routine, and has the potential eventually to trivialize it. The second, as noted above, changes the way matrix multiplication is interpreted, which in many cases results in less computational effort.

There are factorable problems whose structure is such that the factorable approach results in more work: small, dense problems, for example. For these problems, the factorable approach can still be used for easy input, but some of the matrix techniques would be replaced by classical approaches.

Software packages have been written that perform the factoring automatically from natural language input. See Jackson and McCormick (1988) for a history of such efforts, as well as Jackson, McCormick, and Sofer (1989). The latter paper describes a system that allows user input for nonlinear functions in a format similar to FORTRAN, without any requirement on the user to understand the details of factorable functions.

As mentioned above, one fundamental value of factorable functions lies in the simple and computationally efficient forms that result for their Hessians. In fact, factorable programming is based on the existence of, and the simplified operations that result from, these simple forms. The seminal result is that the Hessian of a factorable function can be written as the sum of dyads, or outer products, of gradients of functions in the factored sequence (Fiacco and McCormick 1968, pp. 184–188). This basic result was generalized in Jackson and McCormick (1986). Before explaining the generalization, it is necessary to generalize the concepts of Hessian and dyad.

Let $\boldsymbol{A} \in R(^{n1\mathrm{x}\ldots\mathrm{x}nN})$, and let $\boldsymbol{A}_{i1,\ldots,i\,N}$ denote the $(i_1,\ldots,i_N)$th element of this array. For the purposes of this article, $\boldsymbol{A}$ is called the *Nth-order tensor* of a multivariable function $f(\boldsymbol{x})$ if

$$\boldsymbol{A}_{i_1,\ldots,i_N} = \partial^N f(\boldsymbol{x})/\partial \boldsymbol{x}_{iN} \ldots \partial \boldsymbol{x}_{i_1}.$$

Note that gradients and Hessians are tensors of order 1 and 2 respectively.

An N-dimensional array $\boldsymbol{A}$ is called a generalized outer product matrix if there exists a scalar α, and an ordered set of vectors $\boldsymbol{a}_1,\ldots,\boldsymbol{a}_N$ (where each a_k is $(n_k \times 1)$) such that each element of $\boldsymbol{A}$ is generated by the product of the scalar α and certain specific elements of the vectors $\boldsymbol{a}_1,\ldots,\boldsymbol{a}_N$ as follows:

$$\boldsymbol{A}_{i_1,\ldots,i_N} = \alpha * \boldsymbol{a}_{1,i_1} * \cdots * \boldsymbol{a}_{N,i_N}$$

for $i_1 = 1,\ldots, n_1;\ldots; i_N = 1,\ldots, n_N$, where $\boldsymbol{a}_{k,i\ k}$ represents the (i_k)th element of the $(n_k \times 1)$ vector $\boldsymbol{a}_k$.

The scalar and set of vectors which generate a generalized outer product matrix taken together are called a polyad and are written

$$(\alpha : \boldsymbol{a}_1 \cdots \boldsymbol{a}_N), \tag{1}$$

where order is important, that is, the vector in position j is associated with the jth dimension. A polyad containing N vector factors is an *N-ad*. Also, an expression containing a sum of polyads is a polyadic, and an expression containing a sum of N-ads is an *N-adic*. (The actual addition here is performed as a sum of the associated generalized outer product matrices.) When vector factors in a polyad are repeated, exponential notation is used, as in the case of the symmetric N-ad, $(\alpha{:}[\boldsymbol{a}]^N)$. Note that the representation of a generalized outer product matrix by a polyad is not unique.

For example, $(\alpha \mid \gamma{:}[\boldsymbol{a}_1\ \gamma]\ldots\boldsymbol{a}_N)$ generates the same N-dimensional array of numbers as does (1) for any nonzero scalar γ. Finally, a 2-*ad* of the form $(\alpha{:}\boldsymbol{ab})$ is equivalent to the more familiar dyad of the form $\boldsymbol{a}\,\alpha\boldsymbol{b}^T$, and the two will be used interchangeably.

The generalization mentioned above is that all tensors (that exist) of factorable functions possess a natural polyadic structure. Furthermore, the vector factors that comprise the monads of the gradient are the same vector factors which comprise the dyads of the Hessian, the triads of the third order tensor, and so on. This has important computational implications in mathematical programming. It means that once the gradient of a factorable function is computed, a major portion of the work involved in computing higher-order derivatives is already calculated. Consequently, high-order minimization techniques, previously considered computationally intractable, are once again worthy of consideration (Jackson and McCormick 1986).

It should be noted that, by their very nature, the tensors of factorable functions are ideally suited for computation on parallel processing and array processing computers. Few other such ideal applications in numerical optimization are known. Also, it has been shown (McCormick 1985) that all factorable programming problems have an equivalent separable programming representation, and that efficient algorithms (Falk and Soland 1969; Falk 1973; Hoffman 1975; McCormick 1976; Leaver 1984) exist for finding global solutions to these problems. Thus there exists the potential of finding global solutions to factorable programming problems fast and accurately.

The discovery and development of factorable functions and their uses in mathematical programming is credited to McCormick (1974). Since the discovery of these functions, the theory of Factorable Programming has been further developed and refined. Ghaemi and McCormick (1979) developed a computer code (FACSUMT), which processes the functions in a factorable program and provides the interface to the SUMT nonlinear programming code (see Mylander et al. 1971). A preliminary version of this code is described in Pugh (1972).

Further extensions of factorable programming theory were provided by Shayan (1978), who developed an automatic method for computing the mth order of a solution technique that can be evaluated when the functions are factorable by counting basic operations and basic functions, a more accurate measure of efficiency than the popular technique of counting the number of equivalent function evaluation (Miele and Gonzalez 1978).

The natural dyadic structure of the Hessian of a factorable function was exploited by Emami (1978) to develop a matrix factorization scheme for obtaining a generalized inverse of the Hessian of a factorable function. Ghotb (1980) also capitalized on this structure and provided formulae for computing a generalized inverse of a reduced Hessian when it is given in dyadic form. Sofer (1983) extended this last concept further by utilizing the dyadic structure to obtain computationally efficient techniques for constructing a generalized inverse of reduced Hessian and updating it from iteration to iteration.

Another direction was pursued by DeSilva and McCormick (1978), who developed the formulae and methodology to utilize the input to general nonlinear programs in factorable form to perform first-order sensitivity analysis on the solution vector. This was generalized in Jacksonand McCormick (1988), where second order sensitivity analysis methods were developed, with formulae involving third order tensors used to compute second derivatives of components of a local solution with respect to problem parameters.

It is important to understand that the derivative calculations performed in factorable programming are not estimations, but mathematically exact calculations. Furthermore they are also compact, since factored sequences mimic hand calculations. Thus, this technique is different from symbolic manipulation techniques for differentiation, which tend to produce large amounts of code. The techniques used in factorable programming are efficient exploitations of the special structure inherent in factorable functions and their partial derivative arrays. Moreover, while it is true that some symbolic differentiaters also can recognize functions which can be described similarly as a sequence of rules, each of which can be differentiated, the similarity ends there. Such symbolic differentiaters continue to differentiate the rules, without exploiting the polyadic structure of the result (Kedem 1980; Rall 1980; Wengert 1964; Reiter and Gray 1967; and Warner 1975). It is this latter effort which provides

the real value of factorable functions and which therefore separates the two techniques.

Failure-Rate Function

The failure rate at time t of a unit with lifetime density $f(t)$ and lifetime CDF $F(t)$ is defined by the (approximate) probability $h(t)\Delta t$ that a random lifetime ends in a small interval of time Δt, given that

it has survived to the beginning of the interval. For the continuous case, this is formerly written as

$$h(t) = \lim_{\Delta t \to 0} \left[\frac{\Pr\{\text{failure in}(t, t+\Delta t) | \text{survival up to } t\}}{\Delta t} \right] = \frac{f(t)}{1 - F(t)}.$$

The function $h(t)$ is often also called the hazard rate function, the force of mortality, or the intensity rate function.

Farkas' Lemma

Given a matrix $\boldsymbol{A}$ and a column vector $\boldsymbol{b}$, one and only one of the following two alternatives holds. Either: (1) there exists a column vector $\boldsymbol{x} \geq \boldsymbol{0}$ with $\boldsymbol{Ax} = \boldsymbol{b}$, or (2) there exists an unrestricted row vector $\boldsymbol{y}$ for which $\boldsymbol{yA} \geq \boldsymbol{0}$ and $\boldsymbol{yb} < \boldsymbol{0}$. This lemma can be proved by defining appropriate primal and dual linear-programming problems and applying the duality theorem.

Field Analysis

Howard W. Kreiner
Center for Naval Analyses, Alexandria, VA, USA

Introduction

Field analysis is the practice of operations research usually at the place where the operations occur. It uses observations and data from those operations as they are carried out by the people who normally conduct them. Its purpose may be the immediate modification of an unsatisfactory process, or at longer range, the elucidation of the critical steps in the process for further analysis of options and changes—its vital importance to systems analysis lies in this latter alternative.

As the operations under study are real and current, they involve the use of equipment or machines already in place, and the practices of operators who have been trained in their use. Projections of possible future capabilities and alternative training methods are not a major part of the basic data on which the analysis must be based.

Problems that are visible are those that obviously interfere with the smooth functioning of the system. Their solution must make major differences to be considered useful. There is a need to seek a solution that can improve matters by hemibels (about a factor of 3). Anything less may be lost in the noise of the system. In investigating the causes of problems, many of the potential variables will not lie within the control of the operators or the analyst as attempts are made to identify them. The analyst must think in heuristic terms, rather than those of full scientific rigor.

Case studies often are interesting for their problem-solving methodologies, but as the problems differ in detail, such case studies do not fall into clear groupings that can be characterized as the essence of field analysis. The mathematical content of many, if not most field analyses, is simple, usually not beyond the level of undergraduate mathematics. Therefore, it is methods of behavior, thought, and exposition rather than mathematics that truly constitute the methodology of field analysis.

Historical Origins

The term field analysis arose in the earliest activities of operations analysts in the U.S. Navy. The Navy set up the nation's first operations research organization in 1942. It did so because it was engaged with the Germans submarine forces in a battle that was not going well. Forces, doctrine, and tactics that had grown from experience were proving insufficient to defeat the enemy. The people it brought into the operations research organization, however, were civilian scientists with little or no direct experience of

naval operations. There was only the hope that a fresh scientific view of the situation might produce new methods and the means of victory. The hope was based upon successes of operations research in the British effort against the German bombing campaign.

The scientists at first worked with the statistics of combat derived from action reports. They soon found, though, that full understanding of the action reports required that they have closer contact with the operating forces that engaged the enemy and wrote the reports.

To obtain this contact, they sent scientists to the naval commands deployed against the German submarines. Their purpose was to talk directly with the naval officers and men who performed the combat activities, and to the degree possible, to observe at first hand the circumstances of warfare. Initially, their efforts were intended to insure that the scientists at the home office made proper interpretations of the reports and the statistics they derived. As they became more experienced, and as the aims of the operations research progressed toward model development and predictions of effectiveness, the analysts' purposes and roles with the operating forces also broadened. This pattern of visits and later, longer assignments, became known as the field program, and the analysis done by the analysts at the deployed commands, as the field analyses.

At the end of the war, Morse and Kimball (1946) characterized the program's purposes as: (a) direct help to the service units, (b) securing difficult-to-obtain information for the headquarters organization, and (c) providing to the individual analyst the practical education indispensable in avoiding the pitfalls to which the pure theorist may be subject. They also commented on the administrative factors that made for successful field work. They stressed the need for the command receiving the analyst to invite the assignment and to approve the individual. The analyst should be attached to the highest level of the field activity, take assignments from the commanding officer, and make reports at the same level. There should be regular rotation of analysts at the field command, to bring back to the central staff the experience gained in the field.

Morse and Kimball typified the nature of the scientific work of field analysts in six categories:

1. Analytical
2. Statistical
3. Liaison
4. Experimental
5. Educational
6. Publication

At any field assignment station, however, work would not be limited to just one of these categories; the analysts might do all these types of work in some proportion.

The system of field assignments worked well under the pressure and circumstances of the war. Problem areas were of vital urgency. Help from this promising source was generally welcome at the field commands (though there were instances where it took dramatic analytic successes to establish acceptance for the analyst), and in the senior levels of the service. One instance of initial reluctance overcome by analytic success was Steinhardt's development of barriers against South Atlantic blockade runners (Tidman 1984).

At the end of World War II, the postwar successor to the U.S. Navy's Operations Research Groups, the Operations Evaluation Group continued the practice of field assignments and field analyses. Because of a reduction in the size of the group, and because the activities of the Navy's deployed forces also were greatly curtailed, the field assignments were limited to units of the Navy's test and evaluation forces. The start of the Korean War caused an increase in the size of the parent group, and a revival of the assignment of analysts to fleet staffs and combat operational units.

The activities of operations analysts in the field were not limited to the U.S. Navy. The U.S. Army, both ground and air forces (and later, the U.S. Air Force), also formed analytic groups that sent representatives to field forces. Not all followed precisely the same administrative procedures, but the principal purposes of the assignments were paralleled in each case. Postwar, also, these organizations continued the practice, and expanded their field activities as war and other circumstances required.

The first paper published by the *Journal of the Operations Research Society of America* to report on field analysis in a non-military subject was Thornthwaite (1953). Among operations research practitioners used to the military version of the profession, it was a great relief and cause for elation. It showed that there truly was a possibility that the kind of operations research, field analysis, with which they were most familiar in the military services also could

be applied successfully in the non-military world. More than forty years later, the methods it describes are in use in unchanged form at the site where they were developed. Kreiner (1994) revisits Thornthwaite's paper to fill and clarify gaps in its exposition and make explicit the qualities it exhibits as a fine example of field analysis.

Since then, many other examples of good field analyses have appeared in various formats and publications. As remarked above, they generally have been identified primarily by the subject matter of the problem, rather than as examples of field analysis viewed as a separately defined branch of operations research.

Field Analysis in an Era of Systems Analysis

During World War II, there was a very close tie between the work of the military field analyst and that of the headquarters staff. The initial motivation for creating a field program was exactly that close tie; headquarters staff interest was directed almost exclusively to the day-to-day problems and success of the deployed forces. The guiding principles of operations research formulated in the postwar summaries were identical for the field and the headquarters analyses. In the years since the U.S. creation of formal operations research organizations, this has continued to be true when war dominates the activities of the military services from combat forces to the highest command levels. It also was true to a large extent in peacetime immediately after World War II. The field analysts' assignments were to operational test and evaluation commands concerned with individual combat systems whose procurement decisions depended upon those test results.

The tie has become less close in the military services with the trend to high-level systems analysis at headquarters operations research groups. The increasing complexity and interaction of systems, their cost, and the very long development time for newer combat systems made headquarters command levels more concerned with future systems. It elevated the procurement process to the strategic level, and concentrated the attention of the central military staff on long-term budgetary matters. Headquarters operations research groups necessarily altered their point of view as well. Field commands, however, retained their concern with training their forces to operate and integrate systems already in use. The problem of divergence of interest between the field analyst and the headquarters group did not disappear entirely even during the Vietnam War and the Gulf War. Those wars were limited in character, and the Cold War and the larger threat of nuclear war still tended to dominate budgetary and strategic interests.

For the field analyst, however, the main subjects for analysis continue to be the operations involving the use of equipment already designed, developed, produced and distributed. If the equipment is not quite at this stage, it is at least far enough along in the process to justify operational testing and tactical development. The field analyst's concerns in commercial, nonmilitary government or military activities, are with the practices for employing, and with the training of people to make the equipment and its use as effective and efficient as possible. To the extent that a central group, commercial or military, arranges to provide field analysts and uses the field assignments both for training analysts and to insure realism in describing current and possible future operations, it shares the same objectives. It can be difficult for a central group, however, to balance priorities for attention to field analysis with those of important future systems studies.

A Continuing Role for Field Analysis

Compared with the circumstances at the time operations research first was introduced, there now are greatly improved methods for data collection, and greatly enhanced ability of computers to model interactions of equipment and people. There have been theoretical developments in operations analysis and problem-solving techniques that are reported worldwide in the journals of numerous operations research societies. Yet, if operations research retains its focus on problem solving in operations, there continues to be an important mission for analysis to be done at the point, and in direct observation of the operations under study. This is particularly important when large-scale modeling of operations is a major means of analysis in the headquarters groups. Both during the building of models and afterwards, it can be extremely difficult to review and test all the assumptions and possible omissions of critical factors.

Morse and Kimball made the point that it was a strength of the operations analyst to think in hemibels, to seek improvements in operations that multiply effectiveness by a factor of three or more. This differs qualitatively from the notion of improvements in small increments. The field analyst is in a unique position to see opportunities for hemibel improvements; the analyst she can observe at first hand the factors that control the operation. If there are differences between what has been assumed about those factors and what actually is occurring, the analyst can document them, measure them, and propose changes to exploit the differences in favor of improved understanding, and ultimately, improved operations.

Kreiner (1992) noted an example in radar detection of small targets, in which the field analyst identified assumptions about the statistical character of radar returns. Current data at the field site proved the assumptions to be faulty. Ultimately, the original theory had to be abandoned, and alternate methods devised. Kreiner (1992) also reports on an analytical look at an operational plan that revealed unstated, unconsidered, and erroneous assumptions. The plan assumed static, fixed naval forces, assured of long warning times of possible attack, and manned by pilots expected to fly missions they considered suicidal, although safer, equally effective alternatives were available. When the analysis made these assumptions explicit, the entire plan had to be rewritten.

The field analyst also is in a better position to examine the choice of measures for evaluating operational effectiveness than any counterpart located at headquarters. Larson (1988), though not assigned as a field analyst, nevertheless functioned as one as a customer of a queueing system when he attempted to buy a bicycle for his daughter. In his job as an analyst of such systems, he had accepted the standard measure of average customer waiting time, and the goal of minimizing this measure. As an actual customer, however, he discovered a major deficiency in the measure, a lack of perceived fairness to the individual customer. His article explores the ways to make the queues and the measures of their performance more responsive to the broader interpretation of effectiveness.

The field analyst has another important requirement, the need to develop results in terms that serve primarily the purposes of the customer. Scientific journals, including those of the operations research societies, require presentations that are concise, rigorous, and of enough generality to be of interest to a spectrum of fellow professionals. The field analyst has another audience entirely, that is, the analyst must initially establish a role as a participant in the operations analyzed, lest the activities lack credibility. As an outsider, the analyst may not gain access to the intimate, seemingly tiny details that make up the operation. The field analyst similarly must make reports in operational terms. The audience will classify problems in their own terms, rather than by the methodologies used to solve them. The report must make the same close connection with the immediate problem. It may be important to the analyst to innovate in methodology. The client wants only assurance that the methodology addresses the correct aspects of the problem, that the analyst is competent to apply it, and that the results enable them to improve their operations.

Financial Engineering

John R. Birge
The University of Chicago, Chicago, IL, USA

Introduction

Financial engineering refers to the application of scientific methods to the design, analysis, and implementation of financial products and services. The applications within this domain extend from trading at the nano–second timescale to informing investment decisions that can stretch across centuries. Much of financial engineering can be aligned with classical methods in operations research, including the following functions: (i) asset–pricing, particularly for derivatives, relying heavily on stochastic modeling and simulation; (ii) portfolio optimization and asset–liability management, using various methods from optimization; (iii) trading and hedging, often involving dynamic programming and control techniques; and (iv) risk management, involving many of the principles of reliability theory. The following sections describe basic applications within each of these areas and the associated relevant operations research methods.

Asset–Pricing and Derivative Evaluation

Much of the interest in financial engineering began with the widespread use of the Black–Scholes–Merton formula for option pricing following the publication in the academic literature of their seminal papers describing this pricing method (Black and Scholes 1973; Merton 1973a), although the concepts appeared earlier starting with Bachelier (1900). The formula applied directly to the basic (European) call and put options, which provide the buyer the right (but the obligation) to purchase (for a call) or sell (for a put) an asset (e.g., a share of a stock) at a fixed price (called the strike or exercise price) at a future expiration (or maturity) date. Extensions of this methodology have been applied to many other types of derivative securities that derive their value from the price of a set of intrinsic (or underlying) assets over some specified period of time. They are also referred to as contingent claims since their payoff depends on some unknown outcome.

The basis for this and other asset–pricing models is an application of linear programming duality theory, known as the Fundamental Theorem of Asset Prices (Harrison and Pliska 1981), which states that either the securities market admits an arbitrage opportunity to earn a non–negative risk–free payoff in all future states (and a positive payoff in some state) without any initial investment or there exists a price or weighting on each future state that in expectation yields the current market price for any security in the market. Most pricing formulae can then be derived from assuming that the market does not allow arbitrage (at least for any extended period of time) and that the prices of securities not currently in the market (or whose market prices might be stale or suspect) can be evaluated from the prices of other securities. If markets are complete in representing all possible future cash flows, then prices should be unique in this framework, but even if the market is incomplete, an assumed absence of arbitrage can imply bounds on prices that are consistent with the market, e.g., settings with physical assets such as energy and commodities (Staum 2008).

As an example of the asset–pricing theorem, suppose an asset has future payoff $\mathbf{S}$ distributed as S_i with probability p_i at time $T = 1$ for $i = 1, \ldots, N$ for N future states of the market. (Continuous future cash flow distributions can be modeled in the same way with a more general linear programming model).

Absence of arbitrage implies that no one in the market can purchase or sell an equivalent cash flow to **S** in such a way that always produces non–negative and, with some positive probability, positive surpluses. This result means, in particular, that a buyer cannot sell or purchase at unit price s an equivalent cash flow to a share x of **S** with y in other assets (with current prices f and future prices F_i in state i) and risk–free investing (B at a risk–free rate r that yields $e^r B$ in the future with certainty) and obtain positive future cash flows, i.e., the maximum expected value of a future position for buying a share x with no losses is zero:

$$0 = \max_{x,y,B} \sum_i p_i (S_i x - F_i^T y - e^r B) \tag{1}$$

$$\text{subject to} - sx + f^T y + B = 0, \tag{2}$$

$$- S_i x + F_i^T y + e^r B \leq 0 \, \forall i, \tag{3}$$

$$0 \leq x \leq 1, \tag{4}$$

where the superscript "T" denotes the transpose operator. The feasibility of the dual problem when the value of (1)–(4) is bounded above (no arbitrage) then provides the Fundamental Theorem of Asset Pricing. The dual is:

$$0 = \min_{\lambda \leq 0, \pi \geq 0, \rho} \rho \tag{5}$$

$$\text{subject to} \sum_i S_i p_i + \lambda s + \sum_i \pi_i S_i - \rho \leq 0, \tag{6}$$

$$- \sum_i F_i p_i - \lambda f - \sum_i \pi_i F_i \geq 0, \tag{7}$$

$$- e^r - \lambda - \sum_i \pi_i e^r = 0. \tag{8}$$

For an optimal dual solution, $(\lambda^*, \pi^*, \rho^*)$, $\lambda^* < 0$ (where the strict inequality follows from (8)), $\pi^* \geq 0$, and $\rho^* = 0$;

$$s \leq \sum_i S_i (p_i + \pi_i^*)/(-\lambda^*); \tag{9}$$

$$f = \sum_i (p_i + \pi_i^*) F_i / (-\lambda^*); \tag{10}$$

$$- \lambda^* = e^r \left(1 + \sum_i \pi_i^* \right). \tag{11}$$

If a strictly positive $x^* > 0$ solves (1)–(4), then the inequality (9) must be tight by complementarity. This condition would follow if the cash flow in S_i can be reproduced perfectly by $F_i^T y$ and $e^r B$ with $f^T y + B = sx$, which holds if the market is complete. This then implies

$$\begin{aligned} s &= e^{-r} \sum_i s_i \frac{p_i + \pi_i^*}{1 + \sum_i \pi_i^*} \\ &= e^{-r} \sum_i s_i \frac{p_i + \pi_i^*}{\sum_i (p_i + \pi_i^*)} = e^{-r} \sum_i s_i q_i^*, \end{aligned} \tag{12}$$

where $q_i^* \geq 0$ and $\sum_i q_i^* = 1$, i.e., $\{q_i^*\}$ define a probability distribution (called a risk–neutral or equivalent martingale measure) on S_i for the price s, which is also consistent with the other assets so that $f = e^{-r} \sum_i F_i q_i^*$. In a complete market, everything could be priced this way with the same probabilities; or state prices as in the general equilibrium of Arrow and Debreu (1954). If the market is not complete, then a range of prices $s \in [s_L, s_U]$ would be consistent with a cash–flow that is not completely represented in the market.

The basic principles of replicating a cash flow from existing market instruments with an assumption of no arbitrage or of using a consistent set of prices underly most asset–pricing applications. The following section on portfolio optimization discusses asset pricing theories — the Capital Asset Pricing Model (CAPM) and Arbitrage Pricing Theory (APT) — based on market agents' preferences, but the basic consequences of consistent prices with no arbitrage opportunities account for much of actual pricing practice in financial engineering; see Derman and Taleb (2005) for a discussion of such practical approaches to pricing.

To see the implications of consistent prices, consider the pricing of a simple European call option to purchase a share of a non–dividend–paying stock at time T at a price K. In a complete market with no arbitrage, the Fundamental Theorem of Asset Pricing implies that the value of the call (or premium) C_0 at time $t = 0$ is the present value of the expected future

cash flows using the consistent (risk–neutral or equivalent martingale) probability density q_T on future states at time T that exists from the theorem. Since the payoff of the call option is $(S_T - K)^+$ when the price of a share is S_T at T, the theorem implies

$$C_0 = e^{-rT} \int_0^\infty (S_T - K)^+ q_T(S_T) dS_T. \tag{13}$$

The next step then is to determine the appropriate distribution represented by q_T.

For the distribution of S_T given by q_T, if the risk–free rate r is constant, the no–arbitrage property implies that from any time t when the share has price S_t, the conditional expectation of S_T under q_T discounted back to t must be S_t, i.e.,

$$S_t = \int_0^\infty e^{-r(T-t)} S_T q_T(S_T) dS_T, \tag{14}$$

which is the martingale property of the process $Y_\tau = e^{-r\tau} S_\tau$, such that $Y_s = E_Q(Y_\tau | Y_s)$ for any $\tau \geq s$, where Q represents the probability distribution implied by the no–arbitrage condition at each time τ. This means that, under Q, the prices of all non–dividend paying assets increase at the same exponential rate r. Now, if price changes are the result of random arrivals of new information that push prices up or down in a way that does not change in terms of relative increases or decreases in price over time, i.e., the price changes have the features of a random walk, then, as the arrival rate of information increases, the prices should follow geometric Brownian motion (GBM). Assuming no dividends, a constant risk–free rate, and no changes in the information arrival rate or its effects (which keeps the volatility in the process constant), prices under the distribution given by Q would obey the following stochastic differential equation:

$$dS_t = rS_t dt + \sigma S_t dW_t, \tag{15}$$

where σ is the volatility of the price process and W_t is a standard Brownian motion. If S_t follows the dynamics of (15), then $\log S_T - \log S_0$ is normally distributed with mean $(r - \sigma^2/2)T$ and variance σT, i.e., S_T is log–normally distributed under Q with mean $e^{rT} S_0$ and variance $e^{2rT}(e^{\sigma^2 T} - 1) S_0^2$. This result leads to the Black–Scholes–Merton (BSM) option pricing formula (Black and Scholes 1973; Merton 1973a) by evaluating the integral in (13) with q_T as the log–normal density:

$$C_0 = S_0 \Phi\left(\frac{\log(S_0/K) + (r + \sigma^2/2)T}{\sigma\sqrt{T}}\right) - e^{-rT} K \Phi\left(\frac{\log(S_0/K) + (r - \sigma^2/2)T}{\sigma\sqrt{T}}\right), \tag{16}$$

where Φ is the standard normal cumulative distribution function.

The formula in (16) can be derived in many ways. One approach is to start with the physical model of the dynamics of the price S_t and of the call option value C_t and to note that C_t can be dynamically replicated by continuously adjusting a fraction of S_t and a risk–free bond (which assumes that trading is frictionless or has no transaction cost). An equivalent approach is to model a random walk in prices directly, to solve a dynamic program recursion that gives the fraction to hold of S_t and the risk–free bond at each point to replicate the option, and then to take the limit of this value as the discretization interval reduces to zero. Each approach yields the same formula and the observation that the price does not depend on investors' risk attitudes.

The significance of the BSM formula is that the option price can be found without making an assumption on risk preferences. The actual physical distribution of S_T would be different from that given by q_T if the market includes a non–zero risk premium, but the evaluation can be done under q_T without deciding what that premium should be. The formula does, however, rely on several assumptions, such as a constant risk–free rate, constant volatility, the log–normal density at any point in time, and the completeness of the market to ensure the existence of the equivalent risk–neutral distribution. While much of the work in financial engineering considers deviations from these assumptions, the basic framework provides an efficient description of prices and a methodology for checking price consistency.

From the formula in (16), European put option prices (i.e., the option to sell at a given price) can be found again with a no–arbitrage principle of put–call parity on non–dividend paying assets that, since the payoff of a call minus a puton the same asset at the

same exercise price K and maturity T is the same as the payoff of the asset minus a risk–free bond paying K at T, the present values must be the same as well, i.e.,

$$C_t - P_t = S_t - e^{-r(T-t)}K, \tag{17}$$

where r is the risk–free discount rate (from t to T). Other relationships can be found to bound prices of options at different exercise prices and maturities.

A main emphasis of financial engineering is to determine prices of different types of derivatives and to relax some of the assumptions involved in (16), e.g., see Hull (2011). In general, analytical formulae for payoffs at a fixed point in time can be found under the basic assumptions plus a variety of extensions (some of which require additional assumptions or information on risk preferences to obtain the formulas) including dividends; stochastic risk–free rate; stochastic volatility; different price dynamics, including time–varying drift, non–linear volatility, processes with jumps, and general Lévy processes (Carr et al. 2003; Cont and Tankov 2004; Wu 2008); and different payoff structures, including different linear payoff structures, payoffs on multiple assets (including different currencies and interest rates), 0–1 (digital options), and other non–linear payoff structures, including bonds and convertible bonds.

In addition to derivatives that depend on asset values at a fixed point in time, other derivatives can depend on entire sample paths of prices. Basic examples of such path–dependent options are American options that are identical to the European call and put options described here except that they can be exercised at any time until maturity. They effectively then have two components, the European option value plus a premium for early exercise. In some cases, such as an American call option on a non–dividend paying under the assumptions for the basic BSM model, the early exercise premium is zero, but, in other cases, including the simple American put option, the early exercise premium is positive and can be difficult to compute. These options do not have simple analytical formulas for evaluation and require an approximation or numerical method.

Other path–dependent options include Asian options that depend on the average asset price until maturity, barrier options that depend on whether the asset price ever crosses a threshold (or thresholds), and lookback options that depend on the extreme (minimum or maximum) prices achieved by the option. In these cases, Laplace transforms can yield analytical expressions for these derivatives that can then be inverted (Craddock et al. 2000; Kou 2008a, b). Other analytical approaches include spectral methods that, for example, yield formulas for Asian option values (Linetsky 2004, 2008), and fast Hilbert transform methods (Feng and Linetsky 2008).

In more general and complex settings, pricing can require either numerical solutions of systems of partial differential equations (PDE) or methods based on Monte Carlo simulation. For PDE methods, basic methods in a financial context appear in Tavella and Randall (2000) and approaches appropriate for more general conditions are given in Feng et al. (2008). For Monte Carlo methods, Glasserman (2004) provides a comprehensive review of this methodology's use in all areas of financial engineering.

Portfolio Optimization and Asset–Liability Management

The discussion of the Fundamental Theorem of Asset Pricing in the previous section on pricing applications relied on the absence of arbitrage, i.e., the inability to construct a portfolio of market securities to obtain risk–less profits relative to any given market security. In practice, portfolios include varying levels of investment risk in exchange for a premium on the return of the portfolio. A goal in portfolio construction is then to find combinations to form an efficient portfolio that obtains the lowest possible level of risk for a given return.

Markowitz (1952) formulated this problem of finding an efficient portfolio as a quadratic program to minimize the variance of portfolio returns over a fixed time period subject to meeting a constraint on the expected return over that period. If the proportion of wealth invested in asset i is x_i for $i = 1, \ldots, n$, the expected return of asset i is r_i with $\mathbf{r} = (r_1, \ldots, r_n)^T$, and the covariance between returns on assets i and j is σ_{ij}, where $\sigma_{ii} = \sigma_i^2$, the variance of the return on asset i, with $\mathbf{\Sigma} = [\sigma_{ij}]$, then the Markowitz mean–variance model with return target level r_0 isto find $\mathbf{x} = (x_1, \ldots, x_n)^T$ and portfolio variance $v(r_0) =$

$$\min \mathbf{x}^T \mathbf{\Sigma} x \tag{18}$$

$$\text{subject to } \mathbf{r}^T\mathbf{x} \geq r_0, \tag{19}$$

$$\mathbf{e}^T\mathbf{x} = 1, \tag{20}$$

where $\mathbf{e}$ is a column vector containing all 1's. The set of solutions $(r_0, v(r_0))$ defines the mean–variance efficient frontier of portfolios. Much effort in financial engineering involves finding efficient portfolios using variations on the model in (18)–(20). The basic extensions of the mean–variance model include variations in the utility (which is quadratic here) or in the assumptions on the distribution of returns. The objective represents a wide–range of risk preferences or utilities if returns are normally distributed (since the return distribution of the portfolio is normal as well and is determined by its mean and variance), but if the distribution of returns is not normal, then the quadratic form of preferences appears more restrictive (although it could still be approximately correct). Any implementation of (18)–(20) also requires estimates of Σ and $\mathbf{r}$, which can present some difficulties. Some of the work on portfolio optimization in financial engineering includes compensation for estimation errors, as discussed in Kan and Zhou (2007).

Other approaches consider different utility functions, which are particularly relevant for non–normal distributions. One approach assumes that $\mathbf{\Sigma}$ and $\mathbf{r}$ are only known to be within some range (uncertainty set). This approach is called robust portfolio optimization (Fabozzi et al. 2007; Cornuéjols and Tütüncü 2007). Other alternatives consider different utility forms and non–Gaussian return distributions.

An implication of the mean–variance model is that, if everyone in the market believes the assumptions leading to (18) and chooses an efficient portfolio, then, in equilibrium, the price of each asset in the market simply reflects that asset's contribution to the portfolio's risk. The result is the Capital Asset Pricing Model (CAPM), pioneered by Sharpe (1964) and Lintner (1965), which states that, in an equilibrium, if the market corresponds to an efficient portfolio with expected return r_m and variance on return σ_m^2, then the expected return of any asset i is given by:

$$r_i = r_f + \beta_i(r_m - r_f), \tag{21}$$

where r_f is the risk–free rate and $\beta_i = \sigma_{im}/\sigma_m^2$.

Many of the pricing models in financial engineering use the CAPM as a basis for analysis (although not necessarily as a direct pricing method). Empirical tests of the CAPM suggest that prices may not completely reflect (21) using standard proxies for the market return such as a stock index, but it is not clear how to obtain or measure r_m, the return on the entire market (Fama and MacBeth 1973; Ferson 2003). The market portfolio may, however, be explained by multiple risk factors such as an index and the differences in portfolios of firms based on their size and leverage (Fama and French 1993). This version would suggest that

$$r_i = r_f + \mathbf{b_i}^T\lambda, \tag{22}$$

where λ is the expected excess (i.e., above r_f) returns on the relevant set of risk factors $\mathbf{b_i}$. This conclusion on prices also arises from the Arbitrage Pricing Theory (APT) of Ross (1976) that does not require all investors in the market to follow a mean–variance strategy (but that relies on the availability of many assets). In any case, the relationship in (22) can provide a pricing tool for financial engineering, and also an alternative for constructing optimal portfolios, since the large estimation requirements in determining Σ and $\mathbf{r}$ are replaced with a reduced set for finding the $\mathbf{b_i}$ coefficients. In addition, a financial engineer may have a particular view about a certain asset such that $r_i - r_f = \alpha_i + \mathbf{b_i}^T\lambda$ for some non–zero α_i. In that case, these views can be combined with the data estimates in $\mathbf{b_i}$. A consistent methodology for this is the approach in Black and Litterman (1992), which imposes views on top of a prior based on the CAPM to obtain a posterior distribution on returns.

Another difficulty in the form of (18) is that this model is purely static, while portfolios change dynamically over time. A dynamic version of the mean–variance portfolio considers the utility of a portfolio that is continuously adjusted over time. If the prices of the assets all follow a process like (15) and the drift is r_i for asset i and Brownian motion W_i given with covariances Σ, then the value of a portfolio beginning at time 0, which maintains a fraction x_i in asset i has a value at time T given by

$$w_T = e^{(\mathbf{r}^T\mathbf{x} - \mathbf{x}^T\Sigma\mathbf{x}/2)T + \sqrt{(\mathbf{x}^T\Sigma x)T}Z}, \tag{23}$$

where Z is a standard normal random variable. For power constant–relative risk aversion, the utility

function has the form w^γ/γ for some $\gamma > 0$ (or $log(w_T)$ if $\gamma \to 0$), and the objective function becomes: $E[w_T^\gamma/\gamma] = e^{\gamma(\mathbf{r}^T\mathbf{x} - \frac{1-\gamma}{2}\mathbf{x}^T\Sigma\mathbf{x})}/\gamma$. The utility–maximizing solution in this case is then again a mean–variance efficient portfolio. If an $(n+1)$st risk–free asset is included and the returns given as excess above the risk–free rate, with $x_{n+1} = 1 - \sum_{i=1}^n x_i$, effectively removing the constraint for $\sum_{i=1}^n x_i = 1$, the solution is given by $\mathbf{x}^* = (x_1^*, \ldots, x_n^*)^T = \frac{\Sigma^{-1}\mathbf{r}}{1-\gamma}$ with $1 - \sum_{i=1}^n x_i$ invested in the risk–free asset. This dynamic portfolio can then yield an inter temporal CAPM; see Fama (1970); Merton (1973b); Constantinides (1982); and Duffie (2003) for justification of CAPM pricing in fairly general settings.

In practice, portfolio optimization requires consideration of additional issues such as transaction costs and delays, limited liquidity, and trading restrictions, such as lock–in and vesting periods. These practical considerations complicate models beyond the simple form in (18) and require dynamic considerations over time. In those cases, financial engineering may provide control rules (typically tested with Monte Carlo simulation) or more general stochastic optimization formulations to find $x_t, t = 1, \ldots,$ where $x_t \in X_t$ (some feasible set that may depend on state realizations) to maximize (given x_0)

$$\sum_{t=1}^{\infty} E[f_t(x_{t-1}, x_t, s_t)], \tag{24}$$

where f_t is the utility function, s_t represents a state vector that is revealed over time and the decisions x_t can represent investment, consumption, and trading activity, such as allocations in each asset or asset class, purchases and sales of assets, consumption, and commitments for future sales or purchases. A variety of methods can then be used to solve these problems that take advantage of structural properties of the models; see the summary in Birge (2008).

Trading and Hedging

The dynamic model in (24) represents the general form of models that can also be used for trading assets and hedging their values over time. When the frequency of trading increases, approximations are generally required either in terms of the model parameters (such as the objective) or the range of possible controls. Examples described in this section focus on shorter time horizons than those for the longer–period asset allocation decisions in the previous section. These situations include identifying and exploiting arbitrage opportunities (or market inefficiencies) across markets and securities, minimizing slippage (excess transaction costs) to execute an order, and maintaining a risk–neutral position for a derivative security exposure.

The problem of identifying an exploitable arbitrage requires the rapid consideration of what is often a large number of prices and quick execution of the proposed actions. A simple form of these trading examples might include the comparison of the prices of constituent prices in an index with a security representing the index. Program trading often refers to the practice of automatically identifying discrepancies between these two quantities and executing trades to take advantage of the difference.) As a more computationally–focused application, consider a set of European options (e.g., on an index) on the same underlying, all with the same maturity. Suppose the call options have a highest bid price b_i^c with v_i^c contracts bid at that price and a lowest offered or ask price a_i^c with u_i^c contracts at that price, and suppose corresponding put options with bid prices b_i^p with v_i^p contracts and ask prices a_i^p with u_i^p contracts, all at strike prices, $K_i, i = 1, \ldots, n$. The bid and offered prices should reflect put–call parity and any other relationship implied by the absence of arbitrage, but occasionally trading in each option can lead to inefficiencies that can be exploited (at least to the depth of the orders at bid and offered prices). A linear program can be used to discover these pricing anomalies. Let $x_i^{c\pm}$ and $x_i^{p\pm}$ represent the number of call and put option contracts, respectively, with exercise K_i to trade, where the superscript $+$ indicates a purchase and $-$ indicates a sale. Net borrowing is B at rate r (which can be positive or negative here but could also correspond to two variables with different rates for borrowing and lending). The objective is to maximize payoffs at maturity subject to constraints ensuring no losses:

$$\max \sum_{i=1}^{n+1} \pi_i \tag{25}$$

subject to

$$\sum_{i=1}^{n} (b_i^c x_i^{c-} + b_i^p x_i^{p-} - a_i^c x_i^{c+} - a_i^p x_i^{p+}) - B = 0; \tag{26}$$

$$\sum_{i=1}^{n} (-x_i^{p-} + x_i^{p+}) \geq 0; \tag{27}$$

$$\sum_{i=1}^{n} (-x_i^{c-} + x_i^{c+}) \geq 0; \tag{28}$$

$$\sum_{i=j}^{n} (-(K_i - K_j)x_i^{p-} + (K_i - K_j)x_i^{p+}) +$$

$$\sum_{i=1}^{j} (-(K_j - K_i)x_i^{c-} + (K_j - K_i)x_i^{c+}) + Be^{rT} \geq \pi_i;$$

$$j = 1, \ldots, n; \tag{29}$$

$$0 \leq \pi_i; 0 \leq x^{c-} \leq u_i^c; 0 \leq x^{c+} \leq v_i^c; \tag{30}$$

$$0 \leq x^{p-} \leq u_i^p; 0 \leq x^{p+} \leq v_i^p. \tag{31}$$

Constraints (26) balance cash at origination of the trade. Constraints (27) and (28) ensure no losses outside the range of the exercise prices of options in the market. Constraints (29) give the net proceeds at each exercise price. If a positive objective (25) can be attained, then trading at the current market conditions produces a risk–less surplus at maturity (although the trade is more likely to be un–wound before maturity when the bid and ask orders return to equilibrium).

Pure arbitrages, as when (25) has a positive value, are rare in liquid markets and require rapid execution before additional orders enter the market or previous orders are withdrawn. More common arbitrages are statistical in nature and depend on identifying when current prices depart from an historically valid statistical relationship among prices. Identification of these opportunities may also involve optimization to recognize the strength of the relationship and the departure from the historical conditions and to design a trading strategy that maximizes an objective that may involve risk adjustment.

The identification of patterns or information not yet absorbed in terms of price movements by the market over longer time scales leads to longer–term trading requirements for purchases and sales of varying numbers of assets. When these numbers are large relative to the market size, placing a market order for the full number of shares can have a significant effect on the price and add to the transaction or execution cost (a phenomenon known as slippage). Optimization methods can also be used to minimize slippage by breaking an order for a large number of shares into smaller orders that are submitted sequentially.

Models for optimally choosing these trade sizes balance the price impact of execution with the risk over price changes in delays in completing the execution; examples are given in Bertsimas and Lo (1998) and Almgren and Chriss (2000). In general, these models use a dynamic program, with some approximation. For example, suppose the goal is to buy a total of $s_0 = \sum_{t=1}^{T} s_t$ shares with purchases $s_t \geq 0$ at times $t = 1, \ldots, T$, where the purchase price $p_t(s_t, p_t^-)$ is a function of the number sold s_t and the (ask) price p_t^- immediately before the tth transaction, and the objective is an additive (convex for risk–averse minimization) function, with

$$V_1(p_1^-, s_0) = \min_{s_1, \ldots, s_T \geq 0 : s_0 = \sum_{t=1}^{T} s_t} E\left[\sum_{t=1}^{T} u_t(p_t s_t)\right].$$

The Bellman equation for this dynamic program is

$$V_t(p_t^-, s) = \min_{s_t} \{u_t(p_t(s_t, p_t^-)s_t) + E[V_{t+1}(p_{t+1}^-, s - s_t)|p_t, s_t]\} \tag{32}$$

with boundary condition, $V_T(p_T^-, s) = u_T(p_T(s, p_T^-)s)$. Note that the price dynamics and value function in the future may include some effect of the order size at time t as well as the last price at t. The state space could also be enlarged to include more order book information. With a model of the effect on prices of differently sized orders at different points in time and a model of price dynamics, the dynamic program can be solved to obtain an optimal (with respect to the model) policy.

Another trading function of financial engineers is to maintain a hedging position for a trader with a net position in a given derivative, e.g., either because the trader is a market maker in an exchange–traded

product (and is, therefore, obligated to accept a fraction of the trades within some market responsibility) or has sold an option over–the–counter to a buyer. Much of this trading involves balancing the changes in values from long and short positions using the derivatives of the option prices with respect to the underlying (called delta hedging), but the general optimization framework in (25)–(31) can also be used to minimize the cost in maintaining hedged positions so that net positions do not vary as market conditions change.

Risk Management

Risk management is another broad category of financial engineering practice that generally refers to identifying, analyzing, and controlling the impact of uncertain conditions on financial performance. The types of risks that can affect this performance include:

- Market risk, which generally refers to changes in the prices of assets traded in the market;
- Credit risk, which refers to the likelihood of an economic agent's not fulfilling a financial obligation, such as repaying a loan;
- Liquidity risk, which is sometimes paired with market risk and refers to uncertainty in the depth (or accessibility) of a market for an asset;
- Operational risk, which refers to the risks in executing a process, such as a trade, as intended;
- Behavioral and environmental risk, which is used here to refer to risks not captured in the other areas, such as the prepayment risk of a mortgage loan due to customer choice, changes in mortality affecting the liabilities of a pension fund, changes in the demand for electricity due to weather conditions, and the risk of a regulatory change affecting the tax treatment of an asset;
- Model risk, which is used as another broad category to refer to the risk in basing actions on a model that does not adequately reflect reality.

Comprehensive treatments of the financial engineering applications in these areas appear in McNeil et al. (2005) and, particularly for credit risk, in Duffie and Singleton (2003) and Bielecki and Rutkowski (2004).

The general use of derivatives and optimal asset allocations is often for the purpose of managing risks, such as a firm's exposure to interest rate movements or the exposure of a pension fund to changes in the value of assets and liabilities. The general approaches described in the previous sections can then be used in those circumstances. Other risk exposures focus on the reliability of other market participants. An example of these different types of exposures is the exposure of a bank to credit risk in the form of defaults on loans.

The bank must maintain reserve funds as economic capital to cover losses in the event of defaults. Consider a simple example with n equally–sized loans such that upon default each results in a loss (or loss given default) of L. The bank wishes to reserve sufficient economic capital C to cover all losses until time t with some confidence levelα. Alternatively, the bank requires that no loss greater than C occurs with probability greater than $1-\alpha$ (or C is the α–level Value–at–Risk (VaR) for this portfolio of loans).

The presentation here frames this requirement in terms of reliability theory; see Barlow and Proschan (1975) for fundamentals of reliability theory and D'Amico et al. (2005) for an additional view of loan portfolios from this perspective. In this framework, the bank's loan system fails if C/L or more of the n loans default. This defines a k–of–n system (with $k = \lceil C/L \rceil$). If the state of the system is given by the structure function, $\phi(x, \lceil C/L \rceil, n)$, where $x = (x_1, \ldots, x_n)$ are indicators for the functioning of each loan, then

$$\phi(x,\ \lceil C/L \rceil, n) = 1\left\{\sum_{i=1}^{n} x_i \geq \frac{C}{L}\right\}, \qquad (33)$$

where $1\{\cdot\}$ denotes the indicator function. Now, let $X_i(t)$ be the random variable defined by $X_i(t) = 1$ if the default time T_i of loan i satisfies $T_i > t$, and $X_i(t) = 0$ otherwise. The capital decision is then to find

$$C = \min_{C} \{C | E[\phi(X,\ \lceil C/L \rceil, n)] \geq \alpha.\} \qquad (34)$$

Calculating the reliability depends critically on the correlations between components of X. Vašiček (1987) gave a method for computing $\mathrm{E}[\phi(X, k, n)]$ that is consistent with a CAPM model. This formula assumes that each loan is the debt obligation of an asset with future values consistent with a GBM from a homogeneous set with a uniform correlation ρ between the asset values of any pair of assets.

If each loan in this setup has an equal probability p of defaulting by time t, then

$$\mathrm{E}[\phi(X,k,n)] = \sum_{l=k}^{n} \binom{n}{l} \int_{-\infty}^{\infty} \Phi\left(\frac{\Phi^{-1}(p) - \sqrt{\rho}u}{\sqrt{1-\rho}}\right)^{l} \left[1 - \Phi\left(\frac{\Phi^{-1}(p) - \sqrt{\rho}u}{\sqrt{1-\rho}}\right)\right]^{n-l} d\Phi(u). \tag{35}$$

The limiting distribution on $k = n\theta$ for some fraction θ of all loans as $n \to \infty$ is then

$$\lim_{n\to\infty} \mathrm{E}[\phi(X, n\theta, n)] = \Phi\left(\frac{\sqrt{1-\rho}\Phi^{-1}(\theta) - \Phi^{-1}(\theta)}{\sqrt{\rho}}\right). \tag{36}$$

The formulae in (35) and (36) are useful in extending results for k–of–n systems from standard formulas for independent failures to those with a specific form of correlation, but they require assumptions that are met by few (if any) loan portfolios. They also can be used (with appropriate change of the probability distributions to reflect a risk premium) in computing the value of loan portfolio derivatives, such as credit default obligations. Practical financial engineering implementations in these contexts should, however, involve more detailed analyses to include differences from the simplifying assumptions for (35) and (36). These extensions can, for example, employ Monte Carlo simulation to capture the characteristics of each loan and their relationships.

In this model, the idiosyncratic components and default correspond to a first passage time of the asset below some level, as in the model of default of Merton (1974), but perhaps not exactly equal to the sum of obligations. Extensions of this model form the basis for the methodologies used by Moody's KMV and RiskMetrics Group in their commercial applications.

Concluding Remarks

Methods from operations research are widely applied in financial engineering, with the main areas overviewed here. The topics described illustrate how different techniques from stochastic modeling, optimization, dynamic systems, control, and reliability all contribute to financial engineering practice.

Introduction

Over the last half-century, a strong relationship between operations research (OR) and finance has

developed, resulting in a large and rapidly growing literature. Although most applications have been of OR techniques to finance, finance problems have also stimulated the development and refinement of OR techniques.

Finance problems, and especially those relating to financial markets, are particularly well suited to analysis using OR techniques. These problems are generally separable and well defined, have a clear objective (often to maximize profit or minimize risk), and have variables which are quantified in monetary terms. The relationships between the variables in finance models are usually stable and well defined, so that the resulting OR model is a good representation of the problem. As there are few concerns about human behavior ruling out the implementation of some solutions, the solutions produced by the analysis can usually be implemented. In addition, large amounts of data, both historic and real-time, are readily available and can be used in OR models. Some finance problems involve very large sums of money, so that even a very small improvement in the quality of the solution is profitable to implement.

This review describes the application of OR to problems in the analysis of financial markets (e.g. the markets for debt, equity and foreign exchange markets and the corresponding derivatives markets). A more extensive analysis of OR in financial markets appears in Board, Sutcliffe and Ziemba (2003). For a review of the application of OR to other areas of finance, such as: the management of the firm's finances, working capital management, capital investment, multinational taxation, and financial planning models (such as those developed for banks), see Ashford, Berry and Dyson (1988).

Portfolio Theory

A seminal application of OR techniques to finance was by Harry Markowitz (1952, 1987) when he specified the portfolio problem in terms of optimization over the assumed known means, variances and co-variances of the assets available, and proposed the solution of this problem through quadratic programming. In addition to specifying the portfolio problem in terms of OR techniques, Markowitz also developed solution algorithms for more general quadratic programming problems. This provides an example of the interaction between OR techniques and finance, with the former sometimes being adapted to meet the needs of the latter.

The most obvious application of portfolio theory is in choosing efficient equity portfolios, and empirical papers (e.g., Board and Sutcliffe 1994; Perold 1984 have used quadratic programming for this problem). The technique can also be applied more widely to selecting portfolios of currencies, bonds, or commercial loans. Multi-period portfolio problems have been specified as dynamic programming problems (Elton and Gruber 1971). Mulvey and Vladimirou (1992) used a stochastic generalized network model, and stochastic programming models have become widely used (Ziemba 2003, 2010).

OR researchers have also modified or replaced the quadratic programming approach to portfolio problems, often by explicitly specifying the relevant utility function and using stochastic linear programming with recourse to model risk in a multi-period framework. For example, Bradley and Crane (1972) proposed forming bond portfolios to maximize their expected value using stochastic linear programming to allow for interest rate risk. The scenarios included in portfolio models may be generated by Monte Carlo simulation, prior to the use of stochastic programming to maximize expected utility, e.g., (Golub et al. 1995; Zenios 1991, 1993b; Vassiadou-Zeniou and Zenios 1996; Zenios et al. 1998), who applied this approach to form portfolios of mortgage backed securities.

The investment policy of a pension fund can be formulated using asset-liability management (ALM) models that allow for the correlations between the values of the fund's assets and liabilities. While these problems can be formulated using quadratic programming (Board and Sutcliffe 2005), they have usually been solved in other ways (Ziemba and Mulvey 1998; Wallace and Ziemba 2005). For example, Mulvey (1994) assumed that the objective was to maximize the expected value of a nonlinear utility of wealth function, and specified the problem as a nonlinear network problem, with the simulation of future pension fund liabilities. Mulvey et al. (2008) used multi-period stochastic programming to determine investment policy for a defined benefit pension scheme. Similar asset-liability problems are also faced by insurance companies, for example Cariño et al. (1994, 1998a, b) formulated this

problem for a Japanese insurance company. Klaassen (1998) pointed out that the use of Monte Carlo simulation can bias the results by including arbitrage opportunities in the sampled scenarios. To avoid this, he aggregated an arbitrage-free event tree before its inclusion in a multi-stage stochastic programming model of the asset-liability problem. Surveys of implemented ALM models and their theory are in Ziemba (2003); Wallace and Ziemba (2005); Zenios and Ziemba (2006, 2007).

Another application of quadratic programming is generalized hedging in which the objective is usually to minimize the variance of a portfolio of a given set of assets and the chosen hedging instruments. If the hedging instruments include options, this introduces a nonlinearity into the hedging decision, and Murtagh (1989) devised a nonlinear programming model to hedge foreign currency exposure using a mixture of currency forward and options contracts. Similarly, quadratic programming has been used to construct index tracking portfolios, where the purpose is to select a portfolio of assets (e.g. equities or bonds) which, when combined with a matching short position in the index to be tracked, has minimum risk (Meade and Salkin 1989, 1990; Rudd 1980; Seix and Akhoury 1986). Multi-stage stochastic programming with recourse, in conjunction with Monte Carlo simulation to generate the scenarios, has been used by Vassiadou-Zeniou and Zenios (1996) and Zenios et al. (1998) to track an index of mortgage backed securities; also see Zenios and Ziemba (2007).

A related problem is that of portfolio immunization in which the objective is to construct a portfolio of interest rate dependent securities whose value is the same as some target asset (usually another interest rate dependent asset). There is also a literature on managing the assets and liabilities held by banks (which are taken to exclude equities), where the objective is usually to maximize the value (or expected value) of the portfolio over one (or many) time periods (net of penalty costs from constraint target violations), subject to restrictions of the total investment, maximum capital loss, and various bank regulations. By matching the duration of the portfolio with that of the target asset, the portfolio is immunized against small parallel shifts in the yield curve (the yield curve shows the interest rates for different maturities), see Fong and Vasicek, (1983); Kornbluth and Salkin, (1987); Nawalkha and Chambers, (1996); Alexander and Resnick, (1985). These immunization studies use a risk measure which does not involve squares or cross products of the decision variables, and so linear programming, not quadratic programming, is the solution technique.

In some applications of portfolio theory, the decision variables must be integer. Peterson and Leuthold (1987) and Shanker (1993) used quadratic-integer programming to compute hedging strategies involving futures.

Some authors have argued that formulation and solving quadratic-programming portfolio problems is too onerous, and proposed simplified solution techniques. Sharpe (1963) proposed a single index model which can be solved by the use of special purpose quadratic-programming algorithms. When each asset represents only a small proportion of the portfolio, Sharpe (1967) showed that his single index model can be treated as having a linear objective function. In 1971, Sharpe suggested using a piecewise linear approximation to the quadratic objective function, enabling the application of linear programming to solve portfolio problems. Another proposal is to minimize the mean absolute deviation (MAD), which can be solved using linear programming, rather than quadratic programming (Konno and Yamazaki 1991, 1997; Yawitz et al. 1976; Zenios and Kang 1993; Worzel et al. 1994). Another approach is to specify the problem as choosing between a range of prespecified equity portfolios using data envelopment analysis (Premachandra et al. 1998). A further approach is to reformulate the portfolio problem as a nonlinear generalized network model for which efficient solution algorithms exist (Mulvey 1987).

Portfolio problems, with the twin objectives of maximizing returns and minimizing risk, can also be viewed as goal programming problems with two goals. Additional goals can be introduced, and a number of authors have solved portfolio problems using goal programming, among them Kumar, Philippatos and Ezzell (1978), Kumar and Philippatos (1979), and Lee and Lerro (1973). The stochastic programming literature uses one objective, usually expected wealth maximization, with targets for the other objectives. The non-attainment of targets then yields convex penalties in various periods for the goals. An implemented application of this approach to the Siemens Austria pension fund is Geyer and Ziemba (2008).

Pricing Derivatives

It is very important when trading in financial markets to have a good model for valuing the asset being traded, and OR techniques have made a substantial contribution in this area. Indeed, the very rapid growth of these markets is partly due to the application of OR techniques in pricing models.

In 1977, Boyle proposed the use of Monte Carlo simulation as an alternative to the binomial model for pricing options for which a closed form solution is not readily available. Monte Carlo simulation has the advantage over the binomial model that its convergence rate is independent of the number of state variables (e.g., the number of underlying asset prices and interest rates), while that of the binomial model is exponential in the number of state variables. Simulation is used to generate paths for the price of the underlying asset until maturity. The cash flows from the option for each path, weighted by their risk neutral probabilities (i.e., the probabilities which can be inferred from prices by assuming that investors are risk neutral), are discounted back to the present using the risk free rate, allowing the average present value across all the sample paths to be computed, thus yielding the current price of the option (Boyle, Broadie and Glasserman 1997). As well as generating option prices, Monte Carlo simulation can be used to compute the sensitivities of results to misspecification of model parameters, including the hedge ratio, which are essential for many trading strategies (Broadie and Glasserman 1996).

In the past, it was thought that Monte Carlo simulation could not be used to price American style options because no closed form solutions for their price exist. This was considered a major problem, as the majority of options are American style. Progress has being made, however, in developing Monte Carlo simulation techniques for pricing American style options (Broadie and Glasserman 1997; Grant et al. 1997). Options have also been priced using finite difference approximations, and Dempster and Hutton (1996) and Dempster, Hutton and Richards (1998) have proposed using linear programming to solve the finite difference approximations to the price of American style put options. In addition, American style options can be priced using dynamic programming, Dixit and Pindyck (1994).

Provided a price history is available, a neural network can be trained to produce prices using a specified set of inputs, which can then be used for the out-of-sample pricing (Hutchinson et al. 1994; Bennell and Sutcliffe 2004) of securities.

Mortgage backed securities (MBS) are created by the securitization of a pool of mortgages. For any specific mortgage, the borrower has the right to repay the loan early (the prepayment option), or may default on the payments of capital and interest. Thus, MBS are hybrid securities, as they are variable interest rate securities with an early exercise option. Monte Carlo simulation can be used to generate interest rate paths for future years. Forecasts of the mortgage prepayment rates then permit the computation of the cash flows from each interest rate path, and these sequences of cash flows are used to value the MBS (Zenios 1993a; Ben-Dov et al. 1992; Boyle 1989). This procedure, which can be used to identify mispriced MBS in real time, is computationally demanding and parallel (and massively parallel) and distributed processing have been used in the solution of the problem. Simulation has also been used to price collateralized mortgage obligations or CMOs (Paskov 1997). Other hybrid securities, such as callable and putable bonds and convertible bonds face similar valuation problems to MBS and require similarly intensive solution methods.

There is an active secondary market in loan portfolios which may carry a significant default risk. Del Angel et al. (1998) used a Markov chain analysis with 14 loan performance states and Monte Carlo simulation to generate the probability distribution of the present value of loan portfolios.

Trading Tactics

As well as accurately pricing financial securities, traders are interested in finding imperfections in financial markets which can be exploited to make profits. One aspect of this is the search for weak form inefficiency (i.e., that an asset's past prices can be used as the basis of a profitable trading rule). Among the early attempts to find such exploitable regularities in stock prices were use of Markov chains (Dryden 1968, 1969).

Arbitrageurs seek to exploit small price discrepancies to give riskless profits, and network models have been used to find arbitrage opportunities between sets of currencies (Christofides et al. 1979; Kornbluth and Salkin 1987; Mulvey 1987;

Mulvey and Vladimirou 1992). This problem can be specified as a maximal flow network, where the aim is to maximize the flow of funds out of the network, or as a shortest path network.

OR techniques have been widely used by hedge funds to devise trading strategies. For example, Shaw, Thorp and Ziemba (1995) show how to construct and implement risk arbitrage in the Japanese warrant market, while Mulvey, Ural, and Zhang (2007) examine overlay strategies.

There has been a growing interest in using artificial intelligence based techniques (expert systems, neural networks, genetic algorithms, fuzzy logic, and inductive learning) to develop trading strategies for financial markets (Trippi and Turban 1993; Refenes 1995; Goonatilake and Treleaven 1995; Wong and Selvi 1998). Such approaches have the advantage that they can pick up nonlinear dynamics and require little prior specification of the relationships involved.

Funding Decisions

OR techniques have also been used to help firms determine the most appropriate method by which to raise capital from the financial markets. Brick, Mellon, Surkis and Mohl (1983) put forward a chance-constrained linear programming model to compute the values of the debt-equity ratio each period that maximize the value of the firm. Other studies have specified the choice between various types of funding as a linear goal programming problem (Hong 1981; Lee and Eom 1989).

A different approach to the debt problem is to assume that the firm has found its desired debt-equity ratio and is purely concerned with raising the requisite debt as cheaply as possible. In this case, debt can be treated like any other input to the productive process, and inventory models used to determine the optimal reorder times and quantities (Bierman 1966; Litzenberger and Rutenberg 1972).

The design of callable bonds has been addressed by Consiglio and Zenios (1997a, b), who used nonlinear programming, while Holmer, Yang and Zenios (1998) used a simulated annealing algorithm. Firms which have issued callable debt face the bond-scheduling problem in which they must decide when to call (repay) the existing debt and refinance it with a new issue, presumably at a lower cost. This is a dynamic programming problem and has been modeled as such by Weingartner (1967), Elton and Gruber (1971) and Kraus (1973).

Finally, the problem facing borrowers of choosing between alternative mortgage contracts (e.g., fixed rate, variable rate and adjustable rate mortgages) has been modeled using decision trees (Heian and Gale 1988; Luna and Reid 1986).

Strategic Problems

In recent years, some of the decisions facing traders and market makers in financial markets have been analyzed using game theory (O'Hara 1995; Dutta and Madhavan 1997). Traders in stock markets seek to trade at the most attractive prices, and large trades are often broken up into a sequence of smaller trades in an effort to minimize the price impact. This can be viewed as a strategic problem, and Bertsimas and Lo (1998) used stochastic dynamic programming to compute an optimal trading strategy.

Powers (1987) applied game theory to the situation where a company has two major shareholders, and a large number of very small shareholders. This can be modeled as an oceanic game, in which the two large players behave strategically while the many small shareholders (the ocean) do not. This approach can be used to derive the highest price a large shareholder will pay in the market for corporate control.

Regulatory and Legal Problems

Financial regulators have become increasingly concerned about financial markets with their very large and rapid international financial flows. OR techniques have proved useful in regulating the capital reserves held by banks and other financial institutions to cover their risk exposure. OR techniques have also been used to ensure compliance with various legal requirements by designing appropriate strategies, and to solve other legal problems relating to financial markets.

A key regulatory issue is determining the capital required by financial institutions to underpin their activities in financial markets. An increasingly popular approach to this problem is the value at risk (VaR), which involves quantification of the lower tail

of the probability distribution of outcomes from the firm's portfolio. Portfolios usually include options (or financial securities with option-like characteristics), and these have highly asymmetric payoffs. For such securities, analytical solutions to finding the probabilities in the lower tail of the pay off distribution are unreliable. Riskmetrics™ uses approximations of the probability tail behavior for options that are at or near the money (an option is at-the-money when the current price of the underlying asset is close to the price at which the option can be exercised), and Monte Carlo simulation for other options positions (Morgan and Reuters 1996). A related application of Monte Carlo simulation is stress testing, which quantifies the sensitivity of a portfolio to specified, often adverse market scenarios. Some securities are also subject to credit risk, which has a highly nonnormal distribution for all instruments. Therefore, Monte Carlo simulation is relevant to modeling the credit risk of portfolios of financial instruments (e.g., loans, letters of credit, bonds, trade credit, swaps, forwards) as in CreditMetrics™ (Morgan 1997).

Data envelopment analysis has been used to assist in bank regulation by measuring bank efficiency, which is then used to predict bank failure (Barr et al. 1993; Bauer et al. 1998).

Traders are required to put up margin when they trade options, and Rudd and Schroeder (1982) have developed a linear programming model in which the problem was modeled as a transportation problem.

An extensive set of rules governs the way in which a to-be-announced MBS can be structured, leading to a complex problem in devising a feasible solution. This can be specified as a complicated integer programming problem (with the objective of maximizing the originator's profit). Collateralized mortgage obligations (CMOs) also involve the securitization of a mortgage pool, but in this case the pool is structured into a series of bonds (or tranches), each with a different maturity and risks. Dahl, Meeraus and Zenios (1993) have proposed a complex zero–one programming model for solving this problem, with the objective of maximizing the proceeds from the issue.

Sharda (1987) proposed a linear programming formulation to establish the maximum loss that investors could have sustained from trading in a company's shares. This figure can then be used by the company's lawyers when fighting a lawsuit claiming damages from a misleading statement by the company.

In August 1982, the Kuwait Stock Market collapsed leaving $94 billion of debt to be resolved. This led to the problem of devising a fair method for distributing the assets seized from insolvent brokers among the other brokers and private investors. This problem was solved using linear programming, which reduced the total unresolved debt to $20 billion, saving an estimated $10.34 billion in lawyer's fees (Taha 1991; Elimam et al. 1996, 1997).

Economic Understanding

OR can help in trying to understand the economic forces shaping the finance sector. Using a linear programming model of a bank, Ben-Horim and Silber (1977) employed annual data to compute movements in the shadow prices of the various constraints. They suggested that a rise in the shadow price of the deposits constraint led to the financial innovation of negotiable CDs.

Arbitrage Pricing Theory (APT) seeks to identify the factors which affect asset returns. Most tests of the APT use factor analysis and have difficulty in determining the number and definition of the factors that influence asset returns. To overcome these problems, Ahmadi (1993) suggested using a neural network, which also has the advantage that the results are distribution free.

Concluding Remarks

Mathematical programming is the OR technique that has been most widely applied in financial markets. Most types of mathematical programming have been employed — linear, quadratic, nonlinear, integer, goal, chance constrained, stochastic, fractional, DEA and dynamic. Monte Carlo simulation is also widely used in financial markets — mainly to value exotic options and securities with embedded options, and to estimate the VaR for various financial institutions. In some cases the use of OR techniques has influenced the way financial markets function since they permit traders to make better decisions in less time. For example, exotic options would trade with much wider

bid-ask spreads, if they traded at all, in the absence of the accurate prices computed using Monte Carlo simulation.

Other OR techniques are less used in financial markets. Arbitrage and multi-period portfolio problems have been formulated as network models, while market efficiency has been tested using neural networks. Game theory has been applied to battles for corporate control, decision trees to analyze mortgage choice, inventory models to set the size and timing of corporate bond issues, and Markov chains to valuing loan portfolios and testing market efficiency. One important OR technique — queueing theory — has found little application in financial markets.

This review has shown that OR techniques have been usefully applied to portfolio problems and the accurate pricing of complex financial instruments. They are also used by financial regulators and financial institutions in setting capital adequacy standards.

Fire Safety Modeling and Applications

John R. Hall Jr.[1] and John M. Watts Jr.[2]
[1]National Fire Protection Association, Quincy, MA, USA
[2]Fire Safety Institute, Middlebury, VT, USA

Introduction

Individuals and organizations make decisions where fire safety is an explicit or implicit objective. Much of the modeling available to support decisions where the objective is explicit is drawn from an OR/MS concept or is used within a larger OR/MS framework.

OR/MS professionals may find themselves working on problems and for decision makers where part of the relevant objective function involves a measure of fire loss, risk, or safety. When that happens, they may want to avail themselves of some of the fire safety models and calculation methods developed in the fields of fire protection engineering, fire safety engineering, and fire safety science, to predict or estimate measures of fire loss, risk or safety. Alternatively, the OR/MS professional may encounter such models and methods in the analytic work of others on their project team or competing project teams or advocates. For any of these reasons, those working on issues of fire safety will want to be familiar with fire safety models and applications.

Types of loss may involve fire damage to people or property – the most familiar and most common measures of interest – or may involve fire damage to continuity of mission, business or operations; to the environment; or to cultural heritage.

Among the tools in use, the term "fire model" is normally reserved for physics-based models of the spread of combustion products and other fire effects through a defined space. The term "fire safety science" is also normally used in this way. The OR/MS professional, like the fire protection engineer, may need other models and calculation methods to complete an analysis, including:

- Models of the effects of fire on specified targets, including the health of people (such as burn, heat stress, and toxic effects) and the value and functionality of objects (such as corrosion or degradation of structural strength and integrity).
- Models of the behavior of people and the usage of products, needed to produce timelines of locations of potential targets which will, when combined with timelines of fire conditions by location, produce a timeline of degree of fire exposure for such targets.

OR/MS professionals may be asked to frame the decision problem in terms of a fire risk assessment of each of several alternative courses of action. Some of the fire safety field's fire risk assessment methods are based on fire models and other physical models used within a scenario-based structure. Other methods are not so detailed.

This article provides the construct in which fire safety objectives are established and an overview of fire models and other physical models relevant to fire safety evaluation in terms of the threat and the potential consequences. Most of the material, however, is devoted to an overview of fire risk assessment methods.

Objective-Setting

A generic OR/MS formulation of a decision problem identifies

- a set of controllable variables,
- a set of uncontrollable variables,
- a set of outcomes with measures of their attractiveness, and
- a model that shows how controllable and uncontrollable variables combine to produce outcomes.

The analyst can then optimize the choice of controllable variables or use the model to select the best controllable variables from a limited set of available alternatives.

Some fire safety codes and standards have fairly recently added explicit statements of their goals and objectives. These include protection of people, property, mission, environment, and cultural heritage.

Life safety is the most commonly regulated fire safety objective. It is greatly focused on the occupants of a building, but may also include people who respond to fire emergencies and, in that capacity, may enter a burning building. Measures of effectiveness are typically in terms of expected mortality.

Property protection fire safety objectives may include the facility (structure), as well as its contents (processes, storage, etc.). In many cases, the property protection risk management objective will be related to limiting the spread of fire to a defined area and may be converted to an expected loss value. It is also common to first establish a monetary value for acceptable loss, and then determine the maximum tolerable fire size (i.e., the extent of fire and smoke spread and the potential suppression agent damage that would lead to the maximum tolerable loss).

Continuity of operations objectives typically reflect the maximum tolerable downtime of a process, building or facility due to fire. In many respects, objectives for continuity of operations will follow the analysis used for property loss, but the focus is on the cost associated with a return to operations. Establishing continuity of operations objectives requires the decision maker to determine to what extent the organization understands and values the process, building, facility, or concern.

Environmental protection objectives are typically related to air pollution, ground water contamination, ecosystem damage, and adverse health effects. They may address sustainability issues as well, including recycling and reuse of materials.

Cultural heritage resources represent intangible or non-economic values that may not be recoverable. At risk is the loss of resources such as architecture, artifacts, and art from fire or fire fighting, or the intrusion of fire safety systems on authenticity.

Controllable Variables, Outcomes, and Measures of Attractiveness

In a fire safety context, the controllable variables might be:

- the design characteristics of a building,
- the design characteristics of a burnable product,
- the design characteristics of an object that could provide the ignition heat for a fire,
- the design characteristics of a product that is required to contain, resist, or continue performing a function despite exposure to fire,
- the design characteristics of equipment or a system for fire detection or suppression, or
- the specifications for an educational or training program.

As for outcomes and measures of their attractiveness, it is likely that there will be a variety of interested parties affected by the choices, and they may all have a say in the specification of outcomes. The conventional OR decision maker – who might be the architect or builder of a building or the manufacturer of a new product – is often constrained by codes, standards, and regulations designed to limit the potential harm from an approved design.

In this decision-making environment, analysis is typically performed not as a multi-objective constrained optimization problem, but as an exercise in establishing equivalency; that is, demonstrating that the outcomes associated with the candidate design will be no worse than those that would have occurred with a fully code-compliant conventional design, even if the candidate design does not itself fully comply with the more prescriptive requirements of the code.

Fire Models and Formal Scenario-Based Analysis

It is almost never the case that one can identify, for a fire safety problem, a complete set of controllable and uncontrollable variables, each expressible on a quantitative scale and each linked to needed data. If one could do so, then it is even more unlikely that there would be a validated model linking all variables to each other and to the outcomes of interest. Some type of simplification is necessary.

This section discusses scenario-based approaches to analysis. The fire models described in this section are particularly relevant when the decision maker or the project team insist on the kind of detail and evidence of validity associated with fire protection engineering, which is to say, strong reliance on detailed mathematical models of physical phenomena supported by data taken primarily from laboratory testing of the properties of materials, products,

assemblies and systems. The next section discusses qualitative, semi-quantitative, and purely statistical/empirical methods.

Fire and Behavioral Scenarios

The universe of possible combinations of uncontrollable variables is, in the fire safety analysis world, the universe of possible fire and related scenarios. A fire scenario describes fire conditions as a function of spatial location and time, from the beginning of the fire to its conclusion. Related scenarios are used to provide parallel characterizations of the locations and conditions of potential targets of harm from the fire. Objects that could be subject to property damage, environmental damage, or cultural damage are likely to be fixed, which means the scenario need only describe locations and conditions at the start of the fire, knowing that those locations and conditions will not change during the fire. People who could be injured or killed by fire are a different matter, because they probably will change their locations during the fire. Hence, fire scenarios are likely to be used with behavioral scenarios to produce parallel timelines for fire conditions and conditions of potential victims.

Each scenario is a different kind of fire challenge to the design. A scenario structure identifies a finite number of scenarios, each of which represents many like scenarios and all of which collectively capture the universe. In a complete risk assessment, each representative scenario is weighted by the combined likelihood of the scenarios it represents. In a more typical engineering analysis, a small number of scenarios are considered to represent the most typical and the distinct types of most challenging scenarios. In either type of analysis, the same types of models are used to calculate the predicted consequences (the preferred term for the measure of attractiveness of the predicted outcomes).

Models of Use in Scenario Analysis

There are several comprehensive references that should be consulted for additional information on fire safety models for scenario-based analysis: SFPE Handbook, 2008; Engineering Guide: Fire Risk Assessment, 2006; SFPE Engineering Guide to Performance-Based Fire Protection, 2007; Olenick and Carpenter 2003; NFPA 551 2007.

Fire Models

Fire models predict the change in heat and mass (smoke) conditions over space and time. They do not predict fire initiation or fire growth but rather predict the spread of heat and combustion products. Such models adapt the more general models of fluid mechanics and heat transfer to the specific purpose of fire modeling. (See most of Section 1 in the SFPE Handbook).

Fire models differ greatly in granularity. The earliest fire models treated each room or compartment as a single zone, see Chapter 3–7, SFPE (2008). For several decades, popular so-called zone models used two-zone representations of each compartment, taking advantage of the fact that within a compartment, the most important and pronounced variation in fire conditions is between the upper layer, which fills with fire and smoke first, and the cleaner lower layer, with the two layers separated by a boundary that moves down over time.

Advances in computing speed and power have shifted usage to so-called computational fluid dynamics (CFD) or field models, see Chapter 3–8, SFPE (2008). CFD models represent a compartment by many small control volumes in a grid representation. The laws of conservation of mass, momentum, and energy are used to predict fire conditions in successive time intervals. When zone models were popular, CFD models were commonly limited to representations in thousands of control volumes, while today millions of control volumes are often used in analyses that cost less and take less time than the coarser-grid analyses of the past.

The more sophisticated the fire model is, the more extensive are its associated data needs, including quantities and burning properties of potential fuel sources in the fire area and the spatial dimensions and fire properties of the boundaries of compartments. While there has been extensive verification and validation work on CFD models, with associated development of rules of good practice, there has been far less work on the sensitivity of results to variations in estimated data values for the many uncontrollable variables used by the fire models that must use estimates because of the absence of well-established sources of data.

There is also a tradition of stochastic fire models – notably Markov process (or state transition) models and network model, see Chapter 3–14,

SFPE (2008). Such models do not produce the kind of detailed descriptions of fire conditions by place and time that are produced by zone models, let alone CFD models, but they can provide useful and valid predictions when the fire safety problem does not require such details. For example, it may be quite sufficient for evaluation of a building design to know which rooms and how many rooms were fire involved, without knowing the heat and smoke conditions within any room.

Network models have a notable advantage over CFD and zone models in the area of phase change events. The likelihood and time delay in burning through a barrier, such as a door or wall, is more easily modeled using a network model. The same can be true for window breaking, a random event that produces a qualitative change in ventilation for the fire, and for the deformation or collapse of a load-bearing element.

Traditional fire risk assessment models using event trees can be modified to treat the spread of combustion products as simply a set of events.

Modeling Fire Consequences for Scenario Analysis

Egress. There are a number of models available to predict the movement of people in response to fire cues, see Chapters 3-11, 12, 13 and 17, SFPE (2008). Early models simplified the process in either of two ways. Hydraulic-style models moved people through corridors as if they were ball bearings in a tube. These models tend to predict egress times far shorter than those that are observed in practice. The other approach was to construct a network model with a number of embedded behavioral rules to guide behavioral choices. Whereas the hydraulic model ignored behavioral choices entirely, and thus was primarily of value in modeling large buildings where the timeline was dominated by travel over distance, the network models were designed to concentrate primarily or exclusively on behavior and were primarily of value in modeling small buildings where travel distances are short.

Some of the more popular current egress models adapt the format of CFD fire models. These models track the positions of individuals, as the hydraulic models did not, and so they have been more easily adapted to deal with queueing delays, as well as more complex phenomena such as counter-flows. As with CFD fire models, egress models tend to be more simplified when they are required to model very large spaces and buildings.

There is very little data available to support the behavioral rules needed by egress models both during and before egress. Empirical studies have found large variations in the time spent before egress travel begins. Most fire safety engineering studies assume that people initiate egress shortly after a shared cue, such as a building-wide fire alarm.

From a validation standpoint, most fatal victims of fire are not fatally injured while trying to escape, and almost no large-life-loss fires have involved multiple deaths because egress took too long to complete.

If the fire safety analysis requires a fully developed calculation of expected fire risk, then the failure to use egress models that reflect common practice is a major concern. If the fire safety analysis requires only a focused assessment of equivalency to existing codes, then one would be justified in examining only those behavioral scenarios for which a fully code-compliant design would produce acceptable outcomes.

Toxicity and Damage. For assessments of loss of life or health, models are needed to translate fire conditions at the location of an individual with an unacceptable adverse change in health. This is generally referred to a toxicity model, although the fire effects considered are not limited to toxic effects of smoke, but also include heat effects and effects on escape behavior, such as an inability to find the way to safety through dense smoke, see Chapters 2–4, 2–6, 3–11, SFPE (2008).

A toxicity model is built on thresholds of cumulative dose or instantaneous exposure (concentration) that produce the level of effect defined as unsatisfactory. There has been considerable controversy over the selection of unsatisfactory levels and the specification of thresholds. The earliest toxicity models defined unsatisfactory effect as a lethal dose, which focused attention on carbon monoxide and other narcotic gases. The consensus has shifted to define incapacitation as the unsatisfactory level on the theory that an incapacitated person will be stuck in place in a hazardous environment and is very likely to receive a fatal dose before receiving needed assistance to escape. This has broadened attention to irritant gases, burns, heat stress, and fire effects that act indirectly, such as smoke obscuration that does not physically incapacitate the individual,

but may make attempts to complete egress ineffective. Standards developers are working on even lower thresholds, corresponding to changes in behavior and egress effectiveness, such as reduced speed.

In addition to the controversy associated with shifting the definition of unsatisfactory further and further away from the fatal end-point, there are controversies involved in the inference of human thresholds from primarily animal-based data and on the use of safety factors to reflect the variation in sensitivities across people. The safety factors for sensitivity sometimes appear to take a calculation modification that would help to ensure safety and use it inappropriately in a prediction of likely outcomes. There is some evidence that the use of these standard factors would predict far more deaths and injuries under realistic fire conditions than actually occur.

Similar thinking is required – but is not nearly so advanced – to convert physical fire conditions near targets into estimates of property damage (for example, due to corrosion or simple soiling) or environmental damage (where the targets can be plant and animal species or regions of air, water and land that will, if contaminated, lead to harm to plants and animals).

Fire safety analysis will often compensate for the lack of advanced tools for calculating fire impact by treating any movement of fire effects into the space occupied by targets as an unacceptable outcome. This will produce conservative results, but may not produce practical results unless, for example, the lower zone of a room filling with smoke is assumed to be completely uncontaminated.

Cost. While not strictly part of the calculation of fire consequences, cost will typically be part of the overall assessment of acceptability. ASTM Committee E06 has published a number of standards to systematize the calculation of costs for various building designs.

Modeling Likelihood for Scenario Analysis

Ignition. Most fire safety analyses treat ignition empirically because the data are rarely available to apply existing science about the conditions of ignition for different materials.

If a building design is being assessed, it may be enough to estimate the likelihood of different gross types of initial burning rates (such as extended initial smoldering, ordinary flaming, fast flaming, explosion) and different areas of fire origin. The most challenging areas of origin, however, may not be the most common areas of fire origin.

The typical areas of origin are the rooms that are normally occupied such as living rooms, kitchens, bedrooms, offices, and other site-specific function areas. Fires beginning in concealed spaces, structural areas, or exterior surfaces or nearby properties such as sheds or brush, all are far less common but collectively represent a fire challenge with non-trivial likelihood and possibly heightened potential to evade or defeat protective measures.

Even empirical estimates can be improved through the use of modeling. For example, fire incident data can be used to estimate the annual likelihood of a fire beginning with ignition of a piece of upholstered furniture by a lit cigarette. Laboratory test data can be used to distinguish the relative ease of ignition by cigarette of different parts of the upholstered furniture (for example, cushion, arm, crevice). By chaining together probability estimates, one can develop a final estimate of the needed likelihood specific to the item in question.

As with reliability estimates, there are a number of failure mode models that can also be used, beginning with traditional fault trees, but there is rarely enough data to obtain full value from these sophisticated methods, and they tend to under-emphasize the human errors that historically are involved in most fire ignitions.

System Reliability. For all the different elements of fire safety built into a design, the decision to include the element and the initial specifications of the element will typically be controllable variables, but the status of the element when fire begins will be an uncontrollable variable. This is a generalization of reliability. Will the element be in condition to perform at all, and if so, will it be in condition to perform as designed and intended? This would include detection and suppression equipment that is not able to respond at all or responds ineffectively because of delay or some other problem, see Chapter 5–3, SFPE (2008).

There are many models of system and equipment failure, beginning with simple fault trees, but most cases of failure for most types of protective equipment are entirely or primarily due to human error. Models of behavior are not nearly so well

developed as models of equipment failure, and the data to validate and support behavioral models is largely lacking. For these reasons, fire safety analyses may use empirically based estimates of needed reliability parameters, although there are small quantities of such data available, and the available estimates are rarely able to distinguish different types of equipment, let alone different designs, models or brands.

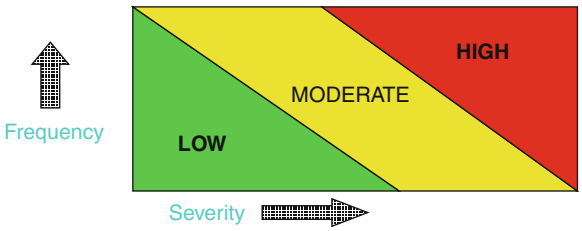
Reliability is an issue not only for active systems but also for passive features. Doors can be chocked open. Walls can be penetrated by holes. Stairways can be unenclosed and permit easy passage of fire and smoke from floor to floor. Empirical data on these failures are even more rare than data on failures of active systems.

Uncertainty. All guidance documents to the use of fire safety models emphasize the importance of uncertainty analysis, but few fire safety analyses provide depth or substantive treatment of uncertainty, see Chapter 13, SFPE (2006) and Chapter 5–4, SFPE (2008).

Research is underway to provide validation and verification for some of the major classes of models, including CFD models. Precision and bias statements are also typically lacking for standard test methods, and the nature of the major fire incident databases makes it very difficult to meaningfully characterize the uncertainty of estimates from the more detailed databases, see Chapter 5–5, SFPE (2008).

Other Risk Models

The more formal approaches described in the previous section tend to be relevant where the decision maker is a regulatory body, seeking an engineering justification for the design or adoption of a proposed requirement, or a builder, seeking an engineering case for declaring an innovative design equivalent in safety to a conventional design that is fully compliant with an existing code. Other fire-safety decision makers do not require this level of engineering detail, which is fortunate, because fire safety decisions often have to be made under conditions where the data are sparse and uncertain. The technical parameters of fire safety evaluation are complex and involve a network of interacting components, the interactions generally being nonlinear and multidimensional.



Fire Safety Modeling and Applications, Fig. 1 Fire Risk Function

Under such circumstances, are results more valid when they come from a detailed engineering analysis using extensive engineering judgment to fill in missing data or from a less-detailed approach that does not require such data but incorporates the key phenomena and interactions in a way that makes sense conceptually? Some decision makers, notably the insurance industry and managers responsible for risk management across a wide range of types of risk (not just fire), have favored the latter approach and have developed a number of different kinds of tools to support such analysis.

Four types of fire risk models are discussed here:

- qualitative fire risk matrix,
- logic diagrams, including decision trees,
- fire risk indexing, and
- stress-strength models.

In the cases of the more generic concepts of logic diagrams and probabilistic models, a specific example of application to fire safety is presented.

Qualitative Fire Risk Matrix

Fire risk is generally considered a function of the two characteristics of an unwanted event or fire scenario, that is, likelihood (frequency) and consequence (severity). Figure 1 illustrates that events with low frequency or likelihood and low severity or consequence have low risk while events with high frequency and high severity are considered high risk.

Throughout the range of likelihood and consequence, there are many levels of risk. The concept of combining these characteristics in the form of a graphical risk matrix was widely adopted in the 1960's as a systems safety technique for military systems and was documented in MIL-STD-882 (DOD 1969). It has since been incorporated in fire risk assessment guides produced by the National Fire

Fire Safety Modeling and Applications, Table 1 Probability Levels

Frequent	Likely to occur frequently ($p > 0.1$)
Probable	Likely to occur several times in system life ($p > 0.001$).
Occasional	Unlikely to occur in a given system operation ($p > 10^{-6}$)
Remote	So improbable it can be assumed this hazard will not be experienced ($p < 10^{-6}$).
Improbable	Probability of occurrence cannot be distinguished from zero ($p \sim 0.0$)

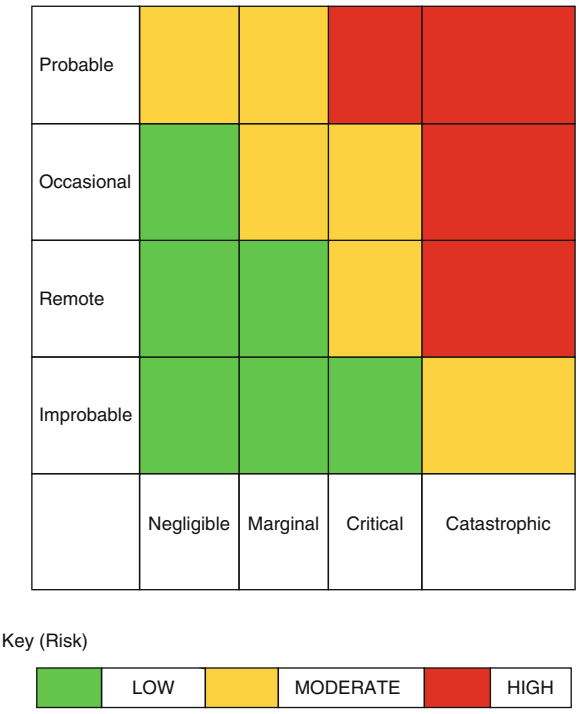
Fire Safety Modeling and Applications, Table 2 Severity Categories

Negligible	The impact of loss will be so minor that it would have no discernible effect on the facility or its operations.
Marginal	The loss will have noticeable impact on the facility. It may have to suspend some operations briefly. Some monetary investments may be necessary to restore to full operations. May cause minor personal injury.
Critical	Will cause personal injury or substantial economic damage. Loss would not be disastrous, but the facility would have to suspend at least part of its operations immediately. Reopening the facility would require significant monetary investment.
Catastrophic	Will produce death or multiple death or injuries, or the impact on operations will be disastrous, resulting in long-term or permanent closing. The facility would cease to operate immediately after the fire occurred

Protection Association (NFPA 551 2007) and the Society of Fire Protection Engineers (SFPE 2006).

The fire risk function can be quantified by applying discrete measurement scales to the axes. It then becomes a means of evaluating the relative level of fire risk for representative fire scenarios involving a building or other system. In this approach, each hazard or fire scenario is assigned a probability level and a severity category. Tables 1 and 2 below are adapted from corresponding tables in MIL-STD-882 (DOD 1969).

The probability levels and severity categories can then be used to represent the axes of a two-dimensional risk matrix such as shown in Fig. 2.



Fire Safety Modeling and Applications, Fig. 2 Risk Matrix

Each fire scenario will have a likelihood category (on the left of the matrix) and a consequence category (at the bottom of the matrix). This will locate each fire scenario within one of the 16 cells of the matrix. According to a scenario's location, the matrix indicates that improbable scenarios with negligible consequences (lower left) represent a low risk and frequently occurring scenarios with greater consequences (upper right) represent high risk levels.

Usually, fire scenarios of low risk are considered to be acceptable. Conversely, fire scenarios of high risk are unacceptable and must be eliminated or have appropriate mitigation strategies implemented. Fire scenarios of moderate risk need to be considered carefully to address whether the risk needs to be mitigated or can be considered to be acceptable. These may be the scenarios that are chosen for more detailed analysis such as that described in the previous section. In such circumstances, the matrix operates like a scenario triage tool.

Logic Diagrams, Including Decision Trees

The main tools for quantifying fire experience and other forms of failure using information on basic

events that contribute to this experience is the logic diagram. There are a number of different types of logic diagrams used in fire risk analysis, usually in the structure of a tree. Among these are:

- Decision a tree
- Fault tree
- Success tree
- Event tree
- Cause-consequence diagram

Decision trees are logic diagrams used to represent the outcomes of decisions and events made at different levels. Fault trees are logic diagrams used to represent the alternative ways in which a system can fail, resulting in a critical event, referred to as the top event in the tree. Success trees are logic diagrams used to represent alternative ways in which a certain goal can be achieved. They can be constructed as the dual of a fault tree or separately as a qualitative logic diagram such as the Fire Safety Concepts Tree, discussed in more detail below. A quantified fault or success tree applies probabilities at every branch, which permits calculation of the overall likelihood of success or failure – useful if the fire safety objectives can be expressed qualitatively – and analysis of which parts of the design provide the greatest leverage to improve the overall likelihood of success or failure.

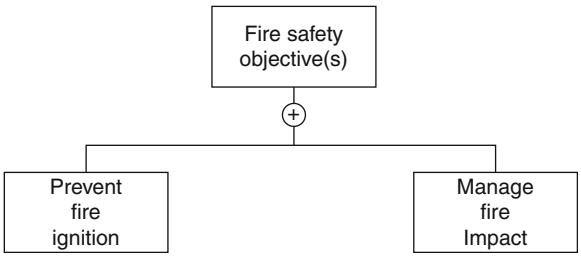
Event trees are logic diagrams used to represent the alternative ways in which a system can continue following an initial critical event, e.g., fire. Cause-consequence trees are logic diagrams that are used to represent causes (backward in time) and consequences (forward in time from a given critical event). Both replace logical relationships with temporal sequencing relationships. A quantified event tree or cause-consequence tree applies probabilities to branching points, similar to a quantified fault or success tree, but also applies costs and benefits to branching points and/or final outcomes. This permits a quantitative calculation of overall risk.

Fire Safety Concepts Tree. The Fire Safety Concepts Tree (FSCT) is a logic diagram with a tree-root like structure (NFPA 550 2007). It branches downward from specified fire safety objectives to identify all possible means of achieving fire safety. Fire safety objectives include life safety, property protection, operational continuity, environmental protection, and heritage preservation. The FSCT is very comprehensive in terms of its included objectives, and is widely used to obtain an integrated overview of the key elements of a project before more quantitative risk analysis is begun.

The Tree, as presented in the figures below, shows the elements that must be considered in building fire safety and the interrelationship of those elements. It enables a building to be analyzed or designed by progressively moving through the various levels of events in a logical manner. Its success depends upon the completeness by which each level of events is satisfied. Lower levels on the decision tree, however, do not represent a lower level of importance or performance; they represent a means for achieving the next higher level.

The Tree requires that the "Fire Safety Objective(s)" (goals) be clearly identified. These objectives describe the degree to which the building should protect its occupants, property contents, continuity of operations, and neighbors. The objectives should be stated with enough detail that success or failure in meeting them is clearly defined, rather than stated in broad or general terms.

The life safety objective, for example, might state that all occupants be safeguarded against the intolerable or untenable effects of the fire. It may be further stated that emergency personnel such as fire fighters, who may be expected to stay in areas considered too dangerous for the occupants, should be protected against unexpected collapse of the building or entrapment. A range of specific life safety objectives may be appropriate for varying types of occupancies. Nursing home requirements, for example, are vastly different from those for offices, and both differ from industrial occupancies or storage facilities.

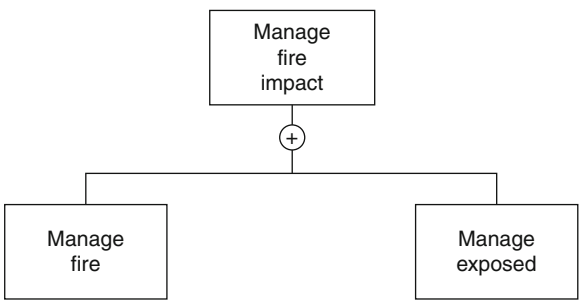


The Tree provides the logic required to achieve fire safety, i.e., it provides conditions whereby the fire safety objectives can be satisfied, but it does not provide the minimum condition required to achieve those objectives. Thus, according to the Tree, the fire

safety objectives can be met if fire ignition can be prevented or if, given ignition, the fire can be managed. This logical "OR" function is represented by the symbol (+) on the Tree.

The "Prevent Fire Ignition" branch essentially is the entry point for what could be elements of a fire prevention code. Most of the concepts described in this branch require continuous monitoring for success. Consequently, the responsibility for satisfactorily achieving the goal of fire prevention is ultimately an owner/occupant responsibility. However, some of the elements along the branch may involve choices of the designer, such as the type of central heating, main cooking, and electrical distribution equipment to be used.

It is impossible to prevent completely the ignition of fires in a building. Therefore, to reach the overall fire safety objective, from a building design viewpoint, a high degree of success in the "Manage Fire Impact" branch assumes a significant role. After an ignition occurs, all considerations shift to that branch to achieve the fire safety objectives.



According to the logic of the Tree, the impact of the fire can be managed through either the "Manage Fire" or "Manage Exposed" branches. The "OR" gate indicates that the objectives may be reached through either or both of the branches, as long as the path selected completely satisfies the fire safety objective. Naturally, it is acceptable to do both, which will increase the probability of success over using only one branch.

The Manage Fire objective can be achieved by any of three different means:

(1) Controlling the combustion process,
(2) Suppressing the fire, or
(3) Controlling the fire by construction.

Here, again, any one of these branches of the Tree will satisfy the Manage Fire event. Thus, for instance, in some fires success is achieved where the building construction controlled the fire. And in other fires, success is achieved by controlling the combustion process, either by controlling the fuel or the environment.

The "Suppress Fire" event is the output of a logical "AND" gate, which signifies that all of the elements in the level immediately below the gate are necessary to achieve the event above the gate. To accomplish the automatic suppression event, for example, all three events–detecting the fire, initiating action, and controlling the fire are necessary. Similarly, to manually suppress the fire, all six events must take place. The omission of any single event is sufficient to break the chain and cause the failure of this automatic suppression event.

In considering the Manage Exposed branch, it can be successful either by limiting the amount or number exposed or by safeguarding the exposed. For example, the number of people as well as the amount or type of property in a space may be restricted. Often this is impractical. If this is the case, the objectives may still be met by incorporating design features to safeguard the exposed.

The exposed people or property may be safeguarded either by moving them to a safe area of refuge or by defending them in place. For example, people in institutionalized occupancies such as hospitals, nursing homes, or prisons must generally be defended in place. To do this, the "Defend Exposed in Place" branch would be considered. On the other hand, alert, mobile individuals, such as those expected in offices or schools, could be moved to safeguard them from fire exposure on either a short term or long range basis depending upon other key design elements, such as a checklist of actions that might be taken. For example, "Provide Safe Destination."

The distinct advantage of the FSCT is its systems approach to fire safety. It considers all aspects of fire safety and shows how they interact to influence achievement of fire safety goals and objectives. Usefulness of the Tree is in providing an overall structure with which to analyze the potential impact of requirements or design concepts on a particular fire safety problem. It can support a decision to use a nontraditional approach to fire safety when accompanied by sound fire protection engineering principles.

The FSCT Tree in its entirety has seven levels of branches. A more complete description of the tree is

found in National Fire Protection Association document, NFPA 550, *Guide to the Fire Safety Concepts Tree* (NFPA 550 2007), which also contains detailed descriptions of tree elements, a glossary, and an administrative action guide.

Fire Risk Indexing

Fire risk indexing (FRI) is representative of the quantitative fire risk assessment that originated with the insurance rating schedule in the early 20th century. The approach has broadened to include a wide variety of applications. In general, fire risk indexing assigns values to selected variables based on professional judgment and past experience. The selected variables represent both positive and negative fire safety features and the assigned values are then operated on by some combination of arithmetic functions to arrive at a single value. This single value can be compared to other similar assessments or to a standard to rank the fire risk. Examples of fire risk indexing are presently included or referenced in current building and fire safety codes. As opposed to the pass/fail criteria of strict code compliance, indexing recognizes the value of building attributes that are superior to code requirements as well as the deficiencies. A broader collection of fire risk indexing models has evolved over the last 30 years.

Indexing refers to the agglomeration of measures of two or more attributes to produce a single summary measure that appropriately reflects all the included attributes. For example, to estimate how cold the weather feels a wind-chill factor combines the wind speed and temperature into a single measure.

Characteristics of FRI. In the spectrum of fire risk assessment methods, FRI is positioned between qualitative checklists and analytical calculation methods. While checklists can be endlessly comprehensive in their scope, this is not always practical or efficient, and the format provides no quantitative decision-making risk information related to either likelihood or severity of consequences. And while analytical calculation can provide a detailed level of resolution that is appealing to fire protection engineers, it is expensive, time-consuming, and highly dependent on large quantities of data, including extensive use of engineering judgments. FRI has the following characteristics:

- Greatly expands the usefulness of checklists by incorporating quantitative measurement
- More practical than analytical calculation methods by facilitating inclusion of fire hazards and safety features for which proven fire models and necessary experimental or field data are generally lacking, e.g., fire department response.
- Can be designed to receive input and adjustment from analytical calculations where appropriate.

Fire risk indexing applications come in many forms. Among the most popular, as described in Chapters 5–10, 12, SFPE (2008), are:

- Fire Safety Evaluation System (FSES)
- International Existing Building Code (IEBC)
- DOW Fire and Explosion Index (FEI)

Decision Analysis Background of FRI. One of the most common and most powerful heuristic decision-making techniques is multiattribute evaluation, an approach that is supported by a large body of knowledge described in the literature of decision analysis and management science. Multiattribute evaluation is used to develop simplified but robust models of complex systems. Values are assigned to important attributes of the problem based on professional judgment and experience. These values are then operated on by some combination of arithmetic functions to arrive at a single score or index. The result can be compared with other similar assessments or to a standard.

As implied above, fire safety decisions require more than one attribute to capture all relevant aspects of the consequences. If there are n attributes (x_1, x_2, x_3, . . . , x_n) for a decision problem, then an evaluation function $E(x_1, x_2, x_3, \ldots, x_n)$ needs to be determined over these measures to conduct a performance assessment. It has been established that if tradeoffs among the attributes do not depend on the levels of the remaining attributes, then a single measure of the overall outcome of a system is given by

$$E(x_1, \ldots, x_i, \ldots, x_n) = \sum_{i=1}^{n} w_i \, R_i \, (x_i)$$

where the w_i are weighting constants greater than zero and the $R_i(x_i)$ are normalizing functions of the attributes. Additional information is in Chapter 13, Rasbash et al. (2004).

Management science has long dealt with this type of problem. A large body of knowledge exists on the subject of Multiattribute Evaluation, closely related

to Multiattribute Decision Analysis, Multicriteria Decision Making, and Multiattribute Utility Theory.

Stress-Strength Models

There are many nondeterministic modeling techniques that have been applied to fire protection engineering problems. These include both stochastic and probabilistic approaches.

Stochastic models of fire growth predict the course of fire development in a building. In these models, various states occur sequentially in space and time according to probability distributions. The most common types of stochastic models used are networks and Markov chains. Other approaches may include random walks, diffusion processes, percolation theory, and epidemiologic models, see Chapter 3–14, SFPE (2008).

Probability models generally deal with a final outcome such as success or failure of a fire safety component, number of fire deaths, economic loss, spatial extent of damage, etc. They consider the outcome as a continuous random variable reaching various levels according to a generated probability distribution. Large values of the variable may follow the extreme-value distribution, see Chapter 5–8, SFPE (2008).

A promising method is the convolution integral or stress-strength model. It is generally well-established in structural integrity analysis and in civil and mechanical engineering applications, thus making it a naturally attractive overall framework for building performance analyses where there are other phenomena as well as fire at issue.

Convolution Integral. Fire safety incorporates many concepts that are not discrete events, including attributes that may exist in a greater or lesser degree, e.g. combustibility, fire resistance, suppression, etc. These attributes can be represented by a probability distribution of occurrence over the range of possible values. A critical value of such an attribute may depend upon the level of another element of the same form. For example, the necessary degree of fire resistance, a continuous variable, is dependent on the level of fire severity to which it is exposed, another continuous variable. One way to combine these elements to calculate the probability that a critical value is reached or exceeded is by using a convolution integral, also referred to as a stress-strength model (Watts 1983).

Let X be a random variable denoting the maximum stress encountered and let Y be a random variable denoting the effective strength. Since the units of stress and strength are the same, their probability density functions may be plotted on the same axes. When strength of the system is y^*, then the reliability of the system (i.e. the probability that the stress will be less than the strength) is the area under the stress curve to the left of y^*:

$$P(X \le y^*) = \int_{-\infty}^{y^*} f(x)dx$$

If the exact strength (y*) is unknown, the reliability is also a function of the strength distribution g(y):

$$P(X \le Y) = \int_{-\infty}^{\infty} \int_{-\infty}^{y} f(x)g(y)dxdy$$
$$= \int_{-\infty}^{\infty} F_x(y)g(y)dy$$

This is the usual form of the stress-strength model.

Stress-Strength Model of a Fire Barrier. Let R be a random variable that represents the fire resistance of the barrier and let S represent the stress or the severity of fire to which the barrier is exposed. Then the characteristic of interest is the probability that the fire resistance will be greater than the fire severity:

$$P(R > S) = P[(R/S) > 1.0]$$
$$= P(X > 1.0) \text{ where } X = R/S$$

and

$\ln X = \ln R - \ln S$, by the properties of logarithms.

If R and S are lognormal random variables, then $\ln R$ and $\ln S$ are normally distributed. It has been shown that a linear combination of independent, normally distributed random variables is also normally distributed. Assuming, therefore, that the fire severity and the fire barrier are independent,

$$Y = \ln X = \ln R - \ln S$$

is a normally distributed random variable with mean $\mu = \mu_{\ln R} - \mu_{\ln S}$

and variance $\sigma^2 = \sigma^2{}_{\ln R} + \sigma^2{}_{\ln S}$.

Now the probability of interest may be expressed in terms of the normal random variable Y:

$$P(X > 1.0) = P(Y > \ln 1.0)$$
$$= P(Y > 0)$$

The standard normal variate is a normally distributed random variable with a zero mean and unit standard deviation. As any normal variate (x) may be represented as a standard normal (z) by the transformation $z = (x\text{-}\mu)/\sigma$.

Thus:

$$P(Y > 0) = P[Z > -(\mu/\sigma)].$$

For any standard normal variable:

$$P(X > x) = P[X \leq (-x)]$$

The probability may then be written in the more usual form:

$$P(R > S) = P[Z \leq (\mu/\sigma)].$$

Thus the probability of a given barrier withstanding a given fire may be represented as a standard normal random variable.

The convolution integral may be used to model the relationship between two elements of fire safety represented by probability distributions. This is referred to in the structural engineering literature as a stress-strength model. The barrier model presented is similar to structural applications. However, this concept is also applicable to the evaluation of suppression systems by defining the convolution of the suppressibility of the system and the suppressibility of the fire. The model is equally suitable in application to ignitibility or other similar fire protection engineering concepts.

On a broader scale, the stress-strength model can be used to evaluate life safety from fire. Two concepts that are commonly used in this regard are ASET and RSET. ASET is a measure of the Available Safe Egress Time, a function of the space and fire growth. RSET is the Required Safety Egress Time, typically determined by calculation of the speed with which evacuation of a building or fire area takes place. If ASET > RSET then the premises are considered safe. Although a safety factor is incorporated in the evaluation, the many assumptions and variations that are inherent in the calculations indicate that a probabilistic treatment such as a stress-strength model, as has been adapted (He 2010), may have useful advantages.

Concluding Remarks

Fire-safety decision making involves objectives, available choices, and a surrounding framework that indicates, with some degree of quantification, how the choices translate into relative success in meeting the objectives. This is a classic OR/MS formulation of a decision problem. Some surrounding frameworks make more extensive use of physical models and laboratory data; they tend to be more attractive and familiar to engineers and, therefore, more appropriate when decision makers or project teams are most attuned to an engineering style of decision making. Other surrounding frameworks rely more on bare-bones logic with limited quantification and that primarily in probabilistic form; they tend to be more attractive to decision makers for whom the engineering aspects are embedded in a much larger statement of the problem. In either setting, there are ways to use OR/MS methods, and there are resources available from other technical fields that can be used in combination with OR/MS methods or in ways similar to traditional OR/MS approaches.

- ▶ Expert Systems

First Feasible Solution

The feasible (usually basic) solution used to initiate the Phase 2 procedure of the simplex method. The solution satisfies both $\boldsymbol{Ax} = \boldsymbol{b}$ and $\boldsymbol{x} \geq \boldsymbol{0}$. The first feasible solution is often a product of the Phase I procedure of the simplex method, while in other instances, it is user-supplied or generated by previous solutions of the problem.

First-order Conditions

Conditions involving first derivatives.

Fixed-Charge Problem

A problem in which a one-time cost is incurred only if the associated variable is positive. The fixed cost is added to the linear variable cost. Problems with linear constraints and fixed charges are usually reformulated using subsidiary binary variables.

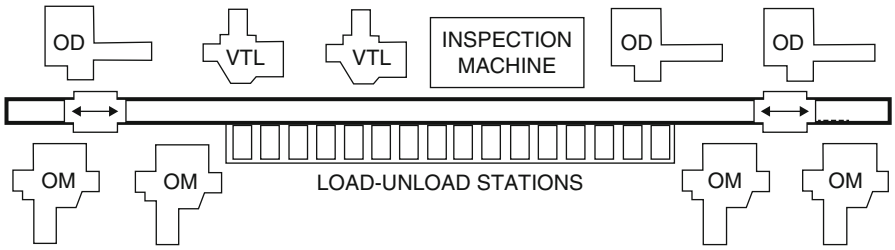
Flexible Manufacturing Systems

Kathryn E. Stecke
The University of Texas at Dallas, Richardson, TX, USA

Introduction

In the metal-cutting industry, a flexible manufacturing system (FMS) is an integrated system of machine tools linked by automated material handling. Because of the versatility of the machine tools and the quick (in seconds) cutting tool interchange capability, these systems are quite flexible with respect to the number of part types that can be produced simultaneously and in low (sometimes unit) batch sizes. These systems can be almost as flexible as a job shop, while having the ability to attain nearly the efficiency of a well-balanced assembly line.



Flexible Manufacturing Systems, Fig. 1 Sundstrand/Caterpillar FMS

An FMS consists of several computer numerically controlled machine tools, each capable of performing many operations. Each machine tool has a limited capacity tool magazine that holds all of the cutting tools required to perform each operation. Once the appropriate tools have been loaded in the tool magazines, the machines are under computer control. During system operation, the automatic tool interchange capability of each machine allows no idle set-up time in between consecutive operations or between the use of consecutive tools. When a new tool is required, the tool magazine rotates into position, and the changer automatically interchanges the new tool with the one that is in the spindle in seconds. Each part type that is machined is defined by several operations. Each operation requires several cutting tools (about 5-20). All tools for each operation need to occupy slots in one or more of the machine tool's magazine.

Each cutting tool takes 1, 3, or 5 slots in a magazine. Magazines can have 40-160 slots, typically sixty to eighty. Tools wear and break, so a computer needs to track the "lives" of all tools. A tool that breaks during the cut can severely damage the part and sometimes the machine or spindle. Tools can be delivered to the FMS either manually or automatically, for example, via automated guided vehicles, with the delivered tools manually or automatically loaded into the magazines. Tooling information is discussed in Stecke (1983) and Hirvikorpi et al. (2007).

An FMS has an automated materials handling system that transports parts from machine to machine and into and out of the system. These may consist of wire-guided automated guided vehicles, a conveyor system, or tow-line carts, with a pallet interchange with the machines. The interfaces between the materials handling system and the parts are pallets and fixtures. Pallets sit on the cart and fixtures hold and clamp the parts onto the pallets. Pallets are identical and fixtures are usually of different types. Thus, fixtures are able to hold securely different types of parts and in different orientations. The number of pallets in an FMS defines the maximum amount of work-in-process inventory in the system.

After some machining, parts are often checked at the machine by automatically interchanging a probe into the spindle. The probe does some at-the-machine inspection of the cuts that were made. After several operations, a cart may bring the part to a washing station to remove the chips before either further machining, refixturing, or inspection.

An example of an FMS, built by Sundstrand Machine Tool Company for Caterpillar Tractor Company, is shown in Fig. 1 (Stecke and Solberg 1981). This FMS consists of four 5-axes mills (OM), three 4-axes drills (OD), two vertical turning lathes (VTL), and an inspection station. The parts machined are housings for automatic transmissions—transmission cases, transmission covers, an assembly of these two, and several sizes of each.

Detailed descriptions of several systems can be found in Stecke (1992). A decision to automate should be based on both economic comparisons and strategic considerations. Assuming that management has decided that flexible manufacturing is appropriate for a particular application, perhaps to increase capacity in a certain department producing changing products or for new families of part types, there are many design issues that have to be addressed. Details and descriptions of these design problems are given in Stecke (1985, 1992).

The amount of flexibility that is needed or desired has to be decided, as this helps to determine the degree of automation and the type of FMS to be designed. Impacting the latter decision is the type of automated material handling system that will move the parts from machine to machine and into and out of the system. Browne et al. (1984), Sethi and Sethi (1990), and de Treville et al. (2007) discuss a spectrum of flexibility types and options.

Efficient and accurate mathematical and other models are useful in helping to define the appropriate FMS design. See Buzacott and Yao 1986; Stecke 1983; and Solberg 1977. Following the development and subsequent implementation of the selected FMS design, models are then useful in helping to set up and schedule production through the system.

FMS Planning and Scheduling

Because of the quick automated cutting tool capability, there is negligible set-up time associated with a machine tool in between consecutive operations, as long as all of the cutting tools required for that next operation have previously been loaded into the machine tool's limited capacity tool magazine. However, determining which cutting tools should be placed in which tool magazine and then loading the tools into the magazine requires some planning and system set-up time. Those set-up decisions that have to be made and implemented before the system can begin to manufacture parts are called FMS planning problems (Stecke 1983). When the system has been set-up and can begin production, the remaining problems are those of FMS scheduling.

The first FMS planning problem is to decide which of the part types that have production requirements (either forecasted demand or customer orders) should be manufactured next during the same time over the immediate time period. This information can be used to help determine the amount of pooling among the identical machine tools that can occur. Pooling, or identically tooling all machines that are in the same machine group, has many system benefits. For example, alternative routes for parts are automatically allowed, and machine breakdowns may not cause production to stop. This is because all machine tools in a group, being tooled identically, are able to perform the same operations.

Another FMS planning problem is to determine the relative ratios at which the selected part types should be on the system. Making this decision correctly can help an FMS to attain good utilization. The limited numbers of pallets and fixtures of each fixture type impact these production ratios. Finally, each operation and its associated cutting tools of the selected set of part types has to be assigned to one or more of the machine tools in an intelligent manner. Different loading objectives that can be followed are applicable in different situations. When all of these decisions have been made and the cutting tools loaded into the selected tool magazines, production can begin. Then the following FMS scheduling problems have to be addressed.

These problems are concerned with the operation of the system after it has been set up during the planning stage. One problem is to determine an appropriate policy to input the parts of the selected part types into the FMS, or efficient means to determine which parts to input next. He and Smith (2007) suggest an approach.

Then, applicable algorithms to schedule the operations of all parts through the system have to be determined. Real-time scheduling is usually more appropriate for these automated systems, as opposed to a fixed schedule. Tool breakage, down machine tools, etc., would totally disrupt a fixed schedule. However, a fixed schedule is useful as an initial guideline to follow. Potential scheduling methods range from simple dispatching rules to sophisticated algorithms having look-ahead capabilities. Machine breakdowns and many other system disturbances should be considered when developing scheduling and control procedures. If the system is set-up during the planning phase with sufficient care and flexibility, the scheduling function will be much easier.

FMS control involves the continuous monitoring of the system to be sure that it is doing what was planned for it to do and is meeting the expectations set up for it. For example, during the FMS design phase, policies should be determined to handle breakdown situations of many types. In any case, it is desirable to reallocate operations and reload the cutting tools (if they have to be) so that the tool changing time is minimized. Monitoring procedures for both the processes and cutting tool lives have to be specified, as well as methods to collect data of various types, e.g., monitoring and breakdown. Tool life estimates should be reviewed and updated. Reasons for process errors have to be found—machine or pallet misalignment, cutting tool wear and detection, chip problems—and the problems corrected.

Because the planning and scheduling problems are complex and require a lot of data to be considered, many of these problems have been framed and subdivided within a hierarchy. The solution of each subproblem provides constraints on problems lower in

the hierarchy. The partition of FMS problems into planning (before time zero) and scheduling (after production begins) is one example of a hierarchy. The FMS planning problems are another hierarchical decomposition of a system set-up problem. Stecke (1983, 1985) describes hierarchical and iterative approaches to several of these problems.

FMS Models

Models are useful in identifying key factors that will affect system performance and to provide insights into how a system behaves and how the system components interact. Models should be applied to help determine the appropriate procedures to design and set up a system or strategies to help run a system efficiently.

Depending on the amount of information that is built into a particular model, simulation has the potential to be the most detailed and flexible model, allowing as much detail as desired or necessary to mimic reality. Simulation can also potentially be the most expensive and time-consuming to develop, debug, and run. Many computer runs may be required to investigate the possibilities before a decision is made. Simulation has been used to help design an FMS and to solve operation problems. Stecke (1981) and Schriber and Stecke (1988) have used simulation models to address some FMS planning and scheduling problems.

Both open and closed queueing networks have been used to model an FMS at an aggregate level of detail. These models can take into account the interactions and congestion of parts competing for the same machines and the uncertainty and dynamics of an FMS. Most simple queueing networks require as input, certain average values, such as the average processing time of an operation at a particular machine tool and the average frequency of visits to a machine. The outputs obtained are average values and are useful for evaluating the performance of a suggested system configuration. Such outputs include the steady state expected production rate, mean queue lengths, and machine utilizations.

Solberg (1977) first suggested the use of a simple, single-class, multiserver, closed queueing network to model an FMS. His computer program, called CAN-Q, analyzes product-form queueing network FMS models. A review of related analytical queueing network models is given in Buzacott and Yao (1986).

Some FMS problems have been formulated mathematically, either as nonlinear integer programs or as linear and integer programs (Stecke 1983). Depending on the problems, some formulations are detailed and tractable and, thus, useful; other formulations, however, are detailed and untractable. Heuristics and algorithmic solution approaches have been developed from the exact formulations. Stecke (1992) describes other FMS models. Each model is useful under different circumstances and for different types of problems. For some problems, a hierarchy of models is used to solve them. Several application areas for flexible manufacturing are given in the following sections.

Flexible Manufacturing Applied to Mass Customization

A flexible manufacturing system can be a key tool for companies that aim to compete using mass customization or mass personalization. Mass personalization has been defined to be a strategy where a company can serve profitably a market of one person at a time . . . rather an extreme application of mass customization (Kumar 2007; Chen and Tseng 2007). Kumar and Stecke (2007) develop a methodology that measures the effectiveness of a mass customization and personalization strategy using a mass customization and mass personalization effectiveness index. The ability of an FMS to produce in batches of size one clearly is an advantage in implementing a mass customization strategy. He and Smith (2007) describe an algorithm that can be used for this purpose. An FMS's ease in producing variants of existing products is clearly useful for mass customization.

Planning Capacity in Flexible Manufacturing

For an FMS, if planned well, there is no setup time in between consecutive operations, thus enabling a very high capacity utilization. Various aspects of capacity planning in flexible manufacturing are discussed in Deif and ElMaraghy (2007), Hassanzadeh and Maier-Speredelozzi (2007), and

Zaeh and Mueller (2007). Koltai and Stecke (2008) specify methods to calculate the available capacity in an FMS without needing to specify part routes through the system, providing a robust capacity planning tool. Matta, Tomasella, and Valente (2007) address capacity-level reconfiguration to match market demands. A Markov decision problem considers both capacity expansion and reduction possibilities.

Reconfigurable Manufacturing

A reconfigurable manufacturing system (RMS) is an extension of an FMS where the system can be quickly changed to provide significant capabilities when needed that did not exist before. An example is a rapid machine tool reconfiguration from 3-axis capability to 4-axis capability. This is not a quick or easy accomplishment without significant advance planning and new (reconfigurable) machine tool design. Various aspects of reconfiguration are discussed in Koren (2010) and Kuzgunkaya and ElMaraghy (2007). Youssef and ElMaraghy (2007) suggest approaches to determine an appropriate RMS configuration that includes machine layout, equipment selection, and assignment of operations to machines.

Introduction

The field of forecasting is concerned with making statements about matters that are currently unknown. The terms forecast, prediction, projection, and prognosis are interchangeable as commonly used. Forecasting is also concerned with the effective presentation and use of forecasts.

Useful knowledge comes from empirical comparisons of alternatives and this entry is concerned primarily with evidence-based or scientific procedures. Scientific knowledge about forecasting has been summarized as a set of principles that are available at the Forecasting Principles Internet Web site.

Before forecasting, one should consider whether it is necessary. Forecasting is needed only if there is uncertainty; a forecast that the tide will turn is of no value. Forecasts are also unnecessary when one can control events. For example, predicting the temperature in your home does not require forecasting because you can control it. Nevertheless, many situations are uncertain, and proper forecasting procedures can help to reduce and assess uncertainty and thereby help managers to make better decisions.

Forecasting and Planning

Forecasting should not be confused with planning. Whereas planning is concerned with what the planner thinks the future should be like, forecasting is concerned with what it *will* be like. Figure 1 summarizes the appropriate relationships between the two activities.

Managers should start by planning. Forecasting procedures are then used to predict outcomes for the plans. If the managers do not like the forecasts, the planning and forecasting processes can be repeated until a plan is found that leads to forecasts of acceptable outcomes. The best plan can then be implemented and actual outcomes monitored so that the feedback can be used in the next planning period.

Progress in Forecasting

A strong emphasis on empirical comparisons of alternative methods has helped forecasting researchers to achieve many advances in forecasting, especially since 1980. The founding of the *International Institute of Forecasters*, a multidisciplinary society of researchers and practitioners, encouraged useful forecasting research. The Institute established two academic journals in the 1980s: the *Journal of Forecasting* and the *International Journal of Forecasting*. The Institute has also organized an *International Symposium on Forecasting* every year since 1981.

Perhaps the most influential paper in the field of forecasting is the M-competition paper (Makridakis et al. 1982). This paper was based on a study in which forecasters were invited to describe and apply the forecasting method that they thought would be best for deriving forecasts for many times series. Entrants submitted their forecasts to an umpire who calculated the errors. This was the first in a series of M-competition studies, the most recent being the M3-Competition (Ord et al. 2000). The M-competitions initiated a remarkable growth in experimental studies and, consequently, a rapid development in knowledge about forecasting. For a summary of progress in forecasting to 2005, see Armstrong (2006a).

Forecasting Methods

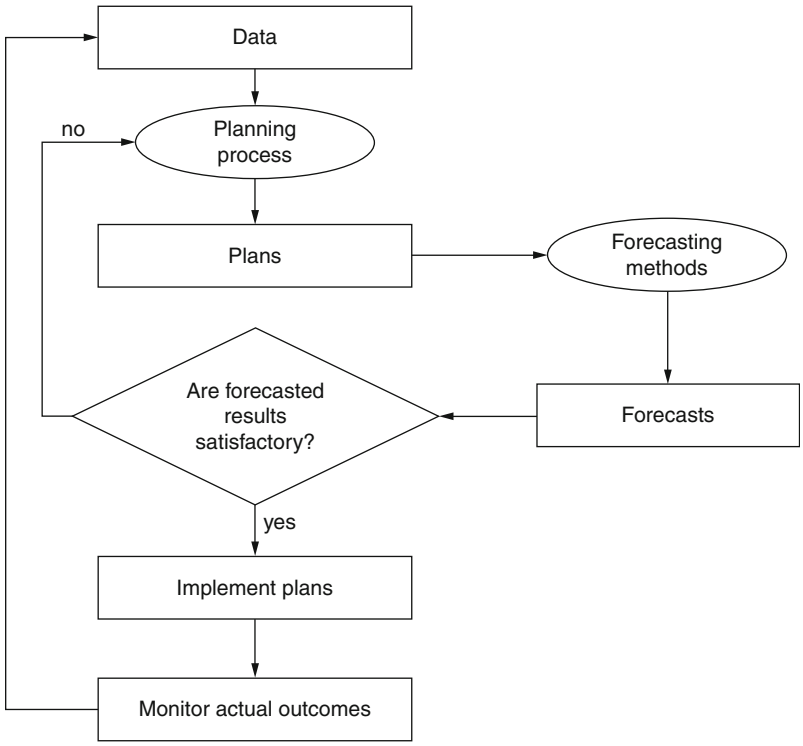
The Methodology Tree for Forecasting (Fig. 2) is a classification schema of all forecasting methods organized on the basis of the source of the knowledge the forecaster has about the situation. Some methods use primarily judgmental or qualitative knowledge while others require statistical data. There is an increasing integration in the use of judgment and statistics in the procedures as one follows the Tree down. Makridakis et al. (1998), and Armstrong (1985) provide instructions on how to use many of the methods.

The most common way to make forecasts is to ask experts to think about a situation and predict what will happen. If experts' forecasts are derived in an unstructured way the approach is referred to as unaided judgment. It is fast, can be inexpensive when few forecasts are needed, and can be appropriate when small changes are expected. It is most likely to be useful when the forecaster knows the situation well, makes frequent forecasts, and gets good feedback about the accuracy of his forecasts, as is the case with short-term weather forecasting and sports betting. Harvey (2001) described principles for improving expert forecasts.

Expert forecasting refers to combining forecasts obtained from experts using validated structured techniques. Which method is most appropriate depends on time constraints, dispersal of knowledge, access to experts, expert motivation, and need for confidentiality. To use expert forecasting methods, one should obtain the services of between five and twenty diverse experts who each have relevant information. Pre-test questions to elicit forecasts from the experts, and specify procedures for combining the forecasts obtained from the experts (e.g., use the median) in advance.

It is best if the experts do not make the their forecasts in a traditional meeting (Armstrong 2006b). The nominal group technique (NGT), developed by Van de Ven and Delbecq (1974), avoids some of the drawbacks that traditional meetings have for forecasting by imposing a structure on the interactions of the experts. Group members work independently and generate individual forecasts. The group then conducts an unstructured discussion to deliberate on the problem. Finally, group members work independently and provide their final forecasts. The NGT forecast is a combination of the individuals' final forecasts.

Consider also the Delphi method for combining the forecasts of experts. Delphi involves at least two



Forecasting, Fig. 1 Framework for forecasting and planning

rounds of anonymous interaction between experts. An administrator summarizes individual forecasts and arguments and reports this feedback to participants after each round. In the light of the feedback, the participating experts provide revised forecasts and further reasoning. The Delphi forecast is a combination of the final round forecasts.

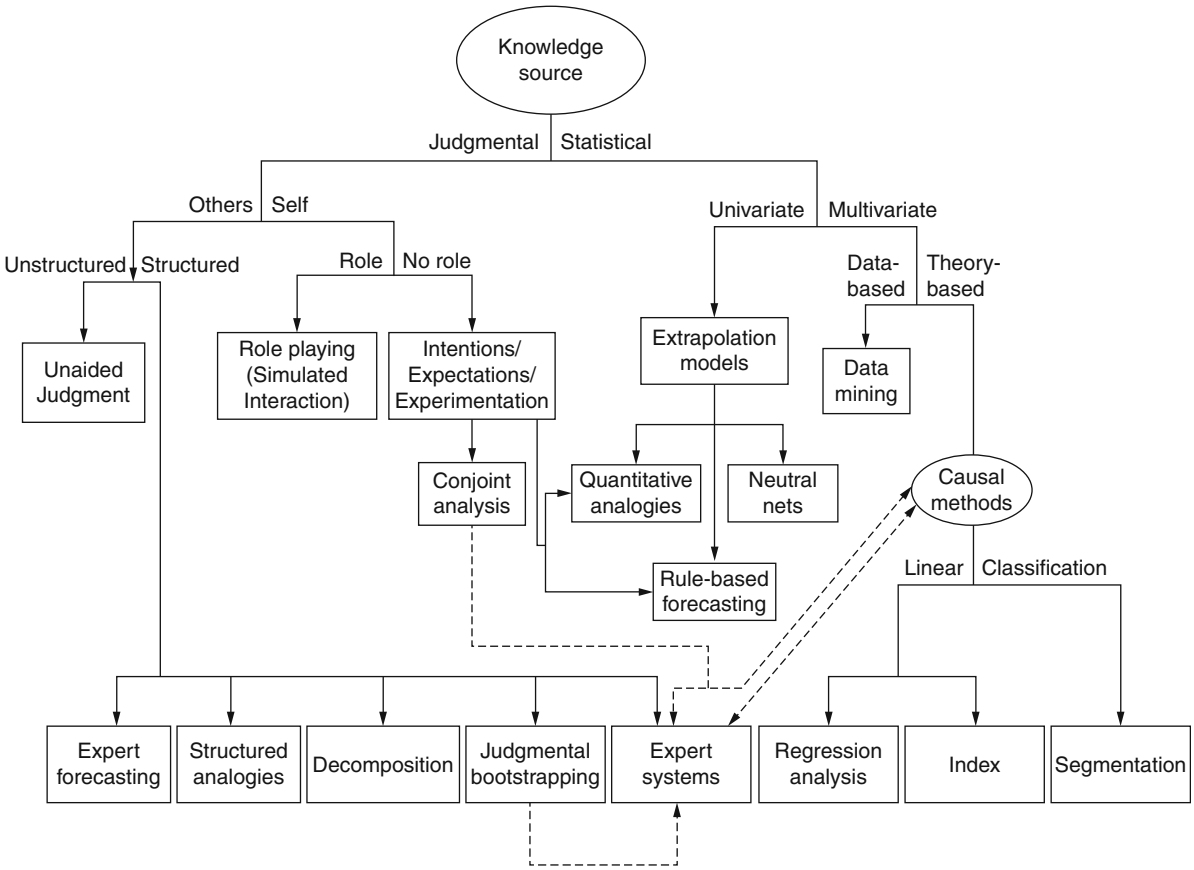
Rowe and Wright (2001) found that Delphi improved accuracy over unstructured groups in five studies, harmed accuracy in one, and the comparison was inconclusive in two. In his summary of the literature, Woudenberg (1991) also found Delphi forecasts to be slightly superior to those from unstructured interactions. Delphi is most suitable if one expects experts to have different information, but it can be conducted as a simple one-round survey for situations in which experts possess similar information. Software for conducting Delphi surveys is available on the Internet, see Principles of Forecasting and Delphi Survey Web sites.

Prediction markets can be useful for combining forecasts to provide continuously updated numerical or probability forecasts. In a prediction market, anonymous participants reveal information by trading contracts whose prices reflect the aggregated group opinion. Incentives to participate in a market may be monetary or non-monetary. Although prediction markets seem promising, to date there has been no published meta-analysis of the accuracy of prediction market forecasts. For a discussion of the relative merits of prediction markets and Delphi see Green et al. (2007).

Where it is not possible or feasible to obtain forecasts from several experts, ask a single expert to provide a second forecast by assuming the first forecast was wrong and specifically considering information that was ignored when making the first forecast. Herzog and Hertwig (2009) called this procedure dialectical bootstrapping.

The structured analogies method uses information about similar situations to obtain forecasts. Experts identify situations that are analogous to a target situation, describe similarities and differences to the target, and then derive an overall similarity rating. The outcome or decision implied by each expert's top-rated analogy is the structured analogies forecast from that expert.

Green and Armstrong (2007) analyzed structured analogies for the difficult problem of forecasting the decisions people will make in conflict situations.



Forecasting, Fig. 2 Methodology Tree for Forecasting

When experts were able to identify two or more analogies and their best analogy was from direct experience, 60% of structured analogies forecasts were accurate compared to 32% of experts' unaided judgment forecasts, the latter being little better than guessing.

Decomposition involves breaking down a forecasting problem into components that are easier to forecast than the aggregate problem. The components are multiplicative (e.g., to forecast a brand's sales, one would separately forecast the relevant population, the purchase rate of the product type, and the market share of the brand). Decomposition is most likely to be useful in situations involving high uncertainty. High uncertainty is common when making forecasts that involve large numbers, such as a country's GDP. Results from three studies involving 15 tests and found that under high uncertainty, judgmental decomposition led to a 42% reduction in error (MacGregor 2001). When the conditions for decomposition were met, decomposition of time series by causal forces reduced forecast errors by two-thirds (Armstrong et al. 2005).

Judgmental bootstrapping is a method for deriving a forecasting model by regressing experts' forecasts against the information the experts used to make their forecasts. The method is useful when expert judgments have predictive validity but data are scarce (e.g., forecasting new products) and outcomes are difficult to observe (e.g., predicting performance of executives). Once developed, judgmental bootstrapping models are a low-cost forecasting method. A meta-analysis found judgmental bootstrapping to be more accurate than unaided judgment in 8 of 11 comparisons. Two tests found no difference, and one found a small loss in accuracy. The typical error reduction was about 6% (Armstrong 2006a).

Expert systems are forecasting rules derived from the reasoning experts use when they make forecasts.

They can be developed using knowledge from diverse sources such as surveys, interviews of experts, or protocol analysis in which the expert explains what he is doing as he makes forecasts. A meta-analysis on the predictive validity of the method found that expert systems were more accurate than unaided judgment in six comparisons, similar in one, and less accurate in another. Expert systems were less accurate than judgmental bootstrapping in two comparisons and similar in two. Expert systems were more accurate than econometric models in one comparison and as accurate in two (Collopy et al. 2001).

If people have valid intentions or expectations about how they would behave in a situation, responses from surveys of intentions or expectations can be used to make forecasts. Both methods are most useful when (1) responses can be obtained from a representative sample, (2) responses are based on good knowledge, (3) respondents have no reason to lie, and (4) new information is unlikely to change people's behavior. The Juster Scale, a zero-to-ten probability scale, is recommended. For example, ask a respondent how likely it is that the respondent will make an international trip in the next 12 months. A quantitative forecast for the population can be derived by averaging the survey responses and multiplying by the population. Intentions are more limited than expectations in that they are most useful when (a) the event is important to the respondent, (b) the behavior is planned, and (c) the respondent can fulfill the plan (e.g., their behavior is not dependent on the behavior of others). Morwitz (2001) provided evidence on the validity of the methods, and guidance on how to conduct the surveys and analyze the data for forecasting.

A meta-analysis involving 47 comparisons with over 10,000 subjects found a strong relationship between intentions and behavior (Kim and Hunter 1993). Another meta-analysis found that purchase intentions provide unbiased predictions of behavior (Wright and MacRae 2007).

One can conduct experiments by varying key causal variables in a systematic way, ensuring that the changes do not correlate with one another. They can be used to estimate relationships and use these estimates to derive forecasts. Experiments can be used for such problems as to predict the effects of different policies or regulatory schemes, or to assess the effectiveness of alternative advertisements. Test markets for new products are a form of experiment.

Role playing involves asking people to think and behave in ways that are consistent with a role and situation described to them. Role playing for the purpose of predicting the behavior of people who are interacting with each other is called simulated interaction. The decisions made in the simulated interactions are used as forecasts of the actual decision. Green (2005) found that 62% of simulated interactions forecasts were accurate for eight diverse conflict situations. By comparison, only 31% of forecasts from the traditional approach (unaided expert judgment) were accurate. Game theory experts' forecasts had a similar level of accuracy: 31%. Experts' unaided judgment forecasts and game theorists' forecasts were little better than chance, which was at 28% for the eight conflicts examined.

Simulated interaction is useful when little or no quantitative data are available, when the situation to forecast is unique or unusual, and when decision makers wish to predict the effects of different policies or strategies (e.g. what pay offer will avoid a strike or what strategy is most likely to induce rebel forces to surrender). Simulated interactions can be conducted quite cheaply by using students to play the roles. In a simplified form, they can also be conducted rapidly. For example, the New Zealand Armed Offenders Squad test different approaches for dealing with an armed stand off by simulating each before choosing which one to employ.

Conjoint analysis is a method for eliciting people's preferences for different possible offerings (e.g. for alternative mobile phone designs or for different political platforms) by exposing people to several combinations of features (e.g. weight, price, and screen size of a mobile phone.) The possibilities can be set up as experiments where variations in each variable are unrelated to variations in other variables. Regression-like analyses are then used in order to predict the combination of features that people will find most desirable.

Extrapolation models use time-series data on the situation of interest (e.g., data on automobile sales from 1947–2010). One extrapolation method is exponential smoothing, which implements the principle that more recent data should be weighted more heavily when forecasting. Quantitative extrapolation methods do not use knowledge about the situation but rather assume that the causal forces that have shaped history will continue to the forecast

horizon. If this assumption turns out to be wrong, forecast errors can be large. As a consequence, one should only extrapolate trends when they are consistent with the prior expectations of domain experts and with long-term trends and variability.

Extrapolation can also be used for cross-sectional data. For example, to predict whether a particular job applicant will last more than a year on the job, one could use the percentage of the last 50 people hired for that type of job who lasted more than a year.

Armstrong (2001b) provides guidance on the use of extrapolation. An example is the advice to be conservative when the situation is uncertain, as is usually the case with long forecast horizons. In such a situation, one should reduce the magnitude of the trend in the data as the forecast horizon increases, a procedure known as trend damping.

Quantitative analogies are similar to structured analogies with the exception that there is ample data to analyze for each analogous situation. Experts identify analogous situations for which time-series or cross-sectional data are available, and rate the similarity of each analogy to the target situation. These inputs are used to derive a forecast. This method is especially useful in situations with little historical data. For example, one could average data from cafés in suburbs identified by experts as similar to a new (target) suburb in order to forecast demand for the services of a café in the target suburb.

Rule-based forecasting combines expert domain knowledge and statistical techniques for extrapolating time series. Experts are used to identify features of the forecasting problem that cannot be identified automatically from the series to be forecast. Primarily, experts are needed to identify the causal forces that are acting on trends in the series. For example, in forecasting the real price of oil, experts might identify that, over the long-term, innovation and discovery act as downward forces but may conclude that, in the short term, political actions will lead to upward pressure on prices. Rule-based forecasting was found to be more accurate than extrapolation methods that did not incorporate expert knowledge, especially for long-term forecasts (Collopy and Armstrong 1992).

Causal models include regression analysis, the index method, and segmentation. These methods are useful if data are available on variables that might affect the situation of interest. Allen and Fildes (2001) found that forecasts from causal models were more accurate than forecasts derived from extrapolating the dependent variable. Theory, prior research, and expert domain knowledge provide information about relationships between the variable to be forecast and explanatory variables. Because causal models can relate planning and decision-making variables to forecasts, they can be used to forecast the effects of different policies.

Regression analysis involves estimating the coefficients of a causal model from historical data. Models consist of one or more regression equations used to represent the relationship between a dependent variable and one or more explanatory variables. They are useful in situations with few important variables and many reliable observations that include data in which the causal variables varied independently of one another.

Important principles for developing regression models are to (1) use prior knowledge and theory, not statistical fit, for selecting variables and for specifying the directions of effects, (2) use simple models, and (3) discard variables if the relationship estimated from the data conflicts with prior evidence on the nature of the relationship.

Because regression models tend to over-fit data, damping the estimated coefficients of a model tends to improve out-of-sample forecast accuracy, particularly if uncertainty is high as occurs when one has small samples and many variables. As this situation is common for many prediction problems, unit (or equal weight) models – the most extreme case of damping – often yield more accurate forecasts than models with statistically fitted regression coefficients (Dana and Dawes 2004). Cuzán and Bundrick (2009) found that equal-weight versions of prominent presidential election forecasting regression models provided more accurate forecasts than the original models.

Damping seasonal factors improves forecast accuracy. Miller and Williams (2003, 2004) developed a procedure for damping seasonal factors estimated from historical data. When they applied the procedure to the 1,428 monthly time series from the M3-Competition, forecasts were more accurate for 68% of the series. Averaging seasonal factors estimated from related series reduced forecast error by about 20% in a study by Bunn and Vassilopoulos (1999) and, in a study by Gorr et al. (2003), pooling of

seasonal crime rate factors across six precincts increased forecast accuracy by 7%.

The index method is suitable for situations in which many causal variables are important. Use prior empirical evidence to identify predictor variables and to assess each variable's directional influence on the outcome. Results from experiments are especially valuable. If possible, draw on findings from meta-analyses. If no data or prior studies are available, independent expert judgments can be used to choose the variables and determine the directions of their effects. If prior knowledge is ambiguous or contradictory and thus does not allow for estimating a variable's directional influence on the outcome, do not include the variable in the model. Index scores are calculated by adding the number of variables that favor the outcome.

The index method is especially useful for selection problems (e.g., which candidate will win an election or which advertisement will pull best). If sufficient historical data are available, index models can be generated to predict numerical outcomes (e.g., a candidate's vote-share) by regressing index scores against historical data. The index method can be used if valid and reliable quantitative data are scarce relative to the number of causal variables or if there is little need for precision in estimating the magnitude of relationships. Armstrong and Graefe (2011) describe the use of the method to make early forecasts of the outcomes of U.S. presidential elections from biographical information about potential candidates. Based on a list of 59 variables, their relative index scores correctly predicted the winner in 27 of the 29 elections from 1896 to 2008.

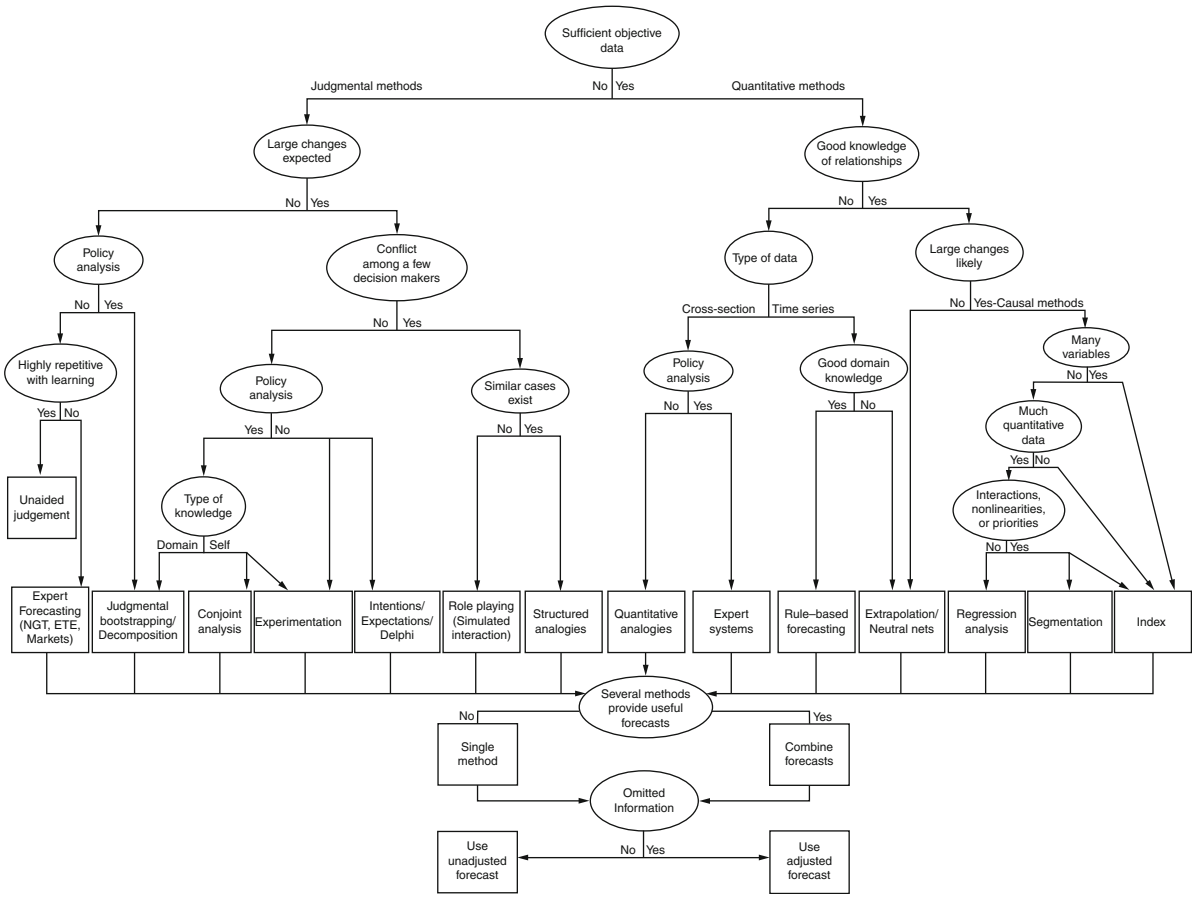
For situations in which some causal variables are much more important than others or if knowing about one causal variable provides knowledge about other causal variables, the take-the-best heuristic (TTB) can be used to infer which of two alternatives is most likely to occur (Gigerenzer and Goldstein 2006). Czerlinksi, Gigerenzer, and Goldstein (1999) compared take-the-best to models estimated using multiple regression and unit-weight models for 20 prediction problems (e.g. forecasting high school drop-out rates, mortality in U.S. cities, salaries of college professors, and obesity among children) for which the number of variables varied between 3 and 19. TTB out-of-sample forecasts were more accurate than forecasts from unit-weight models and forecasts from multiple regression models. Graefe and Armstrong (2012) used TTB to predict the outcomes of the ten U.S. presidential elections from 1972 to 2008 based on information about how well voters believed the candidates would deal with the most important issue facing the country. The TTB model forecasts were similarly accurate to forecasts from methods that incorporate substantially more information, including econometric models and prediction markets.

Segmentation can be applied when a heterogeneous whole can be divided into homogenous parts of roughly equal importance that respond to changes in different ways, and that can be forecast more accurately than the whole. For example, in the airline industry, price changes have different effects on business and personal travelers.

Segmentation is useful when large changes are expected. It is more appropriate than regression analysis when the situation involves interactions among variables, non-linear effects, or causal priorities. Segmentation does, however, require good prior knowledge about the problem and very large sample sizes. Use a priori analysis to identify causal variables and causal priorities. Specify the cut-points (divisions) that will define the segments using a priori analysis in conjunction with inspection of the data. Appropriate forecasting methods should be used to forecast the population and the behavior of individual segments.

Experts prefer the bottom-up approach for segmentation because it allows them to more effectively use their knowledge about the problem. Segmentation is also advantageous because the forecasting errors in the different segments may offset one another. For example, assume that there are ten divisions in a company. Accuracy might be improved by forecasting each division separately, then adding the forecasts. But caution is in order: if the samples of data for the segments are small and the data are erratic, the forecasts might contain very large errors.

Favorable results were obtained in a number of comparative studies on segmentation Armstrong (1985, p. 286–287 and 412–420). Dangerfield and Morris (1992), in their study on bottom-up forecasting, found that forecasts from segmentation were more accurate than global forecasts for 74% of 192 monthly time series from the M-Competition. In a study involving seven teams making estimates of the



Forecasting, Fig. 3 Selection Tree for Forecasting Methods

time required to complete two software projects, Jørgensen (2004) found that the error from the bottom-up forecasts was 51% less than that for the top-down approach.

Selection of Methods

The Forecasting Method Selection Tree, shown in Fig. 3, provides guidance on selecting the best forecasting methods for a given problem. The Tree has been derived from evidence-based principles. Users of this Tree must answer questions about the availability of data and the state of knowledge about the situation for which forecasts are required.

The first question is whether sufficient objective data are available to perform statistical analyses. If not, one must use judgmental methods.

In deciding among judgmental procedures, one must assess whether the future is likely to be substantially different from the past, whether policy analysis is needed and whether the situation involves decision makers who have conflicting interests. Other considerations are whether forecasts are made for recurrent and well-known problems, whether domain knowledge is available, and whether information about similar problems is available.

If much objective data are available and it is therefore possible to use quantitative methods, the forecaster has to determine first whether there is useful knowledge about causal relationships, whether cross-sectional or time-series data are available, and whether large changes are involved.

For situations about which there is little empirical knowledge about relationships, one needs to assess whether policy analysis is required and whether there is expert domain knowledge about the situation.

If there is good prior knowledge about empirical relationships and the future can be expected to differ substantially from the past, the number of variables and

the presence or absence of interactions among them, and the number of observations determine which causal method can be used. For example, regression models that rely on non-experimental data can typically use no more than 3 or 4 variables – even with massive sample sizes. For problems involving many causal variables, variable weights should not be estimated from the dataset (Dana and Dawes 2004). Instead one should to draw on independent sources of evidence (such as empirical studies and experts' domain knowledge) for assessing the impact of each variable on the outcome.

The Forecasting Method Selection Tree provides guidance, but on its own the guidance is not comprehensive. Forecasters may have difficulty identifying which conditions apply to the situation they wish to forecast. In that case, use different methods that draw on different information, and combine the forecasts according to rules determined before the forecasts were made. Imagine you have two forecasts of a quantity: how big would the error of the second forecast need to be in order for the error of the average of the two forecasts to be larger than the error of the first forecast alone? The answer is that the error of the second forecast would need to be bigger than the error of the first forecast if the error was in the same direction (sign) and more than three times the error of the first forecast if the error had the opposite sign.

To increase the likelihood that two forecasts bracket the true value, use forecasts that differ substantially. Batchelor and Dua (1995) found that the extent and probability of error reduction through combining were higher the greater the differences in the underlying theory or method that produced the component forecasts. For example, when combining real GNP forecasts, combining the 5% of forecasts that were most similar in their underlying theory reduced the error compared to the typical forecast by 11%. By comparison, combining the 5% of forecasts that were most diverse in their underlying theory yielded an error reduction of 23%.

Simple averages are a good starting point for combining forecasts. Differential weights should only be used if there is strong evidence about the relative accuracy of forecasts from the different methods. The relative accuracy of forecasts from different methods depends on the conditions. For example, in situations where uncertainty was high, trend extrapolation should be weighted less heavily and naïve extrapolation more heavily (Collopy and Armstrong 1992).

A meta-analysis of 30 studies found that combined forecasts (typically averages of different forecasts from a single type of method) yielded a 12% reduction in error compared to the average error of the components. The reductions of forecast error ranged from 3 to 24%. In addition, the combined forecasts were often more accurate than the most accurate component (Armstrong 2001c). Studies since that meta-analysis suggest that under favorable conditions (i.e., when forecasts are made for an uncertain situation, and many forecasts are available from several valid methods and different data sources) combining reduces errors almost by half (Graefe et al. 2011). Combining forecasts is especially useful if the forecaster wants to avoid large errors and if there is uncertainty about which method will be most accurate.

The final issue addressed in the Selection Tree is whether important information has been omitted in the process of deriving a forecast. One should consider adjustments to the forecasts only when the data do not fully reflect recent events, or experts know about events or changes to come, or key variables were not included in the forecasting process. If one or more of these conditions are met, the forecaster should provide written instructions on how the forecasts will be adjusted, solicit written adjustments from diverse experts, ask for adjustments before the experts see the forecasts, and record reasons for the adjustments (Goodwin 2005).

Judgmental adjustments should be avoided with cross-sectional forecasts such as who will be the most useful employee or whether to operate on a patient. Meehl (1956) summed up the evidence on making predictions about people as follows "... the first rule to follow... is to carefully avoid talking to him, and the second rule is to avoid thinking about him." Lewis (2003) described how Billy Bean, the manager of the Oakland Athletics baseball team followed this advice by contracting players to fit the needs of the team using only performance statistics. The result was a team that won games. Other teams have decided that to be competitive they must also use such methods.

Measuring Accuracy

Use error measures that are relevant to the decision. Ideally, error measures should allow for comparing the benefits from improved accuracy with the costs for obtaining the improvement. This can be difficult to assess in some situations, so one might simply use

the method or methods that provide the most accurate forecasts for the situation. Useful error measures include Mean Absolute Deviation (MAD), Mean (or Median) Absolute Percentage Error (MAPE or MdAPE), and Median Relative Absolute Error (MdRAE). The latter is calculated by dividing the absolute forecast error for a proposed model by the corresponding error for the random walk. The random walk is a simple and easy to understand benchmark model in forecasting. It uses the latest observation as the forecast for all periods in the forecast horizon. These measures are calculated as the mean or median of the following statistics:

$$AD = |F - A| \qquad APE = \left|\frac{F - A}{A}\right| \qquad RAE = \left|\frac{F - A}{F_{rw} - A}\right|$$

where F is the forecast, A is the actual value, and rw is the random walk method.

The selection of a measure depends upon the purpose of the analysis. For example, when making comparisons of accuracy across a set of time series, it is important to control for scale, the relative difficulty of forecasting each series, and the number of forecasts being examined (Armstrong and Collopy 1992).

Two measures of error should be avoided. The first of these, R^2 (which assesses the pattern of the forecasts relative to that of the actual data), is not particularly useful to forecasters and its use does more harm than good when choosing a model to forecast time-series data. The second measure to avoid, Mean Square Error, should not be used because it is unreliable and difficult to explain to decision makers (Armstrong 2001d).

Assessing Forecast Uncertainty

In addition to improving accuracy, forecasting is also concerned with assessing uncertainty. Early approaches to assessing uncertainty used measures of how well forecasts fit historical data as a way to infer forecast uncertainty. This approach can in some cases provide reasonable approximations of prediction intervals for forecasts based on models derived using cross-sectional data, such as with forecasts of how much a house will sell for. However, for time-series data, the historical fit typically leads to prediction intervals that are too narrow. Some empirical studies have shown that over half of actual outcomes are outside the 95% confidence intervals estimated using historical data (Makridakis et al. 1987).

The best approach to assessing forecast uncertainty is to simulate the forecasting situation as closely as possible. Thus, to determine how well one can forecast two years into the future, one examines a sample of ex ante two-year-ahead forecasts and the corresponding actual values. Ex ante means that one looks as if from before and does do not use knowledge about the situation after the starting point for forecasting. Chatfield (2001) describes proper procedures for estimating prediction intervals.

Use of Forecasts

Whether a forecast is used or not depends not only on the intrinsic merit of the forecast, but also the willingness of decision-makers to accept it. Expert reasoning can be persuasive for decision makers. Nevertheless, accurate forecasts are often ignored, particularly when they involve bad news or imply that change is necessary. If possible, one should ask the decision maker to agree on the methods that will be used and to commit to accept forecasts from the agreed upon process.

Scenarios, which are detailed stories about what happened in the future, can increase the chances a forecast will be used by making the forecast seem likely to occur. Techniques for scenario writing include using concrete examples, showing a logical sequence of causal events, using past tense, and having decision makers describe how they would have acted in each scenario (Gregory and Duran 2001).

Concluding Remarks

Progress in forecasting has been due primarily to empirical testing of alternative approaches. Forecasting research has begun to address the conditions under which different methods are most useful. These research strategies have provided many useful findings that have been summarized as principles. The principles can help to improve accuracy, assess uncertainty, and gain the acceptance of forecasts. Often research findings conflict with the expectations of statisticians and decision makers. The conflicts between standard practice on the one hand and empirical findings on the other have meant that practitioners and academics have often been slow to adopt new methods and improved procedures. That state of affairs means that for those who are willing

to use the findings of forecasting research will have many opportunities to improve forecasting and decision-making.

Forward Kolmogorov Equations

In a continuous time Markov chain $\{X(t)\}$, define $p_{ij}(t)$ as the probability that $X(t+s) = j$, given that $X(s) = i$, for $s, t \geq 0$, and r_{ij} as the transition rate out of state i to state j. Then Kolmogorov's forward equations say that, for all states i,j and times $t \geq 0$, $dp_{ij}(t)/dt = \sum_{k \neq j} r_{kj}\, p_{ik}(t) - v_j\, p_{ij}(t)$, where v_k is the transition rate out of state k, $v_k = \sum_j r_{kj}$.

Forward-Recurrence Time

Suppose events occur at epochs $T_1, T_2, \ldots$ such that the interevent times $T_k - T_{k-1}$ are IID positive random variables. Then the forward recurrence time from an arbitrary time t is the time from t to the next occurrence.

Fourier Transform

For any function $f(t)$, its Fourier transform is defined as $\widehat{f}(s) = \int_{-\infty}^{\infty} e^{-2\pi i s t} f(t)dt$, which is equal to $E[e^{-2\pi i s X}]$ if $f(t)$ is a probability density function for random variable X, where i denotes the imaginary number $\sqrt{-1}$.

Fourier-Motzkin Elimination Method

A computational procedure for solving a system of linear inequalities.

Fractional Programming

Siegfried Schaible
University of California, Riverside, CA, USA

Introduction

Certain decision problems in OR/MS, as well as other extremum problems, give rise to the optimization of ratios. Constrained ratio optimization problems are commonly called fractional programs. They may involve more than one ratio in the objective function.

One of the earliest fractional programs (though not called so) is an equilibrium model for an expanding economy in which the growth rate is determined as the maximum of the smallest of several output–input ratios (von Neumann 1937, 1945). Since then, but mostly after the classical paper by Charnes and Cooper (1962), some nine hundred publications have appeared in fractional programming; for comprehensive bibliographies, see Schaible (1982, 1993). Monographs solely devoted to fractional programming include Schaible (1978) and Craven (1988).

Almost from the beginning, fractional programming has been discussed in the broader context of generalized concave programming. Ratios, though not concave in general, are often still generalized concave in some sense. An introduction to fractional programming in this context is Avriel et al. (1988).

Notation and Definitions

Suppose f, g and h_j $(j = 1,\ldots, m)$ are real-valued functions which are defined on the subset X of the n-dimensional Euclidean space $\Re^n$ and let $\boldsymbol{h} = (h_1,\ldots, h_m)^T$ where T denotes the transpose. The ratio considered is given by

$$q(\mathrm{x}) = f(\mathrm{x})/g(\mathrm{x}) \tag{1}$$

over the set

$$S = \{x \in X | h(x) \leq 0\} \tag{2}$$

assuming $g(\boldsymbol{x}) > \boldsymbol{0}$ on X. The nonlinear program

$$\sup\{q(x)|x \in S\} \tag{3}$$

is called a (single-ratio) fractional program.

In addition, the following three types of multi-ratio fractional programs are of interest:

$$\sup\left\{\sum_{i=1}^{p} q_i(x)|x \in S\right\}, \tag{4}$$

$$\sup\left\{\min_{1\leq i\leq p.} q_i(x)|x \in S\right\}, \tag{5}$$

and the multi-objective fractional program

$$\sup_{x\in S}\{q_1(x), \ldots, q_p(x)\}. \tag{6}$$

Here $q_i(\boldsymbol{x}) = f_i(\boldsymbol{x})/g_i(\boldsymbol{x})$ $(i = 1,\ldots, p)$ when f_i and g_i are real-valued functions on X with $g_i(\boldsymbol{x}) > 0$. Problem (5) is often referred to as a generalized fractional program (Schaible and Ibaraki 1983).

The focus in fractional programming is the objective function and not the feasible region S. As in most publications, it is assumed that the h_j are convex functions on the convex domain X yielding a convex feasible region S.

Most of the theory for fractional programs (3)–(6) is developed under the assumption that ratios satisfy the following concavity/convexity condition: f is concave and g is convex on the convex set X (f is to be nonnegative if g is not affine-linear, as below). Such problems are called concave fractional programs. It is to be noted, however, that the objective function in these problems is not concave in general; hence they are not concave programs. Problem (3) is called a quadratic fractional program if f and g are quadratic functions and S is a convex polyhedron.

A special case is the linear fractional program where f and g are affine-linear functions and S is a convex polyhedron

$$\sup\{(\boldsymbol{c}^T\boldsymbol{x} + \alpha)/(\boldsymbol{d}^T\boldsymbol{x} + \beta)|\boldsymbol{A}\boldsymbol{x} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}. \tag{7}$$

Here $\boldsymbol{c}, \boldsymbol{d} \in \mathfrak{R}^n$, $\boldsymbol{b} \in \mathfrak{R}^m$, $\alpha, \beta \in \mathfrak{R}$, $\boldsymbol{A}$ is an $m \times n$ matrix and the denominator is positive on the feasible region. It will be seen below that linear and concave fractional programs have still many properties in common with linear and concave programs.

Single-Ratio Fractional Programs

The following types of single-ratio fractional programming applications can be found in the literature: economic, non-economic and indirect applications.

Economic Applications — The efficiency of a system is sometimes characterized by a ratio of economical and/or technical terms. Then, maximizing the efficiency leads to a fractional program. Examples of such ratios are: profit/capital, profit/revenue, cost/volume, productivity, relative usage of material, return/cost, return/risk, expected cost/beta-index, (expected) cost/time, profit/time, liquidity, earnings per share, dividend per share, weighted outputs/weighted inputs, income/(investment + consumption), mean/standard deviation.

Such ratios arise in resource allocation, transportation, production, maintenance, inventory, finance, data envelopment analysis, and macroeconomics for example. No longer are these rates merely used to control past economic behavior. Instead, the optimization of rates is getting more attention in decision making for future projects. Depending on the form of the functions in the numerator and denominator, many of the ratio optimization problems above are linear, quadratic or concave fractional programs.

Non-economic Applications — In information theory, the capacity of a communication channel can be defined as the maximal transmission rate, thus giving rise to a (nonquadratic) concave fractional program. In numerical analysis, the eigenvalue problem can be reduced to constrained maximization of the Rayleigh quotient, and hence, leads to a (nonconcave) quadratic fractional program. In physics, maximization of the signal-to-noise ratio gives rise to a concave quadratic fractional program.

Indirect Applications — Fractional programs may also arise in the process of solving other optimization problems involving no ratios. Examples are: subproblems in large-scale mathematical programming, deterministic substitutes in stochastic mathematical programming, subproblems in nondifferentiable convex programming, problems in connection with interior-point methods for linear programming, dual location problems, approximations to numerically intractable portfolio selection problems, bounds on the trauma outcome function for emergency medical facilities.

Depending on the original optimization problem, often linear, quadratic or concave fractional programs are encountered.

Properties

Concave fractional programs have the following properties (Avriel et al. 1988):

Proposition 1: A local maximum is a global maximum since the objective function $q(\boldsymbol{x}) = f(\boldsymbol{x})/g(\boldsymbol{x})$ is semi-strictly quasiconcave.

Proposition 2: A maximum is unique if the numerator $f(\boldsymbol{x})$ is strictly concave or the denominator $g(\boldsymbol{x})$ is strictly convex since in this case the objective function is strictly quasiconcave.

Proposition 3: In case of differentiable functions $f(\boldsymbol{x})$, $g(\boldsymbol{x})$, $h(\boldsymbol{x})$, a solution of the Karush-Kuhn-Tucker conditions is a maximum since the objective function $q(\boldsymbol{x})$ is pseudoconcave.

For **linear fractional programs**, the following additional property holds:

Proposition 4: A maximum is attained at a vertex in case of a (nonempty) bounded feasible region S, since the objective function is quasiconvex (in addition to quasiconcave).

Concave and linear fractional programs share not only the above properties with concave and linear programs, respectively, but they can also be related to these programs through transformations. The first transformation below changes the variables, whereas the second one maintains the same variables, but requires a parameter in the transformed problem.

Introducing the new variables

$$y = [1/g(x)]x, \quad t = 1/g(x), \tag{8}$$

It can be shown (Schaible 1976):

Proposition 5: A concave fractional program (3) with an affine-linear denominator can be reduced to the concave program

$$\sup\{tf(y/t)|th(y/t) \le 0, tg(y/t) = 1, \quad y/t \in X, t > 0\}. \tag{9}$$

If $g(\boldsymbol{x})$ is not affine-linear, an equivalent concave program is obtained for (9) by relaxing the equality in (9) to $tg(\boldsymbol{y/t}) \le 1$.

In the special case of a linear fractional program (7), the equivalent concave program (9) becomes the linear program

$$\sup\{c^T y + \alpha t|Ay - bt \le 0, d^T y + \beta t = 1, \quad y \ge 0, t > 0\} \tag{10}$$

where $t > 0$ can be replaced by $t \ge 0$ if (7) has an optimal solution. The equivalence between (7) and (10) was first established by Charnes and Cooper (1962).

In the second transformation, variables and the feasible region are maintained and a parameter is introduced to separate numerator and denominator (Dinkelbach 1967). Consider

$$\sup\{f(x) - \lambda g(x)|x \in S\}, \ \lambda \in \Re \text{ parameter}. \tag{11}$$

If (3) is a concave, linear, or quadratic fractional program, then (11) is a parametric concave, linear, or quadratic program, respectively.

Suppose $f(\boldsymbol{x})$, $g(\boldsymbol{x})$ are continuous and S is a (non-empty) compact set. Then:

Proposition 6: Problems (3) and (11) have the same optimal solutions where $\lambda = \bar{\lambda}$ is the unique zero of the strictly decreasing, continuous function

$$F(\lambda) = \sup\{f(x) - \lambda g(x)x \in S\}. \tag{12}$$

Turning now to duality for fractional programs, it is noted that standard concave programming duality relations are no longer true in case of concave, or even linear-fractional programs. However, Proposition 5 can be used to introduce duality via the equivalent concave program (9) (Schaible 1976). For a detailed presentation of various duality approaches as well as their use in sensitivity analysis, see Schaible (1978), Avriel et al. (1988), and Craven (1988).

The properties of concave and linear fractional programs in Proposition 1–6 allow for at least four different solution strategies (Martos 1975; Schaible and Ibaraki 1983; Craven 1988):

a. direct solution of the quasiconcave (pseudoconcave) program (3);
b. solution of the equivalent concave (linear) program (9);
c. solution of the dual of (9);
d. solution of the parametric concave (linear) program (11).

In the case of d), rather than applying parametric programming techniques, the iterative method *by* Dinkelbach (1967) can be used. It turns out to be equivalent to Newton's classical method for finding the zero λ of $F(\lambda)$ in (12). Various modifications and computational results were discussed in Schaible and Ibaraki (1983).

Multi-ratio Fractional Programs

Maximizing the Sum of Ratios — Problem (4) arises naturally in decision making when several of the rates above are to be optimized and a compromise is sought that optimizes the weighted sum of these rates. Other applications of this model were given by Schaible (1990).

Unfortunately, none of the above properties of concave fractional programs hold anymore if each ratio is a quotient of a concave and a convex function, even in the linear case. Only some preliminary theoretical and algorithmic results are known for this important, but difficult problem (Craven 1988; Schaible 1990).

Maximizing the Smallest of Several Ratios — Apart from the economic equilibrium model by von Neumann (1937, 1945), problems in financial planning and fund allocation under equity considerations give rise to a generalized fractional program (5) (Schaible 1990). Furthermore, the same model is of interest in numerical mathematics in rational approximation involving the Chebyshev norm. In all these examples, the ratios are quotients of concave and convex functions.

Starting with von Neumann (1937, 1945), several authors have proposed a duality theory for concave generalized fractional programs (Avriel et al. 1988; Craven 1988; Schaible 1990). Though different approaches are employed, most duals coincide and are again a generalized fractional program. The objective function of the primal is semi-strictly quasiconcave and the one of the dual is semi-strictly quasi convex (Avriel et al. 1988). Thus a local optimal solution is global in both the primal and the dual. A duality theory has been established for these non-concave problems which is as rich as the one for concave and linear programs.

Concave generalized fractional programs can be solved in either the primal or the dual by an extension of Dinkelbach's algorithm. In case of more than one ratio, this is no longer identical with Newton's method. It gives rise to a sequence of concave (linear) programs as subproblems. The convergence properties are well analyzed. Computational results for various modifications of this algorithm have been encouraging (Schaible 1990).

Multi-Objective Fractional Programs — Problem (6) arises when several rates above are to be maximized simultaneously and, in contrast to the problems in (4) and (5), a unifying objective function is not considered; instead, the decision maker is to be provided with the set of efficient alternatives, that is, all those feasible solutions for which none of the rates can be increased without decreasing another rate. Some theoretical results are known for (6) in case of ratios of concave and convex functions including duality relations (Craven 1988; Schaible 1990). Also, the connectedness of the set of efficient alternatives has been established under limiting assumptions. Additional theoretical and algorithmic results are known for the case of two ratios (Schaible 1990).

Concluding Remarks

Concave single-ratio fractional programs, as well as concave generalized fractional programs, have been analyzed quite successfully, both theoretically and algorithmically. More research needs to be done for the nonconcave case, sum-of-ratios problem (4), and multi-objective fractional programming (6).

Frank-Wolfe Method

- ▶ Quadratic Programming

Free Float

The amount of time a designated activity can be delayed without affecting succeeding activities of a project. This will be the float for the final activity of a chain, or for a single activity which does not lie on a chain with equal float.

See

- ▶ Float
- ▶ Network Planning

Free Variable

A variable that can take on any value, as contrasted to a variable that must take on nonnegative values. In a linear-programming problem, a variable that is free can be expressed as the difference between two nonnegative variables. However, when using the simplex method to solve a linear-programming problem with free variables, it is more effective to eliminate those variables by means of constraints in which they appear.

Introduction

In classical set theory, an element either does or does not belong to a set, being characterized by a membership in the set that may have one of two values: 1 or 0. Fuzzy sets generalize classical sets (in fuzzy set theory often called crisp sets) by allowing the gradual assessment of the memberships of elements in a set. Thus, by use of a membership function valued in the real unit interval [0, 1], each element is assigned a number in that interval, which measures its grade of membership in the set. Fuzzy systems are systems that are modeled using fuzzy sets. They have been widely used for both research and practical applications, even for industrial purposes.

Fuzzy logic provides a convenient way to build models, decision making systems and controllers, by incorporating qualitative knowledge and heuristics. These inherent characteristics of fuzzy logic offer a very attractive way of handling imprecision in the data and/or complex systems, where the derivation of an accurate model is difficult or even impossible.

Fuzzy sets and systems encompass artificial intelligence, information processing and theories from logic to pure and applied mathematics, such as graph theory, topology, control and optimization. The theory of fuzzy sets was introduced by Lotfi Zadeh (1965, 1973). In Zadeh (1973, p. 1), he stated, "... as the complexity of a system increases, our ability to make precise and yet significant statements about its behavior diminishes until a threshold is reached beyond which precision and significance (or relevance) become almost mutually exclusive characteristics."

Indeed, the derivation of mathematical models that can describe in an efficient manner real world problems is quite often overwhelming or even an impossible task due to the inherent ambiguity of characteristics that these problems may possess. The main advantage of fuzzy logic techniques over more conventional approaches in solving complex, nonlinear and/or ill-defined problems lies in their inherent capability of incorporating a priori qualitative knowledge and expertise about system behavior and dynamics.

This renders fuzzy logic systems almost indispensable for obtaining a more transparent and tactile qualitative insight for systems whose adequate representation with exact mathematical models is poor or impossible. Besides, fuzzy schemes can be used either as enabling to other approaches or as self-reliant methodologies providing thereby a plethora of alternative structures and schemes.

For systems involving nonlinearities and lack of a reliable analytical model, fuzzy logic control has emerged as one of the most promising approaches. Fuzzy inference is a step towards the simulation of human thinking. In fact, fuzzy systems generate nonlinear functions according to a representation theorem by Wang (1992), who stated that any continuous nonlinear function can be approximated as exactly as needed with a finite set of fuzzy variables, values and rules. Therefore, by applying appropriate design procedures, it is always possible to design a fuzzy controller that is suitable for the nonlinear system under control.

Fuzzy Sets, Systems, and Applications, Table 1 Critical points in the foundation years of fuzzy logic

First paper on fuzzy systems (Zadeh 1965)
Linguistic approach (Zadeh 1973)
Fuzzy Logic controller (Assilian and Mamdani 1975)
Table-Based Controller (Mamdani,1977)
Heat Exchanger based on fuzzy logic (Østergaard 1977)
Self-organizing fuzzy controller (Mamdani 1977; Procyk and Mamdani 1979)
Fuzzy logic control for cement production (Holmblad and Østergaard 1982)
Fuzzy controllers on Tokyo subway shuttles (Hitachi 1984)
Fuzzy Chip (Togai and Watanabe 1986)
Hardware implementation of fuzzy system (Yamakawa and Miki 1986)
Hybrid Neural-Fuzzy systems (Kosko 1992)

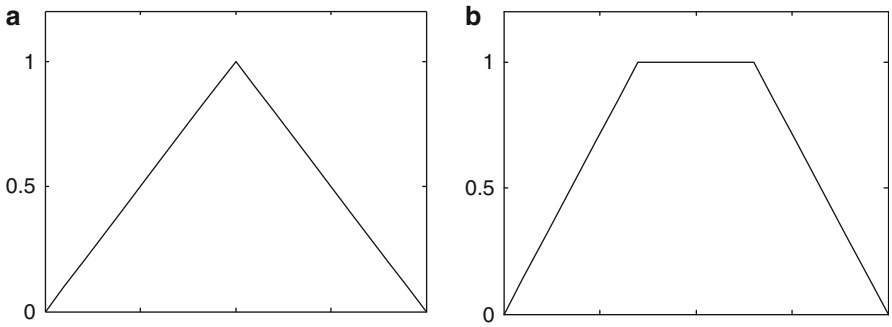
The applications of fuzzy logic have dramatically increased since 1990, ranging from cognitive and decision processes, engineering and industrial applications to systems control, economics and management (Karr and Gentry 1993; Sugeno and Yasukawa 1993; Østergaard 1977; 1990); robotics (Ruan et al. 2003); transportation (Chen et al. 2008); nuclear engineering (Kunsch and Fortemps 2002), medicine (Blanco et al. 2002; Kilic et al. 2002), economics (Gil-Lafuente 2005), see applications section for more. Table 1 depicts some benchmark results in the foundation years of fuzzy logic.

Research on the theory of fuzzy sets is directed towards various disciplines, including possibility theory (Cayrac et al. 1996), fuzzy operators (Pradera et al. 2002; Yager 2002a); fuzzy relations (Naessens et al. 2002; Pedrycz and Vasilakos 2002), measures of information and comparison (Hung 2002; Yager 2002b), non-classical logics (Biacino and Gerla 2002; Novak 2002), algebra (Di Nola et al. 2002); topology (Albrecht 2003).

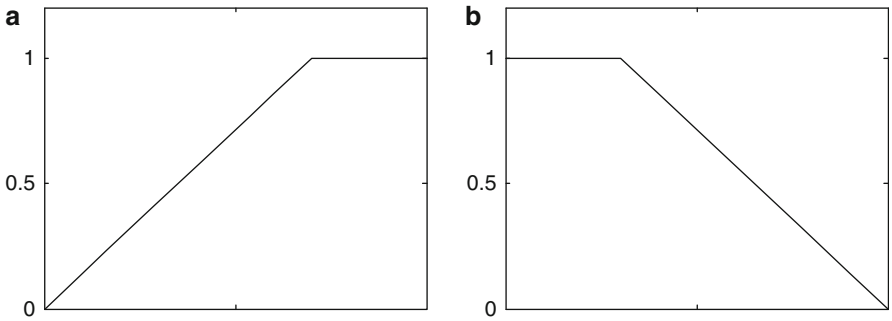
Fuzzy Set Theory

The notion of membership. The membership of an element x in a classical set A is given by:

$$\mu(\mathrm{x}) = \begin{cases} 1 \\ 0 \end{cases}$$



Fuzzy Sets, Systems, and Applications, Fig. 1 (**a**) Triangular; (**b**) Trapezoid membership function



Fuzzy Sets, Systems, and Applications, Fig. 2 (**a**) Monotonically increasing; (**b**) Monotonically decreasing linear membership function

Hence an element is assigned to a set A or not. That can be expressed as:

$$A \cap \bar{A} = \emptyset$$

where the symbol $\cap$ denotes intersection.

On the other hand, fuzzy logic is a logic based on truth-values that are numbers in the closed unit interval [0,1]. Fuzzy logic is thus based on fuzzy sets. A fuzzy set is a set consisting of members with a degree of membership, rather than being either members or not members. The function that ties a number, commonly in the [0,1] interval, to each element of a set (the universe of discourse) is called membership function.

Membership functions. Let X denote the universe of discourse. Every fuzzy set F in X is characterized completely by its membership function.

Definition: The membership function μ_F of a fuzzy set F in X is a function

$$\mu_F : \mathrm{X} \rightarrow [0, 1]$$

The most commonly used membership functions are the following (Dubois and Prade 1980; Zimmermann 1996): Triangular, Trapezoid, Linear, Sigmoidal, Π – type, Gaussian.

The **triangular** membership function (Fig. 1a) is defined as:

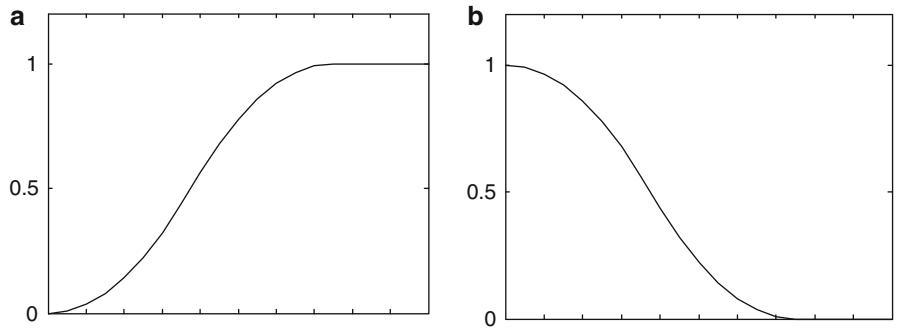
$$\mathrm{Tri}(x;\alpha,\beta,\gamma) = \begin{cases} 0 & x < \alpha \\ \frac{x-a}{\beta-\alpha} & \alpha \le x < \beta \\ -\frac{x-\gamma}{\gamma-\beta} & \beta \le x < \gamma \\ 0 & x \ge \gamma \end{cases}$$

The **trapezoid** membership function (Fig. 1b) is defined as:

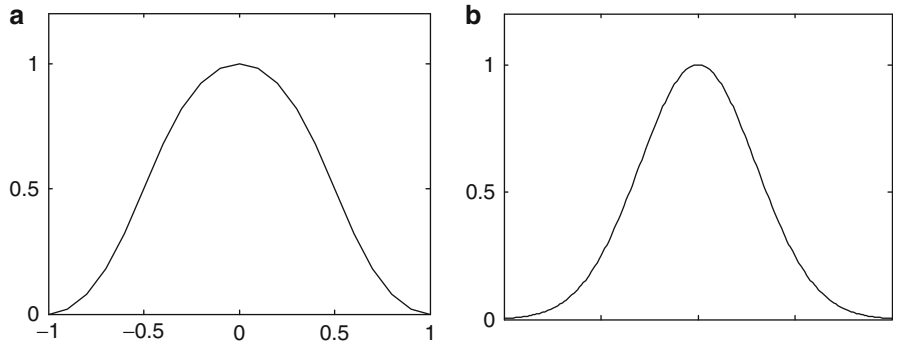
$$\mathrm{Tra}(x;\alpha,\beta,\gamma,\delta) = \begin{cases} 0 & x < \alpha \\ \frac{x-a}{\beta-\alpha} & \alpha \le x < \beta \\ 1 & \beta \le x < \gamma \\ -\frac{x-\delta}{\delta-\gamma} & \gamma \le x < \delta \\ 0 & x \ge \delta \end{cases}$$

The monotonically increasing linear membership function (Fig. 2a) is given by

$$\mathrm{L}(x;\alpha,\beta) = \begin{cases} 0 & x<\alpha \\ \frac{x-a}{\beta-\alpha} & \alpha \le x \le \beta \\ 1 & x > \beta \end{cases}$$



Fuzzy Sets, Systems, and Applications, Fig. 3 (**a**) Monotonically increasing; (**b**) Monotonically decreasing sigmoidal membership function



Fuzzy Sets, Systems, and Applications, Fig. 4 (**a**) Π; (**b**) Gaussian membership function

The monotonically decreasing linear membership function (Fig. 2b) is given by

$$\mathrm{L}(x;\alpha,\beta)=\begin{cases}0 & x<\alpha\\ -\frac{x-\beta}{\beta-\alpha} & \alpha\le x\le\beta\\ 1 & x>\beta\end{cases}$$

The monotonically increasing sigmoidal membership function (Fig. 3a) is given by

$$\mathrm{S}(x;\alpha,\beta,\gamma)=\begin{cases}0 & x<\alpha\\ 2\left(\frac{x-\alpha}{\gamma-\alpha}\right)^2 & \alpha\le x\le\beta\\ 1-2\left(\frac{x-\gamma}{\gamma-\alpha}\right)^2 & \beta\le x\le\gamma\\ 1 & x>\gamma\end{cases}$$

The monotonically decreasing sigmoidal membership function (Fig. 3b) reads:

$$\mathrm{S}(x;\alpha,\beta,\gamma)=\begin{cases}1 & x<\alpha\\ 1-2\left(\frac{x-\alpha}{\gamma-\alpha}\right)^2 & \alpha\le x\le\beta\\ 2\left(\frac{x-\gamma}{\gamma-\alpha}\right)^2 & \beta\le x\le\gamma\\ 0 & x>\gamma\end{cases}$$

The Π- membership function (Fig. 4a) is defined as

$$\Pi(x,\alpha,\beta,\gamma)=\begin{cases}S(x;\gamma-\beta,\frac{\gamma-\beta}{2},\gamma) & x\le\gamma\\ 1-\mathrm{S}(x;\gamma-\beta,\frac{\gamma+\beta}{2},\gamma+\beta) & x\le\gamma\end{cases}$$

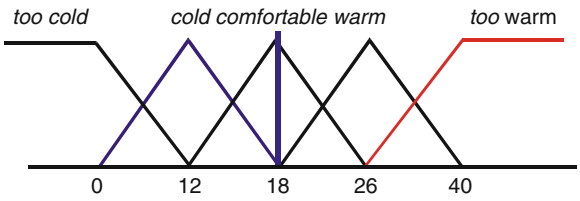
The Gaussian membership function (Fig. 4b) is given by

$$\mathrm{G}(x;k,\gamma)=\exp(-(\gamma-x)^2/2\sigma^2)$$

where σ is the standard deviation

As an example, the room temperature for low-level work activities could be described by the following 5 fuzzy sets characterized by triangular or trapezoid membership functions, where a temperature around 18 °C is a comfortable one, around 26° a warm one (though not during summer!) while above 40 °C is definitely too warm, and around 12 °C can be characterized as a cold while below that too cold (Fig. 5).

Fuzzy logical operations. Fuzzy theory set operations are of utmost importance to the better understanding and design of fuzzy systems. Below the most basic fuzzy set operations are presented, which are defined with respect to their corresponding membership functions.



Fuzzy Sets, Systems, and Applications, Fig. 5 Fuzzy representation of a room temperature

Equality: Two fuzzy sets A and B are ***equal*** on the universe of discourse X if their membership functions are equal for each $x \in X$ iff

$$\forall x \in X : \mu_A(x) = \mu_B(x).$$

Subset: A fuzzy set A is a ***subset*** of B $(A \subseteq B)$ iff

$$\forall x \in X : \mu_A(x) \leq \mu_B(x).$$

Intersection: For the operation of intersection $\cap$ of two fuzzy sets A and B, there is a plethora of definitions in the bibliography. The choice is application dependant.

$$\forall x \in X \mu_{A\cap B} = \left\{ \begin{array}{c} \min(\mu_A(x), \mu_B(x)) \\ \frac{\mu_A(x)+\mu_B(y)}{2} \\ \mu_A(x)\mu_B(y) \\ \ldots\ldots\ldots\ldots \end{array} \right\}$$

Union: The union $\cup$ of two fuzzy sets A and B is also defined in several ways:

$$\forall x \in X : \mu_{A\cup B} = \left\{ \begin{array}{c} \max(\mu_A(x), \mu_B(y)) \\ \frac{2\min(\mu_A(x),\mu_B(y))+4\max(\mu_A(x),\mu_B(y))}{6} \\ \mu_A(x) + \mu_B(y) - \mu_A(x)\mu_B(y) \\ \ldots\ldots\ldots\ldots\ldots\ldots \end{array} \right\}$$

In the third definition, the union is put equal to 1 if the sum is greater than 1.

Complement: The complement A′ of a fuzzy set A is defined as:

$$\forall x \in X : \mu_{\mathrm{A}}(x) = 1 - \mu_A(x)$$

Transformation operators. Another important group of operators that characterize fuzzy set theory are the transformation operators. These act on the membership functions in order to modify the linguistic value of the respective fuzzy set. For example, in the clause "number very close to 10," the transformation operator "very" acts on the linguistic term "close to 10" which corresponds to a fuzzy set. Examples of such operators are given in Table 2 (Ross 1995; Zimmermann 1996).

Fuzzy Sets, Systems, and Applications, Table 2 Examples of transformation operators

Very	$\mu_{\hat{A}}(x) = (\mu_A(x))^n, n > 1$
More/less	$\mu_{\hat{A}}(x) = (\mu_A(x))^n, 0 < n < 1$

Cartesian inner product of fuzzy sets. If $A_1, A_2, \ldots, A_v$ are fuzzy sets defined in $U_1, U_2, \ldots, U_v$, the Cartesian inner product of $A_1, A_2, \ldots, A_v$ is a fuzzy set F in $U_1 x\ U_2 x, \ldots x\ U_v$ with membership function (Yan et al. 1994):

$$\mu_F(u_1, u_2, \ldots u_v) = \cap_i = 1.v\mu_{A_i}(u_i)$$

$$\text{e.g. } \mu_F(u_1,u_2,\ldots,u_v) = \min\{\mu_{A1}(u_1),\mu_{A2}(u_2),\ldots,\mu_{AV}(u_v)\}$$

$$\text{or } \mu_F(u_1,u_2,\ldots,u_v) = \mu_{A1}(u_1)\mu_{A2}(u_2)\ldots\mu_{AV}(u_v)$$

Fuzzy relations. Let U_1 and U_2 be two universes of discourse and the membership function μ_R: $U_1 \times U_2 \rightarrow$ [0,1]. Then a fuzzy relation on $U_1 \times U_2$ is defined as (Zimmerman 1996):

$$R_c = \int_{U\times B} \mu_R(u_1,u_2)/(u_1,u_2) \text{ if } U_1, U_2 \text{ are continuous in space}$$

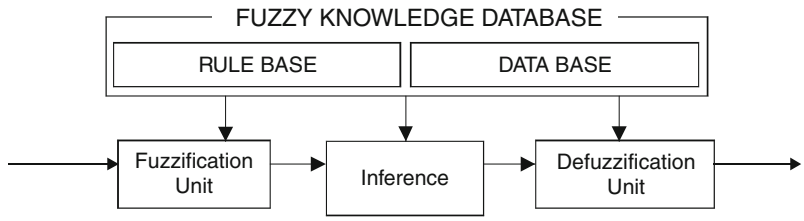
$$\text{or } R_d = \sum_{U\times V} \mu_R(u_1,u_2)/(u_1,u_2) \text{ if } U_1,\ U_2 \text{ are discrete.}$$

Fuzzy Set Composition. Let R_1 and R_2 be two fuzzy relations on $U_1 \times U_2$ and $U_2 \times U_3$ respectively, then the composition of R_1 and R_2 is defined as follows:

$$C = R_1 \circ R_2 = \{(u_1, u_3), \cup(\mu_{R_1}(u_1, u_2) \cap \mu_{R_2}(u_1, u_2))\},$$
$$u_1 \in U_1, u_2 \in U_2, u_3 \in U_3.$$

Implication Rules. Let A and B be two fuzzy sets in U_1,U_2 respectively. Then the implication I:$A => B$ - > $U_1 \times U_2$ is defined as (Zimmerman 1996):

$$I = A \times B = \int_{U_1\times U_2} \mu_A(u_1) \cap \mu_B(u_2)/(u_1, u_2)$$



Fuzzy Sets, Systems, and Applications, Fig. 6 Basic structure of a fuzzy inference system

For example, the rule: "If the error is negative big, then control output is positive big"is an implication error $=>$ control action.

Let the two discrete fuzzy sets $A = \{\Sigma\ \mu_A(u_i)/u_i, i = 1,\ldots,n\}$, $B = \{\Sigma\ \mu_B(v_i)/v_i, i = 1,\ldots,m\}$

Then the implication $A => B$ takes the form:

$$\begin{bmatrix} \mu_A(u_1) \\ \mu_A(u_2) \\ \cdots\cdots \\ \mu_A(u_n) \end{bmatrix} \times [\mu_B(v_1) \quad \mu_B(v_2) \quad \ldots \quad \mu_B(v_m)]$$

$$= \begin{bmatrix} \mu_A(u_1) \wedge \mu_B(v_1) & \mu_A(u_1) \wedge \mu_B(v_2) & \ldots & \mu_A(u_1) \wedge \mu_B(v_m) \\ \mu_A(u_2) \wedge \mu_B(v_1) & \mu_A(u_2) \wedge \mu_B(v_2) & \ldots & \mu_A(u_2) \wedge \mu_B(v_m) \\ \cdots\cdots & \cdots\cdots & \cdots & \cdots \\ \mu_A(u_n) \wedge \mu_B(v_1) & \mu_A(u_n) \wedge \mu_B(v_2) & \ldots & \mu_A(u_n) \wedge \mu_B(v_m) \end{bmatrix}$$

Inference rules. Let R be a fuzzy relation on $U_1 \times U_2$, and let A be a fuzzy set in U_1. The composition

$A^oR = B$,

is a fuzzy set in U_2 representing the implication (conclusion) from the fuzzy set A (fact) based on the implication R (rules). For a multiple input, single output rule base with N rules, the i-th rule is given by

If A_{i1} and ... and A_{ij} and ... and A_{in} then B_i, where

$n =$ the number of input variables x_i

$A_{ij} =$ fuzzy set of input variable x_j in i-th rule

$B_i =$ fuzzy set of output variable y_j in i-th rule

The i-th rule is the implication $I_i = A_i => B_i$, $A_i = \cap_{i=1}^{n} A_{ij}$. Then the implication I_{tot} of N rules is given by $I_{tot} = \cup_{i=1}^{N} R_i = \cup_{i=1}^{N} A_i \rightarrow B_i$.

Fuzzy similarity measures. Fuzzy similarity measures introduce the notion of approximate equality between fuzzy sets. Several fuzzy similarity measures have been proposed, each one with different attributes, see (Pappis and Karacapilidis 1993 and 1995; Wang et al. 1995).

Basic structure of a fuzzy system. The fuzzy knowledge base contains four main types of information: (a) a fuzzification unit (fuzzifier), (b) a fuzzy inference unit, (c) a rule base which essentially maps fuzzy values of the inputs to fuzzy values of the outputs and (d) a defuzzification unit (Fig. 6).

(a) The fuzzifier maps the measured inputs, which usually are crisp values, into the fuzzy linguistic values (fuzzy sets) used by the fuzzy reasoning mechanism.

(b) The fuzzy rules incorporated in the rule base express the input–output relationships usually in an IF-THEN format. For instance, for a two-input, one-output fuzzy system, a fuzzy rule has the general form:

Rule i : IF x is A_i and y is B_i THEN z is C_i

where x and y are input measured variables, z is the controller output variable; A_i, B_i and C_i are linguistic terms (fuzzy sets) such as "negative big", "positive small" or "zero". The if-part of the rule is called condition or premise or antecedent, and the *then-part* is called the consequence or action.

Two are the main approaches in the design of rule bases (Yan et al. 1994):

(i) Heuristic-Mamdani's type approaches (Mamdani 1977; King and Mamdani 1977; Pappis and Mamdani 1977) which provide a convenient way to build fuzzy rules in order to achieve the desired output response, requiring only qualitative knowledge for the behaviour of the system under study.

(ii) Systematic approaches based on Sugeno-type inference systems (Takagi and Sugeno 1985; Pappis and Sugeno 1985; Sugeno and Kang 1988; Sugeno and Yasukawa 1993; Laukoven and Pasino 1995) including hybrid neural-fuzzy frameworks (Kosko 1992), Chebyshev series and Kohonen's networks (Siettos et al. 2002; Alexandridis et al. 2002).

(c) The fuzzy reasoning unit performs various fuzzy logic operations to infer the action for the given fuzzy inputs. During fuzzy inference, the following operations are involved for each fuzzy rule:
   1. Determination of the degree of match between the fuzzy input data and the defined fuzzy sets for each system input variable.
   2. Calculation of the fire strength for each rule based on the degree of match and the connectives (e.g. AND, OR) used with input variables in the antecedent part of the rule.
   3. Derivation of the fuzzy outputs based on the calculated fire strength and the defined fuzzy sets for each output variable in the consequent part of each rule.

(d) The defuzzification unit performs the inverse operation of fuzzification, i.e. extracts the crisp output value from the fuzzy outputs. Several techniques have been proposed for the inference of the fuzzy output based on the rule base. The most commonly used are those of mean of maximum, centroid, and center of sum of areas (Driankov et al. 1993; Ross 1995).

Applications. In developing fuzzy logic and the theory of fuzzy sets, extensive effort has been undertaken by scientists and engineers to deal with a variety of important research topics: inference systems (del Amo et al. 2001); computational linguistics and knowledge representation (Intan and Mukaidono 2002); neural networks (Alpaydin et al. 2002; Oh et al. 2002); genetic algorithms (Spiegel and Sudkamp 2002); information processing (Liu et al. 2002; Hong et al. 2002; Nikravesh et al. 2002); pattern analysis and classification (Gabrys and Bargiela 2002; de Moraes et al. 2002; Pedrycz and Gacek 2002); decision making (Yager 2002b; Wang 2000; Zimmermann et al. 2000; Wang and Lin 2003).

Apart from mathematics and algorithms, fuzzy sets theory has been widely utilized in the context of real life problems (Zimmermann 2001). Such problems are commonly full of uncertainty or approximate reasoning and it is often very difficult to develop mathematical models that can fully describe and incorporate their complexities. In these cases, fuzzy sets theory is essential as it assists on the development of mathematical models that embed imprecision. Fuzzy sets theory has been extensively utilized in the context of operations management, medicine, finance, risk analysis and assessment, water resources management, environmental management, and social sciences. The practical applications of fuzzy logic are wide, indeed, including, among others, process control (Tong et al. 2002); robotics (Ruan et al. 2003); scheduling (Adamopoulos et al. 2000; Karacapilidis et al. 2000; Muthusamy et al. 2003); transportation (Chen et al. 2008); nuclear engineering (Kunsch and Fortemps 2002); medicine (Barro and Marin 2002; Blanco et al. 2002; Kilic et al. 2002); and economics (Kahraman et al. 2002; Gil-Lafuente 2005). A review of specific areas of application of fuzzy sets theory follows.

Management Science: Fuzzy sets theory has been widely utilized in the case of management science. Facets of the theory of fuzzy sets have been incorporated into supply chain management and even strategic management decision-making processes. The potential utilization of fuzzy sets theory has long been noticed in the case of operations management (Zimmerman 1983). More specifically, fuzzy logic has been incorporated into models addressing issues in the context of outsourcing logistics activities (Bottani and Rizzi 2006; Cheng et al. 2008; Liu and Wang 2009); manufacturing and production problems (Lee and Yao 1998; Majozi and Zhu 2005; Liang and Cheng 2009), supply chain modeling (Petrovic et al. 1999; Sevastjanov and Róg 2003; Sheu 2004; Zhang and Lu 2007); optimization of supply chain operations (Silva et al. 2007); and traffic and transportation processes (Teodorović 1994). In addition, fuzzy logic has been used in the context of strategic management (Dutta 1993; Kardaras and Karakostas 1999; Lin and Hsieh 2004; Narukawa and Torra 2007; Xu et al. 2009) as well as marketing (Setnes and Kaymak 2001; Ramkumar et al. 2010). Fuzzy logic has also been applied in industrial applications (Sàrfi et al. 1996; Bansal 2003), including power systems planning (David and Zhao 1991; Ong and Nee 1994; Guan et al. 1995; Ramírez-Rosado and Domínguez-Navarro 2004) and product conformance specification procedures (Bradshaw 1983).

Medical Science: Decision-making processes in medicine science can be hindered due to the complexity of biological systems and high data uncertainty. Fuzzy logic theory provides a means of better modeling related problems. Applications of fuzzy sets theory can be found in the context

of medical diagnosis (Belacel and Boulassel 2001; De et al. 2001; Szmidt and Kacprzyk 2004; Polat et al. 2006); effective management of medical diagnostic problems (Chen 1994) and multiple alternative decision-making problems during medical diagnosis (Cheng and McInnis 1980). Additionally, fuzzy logic has been applied in medical expert systems (Hudson and Cohen 1994) and used for the development of measures for the anxiety induced by a given decision-making process by an individual (Yager 1982). A survey with respect to the application of fuzzy sets theory in medical sciences is given in Abbod et al. (2001).

Social Sciences: Biswas (1995) used fuzzy logic for the evaluation of students' answer scripts. Lalla et al. (2005) utilized fuzzy sets theory for the evaluation of teaching activities, and Smithson (1982) presented tools for applying fuzzy sets concepts to the social and behavioral sciences and examples of their uses.

Financial Science: Here fuzzy sets theory has been utilized in the context of ratio analysis (Gutierrez and Carmona 1988), enterprise financial status synthetic evaluation (Lee and Chang 2009), and in ranking vague economic investment information when a present worth criterion is used (Sorenson and Lavelle 2008). In addition, fuzzy logic has been utilized in the context of multi-objective finance-based scheduling for construction projects under uncertainty (Afshar and Fathi 2009); financial evaluation in the public sector (Ammar et al. 2004); engineering economic decision-making of firms (Kahraman 2008); financial analysis during corporate acquisition processes (McIvor et al. 2004); evaluation of fuzzy financial profitability of load management alternatives (Sheen 2005), development of financial models that assist the identification of different states of one market so that a firm could modify its actions and make successful trades (Van den Berg et al. 2004); financial risk management and credit scoring (Yu et al. 2009) and in other problems in economics and finance (Buckley 1987; Buckley 1992).

Environmental Science: Applications of fuzzy sets theory in environmental science include (Esogbue et al. 1992), where fuzzy sets methodologies were used to solve an optimal flood control planning problem by an integration of structural and non-structural measures with the objective of optimizing the flood damage reduction due to recurrent floods. Koo and Shin (1985) utilized fuzzy sets for multi-objective river quality management under a direct regulation scheme, and Liou et al. (2003) proposed an indicator model for evaluating trends in river quality using two-stage fuzzy set theory to condense efficiently monitoring data. Hanesch et al. (2001) utilized fuzzy c-means cluster analysis and non-linear mapping for tracing the distribution and source of pollutants to assess potential environmental hazards, and McBratney and Odeh (1997) studied the potential applications of fuzzy set theory and fuzzy logic in soil science. Fuzzy logic was applied to timber harvest planning (Boyland et al. 2006) and to environmental risk assessment by Ghomshei and Meech (2000).

Other applications: A sample range of applications of fuzzy sets theory to other real-world problems include: Nguyen (1985) in the context of mining geomechanics decision-processes; Cayrac et al. (1996) for satellite fault diagnosis procedures; McBratney and Moore (1985) for dealing with the continuity of climatic data; Cao and Chen (1983) for meteorological forecasting; developing of electronic video camera image stabilizers (Egusa et al. 1995); handling uncertain image information (Laplante and Sinha 1996); classification of geometric figures and chromosome images through the use of shape-oriented angular and dimensional proximity measures (Lee 1976); the problem of image reconstruction (Nobuhara et al. 2006); the fatigue problem of reinforced concrete decks of bridge structures (Shiraishi et al. 1988); data mining processes (Li and Deogun 2009); disaster control systems planning (Esogbue 1996); etc.

Game Theory

William F. Lucas[1] and Sauleh A. Siddiqui[2]
[1]Claremont Graduate University, Claremont, CA, USA
[2]University of Maryland, College Park, MD, USA

Introduction

Game theory studies situations involving conflict and cooperation. The three main elements of a game are players, strategies, and payoffs. Games arise when two or more decision makers (players) select from various courses of action (called strategies) which in turn result in likely outcomes (expressed as payoffs). There must be at least two interacting participants with different goals in order to have a game. Game theory makes use of the vocabulary from common parlor games and sports. It is, nevertheless, a serious mathematical subject with a broad spectrum of applications in the social, behavioral, managerial, financial, system, and military sciences.

Game theory differs from classical optimization subjects in that it involves two or more players with different objectives. It also extends the traditional uses of probability and statistics beyond the study of one-person decisions in the realm of statistical uncertainty. This latter case is often referred to as games of chance or games against nature in contrast to the games of skill studied in game theory. Many aspects of social and physical science can be viewed as zero-person games since actions are frequently specified by various laws that are not under human control.

Game theory presumes that conflict is not an evil in itself and as such unworthy of study. Rather, that this topic arises naturally when individuals have free will, different desires, and the freedom of choice. Furthermore, this subject often provides guidelines to aid in the resolution of conflict. Game theory also assumes that the players can quantify potential outcomes (as in measurement theory or utility theory), that they are rational in the sense that they seek to maximize their payoffs, and skillful enough to undertake the necessary calculations. The theory of games attempts to describe what is optimal strategic behavior, the nature of equilibrium outcomes, the formation and stability of coalitions, as well as fairness.

There are many different ways to classify games. A significant difference exists between the two-person games and the multiperson ones (also called the n-person games when $n \geq 3$). There is a major distinction depending upon whether games are played in a cooperative or noncooperative manner. The nature of the types or amount of information available to the players is very fundamental in the analysis of games, and this relates to whether the best way to play involves pure or randomized strategies.

A further way to classify games is if they are played over one period or repeatedly over time. Static games are single period games in which all players move simultaneously without observing any other moves.

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

Dynamic games are multiperiod games where players interact by playing simultaneous moves numerous times. Unlike static games, players have some information about past moves and payoffs so they may change strategies as the game proceeds. Evolutionary Game Theory (discussed below) provides a specialized framework for studying dynamic games.

Information and Strategies

Any possible way a player can play completely through a game is called a pure strategy for this player. It is an overall plan specifying the actions (moves) to be taken in all eventualities which can conceivably arise. In theory such pure strategies suffice to solve many popular recreational games such as checkers which have perfect information. A game has perfect information if throughout its play all the rules, possible choices, and past history of play by any player are known to all of the participants. In this case there are no unknown positions or hidden moves, and thus no need for secrecy, deception, or bluffing.

The first general theorem in game theory was published by the logician Ernst Zermelo in 1913. It states that there is an optimal pure strategy for playing any finite game with perfect information. An elementary game with perfect information such as tic-tac-toe soon becomes no real challenge. Each player soon discovers a strategy that prevents the other from winning. From then on this game always results in a draw. On the other hand, Zermelo's theorem is an example of an existence theorem. It does not provide a practical way to determine an optimal pure strategy for many interesting but complex games with perfect information such as chess. Furthermore, one cannot even spell out one pure strategy for chess — one that lists a possible response to all legal moves by an opponent. The challenge of such games comes from the bewildering complexity and imagination involved.

Many other games like the card games known as poker, however, do not have perfect information. Secrecy, deception, randomness, and bluffing are in order. Another level of interest and a new notion of strategic choice enter. Pure strategies no longer suffice for optimal play. The main fundamental concept for such noncooperative games is that of a mixed strategy. A mixed strategy for a player is a probability distribution over the player's pure strategies. The idea is that a player will pick a particular pure strategy with some given probability. This greatly enlarges the realm of strategies from which each player can choose. The tradeoff, on the other hand, is that the players must now view their potential payoffs as averages. They thus resort to maximizing their gains in terms of expected values in a statistical sense. These ideas are best illustrated by the theory of matrix games.

Matrix Games

The best known games are the two-person, zero-sum games. Any game is called zero-sum when the particular payoffs to the players always sum to zero. In the case of two players this states that one's winnings equal the other's losses. There is clearly no room for cooperation in this case. These games are also referred to as strictly competitive or antagonistic. They arise in many sorts of duels, inspections, searches, business competitions, and voting situations, as well as most parlor games and sports contests.

These games are characterized by an $m \times n$ table of numbers and are accordingly referred to as matrix games. The rows of the table correspond to the pure strategies for the first player, denoted by I. The columns are likewise identified with the pure strategies of the second player, II. The numbers within the table itself are the corresponding payoffs received by player I from player II. A negative number in the matrix means that I makes a (positive) payment to II. Each player seeks to select a strategy so as to maximize the player's payoff.

The theory of matrix games can be illustrated by the following 2×2 zero-sum game of matching coins. Player I has two pure strategies: to show heads H or tails T. Player II can likewise select H or T. If the two players' coins match with either two heads or else two tails, then player I wins \$3 or \$1, respectively, from player II. If the coins do not match (one H and one T), then player II collects \$2 from player I. This game can be represented by Fig. 1.

The worse thing that can happen to player I is the maximin value of -2. (This is the largest of the smallest numbers from each row.) Similarly, the minimax value for player II is 1. This is the smallest

		Player II H	Player II T	Row minima
Player I	H	3	–2	–2
	T	–2	1	–2
Column maxima:		3	1	

Game Theory, Fig. 1 A matrix game

loss player II can guarantee and it occurs when player II plays the second column T (while I plays the second row T). There is a gap of \$3 between this maximin value of \$1 and the minimax value of − \$2. Both players can win some of this gap of 3 units if they resort to mixed strategies and are willing to evaluate their payoffs in terms of expected values.

If either player uses the optimal mixed strategy of playing H with probability 3/8 and T with probability 5/8, the player can ensure an average payoff of

$$3(3/8) - 2(5/8) = -1/8 = -2(3/8) + 1(5/8)$$

against any strategy by the opposing player. Using mixed strategies the players can close the gap between -2 and 1 to the game's (expected) value of $-1/8$. This game favors player II who should average a gain of 12.5¢ per play. This game is not fair in the sense that optimal play does not produce an expected outcome of 0. The optimal mixed strategies (3/8, 5/8) for players I and II along with the value $-1/8$ are called the solution of this matrix game. (In general, the two players will not have the same optimal mixed strategy as is the case for this game with a symmetric payoff matrix.)

The main theoretical result for matrix games is the famous minimax theorem proved by John von Neumann in 1928. It states that any matrix game has a solution in terms of mixed strategies. Each player has an optimal mixed strategy which guarantees that the player will achieve the value of the game (in the statistical sense of expected values).

Von Neumann also observed in 1947 that the duality theorem in linear programming is equivalent to his minimax theorem. Furthermore, it is known that the subjects of matrix games and linear programming are entirely equivalent mathematically. Various algorithms are known for solving $m \times n$ matrix games. However, one typically expresses the solution for a matrix game in terms of a pair of dual linear programs and employs one of the popular algorithms used in the latter subject.

Noncooperative Games

When games are not zero-sum or have more than two players, then it is essential to distinguish between whether they are played in a cooperative or noncooperative manner. To cooperate means the players are able to communicate (negotiate or bargain) and correlate their strategy choices before they play. Also, that any agreements made are binding (enforceable). In contrast, each player in a noncooperative game chooses a strategy unaware of the selection made by the other players.

For noncooperative games the primary ingredient to any notion of solution is that of an equilibrium point. A set of (pure or mixed) strategies, one for each player, is said to be in equilibrium if no one player can change strategy unilaterally to obtain a higher payoff. Unfortunately, equilibrium outcomes do not always possess every property that one would desire for a satisfactory concept of solution. Nevertheless, this idea of equilibrium seems crucial to the very notion of what can be called a solution to a noncooperative game. It is the social science analogy to the idea of equilibrium or stability in mechanical systems.

The difficulties that might arise with equilibrium outcomes are illustrated by the following two 2×2, nonzero-sum, two-person games known as the prisoner's dilemma and chicken. These are the driving forces behind escalation (arms races and price wars) and confrontation, respectively. In these two games each player has two strategies: to compromise C or to defect D. The resulting payoffs are indicated in Figs. 2, 3 where it is assumed that each player prefers the outcome of 4 over 3 over 2 over 1. The payoffs in these tables give a pair of numbers (a, b) where a is the payoff to player I (the row player) and b is for player II (the column player). For example, if players I and II select the strategies D and C, respectively, in Chicken (Fig. 3) they obtain the respective payoffs of 4 and 2.

In either of these games, the best overall outcome for the two players when taken together is the strategy pair (C,C) where each compromises and in turn receives the second best payoff of 3. This would be the likely outcome if these games were played

		Player II C	Player II D
Player I	C	(3,3)	(1,4)
	D	(4,1)	(2,2)

Game Theory, Fig. 2 The prisoner's dilemma

		Player II C	Player II D
Player I	C	(3,3)	(2,4)
	D	(4,2)	(1,1)

Game Theory, Fig. 3 The game of chicken

cooperatively. This result, however, is not in equilibrium. Either player can achieve the higher payoff of 4 if the player alone were to switch from strategy C to D. In the prisoner's dilemma the dominant strategy for each player is D. One does better individually by selecting D, no matter what the other chooses. This leads to each receiving 2, their second worse payoff. In chicken the two (pure) strategy pairs (C,D) and (D,C) both lead to an equilibrium result. No one player can switch strategy and do better in either case. However, these two outcomes are not inter-changeable. If both players select D in an attempt to reach the particular equilibrium that would pay them 4, then the resulting strategy pair (D,D) leads to their worst payoffs (1,1). Of the 78 possible static 2×2 games, these two are the most troublesome.

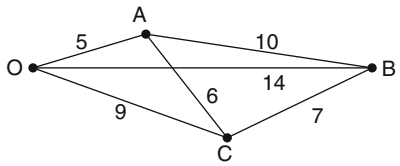
Some noncooperative games have no equilibrium in pure strategies. In 1950 John F. Nash extended von Neumann's minimax theorem for two-person, zero-sum games to prove that every finite multiperson, general-sum game has at least one equilibrium outcome in mixed strategies. Algorithms to calculate equilibria involve nonlinear techniques and often use path-following approaches that may be approximate in nature. There are also many refinements and extensions of the idea of equilibrium described here, and these concepts are fundamental to quantitative approaches in modern economics and politics, as well as system analysis and operations research.

The 1994 Nobel Memorial Prize in the Economic Sciences acknowledged the role of noncooperative game theory. It honored Nash for his fundamental theoretical contributions, as well as some important extensions. Later developments included the repeated play of games with incomplete information introduced by John C. Harsanyi, and aspects of dynamical interaction and evolutionary stability of equilibrium introduced by Reinhard Selten. The 2005 Nobel Prize was again awarded to two game theorists, Robert Aumann and Thomas Schelling, for contributions of game theory to understanding conflict and cooperation.

Cooperative Games

If the players in a game are allowed to cooperate, they typically agree to undertake joint action for the purpose of mutual gain. In this case coalition formation is a common activity, and the additional worth that can accrue to any potential coalition is of primary interest. In practice, the players often solve some optimization problem or consider some noncooperative game in order to arrive at the amount of additional value available from cooperation. The problem that remains concerns how this newly obtained wealth will be, or should be, divided among the players. This latter aspect is again a competition as each participant seeks to maximize their own gain. This may involve negotiations, bargaining, threats, arbitration, coalitional realignments, attempts to arrive at stable allocations or coalition structures, as well as appeals to different ideas about fairness. It is thus not surprising that several different models and solution concepts have been proposed for multiperson cooperative games.

The first general model and idea of a solution for the multiperson cooperative game was presented in the monumental book by John von Neumann and Oskar Morgenstern in 1944 (3rd ed., 1953). Their approach is referred to as the n-person game in characteristic function form. One begins with a set $N = \{1, 2, \ldots, n\}$ of n players who are indicated by 1, 2, …, and n. A characteristic function v assigns a value $v(S)$ to each subset S of N. This number $v(S)$ represents the worth achievable by the coalition S, independent of the remaining players in the complementary set $N - S$. In this context they proposed a notion of solution that they called a solution and which is often referred to now as a stable set. Stable sets proved to have some



Game Theory, Fig. 4 A cost allocation game

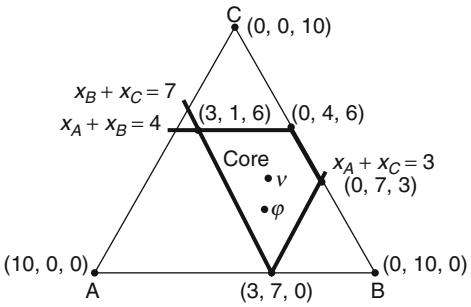
difficulties of both a theoretical and practical nature. They are also rather mathematically involved, and, thus, are not presented here. They are, nevertheless, still a useful tool, especially for the class of games for which the core (see below) is nonexistent. Dozens of alternate solution concepts have since been proposed for these coalition games, and five of these have received the most attention. Three of these solution concepts will be described in the context of the following three-person illustration.

Three neighboring towns A, B, and C plan to tap into an additional water source at O. The costs (in \$100,000) for installing the alternate segments of water pipe appear on the edges in Fig. 4. The joint costs for the various subsets of the three-person coalition $\{A, B, C\}$ are obtained by finding the minimal cost spanning tree for each such coalition. The total cost for the coalition $\{A, B, C\}$ is $c(ABC) = 18$ and it is realized by the link $OACB$. Similarly, the minimal costs for the six other coalitions are:

$$c(AB) = 15 \text{ via } OAB,\ c(AC) = 11 \text{ via } OAC,$$
$$c(BC) = 16 \text{ via } OCB,\ c(A) = 5 \text{ via } OA,$$
$$c(B) = 14 \text{ via } OB, \text{ and } c(C) = 9 \text{ via } OC.$$

(Expressions like $c(\{A, B, C\})$ and $v(\{A, B, C\})$ are shortened to $c(ABC)$ and $v(ABC)$, respectively.)

One can reformulate this problem in terms of the savings available by means of cooperation. Each coalition considers what it saves in a joint project over what it would have cost its members if they were each to make a separate connection to the source O. This savings game has the following characteristic function: $v(ABC) = 10$ [$= c(A) + c(B) + c(C) - c(ABC)$], $v(AB) = 4$, $v(AC) = 3$, $v(BC) = 7$, and $v(A) = v(B) = v(C) = 0$. The three towns can save $10 \times \$100{,}000 = \$1{,}000{,}000$ by acting together. The problem is: how should these savings be allocated to the individual towns? How does one select the three numbers (x_A, x_B, x_C) in the imputation set determined by the relations $x_A + x_B + x_C = 10 = v(ABC)$, $x_A \geq 0 = v(A)$, $x_B \geq 0 = v(B)$, and $x_C \geq 0 = v(C)$? These points are pictured by the large triangle in Fig. 5.



Game Theory, Fig. 5 Solutions to the cost game

One solution concept for cooperative games is called the core. The core consists of those allocations in the imputation set for which every coalition S receives or exceeds its value $v(S)$. No coalition has the capability to improve its total allocation at a core point by going off on its own. For the savings game, the core consists of all imputations (x_A, x_B, x_C) that satisfy the inequalities $x_A + x_B \geq 4 = v(AB)$, $x_A + x_C \geq 3 = v(AC)$, and $x_B + x_C \geq 7 = v(BC)$. This is the four-sided region in Fig. 5. Note that the core is not a unique allocation, and for some games it can be the empty set. However, the core is always non-empty for such cost allocation games.

Another popular solution concept is called the nucleolus. The nucleolus is the one allocation in the center of the core. For the savings game, the nucleolus is the imputation $v = (6/4, 19/4, 15/4)$. (The nucleolus is also defined for those games with empty cores as the unique imputation where the core would first appear when each proper coalition S has its value $v(S)$ decreased uniformly.) If the nucleolus for the savings game is translated back to a cost allocation for the original problem, the following allocation is obtained:

$$\$100{,}000[(5, 14, 9) - v]$$
$$= (\$350{,}000; \$925{,}000; \$525{,}000).$$

In 1951, Lloyd S. Shapley introduced a solution concept that also provides a fair and unique outcome for the savings game. The Shapley value in general gives the average of each player's marginal contribution taken over all possible orderings of a set N of n players. Each one of the $n!$ orderings

(permutations) is a way the full coalition N could build up, one player at a time. There are six orderings of the three towns A, B, and C: (CBA), (BCA), (CAB), (BAC), (ACB), and (ABC). The Shapley value φ_A for town A is accordingly $6\varphi_A = 2[v(ABC) - v(BC)] + [v(AB) - v(B)] + [v(AC) - v(C)] + 2[v(A) - 0] = (2{\cdot}3) + 3 + 4 + (2{\cdot}0) = 13$. A similar calculation gives $6\varphi_B = (2{\cdot}7) + 4 + 7 + (2{\cdot}0) = 25$ and $6\varphi_C = (2{\cdot}6) + 3 + 7 + (2{\cdot}0) = 22$. The Shapley value φ for the savings game is $\varphi = (\varphi_A, \varphi_B, \varphi_C) = (13/6, 25/6, 22/6)$. Note that this point is in the core of this game, although this is not always the case for cost allocation problems. In the original cost problem, φ corresponds to the result ($283,333; $983,333; $533,333).

The various solution concepts for multiperson cooperative games have been applied throughout economics, political science, and operations research. The core is important in the study of economic markets. The nucleolus is viewed as a fair outcome for many bargaining situations. The Shapley value has also been employed as a measure of power for voting systems, where the core is typically the empty set.

Dynamic Games

All previous examples used so far have involved static games. A dynamic game can be thought of as a static game that is repeated for a finite or infinite amount of time. A similar equilibrium concept for a dynamic game can be developed by extending the idea for a static game. The central issue in all dynamic games is credibility. Since players may analyze previous moves and payoffs, strategies trying to predict the other players' moves become very important. Hence, non-credible players often lose out. Since many static games make up a dynamic game, the concept of a subgame equilibrium becomes useful as a means for equilibrium in a dynamic game. A set of strategies for a dynamic game is said to be in subgame equilibrium if all subgames (static portions and their combinations) are in equilibrium. Dynamic games can be played with perfect or imperfect information and can be cooperative or noncooperative.

Consider the finite dynamic version of the Prisoner's Dilemma, which is the static Prisoner's Dilemma repeated N times, and both players know that the game will end after this. Again, as in the static version, the best overall outcome is for both players to play C in each of the N turns. However, as in the static game, this outcome is not in equilibrium. As an example of an optimal deviation, suppose both players play C ($N - 1$) times. In the final move, player I can choose to deviate to D and get a total payoff of $3(N - 1) + 4$ which would have been more than his or her payoff if he or she would have played C for the final move. Player 2 has a similar deviation, in fact this deviation need not take place at the last move and could be played at any stage. One subgame equilibrium of the finitely repeated Prisoner's Dilemma is that both players play D for all the N moves. Clearly, no player has any optimal deviation at any one point in the game. However, to prove this is an actual subgame equilibrium (so that there exist no sequence of strategies that is an optimal deviation from playing D in all moves), a technique called backward induction is used.

After the last turn, no further interaction will be possible. Hence, in the final turn, both players choose the dominant outcome D, and play the equilibrium for the static game. Knowing that they both will defect in the last period, both players play D in the second to last period as well, since they know no matter what happens, the last turn will involve both of them defecting. Hence, using this inductive procedure, it's easy to prove that both players playing D for all periods is a subgame equilibrium. This process of starting from the final move and moving backwards is known as backward induction. Note that backward induction is only a valid technique in a finite dynamic game, as there is no final move in an infinitely repeated game.

Dynamic games can also involve moving sequentially. In a Stackelberg Duopoly, two players choose quantities of production to maximize individual profits. However, one player, the leader, gets to move first and the second player, the follower, moves after observing the first player's move. In the Stackelberg game, the leader often has a higher payoff in a subgame equilibrium. Using backward induction, for a simple finite Stackelberg game, it is easy to figure out the subgame equilibrium. A Stackelberg game is also an example of a mathematical program with equilibrium constraints.

For infinitely repeated dynamic games, the analysis tends to be slightly different. Backward induction can no longer be used to find and prove that a strategy is a subgame equilibrium. To study infinitely repeated games, a discount factor (less than or equal to one) is

introduced to discount future payoffs. Strategies known as trigger strategies comprise equilibria of such games. One widely studied strategy is a tit-for-tat strategy, in which a player cooperates until the opponent stops cooperating. Then the player does not cooperate until the opponent starts cooperating again. Another trigger strategy is a grim strategy, where a player cooperates until the opponent stops cooperating, after which the player proceeds to not cooperate forever. For example, in an infinitely repeated Prisoner's Dilemma, subgame equilibria can be different from both players playing D for all turns. Various grim strategies and tit-for-tat strategies can be devised as subgame equilibria depending on the value of the discount factor.

Dynamic games without perfect information can also be studied. In such games, there is a sender of information and a receiver. The sender observes their type, and sends a message to the receiver about it. The receiver chooses an action after predicting what the senders type will be based on the message received. An example is Spence's (1976) model of job market signaling. A job applicant (sender) knowing about their productive ability (type) sends details regarding their education (message) to an employer or a market of employers (receiver). The wage paid by the employer is then the action of the receiver.

One of the problems with traditional game theory, as outlined above, is that it often does not mirror the actual decisions by human beings and institutions. To achieve equilibrium, players are assumed to be extremely rational and have perfect foresight. Many experiments show that this is not true. Another shortcoming is the presence of multiple equilibria in game theory. There is no consistent method for determining which equilibrium is picked when the game is played out in practical life with real players. The next section provides a brief overview of how recently developed theory has attempted to resolve these problems.

Evolutionary Game Theory

Evolutionary Game Theory is the study of dynamic games that focuses on strategy development by players who interact, usually as part of a large population. By looking at strategy development as opposed to finding equilibrium points, evolutionary game theory overcomes the problem of selection from multiple equilibria. It provides a framework for studying how strategies evolve and which equilibrium point gets picked. Also, by studying strategy, evolutionary game theory does not assume that the players are excessively rational. Fisher (1930) was the first to use evolutionary game theory to understand why some species of mammals have an equal sex ratio even though the majority of males never mate. At other instances, evolutionary game theory has done well to model the behavior of animals, which are assumed to be even less rational than human beings.

The first mainstream introduction of evolutionary game theory was made by Smith and Price (1973) when they published "The logic of animal conflict." While it was of great interest to evolutionary biology, many economists also recognized its use in modeling human behavior. Axelrod (1984) was one of the first economists to apply this theory to cooperation among human players. The essential features of all models in evolutionary game theory is repetition of player moves and the adaptive behaviors and strategies resulting from these repetitions in large populations. A strategy that can withstand changes, or mutations, is regarded as an evolutionary stable strategy. This helps biologists understand the decision making of animals and organisms and helps social scientists extract information about decision-making processes in humans.

The Prisoner's Dilemma also has an evolutionary counterpart. Consider the dynamic Prisoner's Dilemma played repeatedly by a large population. It can be shown that all players cooperating is an unstable equilibrium, in that if a small percentage of the population deviates from cooperating, the dynamics will drive the entire population to defect. Thus defecting in the evolutionary version of the Prisoner's Dilemma is a stable equilibrium. There are evolutionary versions of signaling games and other dynamic games as well. Again, evolutionary game theory analyzes the process of choosing equilibria as opposed to finding them, which is the focus of traditional game theory.

Gaming

William Schwabe
RAND Corporation, Santa Monica, CA, USA

Introduction

Abt (1970) broadly defined a game as "an activity among two or more independent decision-makers seeking to achieve their objectives in some limiting context." Gaming involves the activity itself, whereas game theory uses mathematics to seek the best strategies, the sets of decisions that decision-making players might make.

Games are played for entertainment, sport, teaching, training, and research. As a research method, gaming is used by psychologists, educators, and sociologists interested in how people learn and play games and by operations researchers, other analysts, and decision makers interested in developing, exploring, and testing policies, strategies, hypotheses, and other ideas.

As an OR/MS method, gaming is controversial, often practiced more as an art than a science. Few methods have been so inadequately named, prompting ridicule from skeptics and attempts by adherents to call it something more serious sounding or descriptive, such as operational gaming, simulation gaming, free-form gaming, and, in defense analysis, war gaming and political-military gaming. Although gaming has not been made as scientifically rigorous nor as universally accepted as adherents hoped for decades ago, it has helped importantly in developing strategy, in pretesting policies before actual implementation, and in communicating understanding of operational complexities.

Research games are often played as part of the planning process in developing important policies and strategies for organizations in competitive situations. Accordingly, the results — and sometimes the existence of gaming — are not publicized. For example, several Iraq-Kuwait scenarios were gamed in 1990 before Iraq actually attacked, but they are not fully documented in the open (unclassified) literature. Sources of information on research gaming include special interest sections at operations research/management science professional conferences, reports and bibliographies published by organizations with a tradition of gaming (such as the Naval War College, RAND, and others), the journal *Simulation & Games*, and various books and articles. Shubik (1975) presents comprehensive discussions of gaming, including a game theory background for gaming, analytical, and behavioral models, and examples of games used for a variety of purposes. Brewer and Shubik (1979) provides an historical review of the use of military war games. Dunnigan (2000) details the designing and playing of commercial and professional war games.

Learning from Gaming

People can learn from gaming by designing the game, by playing it, or by analyzing the play or

results (Perla and Barrett 1985). Greenblat (1988) discusses game design as a five-stage process: (1) setting objectives of and constraints on the game, (2) conceptual model development, (3) decisions about representation, (4) construction and refinement, and (5) documentation. Because a game is meant to model one or more important aspects of something that is operationally complex, game design is usually an intense intellectual exercise in analysis. Analysts commonly learn a great deal from the process of designing a game, as is true with other types of model design. Gredler (1994) discusses how Lewinian or Piagetian theories of learning can be applied to game design.

Most games have two or more teams, each representing a decision-making entity, such as a country, a military command, or a business firm, with from one to hundreds of players on a team. Players may be assigned specific roles — a leader of a country, a CEO in a regulated industry, a local warlord — in which they can criticize or embrace the policies of their own or competing governments or organizations. Formal games have rigid rules for play, while seminar or free-form games, have few rules.

Play of a game is usually divided into moves, each being a period of real time during which game time (often posited to be in the future) is assumed to be frozen. Game time is usually advanced further into the future between successive moves; however, it can be advantageous to roll back game time for the final move, to allow players to apply what they learned about possible future consequences in formulating better near-future policies, initiatives, or options (Molander et al. 1996).

Moves usually begin with teams being presented with information that players are asked to accept as true for the purposes of the game and use as a basis for their deliberations and decisions. This information is often in the form of a scenario, a story about how the future might plausibly evolve, carefully crafted to help people "recognize and adapt to changing aspects of our present environment" (Schwartz 1991). The set of decisions made by a player or team during a move period is sometimes called its move. Game administrators, who usually include researchers who designed the game and will analyze its results, are commonly called controllers or referees. Games have usually been played with all participants at one site; however, distributed games can be played with remotely located players communicating via electronic mail or other means.

Despite the make believe aspects of gaming, players often become intellectually (and sometimes emotionally) caught up in the game, engaging in intense, goal-focused thought and discussion. In the process they learn about the issues, about their teammates, and about themselves. Controllers often learn what can go wrong operationally and how signals and other forms of communications between teams can be misunderstood.

Analysis usually begins with a critique at the end of the last game move, attended by players, controllers, and observers. The game director may ask each team leader to present their analysis of what the team saw as the major issues, how they analyzed their options, what they decided, and what results they expected. Whether analysis is more formal than this depends in part on whether the game was designed as an experiment, to yield data or other observations suitable for analysis. If a series of games is played, then there is opportunity for comparative analysis.

Why Game?

Unlike many other techniques of analysis, gaming is not a solution method. The output of a game is not a forecast or prediction, solution, or rigorous validation. The output of a good game is increased understanding.

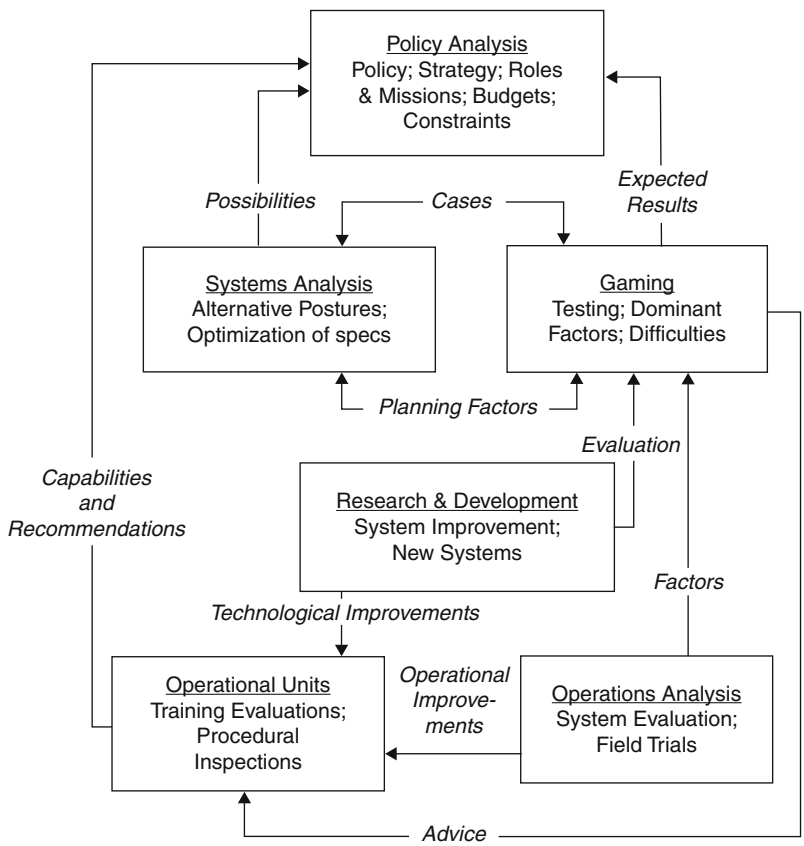
Gaming can do several things: reveal errors or omissions in concept; explore assumptions and uncover the implicit ones; draw out divided opinion; examine the feasibility of an operational concept; identify areas that are particularly sensitive or in which information is lacking (Quade 1975); pool the knowledge of several experts; suggest questions or hypotheses for further study; identify the values or measures of effectiveness (MOEs) that people care about; breadboard approval-winning or implementation of policies; or test strategies for long-term consequences. No matter how rigorous the analysis, gaming can do something an individual cannot do, namely, list the things that would never occur to the individual. It can help identify all the ways that a carefully composed statement can be misinterpreted. As Levine, Schelling, and

Jones (1991) noted, it can also "generate the phenomena of understanding and misunderstanding, perception and misperception, bargaining, demonstrations, dares and challenger's accommodation, coercion and intimidation, conveyance of intent, and uncertainty about what each other has already done or decided on. There are some things that just cannot be done by a single person or by a team that works together."

Prospects for Gaming

The popularity of gaming is cyclical. Its use, however, appears to be on an upward path. Video conferencing and electronic mail networks open possibilities for less expensive games with broader participation, including international play. Advances in computers and software make it easier to develop models to support games, to use them on the fly during games to update scenarios, to query data files in response to player questions during games, and to prepare presentation graphics during the games and for post-game critiques. Videotaping has been used to present scenario updates to players in newscast format and to present pre-taped briefings by experts to players. Expert systems are used to support some games, but the use of artificial intelligence, rule-based agents in gaming is not as active as it was in the 1980s.

Gaming has often not been as well integrated into studies using other methodologies as might be warranted. Gaming is but one form of analysis to inform policy, managerial, or operational decisions. Figure 1, adapted from Paxson (1963), summarizes some of the relationships between gaming and other analysis. Regardless of whether gaming ever achieves the rigor early proponents sought, it appears to have continuing value. Gaming can often respond to changing operational or strategic contexts more rapidly than other methods. Challenges remain in making games less demanding of player time (especially important in enlisting senior officials



Gaming, Fig. 1 Gaming and analysis relationships

as players), in reducing costs of games (including travel costs), and in using game results responsibly and effectively in analyses to inform decisions.

Gamma Distribution

A continuous random variable is said to have a gamma distribution if its probability density can be written in the form $f(t) = a(at)^{b-1} e^{-at}/\Gamma(b)$ where a and b are any positive real numbers and $\Gamma(b)$ is the gamma function evaluated at b. The constant b is called the shape parameter, while a (or various equivalents) is called the scale parameter. If b happens to be a positive integer, then $\Gamma(b) = (b-1)!$ and this gamma distribution is also called an Erlang distribution. Furthermore, if b is either an integer or half-integer (1/2, 3/2, etc.) and $a = 1/2$, the resultant gamma distribution is equivalent to the classical χ^2 distribution of statistics.

General Algebraic Modeling System. An algebraic modeling language for mathematical programming that supports numerous commercial and open source software solvers, including BARON, COIN-OR, CPLEX, Gurobi, MINOS, SNOPT and KNITRO.

Gantt Charts

Steven Nahmias
Santa Clara University, Santa Clara, CA, USA

Introduction

There are three well-known types of Gantt charts: the Gantt load chart, the Gantt layout chart, and the Gantt project chart. A Gantt chart is essentially a bar chart laid on its side. The horizontal axis corresponds to time and the vertical axis to a collection of related activities, machines, employees, or other resource. Bars are used to represent load durations or activity starting and ending times. The Gantt chart is appealing in that it is easy to interpret and can provide a visual summary of a complex schedule.

In principal, the three types of Gantt charts are similar, but each has a somewhat different application. The load chart is used to show the

amount of work assigned to resources (typically equipment) over a given amount of time. Sequencing issues are ignored here. Load charts are useful for showing work assigned to a project, but do not show the progress of an on-going project. The Gantt layout chart is used to block out reserved times on facilities and is one means of keeping track of the progress of an ongoing project.

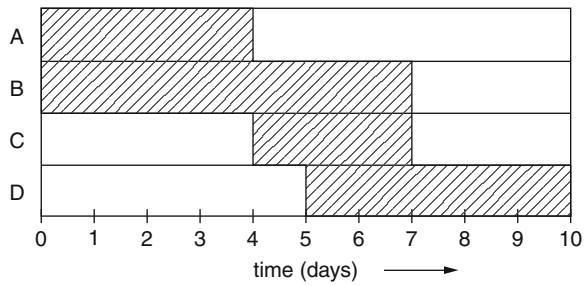
The most popular type of Gantt chart is the Gantt project chart. A Gantt project chart is used to show the starting and ending times of all the activities comprising a project. It can be used to monitor the progress of a project and determine where stumbling blocks may be. Next is an example of a Gantt project chart.

Example

Suppose that a project consists of four activities: A, B, C, and D requiring, respectively, 4, 7, 3, and 5 days. Figure 1 is a Gantt chart representing the starting and ending times for these activities.

According to this chart, A and B are started at day 0 and are scheduled to be completed, respectively, at the start of days 4 and 7. Activity C is begun when A ends on day 4 and is completed at the start of day 7, while D is started on day five and completed on day 10. While the chart shows the start and finish times of each activity, it has the shortcoming of not showing precedence relationships. Specifically, is C required to wait for the completion of A or could C have been scheduled earlier? Does D require A to be completed before it could start? Should D have been started on day 4 instead of day 5? Because of this significant limitation, years later professionals recognized that networks were much more powerful ways of representing projects, since precedence constraints could be incorporated directly into a network structure. Both the Critical Path Method (CPM) and Project Evaluation and Review Technique (PERT) overcome this shortcoming of Gantt charts. Even though it has limitations as a planning tool, the Gantt chart is still one of the most convenient ways to represent a schedule once it is determined.

While Gantt charts vary considerably in format and structure, this example contains the basic elements of all Gantt project charts. Invariably, the horizontal axis corresponds to time, and the vertical axis to a set of



Gantt Charts, Fig. 1 Four-activity Gantt chart

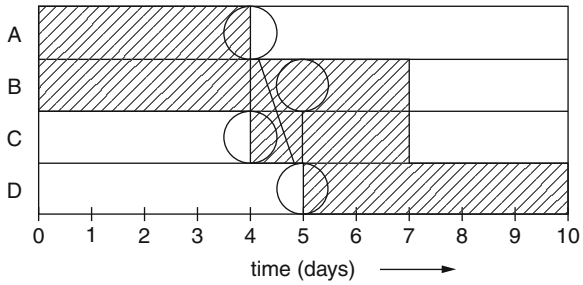
activities (or machines or resources for the other types of Gantt charts). Interpret activities very broadly here. They may be parts of a project, they may be part numbers, or machines or personnel. The bars generally correspond to beginning and ending times for activities, but might have different interpretations in other contexts. For example, they may correspond to a work shifts for personnel or delivery and shipment times for parts.

Implementation Issues

There are some issues one must be concerned with when trying to implement a Gantt chart. One is the way time is measured and scaled. In the example above, time is shown in numbers of elapsed days from an arbitrary day labeled day 0. In practice, it is more common, however, for time to be measured in calendar days. The horizontal axis would correspond to specific calendar dates. While calendar dating makes starting and ending times more explicit, there are other issues to consider as well. How long is a day? In most work environments, a work day is 8 hours. In other contexts, a day may be 24 hours. Another issue is whether operations continue during weekends. There are several ways to handle this problem. The easiest is just to exclude weekend dates from the chart. The interested reader should refer to Battersby (1967) and Clark (1952) where these and related issues are discussed in detail.

Extensions

An extension of the Gantt project chart which was the precursor of modern networks is the milestone chart.



Gantt Charts, Fig. 2 Milestone Gantt chart

Networks are collections of nodes and directed arcs. In the context of project planning, nodes represent completion of a collection of activities, and directed arcs to the durations of specific activities. Developed in the 1940s by the U.S. Navy, the milestone chart is a Gantt chart with circles representing key time periods which occur during the completion of an activity. The milestones could then be linked, in much the same way that nodes are linked on a project network. An example of a milestone Gantt chart is shown in Fig. 2.

The vertical line linking Activities A and C means that C cannot be started before A is complete. In the case of activities B and D, the vertical line there implies that D cannot be started until five days after B has started. (This suggests that B should be represented as two activities.) The diagonal line connecting A and D means that D cannot be started until A is completed.

Uses

The Gantt chart was the precursor to several commercial graphical control systems, many of which are found today adorning the walls of manufacturing facilities throughout the United States. In his classic work, Moore (1967) noted several commercial variations of the Gantt chart available in the 1960s including Productrol boards, Schedugraphs, and Boardmasters. All use a time scale across the top and horizontal lines to picture machines, schedules or orders or whatever is being graphed. Although very popular in the 1950s, these manual techniques have lost favor because computers can quickly update and print progress charts.

History

The concept was originally developed by Henry L. Gantt, a contemporary of Frederick Taylor's, a major force in the development of scientific methods for operations and production control. Gantt developed the idea of a bar chart to monitor project status while he was affiliated with the Army Bureau of Ordnance during World War I. His original intent was to display graphically the status of munitions program for that day. Gantt recognized that time was a key variable against which the progress of a program could be assessed. Gantt's development was certainly a first key step in the development of scientific methods for project management, a powerful tool for project planning. Both CPM and PERT were consequences of the kind of planning recommended by Gantt. Dozens of texts have been written on the subject and the methods have been applied to a large variety of industries. Personal computer software products are widely available which make extensive use of Gantt charts to display schedules. An overview of project planning is given in Nahmias (2009), and more details on project planning techniques can be found in Moder, Phillips, and Davis (1983).

Gaussian Elimination

A computational procedure for reducing a set of $(m \times m)$ linear equations $\boldsymbol{Ax} = \boldsymbol{b}$ to the form $\boldsymbol{MAx} = \boldsymbol{Mb}$, where $\boldsymbol{MA} = \boldsymbol{U}$ is an upper triangular matrix. The variables of the solution vector are found by solving the resulting triangular system for one variable in the last equation, and back-substituting in the next to last equation, and so on. Some form of elimination is central to the simplex method for solving linear-programming problems.

Generalized Erlangian Distribution

The probability distribution of a finite sum of independent, exponentially distributed random variables whose parameters may not be the same. Sometimes, the term is also used for a convex sum of Erlang distributions, which, however, is more often called a mixture.

Generalized Upper-Bounded (GUB) Problem

A linear-programming problem with a set of constraints of the form $\sum_{j \in \boldsymbol{J}} x_j = 1$, where $\boldsymbol{J}$ is a subset of the indices $j = 1, 2, \ldots, n$ and each j can appear at most once in some $\boldsymbol{J}$. This problem is called a GUB problem and a special adaptation of the simplex method is available that reduces the computational burden of having a large number of GUB constraints.

Geographic Information Systems

Paul Gray[1], Thomas A. Horan[1] and James B. Pick[2]
[1]Claremont Graduate University, Claremont, CA, USA
[2]University of Redlands, Redlands, CA, USA

Introduction

The most widely known and used form of a Geographic Information System (GIS), one everyone takes for granted, is the navigation system in our cars - Global Positioning System (GPS) - that shows where you are and tells you how to get to where you are going. Google Maps and Google Earth, two other GIS examples, became standards almost overnight in 2005. Geographic Information Systems, however, are more pervasive and important than that gadget in your car or the free maps available on the Internet; they have millions of users. GIS software combines database management systems, map layers, and visualization to support cartographic display, spatial query, and analytical modeling. They integrate locational, topological, and thematic data to allow constructing, exploiting, and visualizing complex spatial relations among data types at a variety of scales, levels of aggregation, and dimensionality. As such, they are a fundamental tool for Operations Research (OR).

Geographic information technology allows exploiting increasingly available amounts of valuable geographic and spatial data in a form easily comprehended by analysts and decision makers. Among the problems to which GIS has been applied are:

- site selection;
- urban 3D design;
- election administration and redistricting;
- infrastructure management;
- mapping and modeling of Federal geospatial information, such as that of Department of Homeland Security, Department of the Interior, Department of Housing and Urban Development, and Bureau of the Census;
- natural resource exploration;
- public health and safety (e.g., modeling communicable diseases; analyzing natural disasters before, during, and after; emergency response planning; and optimizing dispatch of emergency vehicles);
- real estate marketing, sales, and management;
- renewable energy management (wind, solar, hydro, and geothermal);
- military and defense applications combining GIS with sensors and satellite imagery;
- transportation, fleet management, supply chain, and other logistics; and
- urban and regional planning, including modeling and analysis of cities, populations, urban sprawl, taxation, land use, zoning, utilities and urban 3D design.

GIS Background and Capabilities

The term geographic information system was coined in the 1960s. It now applies to generic capabilities for studying and analyzing spatial phenomena. (Longley et al. 2010; Clarke 2010). They define its capabilities as including:

- collecting, storing, and retrieving spatial location data;
- identifying locations which meet specified criteria;
- exploring relationships among spatial layers and associated data sets;
- analyzing related spatial data to aid in making decisions;
- facilitating assessment of alternatives and their impacts;
- displaying selected environments both visually and numerically.
- modeling spatial phenomena;
- designing solutions to problems based on spatial analysis and visualization.

Databases and Computer Advances

One of the most powerful examples of the essential role of GIS as an earth systems analytic tool is in the efforts to understand the processes of global change. GIS tools combine ecosystem and biological data, meteorological information, distribution of manmade emissions sources, regulatory data, site monitoring data, satellite and aircraft sensing and imaging data. They use the integrated information to simulate the

interactions and impacts of complex natural and manmade systems. The analytic potential of GIS tools is enhanced by the power of GIS visualization. Researchers and practitioners view modeling results in a realistic terrain rendering that facilitates understanding and provides a valuable mode for presenting research results to non-technical audiences (Maguire et al. 2005).

The key to GIS application and the impetus behind its fast growing use is the combination of the availability of massive databases and the continually increasing power of mobile, desktop, and server computer hardware that enable storing and manipulating these databases. The databases are increasingly being stored in large commercial and governmental spatial server farms, such as those of ESRI Inc., Google, and the U.S. Geological Survey. An example of a particularly important national base map is the TIGER files (Topological Integrated Geographic Encoding and Referencing System) located at the U.S. Census Bureau. TIGER is essential to systemizing the many basic geographic layers of government geographies such as census tract boundaries, highways, national boundaries, and administrative districts, so that demographic and economic data can be visualized precisely. The TIGER files are updated and corrected regularly.

Software

Specialized software links attributes (discrete object values) superimposed 2D map layers and higher dimensional geometries through common identifiers. This analysis function permits displaying multiple spatial relationships:

- overlaying combinations of features and recording resulting conditions;
- analyzing networks;
- defining areas in terms of specified criteria; and
- fitting models more accurately through spatial statistics

In practice, for most earth surfaces, a GIS consists of a series of layers, each presenting a particular feature that can be superimposed accurately on top of one another. Each feature constitutes a distinct layer that can be displayed or not, as desired by the analyst. Basic features take the form of points, lines, or polygons, representing the full spectrum of spatial phenomena. For example, lines may represent transportation options, such as railroads or highways. Because the typical map contains vector-based longitude and latitude data, distances traversed along a route are easily calculated and available for inclusion in analysis. A GIS is able to recognize 3D geometry and perform spatial analysis of these more complex forms, for example, to model shadows on the urban landscape from new skyscrapers being built in cities.

A feature supporting analysis of spatial distributions is electronic street addresses, either defined for the ends of blocks or positioned at regular intervals along major thoroughfares. The GIS software typically contains interpolation algorithms enabling the analyst to pinpoint specific phenomena by address, termed geo-coding. There is a competitive industry marketing software and databases products to transform street addresses, or nine-digit zip codes, into map coordinates. In marketing applications, for example, this capability is used to locate customers or potential customers. In school districting, the location of students can be represented.

The display of variable densities or thematic mapping displays (e.g., expenditures, activity levels, or incidents by selected administrative districts) is a standard GIS software capability. For example, the incidence of people aged 60 and over, based on census data, can be displayed by location representing age categories by different gray scales or colors.

The primary mode of building GIS maps is based on vector models using points, lines, and polygons. An alternative approach is to build raster maps in which real world features are shown as pixels on a grid. Each dot becomes a data point in a raster GIS. Most imaging satellites can now create digital/raster images. Although a raster GIS is typically much more hardware and software intensive than vector GIS, it can answer spatial questions that vector GIS cannot. Whereas vector models compute distance with lines that form a network, a raster GIS does not require a line-based network. Thus, a raster GIS can better measure the distances traveled by wolves in Yellowstone National Park in that they do not follow a network.

Raster GIS models are not inherently superior to vector-based models. Both have strengths and weaknesses. They should be considered different

tools to help solve different spatial questions. Historically, a vector GIS was more prevalent than a raster GIS because of the limitations of hardware and software, but advanced GIS software is able to move back and forth seamlessly between vector and raster models. The general user is not even aware that a change takes place. A well known raster GIS product is GRASS (Geographic Resources Analysis Support System) that was initially developed and maintained as public-domain software by the U.S. Army Construction Engineering Research Laboratories. It is now maintained by a private company. The leading GIS products feature both vector and raster capabilities.

In general, the major features of GIS software can be grouped under the headings of user interface, analysis tools, and data management (Longley et al. 2010). The user interface can vary in complexity from dozens of features for client applications such as Google Earth, and up to many hundreds of features in advanced software such as the Web-based ArcGIS. Analysis tools range from traditional simple tools such as query, distance measurement, buffering, and overlays, up to advanced spatial analysis, graphical model building, 3D visualization, space-time modeling, spatial statistics, integrated routing and inventory models, and network analysis (Longley et al. 2010). Data management features include internal tables, linkages to common spreadsheets, and connections to leading relational databases and geo-databases, that are hybrids that combine relational, object, and spatial capabilities. The software can be implemented at the cloud, server, desktop, and mobile levels, and companies now offer families of products that allow these levels to be connected together. For larger firms, enterprise GIS software is offered based on powerful internal and external servers, and can be coupled with business Enterprise Resource Planning software. GIS software markets are increasingly being supported by outsourcing part or all of it.

Spatial Decision Support System (SDSS) for Decision Making

Spatial Decision Support Systems enlarge the standard DSS model of data management, model management, and knowledge management by adding spatial analysis and spatial data components. Thus, an SDSS refines and strengthens conventional DSS analysis by complementing it with spatial analysis and spatial data. SDSSs can be divided into those systems that rearrange existing information and those that generate new information (Nyerges and Jankowski 2010; Longley et al. 2010). To rearrange is to observe data presented in different ways, as in looking at a map of income distribution by census tract to locate retail outlets or target an advertising campaign. New decision-making outcomes can be the result of overlaying regions and spatially analyzing their features in new ways. For example, in site selection, the decision can be affected by layers that define available water, available electricity, school locations, parking availability, and traffic densities as a function of time of day. Such spatial relations are usually not evident in spreadsheet or tabular data.

SDSSs benefit decision making because they provide access to additional information usually in a different format. As a result, managers are provided not only with additional data, but also with more flexibility in which they can view the data The conventional wisdom on the impact of an SDSS is that the political and ethical/moral underpinnings become more explicit, thereby helping decision makers understand the impacts of the choices made.

Earth Systems Analysis

One of the most powerful examples of the essential role of a GIS as an earth systems analytic tool is in the efforts to understand the processes of global change. GIS tools combine ecosystem and biological data, meteorological information, distribution of manmade emissions sources, regulatory data, site monitoring data, satellite and aircraft sensing, and imaging data. They use the integrated information to simulate the interactions and impacts of complex natural and man-made systems. The analytic potential of GIS tools is enhanced by the power of GIS visualization. Researchers and practitioners view modeling results in realistic terrain rendering that facilitates understanding and provides a valuable mode for presenting research results to non-technical audiences (Maguire et al. 2005).

Use of GIS in Urban Planning and Other Policy Making Activities

> Because GIS technology has matured on multiple fronts over the past decades, we are able to consider more of the relevant conditions and impacts when deciding on how to address [a complex systems of human-environment-society] relationships (Nyerges and Jankowski 2010).

Typical planning models tend to be displays of existing facilities, for example, retailing and transportation. The applications tend to involve structured issues, such as allocation, rather than the indefinite set of options policy makers face.

GIS used in urban planning depends upon a series of powerful urban methods and models: population potential, location quotients, grid analysis, network analysis, Markov chains, gravity models, geo-demographic techniques, central place theory, and visual modeling (Nyerges and Jankowski 2010; Greene and Pick 2006). Cities and regions are taken to be complex systems with structures composed of hierarchical subsystems, primarily spatial and nominally static. Planning for these systems consists of optimizing general systems properties, such as idealized population distributions. Difficulties arise from the interactions of systems at the periphery of any region under study.

The early interest in applying computerized capabilities to urban planning issues faced the obstacles of collecting data, task size in terms of data representation, and difficulty in developing appropriate system models (Brewer 1973; Lee 1973). These operational problems coincided with a changing planning philosophy shifting practitioners' interest toward more pragmatic approaches. There is now less emphasis on optimization and more concern with broader-based issues of equity. This transformation in urban planning thrust is evidenced in current demand for data systems for facility location, emergency services planning, resource management and conservation, and property and tax register recordings. Forrest (1990) listed over 60 distinct systems and problem areas to which a GIS might be applied, ranging across such apparently disparate issues as navigation, political redistricting, hazardous waste management, and wildlife protection. GIS systems are toolkits whose designs include enough flexibility to accommodate these multiple dimensions (Nyerges and Jankowski 2010).

In the 1980s, the predominant GIS platform was a stand-alone powerful workstation. It required a substantial personnel and training investment to build a GIS capability. Survey results show it was not until the late 1980s that many city and regional planning departments adopted and used GIS systems (French and Wiggins 1989, 1990). With the advent in the 1990s of powerful, inexpensive desktop computing and software, GIS tools have become a fundamental part of regional planning department infrastructure. In the first decade of the 21st century, GIS platforms moved to mobile and web-based platforms, powered by spatial servers. Modern GIS software has the capability to integrate spatial data and analysis across these different platforms. A GIS is also reinforced by its integration with increasing types of small sensor and locational devices, such as GPS in vehicles, radio frequency Identification, light detection and ranging, and thermal sensors. They allow real-time data to be input into a GIS with the capability for very fast decision making.

Over the last several years, GIS technology has evolved into a platform that encourages direct citizen engagement in urban planning and other policy activities. Government sources increasingly provide data that can be used by any party to analyze policy issues. For example, the U.S. government now provides an extensive array of data through a Web portal aimed facilitating transparency in government affairs (Federal CIO Council 2009). This portal contains a GIS viewer that allows federal data to be rendered in a GIS format and integrated with other data sources.

3D and Interactive Applications

Performance increases and growth in 3D referenced data sets are facilitating the creation of 3D visual models for GIS (Smith and Friedman 2004). Integrative approaches allow the use of 3D GIS for computer-aided design, architectural design, and city planning. For example, 3D models are used to simulate alternative growth strategies for small towns by using a GIS platform and building 3D and interactive applications (Orton 1999). Simulated buildings and their surrounding material and natural environments can be visualized from many perspectives, engage the

public in participation, and lead to design changes and improvements (Longley et al. 2010). The advent of Google Maps, Google Earth, and Microsoft Virtual Earth in 2005 made 3D GIS capabilities available for mass consumption. Although largely not realized as yet, 3D optimization models combined with GIS offer potential for more precise spatial decision-making.

Interactivity is further enhanced through the World Wide Web. The Web's graphic interface is particularly suited to the visual nature of GIS. The ability to access data from remote locations enables interactive databases to be created that can be queried along many number of dimensions. For example, traffic safety conditions can be analyzed by local communities using an interactive Web site, SafeRoadMaps.org, that allows the users to customize the scale and type of analysis based on local community interests and conditions (Hilton et al. 2009).

Examples of OR Analyses Using GIS

The following examples describe OR studies that deal with communications networks, forest management, and personnel assignments. Two of these studies were carried out in an earlier software environment that had fewer capabilities than are above. Nonetheless, the fundamental ideas are still in use and each new group of analysts needs to read the sources and absorb the approaches into their applications.

Modeling Communications Networks: An example of the use of a GIS and visual interactive modeling is given by Anghern and Lüthi (1990). They built a GIS system, Tolomeo, in a Macintosh environment that incorporates elements of modeling-by-example, an expert systems technique. They applied it to the problem of selecting the number and location of switching centers and routes in a communications network. The model displays the geographical area under consideration, the location of existing transmitting and receiving stations, proposed switching centers (nodes), and the transmission channels (arcs). By making the model object oriented, it was possible to attach to each node and arc data defining such quantities as traffic, cost, and transmission times. Users can redefine the network model interactively on the screen. Furthermore, they can create multiple views of the situation, using different visual metaphors. As the user modifies the model, the underlying data are recalculated to show the implications of proposed changes. Constraints and goals can be introduced so that the calculations take into account constraints and show where the current solution fails to meet goals. The modeling-by-example capability provides suggestions to the user on directions for improvement. These suggestions are based on applying optimization.

Forest Management: Two articles, Fletcher et al. (1999) and Epstein et al. (2006), deal with forest management projects in which a GIS was used in conjunction with other OR techniques. Fletcher et al. was based on work by The Pacific Lumber Co. and its GIS contractor, while Epstein et al. involved collaboration between the University of Chile and Oregon State University, working with a group of forestry companies.

In Fletcher et al., the objective was to develop a 120-year, 12-period forest-ecosystem management plan for the company's properties that met the then new state wildlife, fisheries, and timber resource requirements. The company also wanted to make sure that its harvesting would be optimal and the yields would be self-sustaining. The project was done under the auspices of a large lumber company in far Northern California that controlled extensive stands of redwood trees. The contractor built a model that seamlessly integrated a GIS with a database and a policy alternative model and that allowed adaptive management.

They started with using the GIS to divide the 200,000 acres held by the company into 406 strata types with each stratum containing one type of tree. Using GIS overlays of areas of special concern (e.g., stream barriers, wildlife corridors, owl buffers, watersheds), these strata were further subdivided into 7837 areas that were the fundamental decision units in the model. Each unit was defined by the tree type grown, amount of growth, and yield.

A linear-programming solution was first obtained and displayed on a map. Wildlife biologists then performed spatial integration of wildlife habitat types within the long-range planning model to determine reasonableness of the fragmentation, edge effects, and distribution of the watershed assessment areas.

The Epstein et al. article concerns the problem timber firms face in locating harvesting machinery

and transporting timber over a road network, while trying to reduce total cost and lower environmental impact. Optimization and GIS techniques were combined in a model which, for a forested area, locates harvesting machinery, and spatially optimizes the road network for transport of harvested trees to exit points. A mixed-integer programming model optimizes for the route that would incur the lowest total cost of road building and transportation. The model divides the forest into spatial grid coverage of 10x10 meter terrain cells that have associated topographical and production attributes including timber volume. Each cell is defined by 3D coordinates, thus allowing for estimation of slope angles in the predominantly mountainous timberlands. Slopes constrain the type of harvesting machinery (fixed versus vehicular) and the feasibility of locating roads. The user can re-set the locations of harvesting machinery and modify the maximal harvesting costs and allowable slope angles. A heuristic algorithm computes the cost of road building and timber transport over challenging terrain to exit points. Usual practice involves a forest area of 2,500 acres, with 75,000 spatial cells, 100,000 road vertices, 5,000 potential harvesting tractors and 300 fixed harvesting towers. The software has resulted in average operational cost reductions of 15–20 percent for large timber firms such as Forestal Bio Bio, Forestal Monteaguila (Shell Group), and Bosques Arauco S.A.in Chile.

Dispatching and Home Delivery: The retailing giant, Sears, uses a combination of OR models and a GIS to improve routing and scheduling for its truck delivery services:

- logistic delivery system for delivering newly purchased furniture and appliances, and
- product services system for installing and repairing appliances and providing home improvements and services.

Both systems involve sending trucks to customer homes, the first with over 1000 vehicles making 4 million deliveries annually, and the second with over 12,500 vehicles responding to 15 million service calls annually. Although they are run separately, the two systems are remarkably similar from both OR and GIS perspectives.

The original Sears system dates back to the 1990s (Weigel and Cao 1999). The objectives were (and are) (1) to deliver articles or arrive for service within a customer's time window, (2) minimize operational costs, and (3) provide consistent routes for drivers. In an updated version, they were still in operational use in 2010 (Longley et al. 2010).

The systems operate nationally, distributed among regional offices. Their big task is to make sure that items are delivered and calls are answered within a time window agreed upon with the customer. At a simple level, the systems solve the conventional analytic vehicle-routing problem with time windows (VRPTW) which was solved in the 1980s and l990s. At least they would be if the number of destinations were small and fixed, such as a set of warehouses or retailers. However, since the destinations are individual homes and vary from day to day, the standard OR solution is not adequate. The problems are much larger and must be solved in reasonable time every day. To make the systems efficient, they require mating VRPTW and GIS.

The system uses algorithms to build an origin–destination matrix and to improve sequencing and routing among other factors. Not only must the system take into account the customer's time window, it must also deal with labor constraints such as the available personnel, their skills and time for specific jobs, the down time for lunch and other breaks, and their schedule. In addition, the system must take routing into account, using the GIS since driving time varies, for example, by traffic as a function of time of day, the flatness or hilliness of the route, and much more. The algorithms also include intra-route and inter-route improvement routines, based on Tabu Search.

The system works as follows: When customer data are downloaded, the geo-code module locates the customer's x-y coordinates. Based on the street data stored by the GIS, it calculates the distance between all customers, providing the information for the assignment and route improvement modules. Using distances, driving times, time windows, and personnel specialties and other constraints, the computer generates routes. Since special circumstances rise frequently (e.g., customer changes in time windows, service time) and some constraints may be violated, the routings can be over-ridden manually.

Sears has reaped benefits from this system in on-time performance, much reduced daily route-computation time, reduced miles between stops, more customers handled per truck per day, reduced overtime, and reduced drive time.

Concluding Remarks

Geographic Information Systems provide the base for powerful OR analyses that integrate the visual capabilities of the computer with available spatial information and optimization techniques. The GIS capabilities offer the opportunity to change, fundamentally, the way 2D problems, such as location-allocation, and 3D problems are approached. The rise of Web-services and related cloud architectures has provided a means to take GIS from a highly customized application to one that is becoming a ubiquitous analysis tool for business, government, and individuals.

Geometric Programming

Joseph G. Ecker
Rensselaer Polytechnic Institute, Troy, NY, USA

Introduction

Early work in geometric programming was stimulated by Zener (1961, 1962) in his investigation of cost minimization techniques for engineering design problems. Subsequent work by Duffin (1962), Duffin and Peterson (1966), and Duffin, Peterson, and Zener (1967) provided the fundamental groundwork of the subject. Geometric programming refers to a class of optimization problems that have the form

$$\begin{array}{ll}(\boldsymbol{P})\text{minimize} & g_0(\boldsymbol{t}) \\ \text{subject to} & g_k(\boldsymbol{t}) \le 1 \text{ and } \boldsymbol{t}>0\end{array}$$

where $\boldsymbol{t} = (\boldsymbol{t}_1, \boldsymbol{t}_2, \ldots, \boldsymbol{t}_m)$ is a vector of variables and, for $k = 0,1,\ldots, p$, the functions $g_k(\boldsymbol{t})$ are sums of terms having the form

$$u_i(\boldsymbol{t}) = c_i \boldsymbol{t}_1^{a_{i1}} \boldsymbol{t}_2^{a_{i2}} \cdots \boldsymbol{t}_m^{a_{im}}$$

where the coefficients $\{c_i\}$ and the exponents $\{a_{ij}\}$ are arbitrary real numbers. The following is an example of a possible geometric program with three variables:

$$\begin{array}{ll}\text{minimize} & g_0(\boldsymbol{t}) = \frac{40}{\boldsymbol{t}_1\boldsymbol{t}_2\boldsymbol{t}_3} + 40\boldsymbol{t}_2\boldsymbol{t}_3 \\ \text{subject to} & g_1(\boldsymbol{t}) = \frac{1}{2}\boldsymbol{t}_1\boldsymbol{t}_3 + \frac{1}{4}\boldsymbol{t}_1\boldsymbol{t}_2 \le 1 \\ \text{and} & \boldsymbol{t}_i > 0, \quad i = 1,2,3.\end{array}$$

The term geometric programming was adopted because of the role that the geometric–arithmetic mean inequality played in the initial development of a duality theory for problems having the above form. Initially, the class of problems was restricted by requiring that the coefficients be positive and the corresponding terms $u_i(\boldsymbol{t})$ were called posynomials. Thus, the term posynomial programming might well have been chosen instead of geometric programming. Many engineering design problems do have the form of a geometric program where the coefficients are positive. Several examples of such problems are given in Duffin, Peterson, and Zener (1967), in the paper on methods, computations, and applications of geometric programming by Ecker (1980), and in the references of the latter paper.

Geometric programs where some of the $\{c_i\}$ coefficients can be negative are called signomial programs and this class of optimization problems was first studied by Passy and Wilde (1967) and Blau and Wilde (1969). The initial theory of geometric programming has been generalized to a much broader class of optimization problems. The review article by Peterson (1976) shows how the approach to developing a duality theory through the use of inequalities can be generalized to a very broad class of problems.

Equivalence of Posynomial and Convex Programs

Posynomial programs can be reformulated so that the objective function g_0 and the constraint functions g_i are convex. The simple transformation

$$t_j = e^{zj} \quad \text{for } j = 1,2,\ldots,m$$

allows each posynomial term to be rewritten in the form

$$u_i(\boldsymbol{t}) = c_i e^{a_{i1}z_1 + a_{i2}z_2 + \cdots + a_{im}z_m}.$$

Let $\boldsymbol{A}$ be the matrix whose ith row $\boldsymbol{A}_i$ gives the exponents of the ith posynomial term, then $u_i(\boldsymbol{t})$ can be written as

$$u_i(\boldsymbol{t}) = c_i e^{\boldsymbol{A}_i z}$$

where $\boldsymbol{z}$ is the column vector with entries z_i. The matrix $\boldsymbol{A}$ is usually called the exponent matrix. Notice that $\boldsymbol{A}$ is $n \times m$ where m is the number of variables and n is the number of posynomial terms.

For our example three-variable problem, the exponent matrix $\boldsymbol{A}$ is given by

$$\boldsymbol{A} = \begin{pmatrix} -1 & -1 & -1 \\ 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix}.$$

Defining $\boldsymbol{x} = \boldsymbol{Az}$, then each geometric program with positive coefficients can be written so that the objective function and all of the constraints are convex functions of the variables $\boldsymbol{x}$ because then each posynomial term can be written as

$$u_i(\boldsymbol{t}) = c_i e^{x_i}$$

where the linear constraints $\boldsymbol{x} = \boldsymbol{Az}$ are added.

The Dual of a Posynomial Program

Through the use of the geometric–arithmetic mean inequality a maximization problem can be generated from the posynomial program (**P**) above. The maximization problem has a dual variable d_i for each posynomial term u_i so that dual vector is given by

$$\boldsymbol{d} = (\boldsymbol{d}_1, \boldsymbol{d}_2, \ldots, \boldsymbol{d}_n)^T.$$

Let

$$L_k = \text{the sum of the variables } d_i$$

corresponding to the kth function $g_k(\boldsymbol{t})$.

The dual program has the form

$$\begin{aligned} \max \quad & v(\boldsymbol{d}) = \tfrac{c_1}{\boldsymbol{d}_1}\tfrac{c_2}{\boldsymbol{d}_2}\cdots\tfrac{c_n}{\boldsymbol{d}_n} L_1^{L_1} L_2^{L_2} \cdots L_p^{L_p} \\ \text{subject to :} \quad & L_0 = 1 \\ & A^T\boldsymbol{d} = 0 \text{ and } \quad \boldsymbol{d} \geq 0. \end{aligned}$$

The three variable example above has the following dual program:

$$\begin{aligned} \max \quad & v(\boldsymbol{d}) = \left(\tfrac{40}{\boldsymbol{d}_1}\right)\left(\tfrac{40}{\boldsymbol{d}_2}\right)\left(\tfrac{1}{2\boldsymbol{d}_3}\right)\left(\tfrac{1}{4\boldsymbol{d}_4}\right)(\boldsymbol{d}_3 + \boldsymbol{d}_4)^{\boldsymbol{d}_3+\boldsymbol{d}_4} \\ \text{subject to :} \quad & \boldsymbol{A}^T\boldsymbol{d} = 0 \\ & \boldsymbol{d}_1 + \boldsymbol{d}_2 = 1 \\ & \boldsymbol{d} \geq 0. \end{aligned}$$

The duality theory showing how to use a solution to the dual program to obtain a solution to the original primal program (**P**) is developed in Duffin, Peterson, and Zener (1967). The problem (**P**) is called canonical if there is a dual vector $\boldsymbol{d}$ satisfying

$$\boldsymbol{d} > 0 \quad \text{with} \quad \boldsymbol{A}^T\boldsymbol{d} = 0.$$

Canonical problems always have a minimizing point $\boldsymbol{t}^*$ and if, the set of all points satisfying the constraints in (**P**) has a non-empty interior, then the following duality results hold:

1. The dual problem has a maximizing vector $\boldsymbol{d}^*$;
2. The maximum value of the dual is equal to the minimum value for the primal program (**P**);
3. Each minimizing point $\boldsymbol{t}$ for (**P**) satisfies $u_i(\boldsymbol{t}) = d_i^* v(\boldsymbol{d}^*)$ for each i corresponding to the terms $u_i(\boldsymbol{t})$ in the objective function, and $u_i(\boldsymbol{t}) = d^*{}_i / L_k(\boldsymbol{d}^*)$ for all i when $L_k(\boldsymbol{d}^*) > 0$.

The right-hand side of each equation in (iii) is a positive constant and, given a solution $\boldsymbol{d}^*$, one can take common logarithms of both sides of the equations to obtain a linear system in the variables $\log(t_i)$. Typically, this linear system has more equations than variables so it uniquely determines a minimizing vector $\boldsymbol{t}^*$.

Computational Methods

The first published algorithm for solving posynomial programs was a method by Frank (1966) that solves the dual problem and then uses the above duality relations to obtain a minimizing point for (**P**). Blau and Wilde (1971) and Rijckaert and Martens (1976) developed similar methods that solve the Karush-Kuhn-Tucker optimality conditions for the dual problem. Other dual methods have been investigated, as for example in Dinkel, Kochenberger, and McCarl (1974) and in Beck and Ecker (1975).

A class of computational methods that solve (**P**) directly are based on the idea of linearizing geometric that was initially proposed by Duffin (1970). Avriel and Williams (1970) and Avriel, Dembo, and Passy (1975) use the idea of condensing each function into a single posynomial term to formulate a linear program that can be used to obtain an approximate solution to (**P**) even if some of the coefficients are negative. For more details on these types of approaches were given in Dembo (1978).

Gittins Index

For the multi-armed bandit model under certain assumptions, it can be shown that an index policy specifying the choice of the arm with the highest index is optimal. The earliest result establishing this seminal structural result was Gittins (1979), so the resulting index is most commonly attributed to him.

Global Climate Change Models

Hans W. Gottinger
International Institute for Technology Management and Economics, Bad Waldsee, Germany

Introduction

For many years, operations research has impacted the conceptual foundations, the scale and scope of models providing normative and predictive explanations on a potentially serious environmental threat known as the greenhouse effect. To assess long-term socio-economic changes due to the prevalence of the greenhouse effect, integrated models of energy, economy and the environment (EEE) of various levels of complexity have been constructed and put to use (Dowlabati 1995).

Structure of Energy-Economy-Environmental (EEE) Models

Early modeling approaches, in the context of carbon dioxide (CO_2) policies, involved an activity analysis model adapted to the CO_2 problem (Nordhaus 1979, 1980). This is an instructive example of the application of simple optimization models to a quantitative, qualitative and integrated analysis of CO_2 strategies. The analysis contains the major ingredients of EEE models of this kind: (1) the dynamics of the CO_2 cycle, the sources of CO_2 and the diffusion of atmospheric CO_2 and the limits of CO_2 concentrations; (2) the CO_2 energy model, for example a multi-sector activity analysis model which involves step-wise linear programming type optimization over a set of equidistant periods; and (3) the development of control strategies based on shadow prices of CO_2 emissions and costs of abatement.

A new generation of global EEE models (Peck and Teisberg 1993; Nordhaus 1993, 1994) contains special features, for example, the explicit consideration of the dynamics of economy and climate and a real interactive link-up between economic and climate dynamics models, relating to a time path of global mean temperature.

A culmination of efforts in the category of global EEE models has been the work of Nordhaus (1993, 1994). His approach centers around the construction, integration, model assessment and policy analysis of his economic control model DICE (Dynamic Integrated Model of Climate and Economy). DICE is a dynamic, intertemporal, optimal, interactive, welfare-economic control model based on structural equation constraints such as population growth, production constraints, capital stock accumulation, and emission constraints [where greenhouse gases (GHGs) are normalized by their carbon dioxide equivalent in terms of their global warming potential (GWP)]. The model contains a critical economy climate interface that links GHG emissions to their accumulation and transport in the atmosphere, the radiative forcing of the GHGs and their links to climate change. To assess the economic impacts such as damages, DICE contains feedbacks from climate change to economics, by specifying the loss of global output due to climate change. The climate part of DICE relates to specifications of General Circulation Models (GCMs), condensed as a minimodel of climate change to have it fit with the economic interface. Given the structure of DICE, Nordhaus puts his model to test. He first estimates damage profiles of GHG induced damages, for particular sectors as well as enticing the entire GDP loss. Furthermore, he looks at the welfare economic implications (net benefits) of seven major policy strategies to control global climatic changes: (1) no controls; (2) optimal policy; (3) ten-year delay of optimal policy; (4) stabilizing emissions at 1990 rates; (5) 20% emission reduction from 1990 levels; (6) geoengineering; and (7) climate stabilization with upper limit of total mean temperature increase by 1.5 °C from 1990. The net benefits vary significantly in size from each other, where it is remarkable that, in general, more interventionist strategies (stabilization), as strongly advocated by environmentalists, fare much worse than less interventionist ones (except for geoengineering which, of course, is hardly to the environmentalist's delight).

The extent of uncertainty in the model parameters gives rise to estimating the impact range on strategic

outcomes, as well as it applies to regulatory decision making on how to optimally impose regulatory controls to minimize over or undershooting of environmental regulation and policy measures (the value of information of waiting vs. acting).

Another string of models and research results of resource economics (on the depletion of non-renewable resources) could be applied with simple modifications to the CO_2 problem. Under two crucial assumptions, the problem of fossil fuel use in the face of increasing carbon dioxide is parallel to the problem of consumption of a limited resource. The first assumption is that the carbon dioxide absorption rate is sufficiently small to be ignored. The second is that CO_2 impacts follow a step pattern, that is, CO_2 (as a pollution stock) has no impact on productivity until a critical level, M_c, is reached; then if the CO_2 level exceeds M_c, production drops sharply (or more extremely, falls to zero).

A model with endogenous neutral technical progress, as in Gottinger (1998a), has been proposed to provide a better explanation of technical changes used to date in EEE models. Such a model originates from a similar attempt by Chiarella (1980). He proved the existence of a steady state growth path and a simple rule governing the rate of investment in research. Research investment along the optimal path should be carried out until the growth rate in the marginal accumulation of technology equals the difference between the marginal product due to an extra unit of research investment and the marginal product of capital.

Another issue is uncertainty. Here again there is a link with models of resource use for a limited, non-renewable resource when the reserve of the resource is unknown. The key finding of models by Loury (1978) and Gilbert (1979) was that plans for resource use based on the expected level of a resource will be overly optimistic. Gilbert's model is conducive to models of fossil fuel use when the critical CO_2 level is uncertain. Under the above assumptions, this problem is equivalent to determining the rate of fossil fuel use when the critical concentration of atmospheric carbon dioxide is unknown. Their results show that the optimal use of fossil fuel is lower when uncertainty is properly considered than when the expected values are assumed to be certainty equivalents.

A significant additional element is the possibility of undertaking exploration to find new reserves. The parallel in the CO_2 problem is R&D to increase the probability of finding a technology for the removal of CO_2 from the atmosphere.

Issues of Uncertainty

Existing EEE models suffer from poor data, indeterminate structure, and a frequent lack of attention to the consequences of uncertainty. The factors linking energy activities to their environmental effects are known only imprecisely. EEE models rely on behavioral assumptions that are widely questioned, and on parameters that can vary substantially from one model or data source to the next.

Most EEE models, including those well-established and highly used, conceal this uncertainty behind a blanket or output detail: a profusion of fuel prices and quantities, sectoral disaggregation, regional detail, growth rates and target figures, which often steer the analysis toward a desired conclusion. Unfortunately, this complexity rarely contributes to a resolution of uncertainty, and may serve only to increase the error and expense. Concerning models of possible greenhouse effects and CO_2 emissions, uncertainty analysis assumes many facets. It involves: (1) changes in climate to be expected; (2) impact of climate change; and (3) costs of adapting to climate change.

It is appropriate to distinguish between uncertainty about occurrences of events and impacts. Policy uncertainty is also of great concern. For the CO_2 problem, some argue that it is premature to think about doing other than intensive research, others claim that the risks of waiting are simply too great. What is the value of reducing scientific uncertainty? Scenario analysis only provides an indirect treatment of uncertainty, all uncertainties are resolved prior to decision-making. But uncertainty, information and decision-making are intimately connected and a comprehensive approach based on Bayesian decision analysis shows promise (Manne and Richels 1990).

Based on the described structure of EEE models, entire families of models have emerged in Europe,

the United States, and through international organizations (OECD, EU, World Bank, etc.), they range from highly aggregated general equilibrium models to multi-sectoral econometric models (Gottinger 1998a, b).

An interesting problem emerges in dealing with outcome uncertainties in climate change, that is with the timing of regulation. Such a design relates to problems of optimal stopping (Conrad 1992). Choosing the level of GHG emission-limiting regulations that will maximize social welfare by optimally balancing the costs of emission control against the benefits of decreased environmental damage is inherently not possible, because of pervasive uncertainty about the likely size of the critical GHG budget, its relationship to the quantity of GHG emitted, the effects of GHG in the atmosphere, and the appropriate valuation of these consequences. Moreover, learning more about each of these areas of uncertainty can be expected through continuing scientific-technological research, and through observation of atmospheric responses to past and current GHG emissions. Because, overall, it is expected that these uncertainties will diminish over time, the appropriate policy is likely to be an incremental and dynamic one. The risk to delaying before further restricting GHG emissions is that, if significant emission reductions become necessary to prevent serious adverse consequences, their cost may be much larger than if emission reductions begin sooner.

On the other hand, the risk to adopting further restrictions now is that these restrictions may later prove to have been unnecessary; the costs incurred would have produced no benefits. The question is analogous to that of whether to purchase insurance, as formulated by Manne and Richels (1992); by imposing additional regulations now, immediate costs are incurred in exchange for a potential reduction in the costs of preventing and adapting to future GHG accumulation. Gottinger (1995, 1996) attempted to provide insight to this question. First, he developed a general formulation of the policy question which can be conceived as an infinite-horizon, stochastic dynamic program with learning (Bertsekas 1976, Part II).

This formulation clarifies the issues, but is mathematically hard to manage. To provide more explicit guidance, advantage is taken of specific features of this problem to develop a simplified decision framework. Because of the long time delay in the relationships between GHG emissions, accumulation and effects in the atmosphere, the policy choice can be structured so that the environmental damages and benefits are approximately the same under each policy. Thus, the framework focuses attention on a comparison of the expected economic costs of alternative regulatory strategies.

In a different model framework, the aspect of learning has been given further attention by Kolstad (1993), with a survey of relevant approaches provided by Arrow et al. (1994).

Philosophy of EEE Modeling

Because the feedback effects of CO_2 are extremely uncertain, many modelers are reluctant to incorporate these effects in their models. In some scenarios, feedback effects might indeed be unimportant. For example, in models with finite horizons, if CO_2 effects are insignificant until after the horizon of the model no modeling of feedback effects is needed. In models which optimize over an infinite horizon, future effects may change current policies, and feedback effects are always of importance. In these same models, however, feedback effects may make solution much more difficult.

In predictive models with long time horizons, feedback effects will also be important. Further, in predictive models that estimate production and energy use at individual points of time, such as those surveyed previously, feedback effects can be easily included. Experience with the inclusion of feedback effects in optimizing models, shows that they usually lower the optimal initial use of fossil fuels. The longterm changes in fossil fuel use due to feedback effects are more uncertain and dependent on the model. In general, one could say that in most models the feedback slows the economy and thus reduces the demand for fossil fuels in the future. If optimization were included in the models discussed, this effect would be likely.

Given the uncertainty in the severity and timing of feedback effects, the sensitivity of individual models to variations in feedback effects is of much interest.

In proposing a step model of CO_2 emissions, the sensitivity of current fossil fuel use to an ultimate limit on atmospheric carbon dioxide was also examined. It was found that current optimal fossil fuel use was significantly affected by different critical levels of CO_2. A study of the impacts of a critical CO_2 level in a more disaggregated optimizing model would be useful. Including optimization in models expands their applicability but may cause analytic problems and controversy. As with many social problems, an acceptable objective function for carbon dioxide control problems is difficult to define. Any definition will seem both inadequate and overly precise and certainly would be controversial. This may be the reason why the models reviewed did not examine optimal policies. On the other hand, statement of an objective function does not hide or confuse other results and can add many new insights. If feedback effects and an objective function are included in a model, a crude optimization can be performed simply by running the model under a variety of policies.

Including optimization raised several new issues for the models. For example, pollution impoverishes but technical progress enriches the future. The optimizing models show how the curvature of the utility function, determined by the consumption elasticity of utility in the models, tends to smooth or even out wealth over time. Without an objective function being stated, the importance of this redistribution effect in determining fossil fuel use policy cannot be examined. In predictive models, a subjective evaluation must be made of the significance and value of a policy. In an optimizing model, the costs and benefits of policies are automatically compared in an explicit manner.

A final benefit of an optimizing model is the identification of multifaceted responses which may be ignored when policy changes are specified exogenously. Integrated optimizing models respond to problems by adjusting numerous policies endogenously. For example, in multiple state models fossil fuel use, research, and capital all respond to changes in the effects of CO_2.

Global Models

Saul I. Gass
University of Maryland, College Park, MD, USA

Global or world models are concerned with the application of systems analysis to policy problems of intra and international interest. Typical problems of concern include population growth, ecological issues (forestry, fisheries, pesticides, insect infestation), energy and water resource availability and uses, the spread of diseases, and environmental models (acid rain, air pollution), Clark and Cole (1975), Holcomb (1976). Global models are usually highly aggregated in their structure and in their data requirements. Such models, however, can be developed by integrating lower-level and more detailed national or regional models. Of related interest are global and regional predictive models that deal with long-range weather or macro-economic activity.

Although the trail of global models leads back to Malthus and his 1798 publication of *An Essay on the Principle of Population*, the modern development of global models begins with the use of systems analysis in the study of global problems, and the availability of specific tools for analysis such as (Forrester 1961) Leontief's Input–output Interindustry Structure, and Dantzig's Linear Programming Model. In particular, Forrester and his associates brought the use of global models to the attention of governmental officials and to the scientific community by their application of the World 2 and World 3 system dynamics models that are described in *World Dynamics* (Forrester 1971) the and *Limits to Growth* (Meadows et al. 1972), respectively.

The World 3 model considers the world as a whole and evaluates five global indicators and their interactions: population, consumption of nonrenewable resources, pollution, food production, and industrialization. The model's calculations lead to the conclusion that sometime in the twenty-first century, the world will witness a steep decline in food per capita and in population. The general pessimistic conclusion reached by the World 3 model (under varying assumptions such as availability of resources) was that the world will soon be hitting resource, economic, and population limits to growth, and measures must be initiated by the world community to avoid calamity. The model indicated a stable future only if such stringent measures as maintaining a stable (zero growth) world population and capital base, and such measures are applied soon (Meadows et al. 1972; Clark and Cole 1975). Criticisms of this conclusion abound and they address the issues of the model's structure, data, aggregation, and methodological approach. (See, for example, Cole et al. 1973; Schwartz and Foin 1972, and a rebuttal by Forrester 1976).

Other global models have been developed in an attempt to overcome some of the limitations and criticisms of the World 3 model; in particular, note the one by Mesarovic and Pestel (1974). This model divided the world into ten regions and enabled some policy options (e.g., energy resource utilization) to be evaluated. Research in global models continues, with one center for such investigations being the International Institute for Applied Systems Analysis (IIASA). IIASA has initiated a database collection for environmental analyses, developed an acid rain model for Europe, forest resource and pest management models, plus econometric and linear-programming-based approaches to global policy modeling (Bruckmann 1980).

The means of encompassing the complex interactions of the global system into a computer-based model will always be open to criticism. As any model is an approximation of the real-world, surely a model that attempts to encompass the whole world or even major subelements cannot do so with much exactitude. One would not expect it to be so. As noted by Mason (1976, p. 4): "We have seen that ultimately there is no objective way to assess world models." But, there is no reason why investigators, building on such past efforts as those described above and others, cannot develop global models that would be of value to the world's policymakers.

Introduction

Consider an optimization problem of the general form

$$\min\{f(x)|g_i(x) \le 0, i = 1, \ldots, m,\ x \in X\} \quad \text{(P)}$$

where X is a closed convex set in $\mathbb{R}^n$, $f : \Omega \to \mathbb{R}$, and $g_i : \Omega \to \mathbb{R}, i = 1, \ldots, m$, are continuous functions defined on some open set Ω in $\mathbb{R}^n$ containing X. Setting

$$D = \{x \in X | g_i(x) \le 0, i = 1, \ldots, m\},$$

the problem can also be written as

$$\min\{f(x)|x \in D\}.$$

Any point $\bar{x} \in D$ is called a feasible solution of the problem. A feasible solution $\bar{x}$ is called a global optimal solution if it is the best of all feasible solutions, i.e., if it satisfies

$$f(\bar{x}) \le f(x) \quad \forall x \in D. \tag{1}$$

A feasible solution $\bar{x}$ is called a local optimal solution if it is the best among all feasible solutions in some neighborhood of it, i.e., if there exists a neighborhood W of $\bar{x}$ such that

$$f(\bar{x}) \le f(x) \quad \forall x \in D \cap W. \tag{2}$$

Many important practical problems may have many local optimal solutions with different objective function values. The need may then arise to find the best among them, i.e., a global optimal solution.

In convex (linear, resp.) programs where $X = \mathbb{R}^n, f(x), g_i(x)$ are all convex (linear, resp.),

any local optimal solution is global, and efficient algorithms are routinely used for solving these problems. Aside from these cases, finding a global optimal solution is a hard problem requiring quite different techniques. Due to its importance for many applications, global optimization is an active research field (Horst and Pardalos 1995; Floudas and Gounaris 2009; Pardalos and Coleman 2009).

Some typical examples of global optimization applications in operations research and management science (OR/MS) are presented to show the general mathematical structure of global optimization problems. Next, the general concept of branch and bound, the most popular general purpose method for solving global optimization problems, is described. Finally, different classes of global optimization problems encountered in the applications and requiring specialized treatment are reviewed.

Examples from OR/MS

In most mathematical programming problems of form (P) encountered in OR/MS, each function $f(x), g_i(x)$ represents a cost, a performance (return, benefit, ...), or a negative utility (loss, pollution, ...) that depends on the decision variable $x \in \mathbb{R}^n$. The decision maker may want to determine $x \in \mathbb{R}^n$ so as to minimize the associated cost $f(x)$ subject to constraints $g_i(x) \leq 0$ expressing, for example, the requirement that the total cost of i-th resource involved should not exceed certain acceptable limit, or the expected i-th utility should not be less than a certain required level (in addition to constraints $x \in X$ reflecting other "technical" aspects of the problem). A common phenomenon is that economy of scale (or decreasing return) prevails in certain sectors or within certain scale limits, while diseconomy of scale (or increasing return) prevails in other sectors or beyond certain scale limits. Mathematically, economy of scale or decreasing return is modeled by concave or decreasing functions, diseconomy of scale or increasing return is modeled by convex or increasing functions. In more complex situations increasing and decreasing return phenomena may be copresent, and more general types of functions have to be used that are *dc functions* (differences of convex functions), or *dm functions* (differences of monotonic increasing functions).

Recall that a function $f : \mathbb{R}^n \to \mathbb{R}$ is said to be convex if $f(\alpha x + (1-\alpha)x') \leq \alpha f(x) + (1-\alpha) f(x')$ for any $x, x' \in \mathbb{R}^n$, and any real number α such that $0 \leq \alpha \leq 1$; it is said to be increasing if $f(x) \leq f(x')$ for any $x, x' \in \mathbb{R}^n$ such that $x_i \leq x'_i, i = 1, \ldots, n$. A function $f(x)$ is said to be concave if $-f(x)$ is convex; decreasing if $-f(x)$ is increasing.

Global optimization has been applied to many fields such as biomedicine, economics, energy systems, computational chemistry and biology, and computer science (Floudas and Pardalos 2003; Rebennack et al. 2010a; Rebennack et al. 2010b). Three examples in OR/MS are presented here.

Example 1. (Production-transportation planning) Consider k factories producing a certain good to satisfy the demands d_j, $j = 1, \ldots, m$, of m destination points. The production cost is $g(y_1, \ldots, y_k)$ if the factory i produces y_i units, where $g(\cdot)$ is a concave function because of economies of scale. The transportation cost is a function $c_{ij}(x)$ for x units shipped from factory i to destination point j. In addition, there is a shortage penalty $h(z_1, \ldots, z_m)$ to be paid if the destination point j receives $z_j \neq d_j$ units, where $h(z_1, \ldots, z_m) = \sum_{j=1}^{m} h_j(z_j)$, with $h_j(z_j) \leq 0$ if $z_j \geq d_j$, and $h_j(\cdot)$ is a decreasing nonnegative function in the interval $[0, d_j)$. Usually, the penalty function $h(\cdot)$ is convex, so the total production-transportation cost is the function $f(x, y, z) = \sum_{i=1}^{k} \sum_{j=1}^{m} c_{ij}(x_{ij}) + g(y) + h(z)$. This function should be minimized subject to usual transportation constraints: $\sum_{j=1}^{m} x_{ij} = y_i, i = 1, \ldots, k, \sum_{i=1}^{k} x_{ij} = z_j, j = 1, \ldots, m, x_{ij} \geq 0, y_i, z_j \geq 0 \, \forall i, j$.

Even if the transportation costs $c_{ij}(x)$ are linear, this problem cannot be handled successfully by conventional methods of nonlinear programming. Things become more complicated when the transportation costs $c_{ij}(x)$ along certain arcs (ij) are dc functions (for instance S-shaped functions), or some are concave, others are convex (Holmberg and Tuy 1993).

Example 2. (Location planning) A facility has to be constructed to serve n users located at points $a^j \in S$ of the plane (i.e., $S \subset \mathbb{R}^2$). If the facility is located at $x \in S$, then the attraction of the facility to user j is $q_j(h_j(x))$, where $h_j(x) = \| x - a^j \|$ is the distance

from x to a^j and $q_j : \mathbb{R} \to \mathbb{R}$ is a convex decreasing function (the farther x is away from a^j the less attractive it looks to user j). To determine the location of the facility with maximal total attraction, one has to solve the problem

$$\text{maximize} \sum_{j=1}^{n} q_j(h_j(x)) \quad \text{s.t. } x \in S. \tag{3}$$

The function $\varphi(x) = \sum_{j=1}^{n} q_j(h_j(x))$ is generally neither convex nor concave. However, since the functions $h_j : \mathbb{R}^2 \to \mathbb{R}_+$ and $q_j = \mathbb{R} \to \mathbb{R}$ are convex, it can be shown that their compositions $q_j(h_j(x))$, $j = 1, \ldots, n$, are dc, and $\varphi(x)$ a sum of dc functions, hence itself a dc function.

In practice, some of the points a^j may actually be repulsion rather than attraction points. For example, there may exist a garbage dump, a sewage plant, or a nuclear plant in the area, and one may wish the facility to be located as far away from these points as possible. If J_1 is the set of attraction points, J_2 the set of repulsion points, then instead of (3) one should seek to maximize the function

$$\sum_{j \in J_1} q_j(h_j(x)) - \sum_{j \in J_2} q_j(h_j(x)). \tag{4}$$

An even more complex situation occurs when several facilities must be located. In this case, each user will be served by the nearest facility, so the problem is to determine the locations, say x, y and z, of the facilities, so as to maximize

$$\sum_{j=1}^{n} q_j(\tilde{h}_j(x, y, z)) \tag{5}$$

over $(x, y, z) \in S \times S \times S$, where

$$\tilde{h}_j(x, y, z) = \min\{h_j(x), h_j(y), h_j(z)\}. \tag{6}$$

Again it can be proven that $\tilde{h}_j(x, y, z)$ (pointwise minimum of finitely many convex functions) is a dc function, and $q_j(\tilde{h}_j(x, y, z))$ (convex functions of dc functions) are also dc functions. Therefore, again this multifacility location problem appears to be a dc optimization problem (Chen et al. 1992). Note that this problem is sometimes formulated as a mixed integer program, much more difficult to solve.

Example 3. (Multilevel programming) Many decentralized decision-making systems in economics and other fields involve a "leader" (the higher level decision maker) who controls a variable $x \in \mathbb{R}^p$ and a "follower" (the lower level decision maker) who controls a variable $y \in \mathbb{R}^q$. For each decision x made by the leader, the follower chooses y in order to optimize his own objective function $\varphi(y)$, under a constraint set $\Omega(x)$ associated with the decision x, i.e., the response y of the follower to the decision x of the leader is a vector such that

$$y \in \operatorname{argmin}\{\varphi(y') | y' \in \Omega(x)\}.$$

If the objective of the leader is to minimize a function $f(x, y)$, while his own constraint set is $D \subset \mathbb{R}^p \times \mathbb{R}^q$ then the problem he must solve is to choose x so as to

minimize

$$f(x, y) \tag{7}$$

subject to

$$(x, y) \in D, y \in \Omega(x); \tag{8}$$

$$\varphi(y) \leq \varphi(y') \forall y' \in \Omega(x). \tag{9}$$

Even in the simplest cases when all data are linear: $f(x, y) = c_1 x + d_1 y, \varphi(y) = d_2 y, D = \{(x, y) | A_1 x + B_1 y \leq g_1, x \in R^p_+\}$ while $\Omega(x) = \{y | A_2 x + B_2 y \leq g_2, y \in R^q_+\}$, the feedback relation between upper and lower levels creates nonconvexities that cannot be easily handled by standard methods of nonlinear programming.

If $h(x)$ denotes the optimal value of the lower subproblem, i.e., $h(x) = min\{\varphi(y) | y \in \Omega(x)\}$, then the constraint (9) can also be written as

$$\varphi(y) \leq h(x).$$

Often $\varphi(y)$ is a convex function and, as in the just mentioned linear case, for any x^1, x^2 and any $\alpha \in [0,1]$, then $\alpha\Omega(x^1) + (1-\alpha)\Omega(x^2) \subset \Omega(\alpha x^1 + (1-\alpha)x^2)$. It can then easily be checked that $h(x)$ is a convex function, too, and so the constraint (3), i.e., $\varphi(y) - h(x) \leq 0$, is a dc constraint.

Bilevel, and more generally multilevel, programming problems of the above kind have various applications in economics (Stackelberg duopoly model), agriculture (e.g., fertilizer supply, water supply, agricultural policy), financial management, and network design (Wen and Hsu 1991). Thus a host of problems of practical interest in economics, OR/MS and engineering involve dc functions or dm functions in their description. Other problems reported from computer science (VLSI chip design, databases), wireless communications, system reliability, mechanics (structural optimization), physics (nuclear design, microcluster phenomena in thermodynamics), chemistry (phase and chemical reaction equilibrium), or ecology (design and cost allocation for waste treatment systems) can analogously be identified as dc or dm optimization problems (Floudas and Pardalos 1999; Floudas 2000).

A problem (P) where all functions $f(x), g_1(x), \ldots, g_m(x)$ are dc (dm, resp.) is called a dc (dm, resp.) optimization problem. These are two basic classes of global optimization problems. Practically, every global optimization can be reformulated, possibly via a change of variables, as a dc or a dm optimization problem.

Branch and Bound Methods

A popular method for solving a global optimization problem (P) is by using a BB (branch and bound) procedure.

The Generic BB Procedure

For convenience assume that $X = [a,b] = \{x \in \mathbb{R}^n | a_j \leq x_j \leq b_j, j = 1, \ldots, n\}$, so that the feasible set in problem (P) is

$$D = \{x \in [a,b] | g_i(x) \leq 0, i = 1, \ldots, m\}.$$

The generic BB procedure for solving (P) involves two basic operations: partitioning and bounding.

- **Partitioning**: Starting from the initial box (hyperrectangle) $M_1 = [a,b]$, at each iteration a box is selected and subdivided into two subboxes according to a subdivision rule. Through this partitioning process, a tree is generated with the root at M_1 and the nodes represented by the subboxes that appear as successive descendants of the initial box.
  Let $M = [p,q]$ be a box selected for subdivision in a given iteration. A common subdivision rule called the standard bisection consists in dividing M into two equal subboxes using a hyperplane perpendicular to a longest edge of M at the midpoint of this edge. An important property of this subdivision rule is its exhaustiveness, meaning that any infinite nested sequence of boxes M_k generated by it shrinks to a point (i.e., diam $M_k \to 0$ as $k \to +\infty$).
- **Bounding**: At each iteration, two new boxes appear as a result of the subdivision operation. For each new box $M = [p,q]$, a lower bound is computed for $f(x)$ over the feasible points in M, i.e., a number $\beta(M) \in \mathbb{R} \cup \{-\infty, +\infty\}$ satisfying

$$\beta(M) \leq inf\{f(x) | x \in M \cap D\}, \tag{10}$$

$$M_k \cap D = \emptyset \Rightarrow \beta(M) = +\infty. \tag{11}$$

The latter condition, which is essential, amounts to requiring that $\beta(M) < +\infty$ only if $M \cap D \neq \emptyset$.
The number $\beta(M)$ is usually computed by considering an underestimator $\varphi(x)$ of $f(x)$ over a set $\Omega \supset M$, i.e., a function satisfying $\varphi(x) \leq f(x) \forall x \in \Omega$, and taking $\beta(M) = inf\{\varphi(x) | x \in \Omega\}$, where $\varphi(x)$ and Ω are chosen so that the latter problem can be solved easily. Also to obtain tight bounds it is often necessary to replace the partition set M by a suitable smaller set $M' \subset M$: the procedure is then referred to as a branch-and-reduce algorithm.
While computing the lower bounds, it may happen that some feasible points are obtained: the feasible point with smallest objective function value is then recorded as the current best feasible solution (CBS) and the associated objective function value as the current best objective function value (CBV). Once every current box has been assigned a lower bound, all boxes M with

$\beta(M) > CBV$ (in particular those with $\beta(M) = +\infty$) are pruned (deleted). If no box remains after that, the procedure is terminated and CBS gives a (global) optimal solution. Otherwise, a box with smallest lower bound among all remaining boxes is selected for further subdivision, and a new iteration is started.

Proposition. *If bounding is consistent with branching in the sense that*

$$\beta(M) - \min\{f(x)|x \in M \cap D\} \to 0 \quad \text{as } diam\, M \to 0, \tag{12}$$

then as $k \to +\infty$, the box M_k with smallest lower bound at iteration k shrinks to a point which is an optimal solution, while $\beta(M_k)$ tends to the optimal value $min(P)$ of the problem.

Case of a Nice Feasible Set

Suppose the feasible set is nice, i.e., such that a feasible solution can be computed cheaply (as is the case, for example, when each $g_i(x)$ is convex or each $g_i(x)$ is increasing). Then at each iteration k, a current best feasible solution CBS is available that provides an upper bound for $\min(P)$. In that case $\beta(M_k) \le \min(P) \le$ CBS, so if x^k is CBS at iteration k, then as $k \to +\infty$ the sequence $\{x^k\}$ tends to a limit $\bar{x}$ yielding an optimal solution of the problem. Furthermore, this convergence can be sped up by using instead of the standard bisection an adaptive bisection rule ensuring convergence without condition (12) (Tuy 1998, 2000). Given a tolerance $\eta > 0$, by stopping the procedure when $f(x^k) - \beta(M_k) \le \eta$, an η-optimal solution of the problem, i.e., a feasible solution x^* satisfying $f(x^*) \le min(P) - \eta$, is obtained. Thus, everything works well if the feasible set is nice.

Case of a Hard Feasible Set

By contrast, if the feasible set is such that a feasible solution cannot be computed cheaply, then several difficulties may arise with the generic BB method. Namely, in this case it may not be easy to compute lower bounds satisfying conditions (11) and (12), while failing these conditions the algorithm may converge to an incorrect solution which is infeasible and quite far from the optimum. Another drawback is that since at every iteration no feasible solution is available, no partition set can be pruned aside from those M with $\beta(M) = +\infty$, causing an excessive growth of the size of the collection of partition sets to be stored. Also, the convergence accomplished with an exhaustive subdivision process is in general slow. As a result, in finitely many steps the BB procedure can at best give an (ε, η)-approximate optimal solution, i.e., an $\bar{x}$ satisfying $g_i(\bar{x}) \le \varepsilon, i = 1, \ldots, m$ and $f(\bar{x}) \le \min(P) + \eta$. Unfortunately, such an (ε, η)-optimal solution is not guaranteed to be feasible and close to the true optimum, and, moreover, it may change drastically upon a small change of the tolerances ε and η, causing numerical instability problems in practical implementation.

The way out of these difficulties is to reduce any problem (P) with a hard feasible set to a sequence of problems with a nice feasible set. This is possible by using the following result (Tuy 2010):

By simple manipulations, any dc optimization problem (i.e., any problem (P) *where $f(x)$ and all $g_i(x)$ are dc) can be reformulated as an equivalent dc optimization problem with a convex objective function. Likewise, any dm optimization problem (i.e., any problem* (P) *where $f(x)$ and all $g_i(x)$ are dm) can be reformulated as an equivalent dm optimization problem with an increasing objective function.*

So for studying a dc optimization problem (P), one can without loss of generality assume that $f(x)$ is convex. Setting $g(x) = \min_{i=1,\ldots,m} g_i(x)$, the problem (P) can then be written as

$$\min\{f(x)|g(x) \le 0, x \in [a, b]\}, \qquad (\mathrm{P}')$$

where $g(x)$ is still a dc function by a known property of dc functions (Tuy 1998). Now, given any number $\gamma \ge \min(\mathrm{P}')$, consider the problem

$$\min\{g(x)|f(x) \le \gamma, x \in [a, b]\}. \qquad (\mathrm{Q}_\gamma)$$

Since $f(x)$ is convex, this problem has a nice feasible set and can be solved by the above BB method. Clearly $\min(\mathrm{Q}_\gamma) \le 0$ (because $\gamma \ge \min(\mathrm{P}')$) and if the problem (P') is such that

$$\min(\mathrm{P}') = \inf\{f(x)|g(x) < 0, x \in [a, b]\}$$

(a condition satisfied in most cases), it can easily be shown that $\min(Q_\gamma) = 0$ only if $\min(P') = \gamma$.

Based on this relationship between (P') and (Q_γ), the following method (Tuy 2010) can be used to find an η-optimal solution of (P'), i.e., a feasible solution x^* of (P') such that $f(x^*) \le \min(P') - \eta$.

Suppose a feasible solution $\bar{x}$ of (P') is available. With $\gamma = f(\bar{x}) - \eta$, apply the above described BB procedure for solving (Q_γ). If at some iteration k of this BB procedure, the current best solution x^k satisfies $g(x^k) \le 0$, then x^k is a feasible solution of (P') such that $f(x^k) \le f(\bar{x}) - \eta$. Otherwise, $g(x^k) > 0\ \forall k$ and from (12) it follows that $\min(Q_\gamma) = \lim g(x^k) \ge 0$, hence $\min(P') = \gamma = f(\bar{x}) - \eta$, i.e., $\bar{x}$ is an η-optimal solution of (P').

Thus, given a feasible solution $\bar{x}$ of (P'), by solving (Q_γ) with $\gamma = f(\bar{x}) - \eta$ one can either identify $\bar{x}$ as an η-optimal solution of (P') or find a feasible solution x of (P') such that $f(x) \le f(\bar{x}) - \eta$. Since $\eta > 0$, by repeating this procedure finitely many times, one will eventually obtain an η-optimal solution of (P').

To obtain an initial feasible solution $\bar{x}$ of (P'), it suffices to take any number $\gamma > \min(P')$ and apply the BB procedure for (Q_γ).

That is the basic idea of successive incumbent transcending for solving any dc optimization problem (P) with a hard feasible set. An analogous method can be used for solving a dm optimization problem with a hard feasible set: first rewrite it in the form (P') with an increasing function $f(x)$ and a dm function $g(x)$; then find an η-optimal solution of (P') by successive incumbent transcending via solving problem (Q_γ) with adaptively adjusted γ.

Specific Problem Classes

Aside from general purpose methods for global optimization, more efficient specific methods are available to solve specific problems by exploiting their underlying mathematical structure (Pardalos and Romeijn 2002). Other cases with specialized algorithms not discussed below include concave minimization and optimization with differences of monotonic functions or Lipschitz functions (Horst and Pardalos 1995; Horst and Tuy 1996). Furthermore, there is a rich body of literature on tailored decomposition algorithms for global optimization problems (Rebennack et al. 2009).

Quadratic Optimization

A quadratic optimization problem is a problem (P) where $f(x), g_1(x), \ldots, g_m(x)$ are quadratic functions, i.e., $f(x) = \frac{1}{2}\langle x, Q^0 x\rangle + \langle c^0, x\rangle$, $g_i(x) = \frac{1}{2}\langle x, Q^i x\rangle + \langle c^i, x\rangle + d_i$ with $Q^i, i = 0, 1, \ldots, m$, being symmetric $n \times n$ matrices and $c^i \in \mathbb{R}^n$, $d_i \in \mathbb{R}$

To solve a quadratic optimization problem by BB, the basic question is how to compute lower bounds. Two most used bounding methods are reformulation–linearization (Sherali and Adams 1999) and Lagrangian relaxation (Tuy 1998; Floudas 2000).

- **Reformulation–linearization**: Setting $x_i x_j = y_{ij}$ for every (i, j) with $1 \le i \le j \le n$ and $y = \{y_{ij}\}$, every quadratic function $f(x)$ of $x \in \mathbb{R}^n$ can be expressed as an affine function of x, y, denoted by $[f(x)]_\ell$. For example, $[2x_1x_3 + 3x_1^2 - 5x_2x_3 + 8x_3]_\ell = 2y_{13} + 3y_{11} - 5y_{23} + 8x_3$. Moreover, it can be shown that the constraint $p \le x \le q$ is equivalent to the system of quadratic constraints $g_{ij}(x) = (x_i - p_i)(x_j - q_j) \le 0\ \forall i, j = 1, \ldots, n$. Then for $M = [p, q]$, the problem $\min\{f(x) | g_k(x) \le 0, k = 1 \ldots, m, p \le x \le q\}$ can be rewritten as

$$\min\{[f(x)]_\ell \,|\, [g_k(x)]_\ell \le 0, k = 1 \ldots, h, \; y_{ij} = x_i x_j, 1 \le i \le j \le n\}, \tag{13}$$

where the constraints $g_k(x) \le 0, k = m + 1, \ldots, h$, include all the just-mentioned constraints $g_{ij}(x) \le 0$. Clearly (13) is a linear program, with the additional nonconvex constraints $y_{ij} = x_1 x_j, i \le i \le j \le n$. Therefore, as a lower bound for $\min\{f(x) | g_k(x) \le 0, k = 1, \ldots, m, x \in M\}$, one can take

$$\beta(M) = inf\{[f(x)]_\ell \,|\, [g_k(x)]_\ell \le 0, k = 1 \ldots, h\}.$$

It can be shown that this bounding operation satisfies (11) and (12), so the generic BB algorithm using this bounding method is correct, although its convergence is generally slow, due to the large number of additional variables introduced. However, there are various ways to improve the method, for example by adding implied constraints to (13) (Sherali and Adams 1999) or by using the incumbent transcending approach discussed earlier.

- **Lagrangian Relaxation**: For a given problem (P), the function $L(x,u) = f(x) + \sum_{i=1}^{m} u_i g_i(x)$, $u \in \mathbb{R}^m_+$, is called the Lagrangian, and the problem

$$\sup_{u \in \mathbb{R}^m_+} \inf_{x \in X} L(x,u) \qquad \text{(LP)}$$

the Lagrangian relaxation of (P). It is easily seen that $\min(\text{LP}) \leq \min(\text{P})$, so $\min(\text{LP})$ is a lower bound of $\min(\text{P})$. The Lagrangian relaxation is called exact if $\min(\text{LP}) = \min(\text{P})$. This occurs effectively, for example, when $m = 1$ and $X = \mathbb{R}^n$, i.e., when the problem is

$$\min\{f(x) | g(x) \leq 0, x \in \mathbb{R}^n\}$$

where $f(x), g(x)$ are quadratic functions and there is an $x^* \in \mathbb{R}^n$ such that $g(x^*) < 0$. Indeed, it is known that in this special case, the Lagrangian relaxation is exact and equivalent to a SDP (semi-definite programming problem) that can be solved by efficient methods (Ben-Tal and Nemirovski 2001). So, in particular, the minimization of a nonconvex quadratic function over an ellipsoid is equivalent to a SDP, i.e., essentially a convex problem.

In the general case $m > 1, X = [p,q]$, by replacing the constraint $x \in [p,q]$ with an equivalent system of quadratic inequalities as mentioned above, it can always be assumed that $X = \mathbb{R}^n$. Although the corresponding Lagrangian relaxation is also an SDP, it seems difficult to use exclusively this bounding method to produce a convergent BB algorithm. However, it can be incorporated into a convergent primal-relaxed dual decomposition approach (Floudas 2000).

Also note that a quadratic function of the form $\sum_{0 \leq i \leq j \leq n} c_{ij} x_i x_j$ with $c_{ij} \geq 0$ is an increasing function on $\mathbb{R}^n_+$. Therefore, any quadratic function on $\mathbb{R}^n_+$ is a dm function, and thus a quadratic optimization problem (P) where $X = \mathbb{R}^n_+$ can be viewed alternatively as a dm problem and as such can be solved by the method described earlier.

Multiobjective Programming

A multiobjective program is a generalization of problem (P) where $F(x)$ is a vector of k objective functions

$$\min\{F(x) = [f_1(x), f_2(x), \ldots, f_k(x)]^T \mid g_i(x) \leq 0,\ i = 1, \ldots, m,\ x \in X\}$$

where X represents the set of feasible decisions and $f_i(x) : \Omega \to \mathbb{R}, i = 1 \ldots, k$ are the objective functions that the decision maker wants to minimize. A feasible decision x^0 is said to be efficient (Pareto-optimal) if for any $x \in X$, $f_i(x) \leq f_i(x^0) \forall i$ implies $f_i(x) = f_i(x^0) \forall i$; it is said to be weakly efficient if there is no $x \in X$ such that $f_i(x) < f_i(x^0) \forall i$. An efficient or weakly efficient solution achieves a kind of equilibrium and in certain situations the decision maker may want to find an equilibrium minimizing some objective function. For example, starting from a feasible solution, the decision maker may want to reach an equilibrium by the "cheapest" way (see Thach et al. 1996 for an example in bond portfolio optimization). If X_E denotes the set of efficient solutions, then the goal of the decision maker is to minimize a certain function $h(x)$ over X_E, i.e.,

$$\text{minimize } h(x) \text{ subject to } x \in X_E. \qquad (14)$$

In general, the set X_E is nonconvex, so even if $h(x)$ is linear, this is a difficult global optimization problem (Marler and Arora 2004). A relaxed variant of problem (14) is

$$\text{minimize } h(x) \text{ subject to } x \in X_{WE}, \qquad (15)$$

where X_{WE} denotes the set of weakly efficient solutions. It can be shown that when $f_i(x)$ are linear, (15) is equivalent to the problem

$$\min\{h(x) | x \in X, \lambda \in \Lambda, g(\lambda) - \lambda F(x) \leq 0\},$$

where Λ is a simplex in R^k and $g(\lambda) = \sup\{\lambda F(y) | y \in X\}$ is a convex function (so $g(\lambda) - \lambda F(x)$ is a dc function). This allows the use of the BB method discussed earlier.

Fractional Programming

Fractional programming deals with problems where a ratio of two objective functions has to be optimized. Several different forms of fractional programs can be distinguished (Frenk and Schaible 2004; Stancu-Minasian 1997).

- **Single-ratio fractional programs**: For extended real-valued continuous functions $f(x), h(x) : \Omega \to [-\infty, +\infty]$ with finite value on D, single-ratio fractional programs are given in the general form

$$\inf\left\{\frac{f(x)}{h(x)}\middle| g_i(x) \le 0,\ i = 1, \ldots, m,\ x \in X\right\}. \quad (16)$$

  For the special case where $f(x)$ and $g_i(x)$ are convex functions $\forall i$ and $h(x)$ is a positive concave function in D, (16) is called a single-ratio convex fractional program and is a nonconvex global optimization problem. Note that the ratio $\frac{f(x)}{h(x)}$ is not a convex function in general. Typical applications in OR/MS include the maximization of productivity, maximization of return on investments, maximization of return versus risk, minimization of cost versus time, and maximization of output versus input.
- **Generalized fractional program**: Extending (16) to multiple ratios leads to generalized fractional programs of the form

$$\inf_{x \in D} \sup_{1 \le l \le k} \frac{f_l(x)}{h_l(x)}, \quad (17)$$

  with $f_l(x), h_l(x)$: $\Omega \to [-\infty, +\infty]$ for all l and positive functions $h_l(x)$ for $x \in D$.
- **Sum-of-ratios fractional program**: Minimizing the sum of ratios leads to the following optimization problem

$$\inf\left\{\sum_{l=1}^{p} \frac{f_l(x)}{h_l(x)}\middle| g_i(x) \le 0,\ i = 1, \ldots, m,\ x \in X\right\}, \quad (18)$$

  with the same assumptions on the function $f_l(x)$ and $h_l(x)$ as in the generalized fractional programs. Bond portfolio optimization problems are examples of sum-of-ratios fractional programming problems.

Multiplicative Programming

One standard approach to simultaneously optimizing several objectives without a common scale is to optimize the product of these objectives. This leads to consider multiplicative programming problems of the form

$$\inf\left\{\prod_{l=1}^{p} f_l(x)\middle| g_i(x) \le 0,\ i = 1, \ldots, m,\ x \in \mathbb{R}^n\right\} \quad (19)$$

where $f_l : \mathbb{R}^n \to \mathbb{R}^+$, $g_i : \mathbb{R}^n \to \mathbb{R}$. Practical methods for solving these problems are available when each $f_l(x)$ is either quadratic or affine and each $g_i(x)$ is convex, for $p \le 5$ and $n, m \le 100$ (Konno et al. 1997). In particular, linear multiplicative programming problems, i.e., problems (19) where $p = 2$ and all functions f_l, g_i are affine, can be solved very fast by a variant of the parametric simplex algorithm. Applications of multiplicative programming include bond portfolio optimization and economic analyses.

Goal Constraints

Mathematical expressions consisting of resource utilization rates, decision variables, deviation variables, and targeted minimum and maximum resources levels. They are used to model individual resource goals in a goal programming model.

Goal Programming

Marc J. Schniederjans
University of Nebraska-Lincoln, Lincoln, NE, USA

Introduction

Goal Programming (GP), also called linear goal programming (LGP), can be categorized as a special case of linear programming (LP). The origin of GP as a means of resolving infeasible LP problems attests to its characterization as a LP methodology (Charnes and Cooper 1961). GP is now considered a multi-criteria decision making (MCDM) method (Steuer 1986); it is used to solve multi-variable, constrained resource and similar problems that have multiple goals.

GP Modeling

Similar to LP, the GP model has an objective function, constraints (called goal constraints), and nonnegativity requirements. The GP objective function is commonly expressed in minimization form as (Schniederjans 1984):

$$\text{minimize} \quad Z = \sum_{i=1}^{T} w_{kl} P_k \left(d_i^- + d_i^+\right)$$
$$\text{for} \quad k = 1, \ldots, K;\ l = 1, \ldots, L,$$

where i is the goal constraint index, k is the priority rank index, and l is the index of the deviation variables within priority rank. In the objective function, Z is the summation of all deviations, the w_{kl} are optional mathematical weights used to differentiate deviation variables within a kth priority level, the P_k are optional rankings of deviation variables within goal constraints,

the d_i^- values are the negative deviational variables, and the d_i^+ values are the positive deviational variables. The P_k rankings are called preemptive priorities because they establish an ordinal priority ranking (where $P_1 > P_2 > P_3 > \ldots$ etc.) that orders the systematic optimization of the deviation variables.

The fact that the optimization of the variables in the objective function is ordered by the preemptive priority ranking has given rise to the use of the term satisficing. This term results from the fact that a solution in a GP model satisfies the ranking structure while minimizing deviation from goals. [See Simon (1955) for his original definition of satisficing with respect to rational choice.] One of the best features of GP is that the P_k permit the decision makers to rank goals in accordance with their personal preferences, and even weight the importance of those preferences within goals using w_{kl}. The greater the w_{kl} mathematical weighting, the greater the importance attached to its related deviation variable.

The goal constraints in a GP model can be expressed as:

$$\sum_j a_{ij}x_j + d_i^- - d_i^+ = b_i \quad \text{for all } i.$$

The a_{ij} are the resource utilization rates representing the per unit usage of the related resource b_i, and the x_j are the decision variables to be determined. The goal constraints thus seek minimize the deviations from the each goal constraint's right-hand-side b_i goal targets. In essence, this use of deviation variables minimizes the absolute difference between the right-and left-hand sides of each constraint. The d_i^- are termed underachievement variables and the d_i^+ are overachievement variables. The nonnegativity requirements in a GP model are usually expressed as:

$$\left(x_j, d_i^-, d_i^+\right) \geq 0 \quad \text{for all } i, j.$$

When preemptive priorities are not established, the GP model takes on the form

$$\begin{aligned} \text{minimize} \quad & Z = \sum_i \left(w_i^- d_i^- + w_i^+ d_i^+\right) \\ \text{subject to:} \quad & \sum_j a_{ij}x_j + d_i^- - d_i^+ = b_i \quad \text{for all } i \\ & \left(x_j, d_i^-, d_i^+\right) \geq 0 \quad \text{for all } i, j. \end{aligned}$$

The w_i^- and w_i^+ are positive, negative or zero weights. A constraint may not be a goal constraint in that one can let $d_i^- = d_i^+ = 0$ if the condition must be met exactly, as, for example, a fixed budget condition. Such constraints are said to be hard. In contrast, goal constraints are said to be soft, as their goals can be underachieved, overachieved or met exactly, as, for example, a production requirement.

GP Solution Methods

Different solution methodologies exist to solve a variety of types of GP models. The type of GP model depends on special requirements placed on the decision variables in the model. Borrowing from LP, most of the solution methodologies for GP models are based on the revised simplex method. Simplex based-solution methods for GP problems originate from the sequential goal (preemptive priority) procedure of Lee (1972). There are additional methodologies for solving integer GP problems, *zero-one* GP problems and nonlinear GP problems. Like LP, these special types of GP solution methods are based on revised simplex methods, enumeration methods, and the calculus.

Duality and sensitivity analysis information can also be obtained from the simplex based GP solution methods (Ignizio 1982). Duality in GP models is focused on examining trade-offs in deviation between priorities. The software system by Lee and Shim (1993) computes the marginal trade-offs of revising right-hand-side b_i goal targets to reduce deviation from lower priority goals. There are a variety of LP-based sensitivity analysis procedures for GP. Unique to GP is P_k -sensitivity analysis (Schniederjans 1995). In P_k -sensitivity analysis, alterations in sets of k priority level goals are implemented to examine their ordering effect upon the model's solution. Other issues in modeling and overcoming problems with GP methodologies can be found in Romero (1991).

GP Research and Applications

While both GP modeling and GP solution methods share LP origins, there are two characteristics of GP that differentiate the application of GP from LP

problems: multiple goals and an ordinal ranking of the goals to deal with conflict. Since many business and governmental problems contain the same two characteristics, GP became a very popular methodology in analyzing such problems.

During the 1960s and early 1970s, most research on GP focused on revisions of prior LP-type models, but with a ranking of conflicting goals. The series of case applications presented in Lee (1972) typify the work during this period. The most common applications followed functional areas in business, such as budgeting in accounting, portfolio analysis in finance, production planning in management, and advertising resource allocation in marketing. Having examined these areas of application in depth, interest in GP started to wane. In the late 1970s and early 1980s, however, integer (particularly zero-one) GP methodologies appeared and caused a renewed interest in the application of GP. Zero-one GP solution methods permitted the model to be applied in binary outcome situations and broadened the potential application base of GP. Zero-one GP applications include project selection, personnel selection, and logistics. This period also saw the combining of other operations research and management science methodologies within a GP model: the transportation simplex method, assignment method, network models, nonlinear programming, dynamic programming, simulation, game theory, fuzzy programming and heuristic procedures (Steuer 1986).

In the late 1980s and through the 1990s, GP micro-computer software was developed, placing fairly powerful solution capabilities in the hands of practitioners, thus causing another burst of interest in GP applications: planning in small businesses, improving productivity in service operations, and planning product development. GP engineering applications include: planning flexible manufacturing systems, robot selection, strategic planning, metal cutting and inventory lot sizing. Improvements in GP weighting strategies have been developed using the analytic hierarchy process (AHP) (Liao and Kao 2010) and regression analysis (Garcia et al. 2010). GP has also been combined with the analytic network process (ANP) to solve capital asset pricing problems (Aznar et al. 2010).

A GP model's ability to use personal preference information has made it a very useful tool in dealing with socially sensitive issues. Throughout GP's history, applications and models have illustrated how GP is a powerful tool for analyzing public policy issues. Applications include: weapon system selection (Lee et al. 2010) and labor market satisfaction (Marcenaro-Gutierrez et al. 2010).

Gomory Cut

A linear constraint that is added to a linear-programming problem to reduce the solution space without cutting off any integer-valued points. Such cutting planes are the basis of many solution procedures that find integer solutions to a linear constrained optimization problem. The idea is to eventually reduce the solution space so that its optimal integer solution corresponds to an extreme point of the reduced solution space.

Gordan's Theorem

Let $\boldsymbol{A}$ be an $m \times n$ matrix, then exactly one of the following systems has a solution: (i) $\boldsymbol{Ax} < \boldsymbol{0}$ or (ii) $\boldsymbol{A}^T \boldsymbol{y} = \boldsymbol{0}, \boldsymbol{y} \geq \boldsymbol{0}, \boldsymbol{y} \neq \boldsymbol{0}$.

► Goal Programming

Gradient Vector

For the function $f(\boldsymbol{x})$ of the vector $\boldsymbol{x}$, the gradient is the vector of the first partial derivatives (if they exist) evaluated at a specific point $\boldsymbol{x}^{\boldsymbol{0}}$ and is written as

$$\nabla f\left(\boldsymbol{x}^{\boldsymbol{0}}\right) = \left[\frac{\partial f\left(\boldsymbol{x}^{\boldsymbol{0}}\right)}{\partial x_1}, \frac{\partial f\left(\boldsymbol{x}^{\boldsymbol{0}}\right)}{\partial x_2}, \ldots, \frac{\partial f\left(\boldsymbol{x}^{\boldsymbol{0}}\right)}{\partial x_n}\right].$$

It is normal or perpendicular to the tangent of the contour of $f(\boldsymbol{x})$ that passes through $\boldsymbol{x}^{\boldsymbol{0}}$. Its direction is the direction of maximum increase of $f(\boldsymbol{x})$ and its length is the magnitude of that maximum rate of increase.

Graph

A graph $G = (V, E)$ consists of a finite set V of vertices (nodes, points) and a set E of edges (arcs, lines) joining different pairs of distinct vertices.

Graph Theory

Douglas R. Shier
Clemson University, Clemson, SC, USA

Introduction

Graph theory is the general study of the interconnection of various elements. While the origins of graph theory can be traced back to the eighteenth century, this area of discrete mathematics experienced most of its tremendous growth during the latter half of the twentieth century. This rapid growth, both in the development of new theory and applications, reflects the fact that graphs can model a wide variety of natural and technological systems.

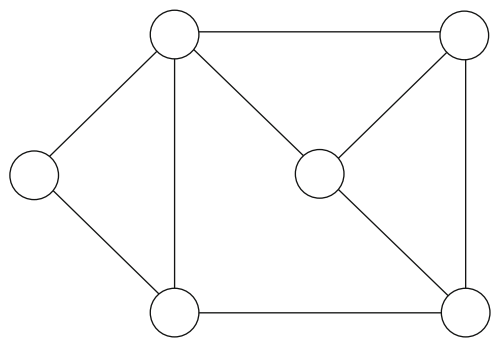
A number of physical systems can be viewed as graphs, composed of nodes (or vertices) connected together by edges (or arcs). For example, a local area computer network defines a graph whose nodes represent individual computers (or peripheral devices) and whose edges represent the physical cables connecting such computers. A telecommunication network consists of access points (and central switching stations) joined by sections of copper wire (and optical fibers); an airline system has airports as its nodes and direct flights as its edges; a street network involves road segments (edges) whose intersections define its nodes; and an electronic switching circuit contains logic gates whose input and output leads form a graph.

In addition, graphs can with equal ease represent logical relationships between elements. For example, the subroutines of a computer program can be represented as nodes of a graph, with edges indicating the flow of control or data between subroutines. A project involving a large number of tasks can be modeled by a graph, with the tasks being nodes and logical precedence relations defining the edges. In an ecological system the edges could indicate which species (nodes) feed upon other species. Examination scheduling at a university can be studied using a graph whose nodes are courses and whose edges indicate whether two courses contain students in common; examinations for such adjacent courses should not be scheduled at the same time. Table 1 shows a sample of other application areas in which graph models provide a useful representation.

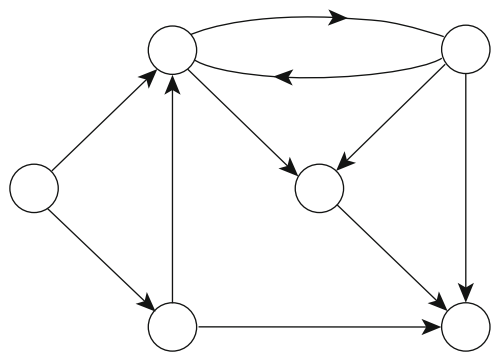
As suggested by these applications, the direct connections between nodes can be bidirectional (such as in making a telephone call, or in traversing a major highway) or there can be a specific orientation implied by the relationship (as the precedence relation in a project graph, or the predator–prey relation in an ecological graph). Consequently, graph theory treats both undirected graphs (in which the underlying relationship between nodes is symmetric) and directed graphs, or digraphs (in which the relationship need not be symmetric). These two graph models are pictured in Figs. 1 and 2, respectively. In this exposition, the focus is on undirected graphs, since the analogous concepts for digraphs are usually apparent. Throughout $G = (N, E)$ will indicate an undirected graph with node set N and edge set E.

Graph Theory, Table 1 Graph models

Application area	Nodes	Edges
Information theory	Strings of binary digits	Single-bit changes
Radio broadcasting	Broadcast stations	Interference
Genealogy	Family members	Parent/child relation
Sociology	Individuals	Interaction patterns
Architecture	Rooms	Accessibility
Electronics	Junctions	Wires
Personnel assignment	Applicants, jobs	Compatibility
Politics	Nations	Alliances
Genetics	Chromosome segments	Overlapping
Engineering	Joints	Beams
Commerce	Web sites	Hyperlinks



Graph Theory, Fig.1 An undirected graph



Graph Theory, Fig. 2 A directed graph

One of the earliest applications of graph theory was to the structure of molecular compounds, in which atoms (nodes) are joined by chemical bonds (edges). The task of identifying which chemical compounds are

structurally the same is reflected in the graph-theoretic concept of isomorphism, meaning that two given graphs are the same up to relabeling of their nodes. In addition, each atom has a valency that indicates the number of other atoms to which it is connected. In graph-theoretic terms this is called the degree of the node, the number of edges with which it is incident. This concept provides a quantifiable measure of local connectivity. For instance, the degree of a node in a communication network indicates the relative burden on that node in transporting information, so a robust communication system would be designed to avoid nodes with large degrees. Since such systems support point-to-point communication, a more global measure of connectivity is also needed. Thus, a fundamental concept is that of a path between nodes i and j: an alternating sequence of nodes and incident edges leading from node i to node j. A cycle is a closed path. The graph G is connected if every pair of distinct nodes is joined by a path in G. The distance between two nodes of G is defined as the smallest number of edges in a path joining the nodes. Then an overall measure of compactness of the graph is given by its diameter: the maximum distance between any two of its nodes.

Eulerian and Hamiltonian Cycles

In certain applications, specific types of paths or cycles are sought in the graph. For example, an Eulerian cycle is a cycle in the graph G that traverses each edge of G exactly once. This concept models the task of efficiently routing trucks for collection of trash throughout a city, since multiple passes along a road are not desirable. Another application occurs in planning police beats, in which every street of an area needs to be patrolled. A Hamiltonian cycle in G is a cycle in the graph that visits each node exactly once. This concept has been applied to the temporal sequencing of artifacts found at archaeological sites, the manufacture of electronic circuit boards, DNA mapping, order picking in a warehouse, and vehicle routing. The concepts of Eulerian paths and Hamiltonian paths are defined analogously.

In designing a logistics system it seems prudent to require several paths joining nodes i and j, thus providing redundant routes for sending messages in case of node or edge failures. For example, an adversary might select various edges (bridges, roads) for destruction in order to disrupt the flow of materiel from node i to node j. An i-j cutset is a minimal subset of edges whose removal disconnects i from j in G. To disrupt communication between i and j in an efficient manner, the adversary might then attack an i-j cutset having the minimum size (number of edges) λ_{ij} (G). The celebrated max flow-min cut theorem of networks (Gross and Yellen 1999) shows that the maximum number of edge-disjoint paths joining i and j equals the minimum number of edges in an i-j cutset. An analogous conclusion holds if the paths are node-disjoint and the cutsets are defined in terms of nodes. This min-max relationship is known as Menger's theorem (Chartrand and Zhang 2005).

Trees

A related concept addresses the connectivity of all nodes, rather than just a specified pair. A tree is a connected graph containing no cycles, and a spanning tree of the graph $G = (N, E)$ is a tree with node set N and whose edge set is a subset of E. Any spanning tree thus supports communication among all nodes of the graph. On the other hand, a cutset of G is a minimal set S of edges whose removal disconnects some pair of nodes in the graph. The edges of S must intersect the edge set of every spanning tree of G. An overall connectivity measure for the graph G is the minimum size $\lambda(G)$ of a cutset in G. Interestingly, the number of spanning trees of a graph can be computed efficiently, using the matrix-tree theorem (Chartrand and Zhang 2005); by contrast, counting the number of cutsets is *NP*-hard.

Trees find many other applications in the theory of graphs. Trees can be used to model the organizational hierarchy of a corporation, the table of contents of a book, the possible evolutionary history of species, or the syntactic structure of languages. Trees also serve as useful data structures for organizing elements of a database for subsequent retrieval and updating. For example, the branch-and-bound method for integer-programming problems is implemented using a tree structure. In addition, trees are used by compilers of computer languages to provide a concise representation of arithmetic expressions. Various ways of traversing trees (in particular depth-first search and breadth-first search) are important in

designing efficient algorithms for network optimization problems. Also of relevance to operations research is the fact that spanning trees correspond exactly to basic solutions for linear programming problems formulated on graphs.

Evolving Networks

What accounts for the structure of real-world networks and how do they continue to evolve? These questions have led to the investigation of small-world networks and scale-free networks. Rather than following the classic random networks studied by Erdös and Rényi (Watts 2003), many important networks such as the World Wide Web, social networks, cellular metabolic networks, and airline networks have characteristics quite different from those of random networks. In one model of random networks, the adjacencies of each node are randomly selected (controlled by a fixed connection probability p); in another model, a graph with n nodes and m edges is randomly selected from among all graphs having n nodes and m edges. Both models lead to quite similar characteristics. Specifically these classical random graphs have small clustering coefficients and small average (shortest) path lengths. The clustering coefficient simply measures for a typical node the average number of neighbors of the node that are in turn neighbors of one another. The average path length measures for a typical node the average number of steps (edges) needed to reach another node in the most efficient way (fewest number of edges).

By contrast, many real-world networks exhibit substantially larger clustering coefficients: e.g., in a social network, friends of a given node are likely to be friends of one another. In groundbreaking work, Watts and Strogatz (1998) studied the prevalence and construction of small-world networks in which nodes are typically not very far apart (small average path length) but have significantly higher clustering coefficients than in random networks. Another model for real-world graphs was first developed by Barabási and Albert (1999). These scale-free networks also have small average path lengths and significant clustering coefficients, yet typically contain a number of hub nodes with relatively large degree. More specifically, in scale-free networks the distribution of node degrees follows a power law: the proportion of nodes having degree k is proportional to $k^{-\beta}$, where $2 \leq \beta \leq 3$ typically holds. By contrast, the distribution of node degrees in small-world networks follows a binomial distribution. A variety of dynamic graph models have been proposed to account for the creation and expansion of scale-free networks. For example, such networks can grow by means of preferential attachment: new nodes are successively added and (probabilistically) linked to existing nodes according to the degrees of the existing nodes. They can also grow by a certain type of copying mechanism.

Embeddings and Colorings

Special types of graphs find application in the layout of circuit boards, in which it is desired to place the components and their connections so that no two wires meet except at a component. This corresponds to an embedding of the graph in the plane so that edges only intersect at nodes. Kuratowski's theorem provides an elegant characterization of which graphs are in fact planar. More generally, any graph G can be decomposed into a number of edge-disjoint planar subgraphs, and the minimum number of such subgraphs is termed the thickness $\theta(G)$ of the graph. For example, highways are designed to minimize the number of overpasses required. Planar graphs G are also of interest because a dual G^* of such graphs can be defined. In particular, the cycles of G are in one-to-one correspondence with the cutsets of G^*.

Coloring the nodes of a graph also arises in several applications. A proper coloring of G with k colors is an assignment of these colors to the nodes of G such that adjacent nodes are colored differently. For example, if the nodes of G represent courses and edges represent conflicts (courses that cannot have examinations scheduled at the same time), then a proper coloring of G with k colors defines a conflict-free schedule using k time periods. In another application, suppose the graph G indicates a compatibility relationship between tasks. A k-coloring of the complement of G (a graph whose edges are those node pairs not appearing as edges of G) then yields a partitioning of the nodes of G into k groups of mutually compatible tasks. The minimum number of colors $\chi(G)$ needed to color G properly is termed the chromatic number of G. The famous four-color conjecture, proposed in 1852 and finally proved in 1976, states that $\chi(G) \leq 4$ holds for any

planar graph G. Coloring problems also arise in the assignment of frequencies of the electromagnetic spectrum. Locations that are nearby must be assigned different frequencies to avoid interference, and the efficient allocation of frequencies then involves coloring the underlying neighborhood graph using the fewest number of colors.

Matchings

A matching is a set of mutually nonadjacent edges in G. A maximum size matching is a matching of G having the largest number of edges. These concepts arise in various applications, such as assigning personnel to jobs, target tracking, crew scheduling, and scheduling on parallel machines. In another example, pairs of pilots are to be assigned to aircraft that serve international routes. Two pilots are considered compatible if they are fluent in a common language and have comparable flight training. Finding a largest set of aircraft to fly with compatible pilots then requires finding a maximum size matching in the associated compatibility graph. In telecommunications, the problem of exchanging unique pieces of information so that all users will quickly know the totality of information can be viewed as a problem of constructing a sequence of matchings; each matching represents a set of simultaneous exchanges that can be carried out in a single time period. The arrangement of simultaneous kidney exchanges between multiple pairs of compatible (but unrelated) individuals has been carried out using maximum size matchings; see kidney paired donations on the World Wide Web.

Optimization

One important aspect of graphs is that they distill the essential adjacency relationships between objects. Another is that they suggest certain optimization problems. It is apparent that determining the connectivity $\lambda(G)$, thickness $\theta(G)$, and chromatic number $\chi(G)$ are graph optimization problems. Other graph optimization problems arise directly from applications in which it might be required to optimally schedule courses, allocate facilities, route goods, or design computer systems, relative to some objective function and subject to appropriate constraints. As a specific example, it might be required to design a minimum diameter communication graph with $\lambda_{ij}(G) \geq k$ for all distinct node pairs i and j, using a fixed number of edges.

More generally, quantitative information may be associated with the nodes and/or edges of a graph, reflecting the cost, time, distance, capacity, or desirability of these components. A variety of graph optimization problems are then apparent: (1) find a spanning tree of G having minimum cost (minimum spanning tree problem); (2) find a minimum length path joining two nodes of G (shortest path problem); (3) find the maximum amount of material that can feasibly flow from an origin node to a destination node (maximum flow problem); (4) find a minimum cost Hamiltonian cycle in G (traveling salesman problem); (5) optimally locate facilities on the edges of G to serve demands arising at the nodes (facility location problem); (6) find a maximum weight set of nonadjacent edges in G (maximum weight matching problem); (7) find a minimum cost traversal of all edges of G such that each edge is used at least once (Chinese postman problem).

There are additional application areas in which graphs are used to model a variety of physical and logical systems. While the discussion has concentrated on undirected graphs, directed graphs are pertinent in other areas, such as in representing the state diagram of a Markov chain. Connectivity in this digraph G can be used to classify the states of the chain, and the (directed) cycle lengths in G define the periodicity of the chain. Directed graphs are also the basis of project planning models. Clearly the hyperlink structure of the Internet can be modeled with directed edges, indicating which Web pages link to others; the ubiquitous PageRank algorithm (Langville and Meyer, 2006) used by search engines to rank the relevance of Web pages for a search query is carried out on this directed graph. In essence, the algorithm calculates the importance of a Web page recursively by taking into account the importance of each Web page linking to it.

The study of optimization problems on graphs and digraphs has in turn stimulated research into the design of effective algorithms for solving such problems, as well as determining when these problems belong to an inherently difficult class of problems (NP-hard problems). In the latter case, it is important to

identify special types of graphs (e.g., planar graphs) for which the computation can be carried out efficiently, even though there may not exist an efficient solution method applicable to all graphs. Several heuristics for the traveling salesman problem utilize the minimum spanning tree of the graph and an associated Eulerian cycle, both of which can be efficiently computed.

Further Reading

The book by Biggs et al. (1976) provides an excellent reference for the history of graph theory. Bondy and Murty (1979), Fulkerson (1975), Gross and Yellen (1999), Michaels and Rosen (1991), and Roberts (1976) discuss a variety of applications of graphs. Wilson and Watkins (1990) and Chartrand and Zhang (2005) give nice introductions to the theory of graphs, with more advanced treatment provided in Diestel (1997) and West (1996). The books by Barabási (2002), Buchanan (2002), and Watts (2003) are very readable introductions to small-world and scale-free networks. Algorithmic aspects of graph theory are discussed in Evans and Minieka (1992).

Greedy Algorithm

A heuristic algorithm that at every step selects the best choice available at that step without regard to future consequences. A greedy method never rescinds its choices or decisions made earlier. A greedy method is usually applied to an optimization problem for which the method attempts to determine an optimal solution (least cost, maximum value), with no

guarantee that the optimal solution will be found. Kruskal's and Prim's minimum spanning tree algorithms are greedy methods that do produce an optimal solution.

Group Decision Computer Technology

Dennis M. Buede
Innovative Decisions, Inc., Vienna, VA, USA
George Mason University, Fairfax, VA, USA

With the rise of computer technology and the success of quantitative decision support technology, there has been a great deal of interest in moving these technologies into the boardroom, so to speak. There is no commonly accepted approach for supporting group decision making, see Dennis and Gallupe 1993; DeSanctis and Gallupe 1987; and Nunamaker et al. 1993. The oldest approach is decision conferencing (Watson and Buede 1987), which started in 1979 and has spread but not exploded. Decision conferencing is a group process that is led by a decision analytic facilitator. The facilitator employs simple decision analysis models to focus the group's discussion on the objectives, options, and uncertainties. The facilitator also mixes analytic activities with creative problem structuring and option generation activities. The decision conference can be as short as two days or may involve several two to three day sessions. References for decision conferences include Phillips (1984) and Reagan-Cirincione (1992).

There are a range of approaches for group decision support that place a computer in the hands of each participant. This approach still employs a group process facilitator, although there is some disagreement about the importance of the facilitator amongst the researchers and practitioners in this area. The computer technology is designed to enhance the productivity of the individual and the communication of information among individuals. The effectiveness of computer technology as a communication medium when the group has a single decision focus is questioned by some. Computer technology, however, opens the group's options in terms of whether they meet at the same place or even at the same time. The major options of the group have been named: same time, same place; same time, different place; different time, same place; and different time, different place. Substantial work and adaptation has taken place in this area, see Dennis and Gallupe 1993; and Nunamaker et al. 1993.

Developments over time have seen these two extremes of decision conferencing and computer-supported and linked individuals merge. The individuals now have button boxes that feed a single computer via infrared beams. The individuals are able to input their votes or numeric judgments into the computer that displays the results and spurs discussion and debate. The results of the group inputs can then be recorded and incorporated into a broader analysis.

Group process support continues to be an expanding research and application area. For the group process to be considered successful, researchers must show that the group acting with decision support can be more effective than the second most effective of the group (Reagan-Cirincione 1992). The group must be provided with both cognitive support and social support in their activities; there is no lack of options for providing this support (see Connolly 1993; Nunamaker et al. 1993; and Huber et al. 1993).

Group Decision Making

Fatemeh Mariam Zahedi
University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Introduction

Group decision making focuses on problems in which there is more than one decision maker and more than one choice. The choices or alternatives have multiple attributes. In other words, the decision makers must consider more than one objective or criterion in their decision. Hence, group decisions involve multiple criteria and multiple decision makers. Since preferences and objectives of individual decision makers vary and may be in conflict, arriving at a decision is far more complex in a group setting than in individual cases.

Group decision covers a wide range of collective decision processes and encompasses numerous methods designed under various assumptions and for different circumstances. One can divide the group decision approaches into the following categories: utility theory, group consensus, group analytic hierarchy process, social choice theory, and game theory.

Group Utility Analysis

Group utility theory is based on the von Neumann-Morgenstern utility function. This method assumes that there is a multicriteria utility function U_i (x_1, x_2,. . ., x_m), where i represents member i, x_m represents the mth attribute, and m is the number of attributes. Based on the assumption that the utilities of members are functionally independent, the group utility function is computed as the aggregation of the member utility functions by one of the following two function types.

The additive form of the function is

$$U = \sum_{i=1}^{n} W_i U_i$$

where n is the number of attributes, and the multiplicative form is

$$wU + 1 = \sum_{i=1}^{n} (ww_i U_i + 1),$$

where w and w_i are scaling constants satisfying $0 < w_i < 1$, and $w > -1$, and $w \neq 0$. The estimation of member utility functions follows the assumptions and procedures used in estimating the individual multicriteria utility functions. The important question in the group utility estimation is the determination of the scaling constants. Keeney and Kirkwood (1975) suggested that these constants could be determined either by a benevolent dictator or internally by group members.

To resolve the problem of assigning weights to the utility functions of group members, two methods have been proposed. First, Bodily (1979) suggested the delegation process. This method is an iterative process for combining the utility functions of group members. The idea is that each member should assign weights to other members. This process assumes that each member is adequately familiar with the views and utilities of other members. Each member replaces his or her utility by linearly combining other members'

utilities. Members will not know the weights assigned to them by others. The method consists of the following steps:

Step 1. A delegation subcommittee for member i is formed consisting of the remaining $n-1$ members. Member i assigns a weight w_{ij} (a value between 0 and 1) to member j, and repeats the weight assignment for all $n-1$ members. The $n-1$ assigned weights should sum to 1. The weight for member i is 0; that is, $w_{ii}=0$.

Step 2. The combined utilities of the delegation subcommittee are computed as

$$u_i^1 = \sum_{j=1}^{n} w_{ij} u_j,$$

and replaces member i's utility. This process is repeated for all members.

Step 3. Step 2 is iterated for a second time as

$$u_i^2 = \sum_{j=1}^{n} w_{ij} u_j^1,$$

and for the rth time as

$$u_i^r = \sum_{j=1}^{n} w_{ij} u_j^{r-1}.$$

In matrix form, the iteration can be represented as

$$U^r = PU^{r-1},$$

where

$$U^r = \left[u_1^r, u_2^r, \ldots, u_n^r\right].$$

If the process is repeated adequately, one can show from a theorem in Markov processes that under certain conditions, $\boldsymbol{U}^r$ converges and represents the group utility function.

Brock Method

Brock (1980) developed a method for estimating the weights for aggregating the utilities. The Brock Method is based on the assumptions that the solution for the group decision should be Pareto optimal, obtained from the additive combination of member utilities, and that utility gains should be distributed based on the needs of the affected parties. The needs are defined as the intensity of desire, computed as

$$\frac{u_i - d_i}{u_j - d_j} = -\frac{du_i}{du_j} \quad \forall i, j.$$

Brock showed that the relative weights of members' utility functions are the reciprocals of the above coefficients.

Group Consensus

Group consensus methods combine the observed preferences of members to create consensus points. These points are used to estimate the consensus function for the group. Group consensus methods do not require explicit estimation of member utility functions and may not necessarily lead to the estimation of a function for the group. This approach is in contrast with the utility approach, in which the utility functions of members are estimated, then combined to arrive at a group utility function.

Krzysztofowicz Method — The Krzysztofowicz method (1979) is based on the following assumptions:

1. The group utility function can be decomposed into functions (W_i) of its attributes (x_i) and these functions could be combined via another function (H) such that:

$$W(x_1, x_2, \ldots, x_n) = H(W_1(x_1), W_2(x_2), \ldots, W_n(x_m))$$

2. where $W_i(x_i)$ is the group marginal utility of attribute x_i and m is the number of attributes relevant to the group decision.
3. The group's observed preference is the result of combining members' observed preferences by the decision rule d.
4. The group members are divided into subgroups of experts. Each subgroup has expertise in a subset of attributes, and each subgroup is responsible for estimating $W_i(x_i)$.

5. Each member and subgroup behave according to the axioms of utility theory.

In this method, the group is divided into sub-groups. Each subgroup estimates $W_i(x_i)$ based on its expertise. The group's marginal utility functions of attributes are then combined by H, which is either an additive or multiplicative function, similar to those in the group utility theory.

In the subgroup estimation of $W_i(x_i)$, the expressed preferences of members are combined by the decision rule d. This leads to a series of consensus points from which the function $W_i(x_i)$ is estimated.

Zahedi Group Consensus Method — This method (1986a) is based on the following assumptions:

1. Preferences of individual members are uncertain.
2. The relative weight (or importance) of a member is inversely proportional to his or her degree of uncertainty in his or her response.
3. Standard deviation is the measure of uncertainty.
4. A member's preference response has a normal probability distribution.
5. Correlations among members remain constant over various alternatives.
6. A consensus point is generated by combining the members' expressed preference responses such that the combined point has the minimum variance or uncertainty.
7. The consensus function is estimated based on the generated consensus points.

Based on the above assumptions, the following steps lead to the estimation of the group consensus function:

Step 1. For each multicriteria alternative a, member i assigns an interval score $[x_{ai}, y_{ai}]$.

Step 2. Estimate the mean and standard deviation of the interval by

$$\begin{cases} \hat{U}_{ai} = \frac{y_{ai}+x_{ai}}{2} \\ \hat{\sigma}_{ai} = \frac{y_{ai}-x_{ai}}{6} \end{cases}$$

Step 3. Compute group member correlations by

$$\hat{\rho}_{ik} = \frac{\mathrm{Cov}\left(\hat{U}_i, \hat{U}_k\right)}{\sqrt{\mathrm{Var}\left(\hat{U}_i\right) \cdot \mathrm{Var}\left(\hat{U}_k\right)}},$$

where i and k are members. Form a covariance matrix among group members for alternative a by using the standard deviations obtained in Step 2 and pairwise covariance obtained in Step 3. This matrix is symmetric of size n, where n is the number of group members. The main diagonal elements are the variances of n members. The off-diagonal element of row i and column j is $\hat{\sigma}_{ai}\,\hat{\rho}_{ik}$.

Step 4. Compute member i's weight for alternative $a(w_{ia})$ by

$$w_{ia} = \frac{\sum_{k=1}^{n} \alpha_{ika}}{\sum_{h=1}^{n}\sum_{k=1}^{n} \alpha_{hka}},$$

where α_{hka} is the element of the inverse of the covariance matrix computed at Step 3.

Step 5. Compute the consensus point for alternative a by using the results of Steps 2 and 4 in

$$\hat{U}_a = \sum_{i=1}^{n} w_{ia}\hat{U}_{ia}.$$

Step 6. The consensus point could be used directly for selecting the alternative with the highest consensus value. Furthermore, one can estimate the group consensus function by using the consensus points as the dependent variable in a regression analysis in which the independent variables are attribute values.

In the Zahedi method, consensus values and the consensus function are obtained directly from the preference responses of members. It does not assume the existence of utility axioms and does not require members' utility estimation.

Nominal Group Technique — The nominal group technique was first proposed by Delbecq and Van de Ven (1971). The idea of nominal group technique became one of the methods of consensus generation in total quality management (TQM). In this technique, the ideas are generated in silence and recorded, then they are discussed in group, their importance is voted upon, and the final vote is taken. It has the following steps:

Step 1. The team leader presents the group with the description of the problem and each member records his or her idea or solution individually in silence.

Step 2. The leader asks members to express their ideas one at a time and records them on a chart.

Step 3. Members discuss the recorded ideas so that all members understand each idea.

Step 4. Each idea is voted upon and ranked by members and the average ranking for each idea is computed.

Step 5. Another round of discussions clarifies the position of various members.

Step 6. The final vote is taken by a procedure similar to that of Step 4.

Delphi Method — The Delphi method, developed by Dalkey (1967), is used for generating consensus among members who are not in the same location. It involves written questionnaires and written answers. In this method, the group leader identifies the problem or the question, identifies group members, and contacts them. A sample of group members is selected by the group leader. The method goes through iterations of the following steps:

Step 1. Design the questionnaire to be answered by the selected group members.

Step 2. Have members complete the questionnaire.

Step 3. Analyze responses, make changes in the questionnaire, and include the aggregated responses from the previous round. Ask the members to react to the results of the previous round.

After a number of iterations, the final results are computed, and alternatives are ranked accordingly.

Iterative Open Planning Process — Ortolano (1974) suggested the open planning process. In this method, the activities are divided into four stages: problem identification, plan formulation, impact assessment, and evaluation. There are two sets of decision makers: planners and the affected public. Planners and the public interact at each stage.

- At the problem identification stage, planners determine and evaluate factors from many perspectives and the public articulates problems and concerns.
- At the plan formulation stage, planners delineate alternatives and the affected public suggests alternatives.
- At the impact assessment stage, planners forecast and describe the impacts, while the affected public assists them in describing the impacts.
- At the evaluation stage, planners organize and display information on alternatives and impacts, and the affected public evaluates impacts, makes tradeoffs, and expresses preferences.

These stages take place concurrently and the planners and the affected public repeat the process a number of times.

Group Analytic Hierarchy Process

The analytic hierarchy process (AHP) method was developed by Saaty (1977) and extended to group decision making by Aczel and Saaty (1983). In this method, the alternatives receive a score computed via AHP. This method does not require estimation of utility functions and does not assume axioms of utility analysis. The group AHP method consists of the following steps (Zahedi 1986b).

Step 1. A decision hierarchy is created based on the nature of the decision problem. This hierarchy has multiple levels. At the upper-most level, the decision goal is specified as selecting the best alternative. The next level consists of categories of the attributes that are of importance in the group decision. The next level details each category of attributes into finer and more tangible features. The lowest level of the hierarchy contains the decision alternatives.

For example, for selecting the best car, the highest level of the hierarchy has the selection of the best car as its only element. The second level of the hierarchy includes cost, safety, and design attributes. At the third level of the hierarchy, these attributes are divided into more specific attributes. For example, the cost attribute may be divided into purchase price, preventive maintenance costs, and repair costs at the third level. The safety attribute may be divided into accident outcomes and frequency of breakdowns. The design attribute may be divided into esthetics, driver comfort, and space. The fourth level of the hierarchy includes the decision alternatives — cars to be selected — say, Toyota, Ford, and GM.

Step 2. At each level of the hierarchy, elements are compared pairwise for their role or importance in each element on the level immediately above. The input matrix for the pairwise comparisons has the following form:

$$A = \begin{pmatrix} a_{11} & a_{12} & a_{13} & \cdots & a_{1n} \\ a_{21} & a_{22} & a_{23} & \cdots & a_{2n} \\ a_{31} & a_{32} & a_{33} & \cdots & a_{3n} \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ \cdot & \cdot & \cdot & \cdots & \cdot \\ a_{n1} & a_{n2} & a_{n3} & \cdots & a_{nn} \end{pmatrix}$$

where $a_{ij} = 1/a_{ji}$ for all $i, j = 1, 2, \ldots, n$, $a_{ii} = 1$, and n is the number of elements of one level being compared

pairwise for their role in accomplishing one of the elements on the upper level.

For example, Toyota, Ford, and GM cars could be compared pairwise in their purchase price to get a pairwise comparison matrix A. The size of this matrix will be 3. One such matrix is needed for each of the elements of the prior level — purchase price, preventive maintenance costs, repair costs, accident outcomes, frequency of breakdowns, esthetics, driver comfort, and space.

Step 3. At this step, a computational method is used to reduce the matrix of pairwise comparisons into a vector of local relative weights. The best known and most widely used computational method is the eigenvalue method, in which the local relative weights are computed as $AW = \lambda W$, were W is the vector of local relative weights, which is the largest eigenvector of $\boldsymbol{A}$, and λ is the largest eigenvalue of matrix $\boldsymbol{A}$.

Step 4. At this step, the local relative weights are combined to arrive at one vector of global relative weights for alternatives at the lowest level of the hierarchy in accomplishing the goal specified at the highest level of the hierarchy. The alternative with the highest global relative weight is the best choice, according to the AHP.

Applied to the group decision setting, the group must reach a consensus as to the structure of the hierarchy at Step 1. At Step 2, there will be a matrix of pairwise comparison elicited for each member of the group. The group pairwise matrix is computed from combining the member matrices. Each element of this matrix is the geometric average of the corresponding elements of the member matrices.

For example, assume that there are four decision makers involved in the decision to purchase a car. When three cars are compared pairwise for purchase price, one matrix of pairwise comparison is created when there is only one decision maker. When there are four decision makers, there will be four such matrices. To compute the group matrix for comparing cars, g_{ij}, the ijth elements of the four matrices are multiplied and then raised to one-fourth power, so that $g_{ij} = (a_{ij}^1\ a_{ij}^2\ a_{ij}^3\ a_{ij}^4)^{1/4}$, where the superscript on a_{ij} represents the decision maker and g_{ij} is the geometric mean of the four decision makers' pairwise values. Steps 3 and 4 of the group AHP are the same as those of the single-decision-maker AHP.

Extensions of The Group Analytic Hierarchy Process

The group AHP has been extended in a number of ways by synthesizing it with other methods and approaches, such as entropy optimization, Bayesian estimation procedure, and data envelopment analysis.

1. Gass and Rapcsák (1998) have extended the group AHP method to the case where the decision makers do not have equal voting power. In their formulation, there is one relative-weight vector $\boldsymbol{W}_i$ for each decision maker $i = 1, 2, \ldots, m$. They formulate an optimization problem that minimizes one of the Hölder-Young distances of the weighted sum of the relative weight vectors from the unknown vector $x = (x_1, x_2, \ldots, x_n)$. The solution to this entropy optimization problem is

$$x_j = \left[\sum_{i=1}^{m} \left(\frac{v_i}{v}\right) w_{ij}^{\alpha}\right]^{1/\alpha}, \quad j = 1, 2, \ldots, n,$$

where v_i is the voting power of decision maker i, and

$$v = \sum_{i=1}^{m} v_i.$$

In this set of solutions, α varies from 0 to 1. In a special case, the above solution set yields an explicit form that corresponds to the geometric mean in the following form:

$$x_j = \prod_{i=1}^{m} w_{ij}^{v_i/v}, \quad j = 1, 2, \ldots, n,$$

where x_j is the relative weight of alternative j for the group.

2. Gargallo et al. (2007) have developed another extension of the group AHP in which a Bayesian estimation procedure has been used to compute the priorities in the group AHP analysis. In this approach, the individual priorities are assumed to have a mixture of normal distributions. Using a hierarchical cluster algorithm, this method identifies opinion subgroups within the group.
3. Ramanathan (2006) *and* Wang and Chin (2009) have extended the group AHP and synthesized it

with the data envelopment analysis in order to address inconsistencies in input matrices in the group. Wang and Chin (2009) have suggested a data envelopment method to compute the best local priorities regardless of the extent of inconsistencies in the pairwise comparison matrices.

4. Dong et al. (2010) have combined the group AHP with the Chiclana et al. (2008)'s consensus framework to develop the AHP group consensus model. They define a consensus index to represent the extent of agreement among individual decision makers' input matrices, and propose two AHP consensus models that could result in an improved consensus index.
5. Monroe-Jimènez et al. (2008) have also proposed a method for the identification of consensus among a group of decision makers. They present the consistency consensus matrix for the purpose of consensus building within the decision group, particularly in large groups, such as democratic voting.
6. Although not an extension of AHP, fuzzy group decision making has emerged as yet another method in handling group decisions (see, for example, Gabriella and Yager 2006 for a review). Li (2010) suggests a fuzzy multi-attribute group decision making in which input information (equivalent to the matrices of pairwise comparison in AHP) are non-homogeneous, in that the preferences for attributes could be expressed in four different formats: qualitatively in linguistic terms, fuzzy numbers, interval values, and real numbers. These formats of preference expression and elicitation are similar to those available in the AHP approach. Li (2010) has proposed a method to transform the non-homogeneous inputs to a fuzzy group decision making formulation. In this approach, decision makers are viewed as attributes. The solution to this approach is called a compromise solution, which maximizes the group utility of the majority and minimizes individual regret for the minority (p. 99).

Social Choice Theory

The group decision problem was of interest as early as the eighteenth century, when Borda studied voting problems in the 1770s, and Marquis de Condorcet noticed the paradoxes and problems of majority rule in the 1780s. One example of such problems is that of three alternatives a, b, and c, where a is preferred to b, b is preferred to c, and c is preferred to a. Attention to methods for making a social choice continued in nineteenth century and greatly intensified in this century.

One way to arrive at a group decision is through voting, which also falls under the heading of social choice theory. Social choice theory investigates the process of arriving at a group decision in democratic societies through the expression of the majority's will. Voting involves selecting an alternative or candidate based multiple criteria. It involves two processes: voting and the aggregation method for determining the winner, that is, voting and counting the vote. There are a number of methods for voting, such as bivalue (yes, no), rating, and ranking the alternatives. Counting could be a simple counting of yes or no votes, averaging the rates, or a more complex aggregation method using ranks.

Social Welfare Function — In the social welfare function, the voting and counting processes are given a formal mathematical structure. Each member has a utility function based on which he or she determined the ordinal ranking of all alternatives. A member's ordering of alternatives is called the preference profile. The social welfare function is a rule for structuring group preference orderings of alternatives from the members' preference profiles. Obviously, there are numerous ways to arrive at group ordering alternatives. Arrow sought to limit the number of possible group orderings of alternatives, which led to his famous impossibility theorem.

Arrow's Impossibility Theorem — Arrow (1951) observed that by imposing rational conditions, one can reduce the number of solutions in the social welfare function. He postulated that:

1. All possible choices are already included in the problem set.
2. If one alternative is dropped such that the preference relations remain unchanged, the group preference will not change.
3. For any given two alternatives, the group can express its preference of one over the other.
4. There is no individual in the group whose preference represents the group preference.

5. Assume the group prefers alternative 1 to 2. If one member's preference for alternative 1 increases without affecting the pairwise preference ordering of other alternatives, the group will continue to prefer alternative 1 to 2.

Arrow's famous impossibility theorem states that there is no social welfare function that satisfies all of the above five properties.

Note that in voting and the social welfare function, the strength of members' preferences is not taken into account, whereas in utility theory, consensus generation methods, and AHP, the strength of members' preferences is incorporated into the method. In utility theory and consensus generation methods, members' preferences are assigned relative weights, relative to their importance in the group decision.

Boiney's Envy-Based Fair Group Decision — Boiney (1995) developed a model for fair choice among limited options under uncertainty when preferences are heterogeneous. The measure of fairness in this model is built on the degree of envy. Pairwise envy is defined as

$$e_{ij}(x) = \max\left(0, u_i\left(x_j\right) - u_i(x_i)\right),$$

Where e_{ij} is i's envy of j, x_i is i's bundle of goods, x_j 's bundel of goods, and u_j is i's utility. Individual i's envy is

$$e_i(x) = \frac{1}{n-1}\sum_j e_{ij}(x),$$

where the constant $(n - 1)$ is used to normalize the extent of envy between 0 (no envy) to 1 (maximum envy). Under certain conditions of linearity, independence, monotonicity, and anonymity, group envy could be computed as the (weighted) average of individual envies, where weights, if used, are the relative importance of individuals. Using this measure of envy, Boiney defined ex post and ex ante measures of unfairness, combining them into an overall measure of fairness F. This measure is, in turn, combined with the group utility function to determine social preference function, which could be used in making a fair and efficient choice among limited options.

Game Theory

Game theory has been developed in the context of decision makers (or players) who are in conflict. Game theory, however, has been extended to include a cooperative n-person game, in which the players cooperate with one another in order to maximize their own gain or payoff. The Nash-Harsanyi and Shapley methods are among the game-theoretic methods of group decision.

Nash-Harsanyi Bargaining Method — Nash (1950, 1953) developed the two-person cooperative game, which was generalized to the n-person cooperative game by Harsanyi (1963). In this model, one can find a unique solution to the n-person cooperative game problem by solving the following:

$$\begin{aligned} &\max_{x_i} \prod_{i=1}^{n} (x_i - d_i) \\ &\text{s.t.} \quad x_i \geq d_i \quad x \in P; D = (d_1, d_2, \ldots, d_n), \end{aligned}$$

where P is the set of payoff vectors, and D is the payoff when disagreement exists.

The above formulation is based on the following assumptions:

1. No payoff is better than the solution of the above formulation.
2. The players' payoffs are the same.
3. The linear transformation of all payoffs does not change the solution to the above problem.
4. Assume there are two games 1 and 2 with the same payoffs for disagreement, and the payoff vector of game 1 is a subset of the payoff vector of game 2. If the solution of game 2 is in the payoff vector of game 1, then it is also the solution to game 1. This assumption ensures that adding nonoptimal payoffs does not change the optimal solution.

Harsanyi (1977) has shown that the above formulation can also be derived from Zeuthen's principle that the player who has the highest risk-aversion toward conflict always makes the next concession.

The Shapley Value — If the utility of the players is transferable — that is, one player can transfer money, goods, or services to another player such that the sum of the two players' utilities remain the same — then the Nash-Harsanyi solution does not hold. This is due to the fact that there would not be a unique payoff vector

for disagreement. Shapley (1953) provides a solution for an n-person cooperative game with a transferable utility function.

A *coalition* is defined as a subgroup of members. The grand coalition consists of all the group members. If a member i joins a coalition, his or her marginal contribution to the coalition C is specified as $V(C) - V(C - i)$. The payoff to member i should be the average marginal contribution of the player to the grand coalition. Assume that the grand coalition is formed by members gradually joining the coalition and the order of members joining the coalition is equally likely, then the payoff of each player, (P_i, $i = 1, 2,\ldots, n$) or the Shapley value, is

$$P_i = \sum_{C \subseteq N} \frac{(c-1)!(n-c)!}{n!} V(C) - V(C - i),$$

where c is the number of players in C, n is the number of players, and N is the set of players.

The above solution is based on the following assumptions:

1. The value of the entire game is the sum of the payoffs to members.
2. All members receive an equal payoff.
3. If a game consists of two subgames, the payoff of the game is the sum of the payoffs of the two subgames.

Computer-Based Group Decision Process

A number of computer-based methods have been developed to facilitate the group decision process in various circumstances. These systems can divided into two groups: intelligent systems and group decision support systems.

Intelligent Systems for Group Decisions — In a sequential group process, there is more than one party involved in a negotiation process that takes place sequentially through time. One can use the artificial intelligence and expert system techniques to facilitate the process. A number of such systems have been developed.

Sycara developed PERSUADER, which simulates the labor-management negotiation process (Sycara 1991). This system uses frame-based knowledge representation and case-based reasoning of artificial intelligence with graph search and multi-attribute utilities to propose problem restructuring for simulated negotiations. The system restructures the problem by (1) introducing new goals, (2) substituting goals, and (3) abandoning goals.

The logical representation of the negotiation process using the framework of mathematical logic is another way to model the group negotiation process. Kersten et al. (1991) showed how one can model negotiation and restructure it for arriving at a negotiated solution.

Group Decision Support Systems — Group decision support systems refer to computer-based systems and methods developed to facilitate group decision making. One category of such systems is the electronic meeting system (EMS), which consists of a collection of hardware, software, audio and video equipments, and group procedures to create a supportive environment for the group decision process (Dennis et al. 1988).

These systems are designed for various purposes:

- Generating group options and brainstorming.
- Supporting and improving communication among the group members.
- Increasing participation.
- Providing computational and procedural support for the group process.

There are different conclusions regarding the existence and extent of positive contributions of such systems (Jessup and Valacich 1993; Fjermestad and Hiltz 1999). However, group decision support systems have gained increasing acceptance within industry as tools that increase the efficiency of group decision processes.

Intelligent Agents — The use of group decision methods has found an unexpected application in creating multiagent intelligent systems. Although there is no consensus regarding the definition of software agents, one can describe it as components that take actions on behalf of users (ACM 1999). Capturing users' preferences is one of the important aspect of software agents developed for electronic commerce (Maes et al. 1999). If multiagents act on behalf of one entity and need to come to an agreement regarding an action, then they need to apply group decision methods for arriving at a consensus.

Issues in Decision Making in Interactive Groups

The use of computer-based group decision making has generated interest in factors that may impact the outcome and quality of group decisions. These factors include group facilitation, anonymity of group members, group size, nature of decision, decision process, and groupthink (Bostrom et al. 1993; El-Shinnawy and Vinze 1998; Esser 1998; Fjermestad and Hiltz 1999).

An important property of the group decision is the number of new ideas and information initiations during the course of decision making. Silver (1995) posited that the number of ideas and negative evaluation of them are the most important determinant factors of group decisions. He formulated a two-stage optimization heuristics for the dual motives of group members: maintaining their relative status in the group and contributing to group objectives. At the first stage, the members maintain their status by contributing ideas that minimize the probability of receiving negative evaluations. At the second stage, members contribute ideas that incrementally increase the probability of receiving negative evaluations in proportion to their relative status, in order to contribute to the group decision quality.

Health Care Management

Yasar A. Ozcan
Virginia Commonwealth University, Richmond, VA, USA

Introduction

The techniques of operations research have found their way into health care management, not just in the logistical and managerial support of clinical services, but in the central decision processes of disease screening, diagnosis and therapy, and in medical education. Hundreds of citations to operations research and its associated analytical techniques are to be found in the medical literature and are accessible in the U.S. National Library of Medicine's on-line MEDLARS system. The early applications spawned new professional organizations and journals, now thriving in the medical arena. Many operations research applications are indexed to the near synonymous term, Medical Informatics, the application of computers and information technology to the broad field of health care. Operations research techniques that most frequently applied to solve managerial issues in health care organizations can be

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

found in health care management text books (Ozcan 2009; Shiver and Eitel 2009). To understand the position of operations research in the medical literature, a simple rule helps: medical informatics relates to medicine and health care as operations research relates to the work of business and industry. Both place a heavy emphasis on exploitation of the potentials of computer and information technologies. In addition to these, in conjunction with bioengineering and medical physics, more recent advances in computational biology and medical applications had used OR in treatment design and in genomics. These applications range from optimizing the dose and location of radiation treatments to optimization and simulation models to identify correct diagnosis and treatment for genetic variants of some diseases (Greenberg et al. 2009); similarly, using optimization and extensive classification systems to predict immunity to a vaccine without exposing individuals to infection (Lee 2010); abnormal brain activity (Chaovalitwongse et al. 2008). In short, to address contemporary issues in health care, diverse disciplines including electrical engineering, biomedical engineering, industrial engineering, and medicine attempt to bridge a vital gap between operations research and medical research with the help from data mining, signal processing techniques can be used to tackle the most challenging problems in modern medicine (Chaovalitwongse et al. 2010). Major traditional operations research methods that predominate in health care applications include stochastic models, computer simulation, mathematical programming, and decision analysis.

Simulation and Stochastic Models

Computer simulation plays an important role in teaching, research, and development of medical practice, expanding beyond its early role as a mimic of complex stochastic processes. A review of over hundred documents indexed both to simulation and medicine reveals a range of applications from the traditional Monte Carlo representation of physiological processes to three-dimensional imaging. An example of use of computer simulation to develop a protocol for burn care is given by Roa and Gomez-Cia (1994). Many applications are devoted to medical education by simulation of clinical problems, either through random sequences of events in diagnosis and therapy or the responsive behavior of images or a manikin, a move toward virtual reality. Examples of simulation as an instructional aid in a clinical setting are: in cardiac care (Lipner et al. 2010; Kobayashi et al. 2010), prostate care (Wang et al. 2010), training and teaching in obstetrics and gynecology (Dayal et al. 2009), training in anesthesiology (Waisel et al. 2009).

Serving as a decision support tool, computer simulation offers management detailed information about the processes of health care, enabling management to make better decisions through performance data on a variety of issues of in terest before any change was introduced within the process. Thus, use of computer simulation makes information better and faster without requiring intensive financial and resources, especially when there are a number of alternatives under consideration. Computer simulation has found its application particularly in both estimating and forecasting of several issues involved in hospital industry, with the primary objective of guiding hospital management and policy makers about evaluating alternatives involved in allocation of scarce resources or anticipating results from certain changes that can be made to solve the problems identified. Some examples of simulation and stochastic programming as a management aid in a hospital setting:

- Application of stochastic programming and simulation of nurse assignments (Punnakitikashem et al. 2008; Sundaramoorthi et al. 2010);
- Analysing management policies for operating room planning using simulation (Persson and Persson 2010);
- Reducing patient wait times and improving resource utilization using simulation at ambulatory cancer care units (Santibáñez et al. 2009);
- Redisign of hospital based pharmacy delivery processes using simulation and oprimization (Augusto and Xie 2009);
- Improving patient flow at outpatient settings (Chand et al. 2009);
- Simulation of strategies for cervical cancer screening (McLay et al. 2010).

The field of epidemiology, lying within the domain of medicine, has been attractive to stochastic model building and simulation. Understanding the origin, spread, and decline of epidemics is essential to recognition of causal agents and vectors of transmittal and the development and evaluation of prevention

measures. The complexity of epidemics and interventions to control them often defies a purely mathematical analysis. In early studies of mathematical epidemiology, Bailey (1967) used computer simulation to predict both temporal and spatial progress of epidemics, expressed in stochastic models. Examples of stochastic models and simulation are found in epidemic models of HIV/AIDS (Rossi 1999; Rauner 2002). The problem of allocation of resources for this disease is addressed by Brandeau et al. (2005).

Mathematical Programming

Increasing health care costs, in particular hospital costs, have provided incentive for health care researchers to analyze performance of hospitals through mathematical programming techniques. Growing interest in performance has led to increasing applications of various efficiency measurement techniques, as a means of evaluating performance. Proposed methods to measure efficiency can be classified into two broad categories: parametric and non-parametric methods. The former assumes a particular functional form, for example, Cobb-Douglas method, while the latter does not assume a functional form, for example, Data Envelopment Analysis (DEA) method.

DEA is a mathematical programming tool that is designed to evaluate how efficiently an organizational entity, called the decision-making unit or DMU, produces a mixture of outputs with an available mixture of inputs. The power of DEA methodology as a multifactor productivity tool in contrast to unidimensional ratio analysis and central-tendency-based regression analysis has been demonstrated in the health care literature (Sherman 1984; Sexton 1986; Huang 1990; Sherman and Zhu 2006, chapter 5; Ozcan 2008). In particular, DEA is recognized as a superior method to identify the sources and amounts of inefficiency in the use of inputs. Pioneering uses of DEA by Charnes et al. (1978, 1981) were followed in the operations research field by many applications across service and program-oriented industries. In health care, Sherman (1984) applied DEA to hospital multifactor productivity studies. Some studies in the health care organization or program efficiency arena followed the Sherman study for benchmarking hospitals (Clement et al. 2008; Nayar and Ozcan 2008; Sikka et al. 2009; Kazley and Ozcan 2009; Ozcan and Luke 2010; Sahin et al. 2010; Ozcan et al. 2010; Lobo et al. 2010), nursing units (Mark et al. 2009), ambulatory surgery centers (Iyengar and Ozcan 2009), and nursing homes (Ferrier and Valdmanis 1996; Björkgren et al. 2001; Knox et al. 2003).

Decision Analysis in Medical Decision Making

The notion of tradeoff among benefits and losses carries through to decisions made under certainty in screening and clinical diagnosis, where the costs of missing a case — a false negative — are balanced against the costs of interpreting as present a condition not there — a false positive. The expression in the normal form of search for a Bayesian solution, that is, as a minimization of expected loss, bears strong resemblance to linear programming, but the evolution of medical decision theories has yielded a number of new approaches. Nearly parallel in time to the early applications of operations research to the logistical and organizational problems of health services, examples of the techniques appeared directly in the procedures of diagnosis and therapy. The availability of large databases linking patient signs, symptoms, and other descriptors to disease states has led applications of statistical analysis and value theory to diagnostic processes and choice of therapy. A review by Barnoon and Wolfe (1972) cited early work on the logistical foundations of diagnosis (Ledley and Lusted 1959) and on disease screening (Flagle 1967), demonstrating that the optimal screening level of a test is a specific function of prevalence of undetected disease and their relevant costs, or regrets, of false negative and false positive determinations. The applications of linear programming, pattern recognition and decision support systems for breast cancer diagnosis are described in Mangasarian et al. (1990), Wolberg and Mangasarian (1993), and Mangasarian et al. (1995).

Improvement in screening through increases in sensitivity and specificity of test still remains an objective, and is aided by multivariate analyses made possible by large databases and clinical trials. Emergence of the term, "Computer-Aided Diagnosis," has accompanied many efforts to sharpen the statistical relationship between symptoms and disease (Chan et al. 1999; Nawano et al. 1999; Lowe and Harrison 1999). Turning attention to treatment,

knowledge gained from statistical analysis and systematic compilation of outcomes has led beyond estimation of diagnostic probabilities to a large enterprise in expert systems, in which the process of successful therapy are expressed in algorithmic form built around a patient database interfaced to a knowledge base (Wang et al. 1998). Beyond expert systems to diffuse and implement protocols, efforts have been made to understand and emulate the decision process itself — an approach to artificial intelligence (AI). Early development in AI related to specific diseases is reviewed by Szolovits and Pauker (1978). There are also applications of AI processes in medical care using neural networks and applying them to computer-aided decision processes (Chaudhry 2008; Eken et al. 2009).

Concluding Remarks

Two major patterns are discernible in the evolution of medical practice aided by growing databases, improving analytic techniques, and new communication technologies. First is the formalization of decision processes in the multi-disciplinary protocols or practice guidelines based on outcomes of research and technology assessment. The major challenge in developing guidelines is that of creating flexible guidelines that are applicable to broad patient populations and practice settings that differ substantially (Dawson, 1997). Therefore, development of practice guidelines is an important area of interest for physicians and operations researchers.

The format of guidelines, which often contain a prescriptive algorithm familiar to operations researchers, also quite frequently contain a version for patients. This marks the enlightened involvement of patients in decisions about choice of therapeutic strategies, such as optimal and personalized treatment design thanks to new biological findings and imaging technologies (Lee 2010). Other developments include the incorporation of medical decision processes in chronic disease management, as well as optimizing the capability and efficiency of the delivery systems through supply–demand alignment while reducing variability in delivery (Carter 2002; Greenberg et al. 2009; Lee 2010). A collaboration of a physician and OR analyst has remained, while the concepts have become internalized in the medical decision process.

Health Care Strategic Decision Making

Roice D. Luke and Yasar A. Ozcan
Virginia Commonwealth University, Richmond, VA, USA

Introduction

The joining of operations research/management science (OR/MS) and strategy may, at first, seem a bit incongruous, as they often address issues at very different levels within organizations. OR/MS typically deals with the internal workings and performance of organizations, strategy with external market conduct and consequent gains (or losses) in competitive advantage. The presumed bright line dividing operations from strategic decision making, however, does not always hold. Indeed, the field of strategy has long recognized the role internal systems management can play in driving advantage.

Internal considerations have always been part of strategy analysis. It is notable that the rather well-known analytical framework of strengths, weaknesses, opportunities, and threats (SWOT) addresses internal organizational strengths and weaknesses, as well as external opportunities and threats (Andrews 1971). And, the so-called resource-based view (Barney and Clark 2007), takes a decidedly internal perspective in assessing strategy by suggesting that competitive advantage is dependent on an organization acquiring (and sustaining the distinctiveness of) superior resources and capabilities.

The predominant view in the field of strategy, the market structural perspective, focuses mostly on external concerns within markets, most particularly on two sources of advantage: distinctive positioning relative to consumer preferences and the buildup of market power as might be accomplished through acquisitions and mergers and/or integration of existing business units. But, internal considerations emerge even within this perspective. For instance, Michael Porter – the primary proponent of the market structural perspective – has highlighted the need for organizations to align internal activities, which collectively comprise their so-called value chains (Porter 1985).

Thus, while OR/MS tends to focus on the internal and strategy analysis on the external, these two

perspectives can be and often are overlapping and complimentary. It follows that the key distinction is not internal versus external, but the degree to which solving an organizational problem is important strategically, that is, the degree to which it may contribute to an organization's market advantage. For example, a decision about staffing may be operational or strategic, depending on such factors as the resource scarcity, impact on the bottom line (and, on gains/losses in competitive advantage), disruptiveness of the decision outcome to an organization, and so on. Hospitals commonly fight over physicians who specialize in clinical areas that are of critical importance to them, including, in particular, physicians in the areas of cardiac surgery, orthopedics, obstetrics, oncology, and a number of other areas. Thus, the characterization of those decisions, as well as the management level at which they are made, is likely determined by such factors as complexity, uncertainty, and impact.

This article argues that internal decisions have recently become much more important strategically than was the case in the not too distant past. This is especially true for acute care, a sector to which OR/MS techniques have been extensively applied in addressing a great diversity of management problems. The increased relevance of such applications, however, is attributable to the significant restructuring that has occurred over the last several decades, the result of which was to produce a great many complex, highly intra-dependent provider clusters that dominate markets nationally. Within just a few years, health care delivery systems in the United States (and in the many other countries around the world) grew significantly in scale, product scope, and inter-organizational complexity; and, importantly, this occurred mostly at local and regional levels (Luke 2010). The growth in common ownership, combined with high spatial proximities. introduced very important inter-organizational interdependencies that have increased exponentially the need for multi-unit coordination and rationalization and, consequently, the need for the combined application of system optimization and OR/MS techniques.

Regionalized health care systems must rationalize costly resources and capabilities across system members, a task that heretofore could only be accomplished by informal coordination or as the product of government regulatory effort, neither of which, over the years, did much improve inter-organizational coordination (Bice 1984). The complex organizations that have formed, in other words, have become true laboratories within which OR/MS and strategy analysis can be joined to transform system spatial coordination into competitive advantage.

This article shows that the wave of mergers and acquisitions, especially those that occurred in the 1990s, produced a large number of provider clusters in this country, which, as a result, has created important opportunities for OR/MS to address truly strategic issues affecting health care organizations. These clusters combine hospitals and other providers within local markets, which clusters now must make a large number of cluster-level operational decisions, many of which could have great impact on competitive strategy.

What follows is divided into three sections. The first summarizes why clusters have formed, thereby providing the basic rationale for why application of OR/MS tools and techniques to these systems is needed. The second describes patterns of cluster formation across the country for the purpose of identifying the configurational diversity that complicates the application OR/MS tools to solving cluster problems. And, the third concludes by summarizing strategically relevant organizational issues that arise when one addresses system problems within local and regional health systems.

Clusters: An Emerging Concept in Health Care

The idea that geographic clustering could lead to improved performance is neither new in health care nor is it limited to the health care industry. Economists have long argued that geographic proximities and associated inter-organizational coordination can have a major impact on organizational and competitive performance. For example, Marshall (1920), focused on the economics of geographical proximities that could lead competitors to locate near one another. His work on industrial districts in England created the theoretical foundations upon which a number of fields, including economic geography, location theory, and the study of clustering have been built.

In the early 1990s, Michael Porter (1996), the leading expert in the field of strategy, argued that

spatial clustering should become a central focus of scholarly investigation, not only for the study of individual companies, but also of whole industries and even nations. All of these, he reasoned, could experience significant gains in competitive advantage were they more actively to promote the formation of local clusters. As he pointed out, geographic proximities "amplify many of the productivity and innovation benefits" attributable to multi-organizational production, largely by reducing transaction costs, improving communication flows, and increasing opportunities to share and innovate as collectives (Porter 1996, p. 222).

Porter identified a number of specific economies that interdependent organizations derive from shared geographic proximities. These included: productivity improvements (e.g., due to shared access to specialized inputs and employees), sharing in technical and market information, improved coordination with complementary businesses and support institutions, innovations through cross-company and cross-industry collaboration, new business formation, collaboration in quality improvement, shared technology. Porter even suggested that the study of geographic clusters could produce greater understanding of the dynamics of production and competition than would be possible were one to focus exclusively on individual firm or industry-level behaviors. This is because clusters often represent natural and relatively complete production arrangements, within which the full range of vertical and horizontal interactions among organizations occur.

Porter also identified two structural dimensions that could be key to improving cluster performance: configuration (how and where cluster production activities are distributed in geographic space) and coordination (activities that integrate production and management systems across cluster members). Note that these two dimensions are equivalent to Lawrence and Lorsch's (1967) concepts of differentiation (equivalent to configuration) and integration (equivalent to coordination). The difference is that Porter applied these to organizations located within the same general geographic space, whereas Lawrence and Lorsch did not consider geography in their analyses. Porter's argument is that geographic proximities greatly enhance the potential for exchanging and centralizing functions, facilitating communications across clustered members, and resolving inter-organizational conflicts and the need for compromise. Both Porter (and Lawrence and Lorsch) recognized that configuration (or inter-organizational differentiation) comes first, after which coordination is needed to ensure that the interdependent, spatially proximate and increasingly specialized organizational units collectively achieve a unity of effort.

From the perspective of this article, it should be clear that OR/MS applications can contribute to both configuration and coordination, by enabling better analysis and planning for optimal configurations and designing systems that help multi-organizational configurations become integrated/holistic systems. The health care clusters are described below and some of the configurational diversity that distinguishes them are illustrated. Then some specific issues that uniquely arise when OR/MS techniques are applied to the clusters are identified. While coordinative arrangements per se are not addressed here, it is suggested that these techniques apply to both the configurational and coordinative problems health care clusters face.

The idea that clusters might improve performance is also not new in health care. Fox (1986) argued that the regional model of delivery organization has been at the core of public policy in the U.S. and England for nearly a century. In the early decades of the last century, the industry focused on fragmentation, a problem that plagued this industry from the beginning of modern medicine (Starr 1982; Stevens 1989). In the first third of the last century, the Committee on the Costs for Medical Care produced a number of reports recommending major reforms in health care, many of which focused on ways by which coordination between physicians and hospitals could be improved (Falk 1958). In the 1940s and through the 1970s the focus shifted to a concern with costs and duplicated capacity, especially within the increasingly complex and costly acute care sector (Stevens 1989). In this period, a series of federal and state-sponsored planning efforts – from the Hill Burton Act in 1946 to the National Health Planning and Resources Development Act of 1974 – addressed primarily the rationalization of capacity locally and regionally. These efforts, however, had little impact on system structures, let alone on patterns of coordination, for many reasons, but mostly because the industry successfully defended historic expectations for professional and organizational autonomy (Bice 1984).

With passage of Medicare and Medicaid in 1965, the policy focus began to shift away from system strategies and coordination toward the use of regulation and incentives to control rapidly rising costs. Inter-organizational coordination reemerged in the Health Maintenance Organization Act of 1973, but as it turned out, this produced little change at the level of health services delivery. Twenty years later, in the context of rising pressures for health care reform, the failed Clinton Health Security Act of 1993 sparked enormous system change, especially within the hospital sector (Sisk and Glied 1994). In those years, industry advocates promoted their own version of a system model, which they labeled integrated delivery networks (IDNs). Thus, in the early 1990s, almost as if in anticipation of a successful effort to reform the industry, the hospital sector proposed that informal local and regional provider collectives form (the IDNs; AHA, Section for Health Care Systems 1990). They argued that structures of inter-organizational coordination would help to establish the clinical and management systems needed to ensure that patients and information would flow smoothly through the complex latticework of local provider systems. The industry proposals also acknowledged the need to restructure capacity (configuration changes), but choose to play these down, emphasizing patient flows over system reconfiguration.

As it turned out, the hospital sector gave mostly lip service to clinical integration while it engaged in one of the most significant periods system restructuring ever to have occurred in the industry's history. As discussed below, not only did hospitals rush into multi-hospital systems, but they formed clusters in an effort to consolidate local markets. And, those clusters have since discovered the power of inter-organizational strategies for incorporating physician practices, creating ambulatory surgery centers, expanding into other clinical areas (e.g., long-term care), restructuring clinical capacities and functionality across cluster members, and coordinating infrastructure.

It is notable that even the Veterans Health Administration (VHA) became involved in the movement toward regional models. In 1995, the VHA restructured its network of historically highly independent hospitals and clinics forming regionally coordinated Veterans Integrated Service Networks (VISNs; Perlin 2006). And, the VHA combined this innovative strategy with an integrated information system and a shift in emphasis toward ambulatory care—all of which would be coordinated by the VISNs. These changes, in combination, appear to have had a major impact on VHA health system performance (Ozcan and Luke 2011).

It is also significant that many of the advanced nations of the world have been adopting the regional model as an explicit policy strategy (Luke 2010). Canada, Australia, New Zealand, Scotland, Wales, most of the Scandinavian nations, a number of central European nations (e.g., Spain, Italy, and Portugal) are all heavily invested in regional strategies (Lewis and Kouri 2004; Gauld 2003; Healy et al. 2006). While it has not organized regional provider systems as such, England created 10 regional entities, called Strategic Health Alliances (SHAs), that are responsible regionally for overseeing and evaluating care, ensuring government policy is implemented, and recommending changes at the provider and institutional levels. England also plans and implements its IT strategies and operates its supply channel through regionalized configurations.

It is important to point out that the business clusters examined by Porter represent geographic combinations of otherwise independent companies, many of which are even direct competitors. By contrast, the health care clusters are more formally structured arrangements that, as a result, should have the advantage in overcoming the many sources of resistance that complicate inter-organizational reconfiguration and coordination among otherwise independent entities. On the other hand, formal structures do not guarantee that the clusters will be able to control their hospitals, let alone the physicians who join them. All providers groups historically have resolutely defended their autonomies and many even today are unwilling to abandon those autonomies despite having become members of systems. As a result, the clusters often face significant challenges in reforming and restructuring. It thus should be no surprise that the health care literature has thus far reported only limited performance improvements attributable to cluster formation (Bazzoli et al. 2004). Of relevant interest, however, is the use of Data Envelopment Analysis (DEA) in the study of the efficiency of hospital-based clusters (Sikka et al. 2009).

Nevertheless, as the systems mature and the environment changes, the clusters are likely to find

ways to overcome historic and future constraints to system rationalization. External pressures will likely spur changes and refinements within the clusters over time. Such pressures include growing technological complexities, the continuing probability of an extended downturn in the economy, the broad effects of health care reform, continued restrictions on payment, continued demographic change, increasing consolidation in the markets and consequent increases in competitiveness (non-price competition), continued substitution of ambulatory for acute care and the consequent need to integrate acute and other delivery modalities, and other important system and environmental changes. Within this powerful mix of forces and pressures for change, OR/MS analysts are likely to find many opportunities to apply their tools and techniques to help systems improve performance and gain competitive advantage within their markets.

Patterns of System Formation in the US

This section describes the configurational diversity that exists among the clusters. To illustrate this diversity, the focus will specifically be on the configuration of acute facilities, the lead, largest, and most important entities in most clusters. In so doing, it is recognized that many of the clusters are heavily invested in other related businesses, many of which are highly interdependent with the hospitals in terms of operations, production, and strategy.

The focus is specifically on three configurational dimensions: 1) number of hospitals per cluster, 2) the geographic dispersion of the hospitals, and 3) the hierarchical diversity among cluster hospital members. Using a national database on hospital systems, these three configurational characteristics have been reported, updated for the year 2009. (The hospital data are based on 25 years of monitoring system memberships and markets, the most recent full update was completed in 2009. This was supplemented by 2007 American Hospital Association Annual Survey data for individual hospitals).

Before examining the clusters, however, it is essential that they be distinguished from their parent organizations, the multi-hospital systems (MHSs). The MHSs are companies that own, lease or manage two or more hospitals, whereas the clusters are subunits of the MHSs; specifically, they are combinations of two or more same MHS hospitals that are located in the same geographic areas.

It is noted that some MHSs are themselves clusters (e.g., the 5 hospital INOVA health system located within the Northern Virginia part of the Washington D.C. metropolitan area). Other MHSs are dispersed much more widely in space, although many (but not all) of these operate one or more clusters. The Hospital Corporation of America, for instance, operates multiple clusters that are located in markets across the country. Alternatively, the for-profit SunLink Healthcare Corporation operates seven hospitals and nursing homes that are located in rural areas in the Midwest and South, no one of which is close enough to any of the others to constitute a cluster.

As of 2009, a total of 56 percent or 2,688 of 4,767 acute care hospitals nationally were members of 418 MHSs. The companies that operate these hospitals differ importantly by ownership. A total of 55 percent of MHS hospitals are in not-for-profit systems, 23 percent in for profit, and 22 percent Catholic systems. This compares to the distribution of MHSs by ownership, which breaks down to 79 percent not-for-profit, 9 percent for profit, and 11 percent Catholic. When examined together, these two distributions show that most for profit and Catholic MHSs are much larger on average, whereas the more numerous not-for-profit MHSs are far smaller as systems.

While the number of hospitals in MHSs grew significantly over the past 20 years, and especially so within the mid-1990s when the industry experienced a spike in mergers and acquisitions, the growth overwhelmingly favored not-for-profit hospitals and systems. Virtually all of the net growth in this period can be attributed to the not-for-profit sector (Luke 2010). This is very significant, for a number of reasons. First, and most importantly, a number of large, often referral not-for-profit hospitals took the initiative in this period to form systems and these hospitals mostly chose as partners other hospitals that were located within and/or around their same metropolitan areas. This development, therefore, not only generated a significant increase in the number of clustered system hospitals, but also produced a number of large and powerful hierarchical model types, which join together referral with community hospitals (as well as with other provider entities) into highly interdependent, hub-spoke cluster configurations.

Second, most of the restructuring affecting for profit and Catholic systems involved mergers among systems as opposed to new hospitals joining systems. But, these mergers also produced a number of important clusters, as the combined systems often brought same market hospitals together into clustered configurations. The key point is that clusters grew rapidly in this period, which dramatically altered the landscape of health care. And, this development has created a large number of very important entities that now need to be refined, rationalized, and optimized—a task, if properly performed, could produce very consequential strategic outcomes for these new and important organizational entities.

The Clusters

The central problem in defining clusters is specifying the outer geographic limit within which hospitals would appropriately be considered members of clusters. The most common approach is to define them as combinations of two or more same system hospitals located within the same CBSAs (core based statistical areas); METSAs–metropolitan statistical areas or MICSA–micropolitan statistical areas; e.g., see Cuellar and Gertler 2003 and 2005; Luke et al. 2003. While this is a highly reliable approach, it is also true that many same system hospitals are located outside the urban boundaries, in nearby rural or other urban areas. These often interact operationally and strategically with their urban partners, and thus they should be joined with their nearby urban partners in designating cluster memberships. On the other hand, relaxing the boundaries to include such other hospitals introduces error at the outer limit – how far out should one extend the boundaries to find the same cluster members?

A number of techniques for identifying the regional clusters were explored, including by setting distance breaks (e.g., 30 miles, 60 miles, 90 miles, etc.; Wong et al. 2005). However, such proved highly arbitrary, given that regionalized configurations vary dramatically from one to the other. Among the hospitals operated by the 15-hospital East Texas Medical Center Regional Healthcare System (ETMC), which operates out of 200,000 population Tyler, Texas, are two regional hospitals each of which is located about 110 miles from the system center (the location of the major ETMC referral center) in Tyler. One is north in Clarkesville and the other is south in Trinity. Both are operated as regional spokes in the hub-spoke ETMC system. By comparison, HCA operates two hospitals that are about the same distance apart – HCA's 194-bed St Lucie Medical Center, located in the Port St. Lucie-Fort Pierce, FL Metro area, and 235-bed Osceola Regional Medical Center, located in Kissimmee in south Orlando. HCA incorporates the former within its Miami cluster (within its East Florida Division) and the latter within a much smaller Orlando cluster (and more generally within its West Florida Division). Clearly, distance is not the only consideration required for designating cluster boundaries. Many other factors come into play, such as market density (both urban and rural), system ownership type, system organizational strategies, system size and complexity, and so on.

Fortunately, most clusters are relatively easy to identify, especially in the many cases in which their facilities are grouped exclusively within or just surrounding single metropolitan areas (such as was the case for the ETMC system). A small number of the regional clusters, however, were more difficult to identify, again, mostly those that combine hospitals run by the more dispersed, multi-hospital systems (which are mostly for profit and Catholic systems). Many of the clusters in these MHSs were easily discerned (e.g., the HCA clusters in Denver, Kansas City, Richmond, and in most other large metropolitan areas), but others were not. For the latter, a process of hospital inclusion, beginning with the largest markets per MHS, looking for same market and nearby same state combinations, and then working through the remaining hospitals to identify additional spatially-proximate combinations was used. Those few systems that specialize in small urban and non-urban markets (e.g., Community Health Systems and Lifepoint) presented the greatest challenge in identifying clusters. Accordingly, some judgment was required for a small number of clusters and cluster members belonging to systems such as these.

A total of 505 urban clusters and 638 regional clusters among 418 MHS chains operating in the U.S. have been identified. These represent 59 and 91 percent, respectively, of all MHS hospitals. Once the boundaries are relaxed and nearby hospitals (outside primary urban and/or rural centers) are

included, the number of hospitals and clusters obviously rises considerably – by 880 hospitals (a 56 percent increase) and by 134 clusters (a 26 percent increase). Clearly, a choice to use urban boundaries only would result in a very significant underrepresentation of clusters. Such a choice also would affect the configurational characteristics of the clusters, such as their relative dispersion and the combinations of large and small hospitals and other providers within the clusters. In what follows, therefore, the emphasis is on the regional (as opposed to the urban) approach to defining and measuring clusters.

Cluster Configurations. The important point in this article is that the clusters come in many different forms, the characteristics of which should be important when applying OR/MS techniques to solving system problems. Three configurational dimensions were identified earlier in the paper (focusing on the acute care facilities within the clusters) – cluster size (numbers of hospitals per cluster), geographic dispersion, and hierarchical diversity. It is probable that the size of the cluster itself will affect the other configurational dimensions. Larger clusters will likely have larger central hospitals, more dispersion, and more diversity in business units. It is also likely that the size of the market will affect the patterns as well. For instance, the dispersion of facilities beyond the urban boundaries is very much greater in smaller than in larger markets. Also, the size of the central or lead hospital facility per cluster tends to be much larger in the larger markets. Further, the size of the smaller hospitals in each cluster are likely to be much smaller in the clusters that emanate out of smaller urban areas. Thus, given the likely importance of both cluster and market size, control for these two dimensions is emphasized in the analyses below.

Cluster size. The average number of hospitals per cluster is just under four hospitals per cluster. Two-hospital clusters represent 39 percent of the total, which means that just over 60 percent of clusters have three or more hospitals in them (25 percent are five or more). This suggests that many of the clusters represent much more than mere hospital/hospital mergers, but rather mature (in terms of size and scope) multi-organizational groupings. As might be expected, the larger clusters tend to be found in the larger markets of one million population and over – 4.4 hospitals per cluster – compared to those in the smaller markets – 3.4 hospitals per cluster. While this relationship is statistically significant, there is much variation across market size categories (as reflected in the very large ETMC system described above).

Hospital dispersion. Within clusters, the average miles per cluster from the urban center (defined by the location of the largest hospital in the cluster) to each cluster member is about 21 miles. As would be expected, the averages increase by cluster size and decline with market size. The relationship with market size reflects a common pattern in which clusters located in larger markets tend to combine urban members, whereas those located in smaller markets often spill over to nearby rural and other urban areas. The average distances are 16 miles for clusters centered in markets of one million and over and 24 miles for those centered in markets fewer than one million. Clusters centered in the smaller markets, in other words, are very much more likely to incorporate within them more distant hospitals located outside their urban boundaries. The distances rise with cluster size, as follows: 2 hospitals – 14 miles, 3 to 4 hospitals – 22 miles, 5 to 6 hospitals – 28 miles, and 7 & over hospitals – 33 miles. (Means in the market and cluster size comparisons are significantly different). This reflects the need for clusters, as they grow, to reach further out in distance to find additional cluster partners.

Hierarchical configuration. This reflects the degree to which clusters combine large and small hospitals (the hub-spoke model). The range in bed size averages 278 beds, which suggests considerable variation across individual cluster members in the size of their hospitals. The significance of this is that differentiation among the cluster members indicates possibilities for within cluster rationalization of function and service capacity. And, the range is positively associated with cluster and market size. The ranges by cluster size are: 170, 288, 383, and 481 beds for clusters with 2, 3–4, 5–6 and seven and over hospitals per cluster. For 1 million and over markets, the average range in beds is 326 beds and for those centered in markets under one million, it is 240 beds. (All of these means are statistically significantly different from one another.) This suggests that the larger clusters located in the larger markets represent

those clusters that are most likely to exhibit significant functional differentiation among cluster members.

Considering the three dimensions together (size, dispersion, and hierarchy), it is clear that the clusters come in very different configurational combinations. And, these also vary directly with market size. The larger market clusters tend to be larger, less widely dispersed, more contained within the urban boundaries, and more hierarchical, by comparison to those in smaller markets.

Analytical Challenges in Studying Clusters

The most important challenge that arises when studying multi-unit business organizations (as opposed to studying free-standing facilities) is the analytical problems become exponentially more complicated. This is all the more true for spatially interdependent entities, such as the health care clusters. To help make this point clear, four issues are discussed that highlight some of the analytical challenges inherent in the study of geographically configured, multi-organizational forms: boundary specification, intensity of interdependencies, business unit diversity, and aggregation.

Boundary specification. This issue was raised above when the specification of the spatial boundaries of clusters were discussed. But, this is important for the OR/MS analyst as much as it is for the health services researcher. A too narrow definition of cluster boundaries risks under representing the total resources involved in the delivery of services, which could significantly affect optimization solutions involving multi-organizational systems. The reverse would be true for a too broad definition of cluster boundaries. Obviously, the boundary specification problem is less of a concern for clusters that are limited to urban areas or even are located within single counties. However, as discussed, many clusters spread well outside such boundaries, including, in particular, clusters that are centered within smaller urban markets. The boundary specification problem makes it necessary for the OR/MS researcher to grapple with the distinctive geographies, the logic of individual system design, and, importantly, the diversity and complexity of the management problems being addressed.

Intensity of interdependencies. Differences in the intensity of interdependencies can greatly compound the organizational boundary issue. Interdependencies will vary by location, functional capabilities, facility size and power, tightness of legal ownership arrangements, distinctive characteristics of parent organizations, and many other organizational characteristics. For example, a small, relatively distant hospital might have a tight and intense relationship with an urban centered, same system, referral hospital member, whereas a large, suburb-based (and much more geographically proximate) hospital might be very much more self sufficient with regard to its nearby referral partner. Given its self sufficiency, the suburb member might even be a fierce competitor with its same system partner. On the other hand, the more geographically proximate same system facilities might have more opportunities to engage in other coordinative activities, such as integrating purchasing and supply distribution, physician recruitment, IT strategies, the establishment of other related businesses within their metropolitan areas (e.g., ambulatory surgery centers), marketing activities, laboratory and other clinical and technological support activities, and so on. Each cluster, in other words is likely to be somewhat unique in how it captures the synergies of same system membership and geographic proximities.

Facility interdependencies will vary not only across clusters, but also across markets. The Wellstar health system, for instance, that operates five hospitals in the northwest quadrant of Atlanta, is likely to view system interrelationships among its hospitals far differently than will the New York Presbyterian Health System that geographically concentrated throughout the densely populated New York metropolitan area. Facilities in the latter tend to be larger and much more independent, given history and other factors.

It should be clear that OR/MS analysts must take particular care to ensure that they understand the particular configurational, structural, integrative and competitive features of the clusters they study.

Business unit diversity. The clusters also vary greatly in their diversity of business units. Indeed, the U.S. health care clusters are becoming far more than acute care agglomerations; many are expanding more rapidly into clinical areas well beyond acute care. This has important implications for how one conceptualizes

the clusters as production systems. Some of these other businesses are highly interdependent with cluster acute care activities, others are only tangentially related. Ambulatory care surgery is perhaps the most interconnected, because every case that is performed in the ambulatory setting represents a lost admission (and, lost revenues) to a hospital. However, this is not just a relationship of financial substitution. Hospitals provide much needed back up to their free-standing ambulatory surgery centers, by covering them in the event complications arise, providing ancillary services, coordinating site of surgery, recruiting physicians and staff, offering supply channel and other management support, and so on.

The largest private hospital chain in the country, HCA, has invested heavily in ambulatory surgery centers. HCA owns and operates 105 freestanding surgery centers and about 165 hospitals nationally, as well as in London. Significantly, all of HCA's surgery centers are located in markets in which HCA already has at least one hospital. This suggests that HCA is not investing in ambulatory businesses per se, but rather is investing in this rapidly growing business as an extension of the acute care business and to strengthen market positions within the markets in which the company already has facilities. Ambulatory surgery centers thus have become major components of the clusters' overall production and market strategies and, therefore, should be incorporated into the overall analyses of cluster operations and performance.

Many other system and production interrelationships also need to be understood when assessing cluster performance. The urban/rural clusters offer a particularly interesting example of high interdependencies among spatially distant cluster members. The Tyler, Texas-based ETMC health system, is actively engaged in integrative and support activities between its hub facility and the smaller, highly dependent rural facilities. ETMC, for example, operates emergency transport systems (both helicopter and ground systems), mobile imaging and other clinical services vehicles, and a network of clinics and specialty service centers that support their geographically sprawling system. Notably, there is no single template for how the clusters are configured or what particular services and business units they offer. There are general patterns, but every cluster is comprised of a unique mix of resources, capabilities, competitors, geographic constraints, and environmental conditions that determine their mix of providers and patterns of interrelationships. The key point is that distinctive combinations of facilities and businesses in geographic space greatly increases analytical complexity, making it essential that the systems are analyzed as integrated production systems (Ozcan 2009).

The foregoing is further complicated by the regulatory and legal contexts within which multi-organizational coordination takes place, especially within shared geographies. For instance, health systems are subject to Federal policies promulgated by CMS (Federal Centers for Medicare and Medicaid Services) that greatly increase the strategic importance and the urgency with which systems engage in coordination to achieve system improvements. As an example, the government's use of "meaningful use" criteria (require providers to meet minimum standards in the use of certified electronic health record technologies) to support bonus payments to health care providers makes it all the more important that their investments in costly and strategically significant health information technologies be examined at the cluster level (Blumenthal and Tavenner 2010; Ford et al. 2010; and Hikmet et al. 2007).

Aggregation. Related to the above is the problem of aggregation. This issue may not be as important when examining single-facility organizations. But, when multiple, geographically configured units are studied as if they were single production systems, it becomes necessary to address issues of standardization and weighting. Often this is a simple matter of summing across the units as if they were mere extensions of a production system. But, the diversity that exists across hospitals, let alone, between hospitals and other provider units, makes it necessary to consider how to count inputs and outputs. How, for instance, does one weight hospital-based surgeries versus ambulatory care surgeries? How does one weight outpatient visits versus emergency department visits. These problems exist even when examining single organizations, but they are magnified when evaluating multi-organizational systems that are as large and complex as are the clusters.

Heavy-Tailed Distribution

A probability distribution that has more probability in its tail than exponentially decaying densities such as the normal (Gaussian) and exponential distributions. Sometimes also called fat-tailed distribution, particularly in the finance community. The precise technical definition may differ in the literature, but a commonly used one is the following: The cumulative distribution function F is heavy-tailed if there exists a $\gamma > 0$ such that

$$\lim_{x \to \infty} e^{\gamma x} F^c(x) = \infty,$$

where the superscript c denotes the complement.

Special cases include long-tailed distributions and subexponential distributions. The most commonly known heavy-tailed distributions are also long-tailed and subexponential, including the lognormal, Pareto,

and Weibull with certain shape parameter values (one-tailed), and the student-t, Caucy, and family of stable distributions (two-tailed).

Heavy-Traffic Approximation

As the traffic intensity of a queueing problem approaches 1 (from below), the measures of effectiveness for the system often take on patterns which become essentially insensitive to the exact form of the input and service processes defining the system and, for example, may depend only on expectations and variances. As an illustration, the distribution for line delay of the general G/G/1 queue with utilization rate $\rho = 1 - \varepsilon$ can be well approximated by $W_q(t) = 1 - \exp(-at)$, where $a = (1/2)$(interarrival time variance + service-time variance)/(mean interarrival time − mean service time).

See

- ▶ Queueing Theory

Hedging

In finance, a trading strategy that leaves one indifferent to market outcomes. For example, a delta hedge of a stock option is intended to make the portfolio indifferent to whether the underlying stock price increases or decreases.

Hessenberg Matrix

A matrix that would be upper triangular except for having nonzero elements immediately below the main diagonal. Such matrices arise when trying to preserve sparsity in computing a matrix inverse.

See

- ▶ Matrices and Matrix Algebra

Hessian Matrix

For a function $f(\boldsymbol{x})$ of the n-dimensional vector variable $\boldsymbol{x}$, the Hessian, denoted by $\nabla^2 f(\boldsymbol{x})$, is an $n \times n$ square matrix of second-order partial derivatives (assuming they exist) evaluated at a specific point $\boldsymbol{x}$, with the $(i, j)th$ element given by

$$\nabla^2 f(\mathbf{x})_{ij} = \frac{\partial^2 f(\mathbf{x})}{\partial x_i \partial x_j}.$$

If the second partial derivatives are continuous at $\boldsymbol{x}$, then the Hessian is a symmetric matrix.

Heterogeneous Lanchester Equations

Differential (of difference) equations equating force size changes for each of several weapons systems (components) on each side to sums of the products of coefficients and component force sizes. The concept is that each component is attrited to some degree by each component of the opposing side; however, the killing mechanism and rate depend on the pairing. Hence, each term defines the mechanism (such as square law or linear law) and rate (the coefficient) and the sum of

the terms defines the total attrition for the system. Therefore, rather than the two equations of a homogeneous Lanchester law, there is one equation for each component of each side.

Heuristic Procedure

For a given problem, a collection of rules or steps that guide one to a solution that may or may not be optimal. The rules are usually based on the problem's characteristics, intuition, hunches, good ideas, or reasonable processes for searching.

Introduction

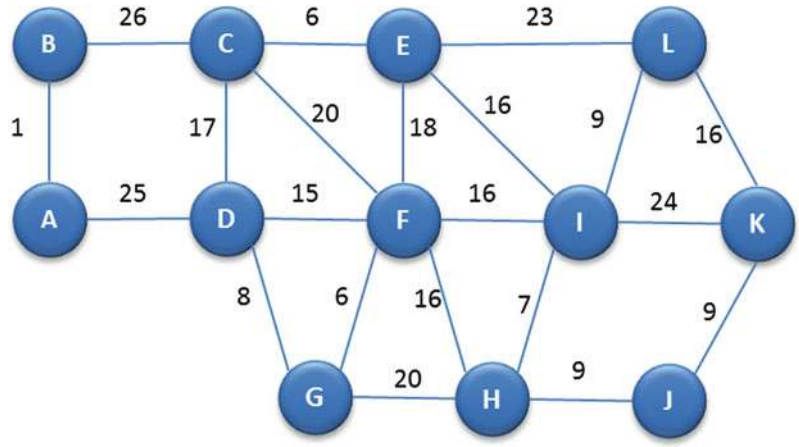
The word heuristics derives from the Greek *heurisken*, which means to find or to discover. In general, for a given problem, a heuristic procedure is a collection of rules or steps that guide one to a solution that may or may not be the best (optimal) solution. The rules are usually based on the problem's characteristics, reasonable processes for searching, plus one's intuition, hunches, or good ideas.

In general, heuristics describes a class of procedures for finding acceptable solutions to a variety of difficult decision problems, that is, procedures for searching for the best solutions to optimization problems. The solution set of most real world optimization problems often include a large or even an infinite number of possible solutions, as well as a criterion or a set of criteria to evaluate the merit of a solution. These problems may be stated as finding the values for a set of decision variables for which one or more objective functions reach a minimum or a maximum value. Restrictions may be placed on the values of individual variables or combination of variables. In what follows, important operations research models are discussed first to help illuminate the main theme of heuristics.

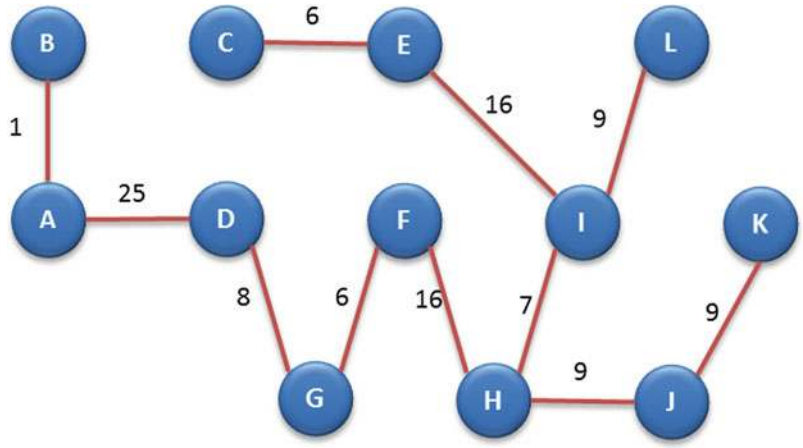
Illustrative Examples

Optimization problems are found in many areas of business, engineering, and science. Some problem classes are relatively easy to solve. For instance, consider a simplified version of a problem that arises in telecommunications in which it is desired to connect a number of customers in a network using the least amount of cable. Figure 1 shows a network of 22 possible cable links joining 12 customers (labeled A to L) and the costs of the potential links. Note, that with 22 links, there are many ways a subset can be selected that would connect all customers. The problem is to find the subset with the least amount of total cable. That is, for each customer, one of the possible links that connects the customer has to be chosen. For the network in Fig. 1, can 11 such links (decision variables) be found?

It is well know that the optimal solution (i.e., the connection that guarantees the minimum cable cost) can be found by a simple procedure that starts with choosing the link with the smallest cost in the network. Similarly, the remaining links are chosen successively to minimize the increase in total cost at each step, where the links considered meet exactly one customer from those that are endpoints of links previously chosen. The resulting solution is called a tree, which is defined as a set of links that contains no cycles, i.e., the tree contains no paths that start and end at the same customer (without retracing any links). In Fig. 1, the first link to be added to the solution is A-B, with a cost of 1. To minimize the additional cost of connecting a new customer, the A-D link must be



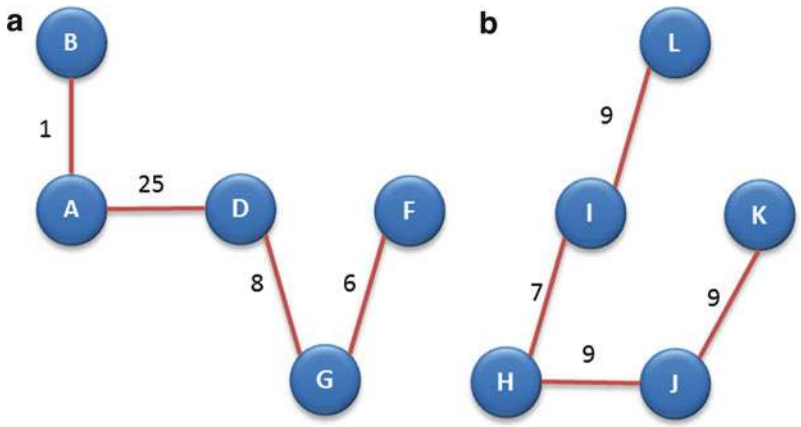
Heuristics, Fig. 1 Illustrative network with 12 customers



Heuristics, Fig. 2 Minimum spanning tree

chosen. That link has a cost of 25, resulting in a total cost of 26 to connect A, B, and D. Now, it is possible to connect either customer C, F or G. Cost minimization dictates that link D-G should be added, resulting in customer G to be connected to the partial solution with a total cost of $1 + 25 + 8 = 34$. The next candidates to be connected to the current tree are customers C, F, and H. The link with the minimum cost between the end points of the current tree and the candidate customers is G-F with a cost of 6. After adding this link, the total cost is 40. Subsequent links are added in a similar fashion, resulting in the tree shown in Fig. 2 that has a total connection cost of 112. The above process can be interpreted as a heuristic approach to solving the connection problem by someone uninitiated in any formal knowledge of trees or related matters.

The tree shown in Fig. 2 is called a minimum spanning tree. It can be shown to be a least cost optimal tree for the problem. The procedure avoids cycles because it is easy to verify that no optimal solution of the problem includes a cycle, since a cycle adds an unnecessary link and therefore additional cost (assuming that all costs are strictly positive). Note that an alternative optimal solution is available in which the F-H link is replaced with the F-I link. Since ties are arbitrarily broken, either solution is acceptable and optimal. The procedure is exact, that is, it guarantees an optimal solution; it is simple and can be applied to very large networks. Unfortunately, the great majority of optimization problems are not as easy to solve. In fact, sometimes what seems to be a simple change to a problem definition may turn the problem from easy to hard. For example, if the problem of



Heuristics, Fig. 3 (**a**) Heuristic solution versus (**b**) optimal solution

finding the minimum-cost connection of all customers is changed to finding the minimum-cost connection of a subset of customers, the problem becomes extremely difficult. This is known as the minimum k-tree problem and consists of finding a tree with k links so that the sum of the costs is minimized. Figure 3a shows the solution that is obtained from the application of the procedure described above for the case of $k = 4$. However, this solution (with a cost of 40) is not optimal for the minimum k-tree problem. The optimal solution is shown in Fig. 3b and has a total cost of 34. A solution procedure that is exact (i.e., optimal) for the minimum spanning tree problem becomes a heuristic for the minimum k-tree problem.

Linear programming is one of the most valuable mathematical modeling techniques in operations research. As an example that reflects the main heuristics theme of this article, consider a relatively simple linear-programming model known as the continuous knapsack problem. Here, there are 10 items available to be placed in a knapsack whose associated weights are given in the subject to inequality; the utility or value of each item to the person with the knapsack is given in the maximize objective function, e.g., item 1 has a weight of 5 and a utility of 67. Note that this example allows a fraction of an item to be placed in the knapsack.

$$\begin{aligned}\text{Maximize}\quad & 67x_1 + 500x_2 + 98x_3 + 200x_4 + 120x_5 \\ & + 312x_6 + 100x_7 + 200x_8 + 180x_9 + 100x_{10} \\ \text{Subject to}\quad & 5x_1 + 45x_2 + 9x_3 + 19x_4 + 12x_5 + 32x_6 \\ & + 11x_7 + 23x_8 + 21x_9 + 14x_{10} \leq 100 \\ & 0 \leq x_j \leq 1 \quad \text{for j} = 1, \ldots, 10\end{aligned}$$

Linear-programming problems are typically solved using standard techniques such as the simplex algorithm. The problem above, however, has a special structure that makes it easy to find the optimal solution by applying what can be considered to be an obvious heuristic approach. Specifically, an optimal solution procedure to this problem can be found by performing three simple steps:

1. Order the variables by their decreasing "bang for the buck" ratio. The ratio is calculated by dividing the objective function coefficient (utility) by the corresponding constraint coefficient (weight).
2. Consider each variable in order, one at a time, and set its value as large as possible without violating its upper bound of 1 or the 100 capacity restriction.
3. When capacity is reached, set the remaining variables to zero.

For convenience, the variables in this example have been ordered by their bang for the buck ratio. The procedure may then be applied by simply considering the variables in the order as specified by their index value. The application of the three steps requires setting the first 5 variables to their maximum possible value of 1 with an associated total utility of 67 + 500 + 98 + 200 + 120 = 985; the total weight is 5 + 45 + 9 + 19 + 12 = 90. Since variable 6 has a weight of 32 and the remaining capacity is 10, then this variable cannot take on its maximum value of 1. Thus, variable 6 is set to a value of 10/32 = 0.3125. The additional utility is (0.3125 × 312) = 97.5 for a total objective function value of 985 + 97.5 = 1,082.5, the optimal value to the example. The three-step procedure is an exact method for this problem because it guarantees to find an optimal solution.

The problem may be transformed into an integer-programming model, by requiring the variables take on integer values, in this case 0 or 1. This interpretation requires each variable to be either wholly selected for inclusion in the knapsack, or not selected at all, until the knapsack reaches its limited capacity or falls below it as the selection of any other item will exceed the capacity. Again, the objective function coefficients represent the utility of the item, the constraint coefficients represent the weight of the items, and the right-hand-side of the equation indicates the total weight limit (or capacity of the knapsack). One logical solution approach to finding a solution is to apply the bang for buck method and then stop when it is not possible to select another item without violating the capacity limit. This may be achieved by simply assigning a value of zero to the variable that has a fractional value in the solution to the continuous problem (i.e., the one that does not force the variables to take on integer values). In particular, the rounded solution to the example above is such that the first five variables (x_1 to x_5) take on values of 1 and the last 5 variables (x_6 to x_{10}) take on values of zero. The total utility of this solution is 985 with a total weight of 90. It turns out, however, that this solution is not optimal. The method that is exact for the continuous case becomes a heuristic for the integer case. Finding the optimal solution would require an additional search that would replace item 5 with item 9. That is, variable x_5 should be set to 0 and x_9 to 1. The net gain in utility is 60 for a total utility of 1,045 and the total weight becomes 99.

The Role of Heuristics

The preceding examples illustrate the notion of problem difficulty. It is often possible to readily find optimal solution to some problems, while what may be perceived as a simple change to the problem may increase considerably the difficulty of finding an optimal solution. The meaning of a difficult problem is captured by the computer-science term NP-hard, which is commonly applied in the context of algorithmic complexity. A difficult optimization problem is one for which it is not possible to guarantee that the optimal solution will be found within a reasonable computational time. The existence of a great variety of difficult problems that arise in practice motivated the development of efficient procedures capable of finding good (or acceptable) solutions even when these solutions could not be proven optimal, that is heuristic methods. The development of a heuristic method is usually concerned with both solution speed and solution quality. A definition of heuristics in the context of optimization is the following:

A heuristic is a well-defined intelligent procedure — based on intuition, problem context and structure — designed to find an approximate solution to an optimization problem.

In contrast with exact methods that are designed to find optimal solutions, heuristic methods find solutions that are not necessarily optimal. The time that exact methods require for finding and proving the optimality of a solution is typically orders of magnitude larger than the time required by a heuristic. The effectiveness of a heuristics depends on the quality of the approximations that it produces. Heuristics have not always been accepted as an elegant and perhaps even valid form of optimization, as noted by Fred Glover (1977, p. 156):

> Algorithms are conceived in analytic purity in the high citadels of academic research, heuristics are midwifed by expediency in the dark corners of the practitioner's lair . . . and are accorded lower status.

The effectiveness of heuristics, particularly when applied to difficult practical problems (such as those in the area of combinatorial optimization), has made them popular among practitioners and academics, as reflected by the increased number of articles and publications devoted to them. Combinatorial optimization is a fertile area of application for heuristics because it includes a large number of practical problems that are difficult to solve (within reasonable computer time) by means of exact procedures. The objective of these problems is to maximize or minimize a function over a finite set of solutions. No conditions or properties are placed on the form of the objective function and the set of feasible solutions tends to be so large that evaluating them all to search for the best is impractical. The minimum k-tree and the knapsack problems fall within the area of combinatorial optimization. There are several reasons for employing heuristics when facing an optimization problem:

- The problem is such that no exact solution method is known for it.
- Known exact solution methods are computationally expensive and, therefore, they are able to solve only small instances of the problem.

- The flexibility of the heuristic approach enables the incorporation of realistic problem features that otherwise would be difficult to model.
- A heuristic method is used within an exact procedure to generate an initial solution or to guide the search.

Typically, heuristic methods are developed for a particular class of problems. That is, most heuristics are context dependent. For example, there are many heuristics for scheduling jobs in production settings that take the form of dispatching rules: FIFO (first in first out) specifies that jobs should be processed in the order in which they arrived, SPT (shortest processing time) suggests to process the smallest (in terms of estimated duration) jobs first, and EDD (earliest due date) gives preference to those jobs that are more immediately due. Some of these dispatching rules are indeed optimal under certain limited circumstances, but for the most part they are applied as heuristic procedures.

Heuristics are also found in more general settings for which the context is provided by the modeling framework, e.g., the class of problems that may be modeled as integer programs that are solved with exact methods based on branch and bound. These methods are such that the search for the optimal solution results in the examination of many partial solutions. Within this structure, it is desirable to eliminate search directions that can be ruled out because it is possible to determine that they lead to suboptimal solutions. This can be accomplished by improving the quality of the best-known solution, also referred to as the incumbent solution. If a partial solution consists of a subset of variables for which their integer values have been fixed by a sequence of systematic decisions, with the remaining variables holding fractional values, a rounding heuristic may be applied to convert the fractional values into integers to obtain a complete solution to the problem. If the rounded heuristic solution becomes the incumbent solution, some branches of the search tree may be eliminated. The optimization software Cplex allows the use of heuristics during the branch and bound process. These heuristics may be used to find feasible solutions quickly, avoid exploring unproductive subtrees, and diversify the search. Within this framework, the combination of branch and bound and local search heuristics has been suggested and applied to tackle difficult integer-programming problems. Furthermore, a branch-and-bound process that is terminated prematurely and hence not allowed to confirm the optimality of an incumbent solution is considered a heuristic method.

Classification of Heuristics

Although most heuristics are designed for specific problems, it is possible to classify them into five general categories:

- **Decomposition**: These procedures decompose the original problem into subproblems that are simpler to solve. The solutions to the subproblems are merged to provide a solution to the original problem.
- **Induction**: These procedures are based on the notion that solution strategies learned from small or simplified instances of the original problem may be applied to the original problem.
- **Reduction**: This technique consists of identifying properties that are common to good or optimal solutions and introducing them as problem constraints. The goal is to reduce the solution space and hence simplifying the original problem. The risk in doing so is that the optimal solution may be unintentionally left out.
- **Construction**: Many heuristics fall into this category, which includes all those procedures designed to build solutions by applying a sequence of selection steps. The selections are typically deterministic and are based on a measure of merit for choosing elements that are not yet in the solution.
- **Local Search**: These procedures operate on an existing solution to the problem with the goal of improving it. The neighborhood (as defined by a move mechanism) is explored at each step and the process continues as long as it is possible to move to a neighbor with a better objective function value.

The merit of heuristic procedures is judged by their efficiency (i.e., computational effort), the average quality of the solutions that they produce, and their robustness (i.e., their ability to avoid extremely inferior solutions). To assess the performance of a heuristic procedure, researchers and practitioners usually rely on the following five methods:

- **Comparison against optimal solutions**: Occasionally, it is possible to find optimal

solutions to a limited number of instances of the problem of interest. The solutions obtained by the heuristic may be compared to the optimal solutions to measure, for example, the percent deviation from optimality.

- **Comparison against bounds**: When optimal solutions are not available, it is possible, in some situations, to calculate bounds that can be used to assess solution quality. Of course, the quality of the assessment depends on the quality of the bound, as measured by its proximity to the optimal solution.
- **Comparison with an incumbent solution from a truncated search of an exact method**: A common practice when attempting to solve difficult problems (e.g., those formulated as integer programs) consists of applying an exact procedure, such as branch and bound, for a limited computational time. If successful, the search yields a feasible incumbent solution and an optimality gap. These values may be used to assess the quality of a heuristic solution.
- **Comparison against other heuristics**: If alternative heuristics for the problem of interest are available, their solutions can be used as benchmarks for comparison purposes.
- **Worst case analysis**: This assessment method is quite popular and consists of identifying a bound for the worst possible performance of the heuristic procedure. The advantage of this analysis is that it provides a guarantee that the performance of a procedure (typically measured as a deviation from the optimal solution) will never fall below a certain value. The disadvantage, however, is that knowledge of this worst case does not give information on average or best performance. Also, the worst-case analysis is not trivial for most heuristics.

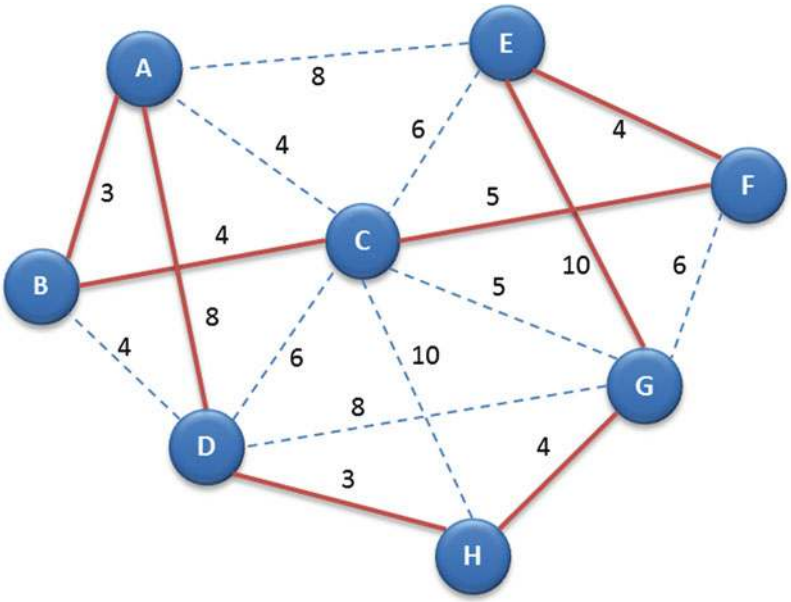
Construction Search Heuristics

Construction and local search heuristics have become the cornerstones of the development of many metaheuristics that include strategies to search the solution space beyond local optimality (Glover 1986; Glover and Kochenberger 2003). The attitude towards the development and application of heuristics and metaheuristics as tools for optimization has changed over the years, gaining their recognition as valuable methods of analysis. In some application areas, such as scheduling, heuristics and metaheuristics are indeed the main solution approaches. Morton and Pentico (1993) make an excellent case for heuristics in scheduling production systems and project management. Related to scheduling and sequencing is the traveling salesman problem (TSP). Its objective is to find a tour (cyclic permutation) that visits a set of cities such that the total distance traveled is minimized. The TSP represents an appropriate context to illustrate the principles associated with construction and local search heuristics.

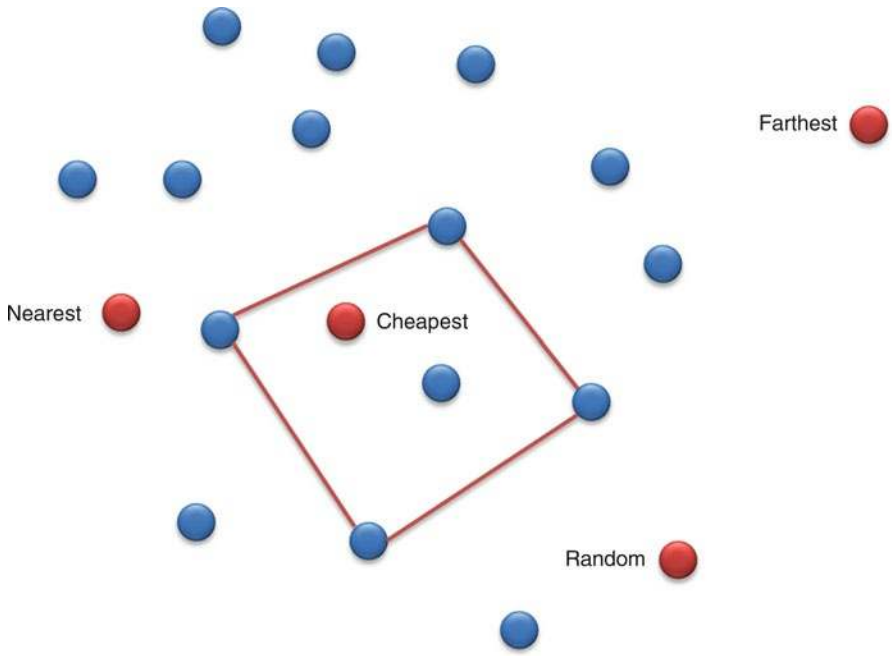
The TSP is typically stated in terms of a problem on graphs. Given a complete graph (i.e., a set of nodes and edges that connect each node to all others) and a distance matrix, the TSP consists of finding the shortest Hamiltonian cycle (tour) in the graph. The symmetric variant of the TSP, used for illustrative purposes below, assumes that the distance from one node to any other is the same in both directions. Figure 4 shows a partial representation of a graph with 8 vertices, in which, for the sake of clarity, not all possible edges (dotted lines) are included and a tour is shown by solid lines.

The nearest neighbor procedure is probably the most intuitive heuristic for obtaining a tour. It starts by randomly selecting a node in the graph. Then, it adds the edge that connects the node that is closets to the last node added to the partial tour. The procedure terminates after all nodes have been included and the edge that connects the last node to the first one is added to the tour. This procedure is an example of a so-called greedy heuristic because at each step it selects the most attractive option without considering that this can lead to inferior choices in future steps. That is, the selection of the next element to be added to the solution is myopic.

An alternative approach to obtaining a relatively good tour is the insertion procedure. In this heuristic, nodes are inserted in the best position of the current partial tour. That is, the node is inserted in the position that results in a new subtour of minimum length. As shown in Fig. 5, four different criteria are typically considered for the selection of the node to be inserted: the nearest (closest to the nodes in the subtour), the cheapest (closest to the edges in the subtour) the farthest and one at random. The selection of the farthest may seem counterintuitive, but since this node will become part of the tour at



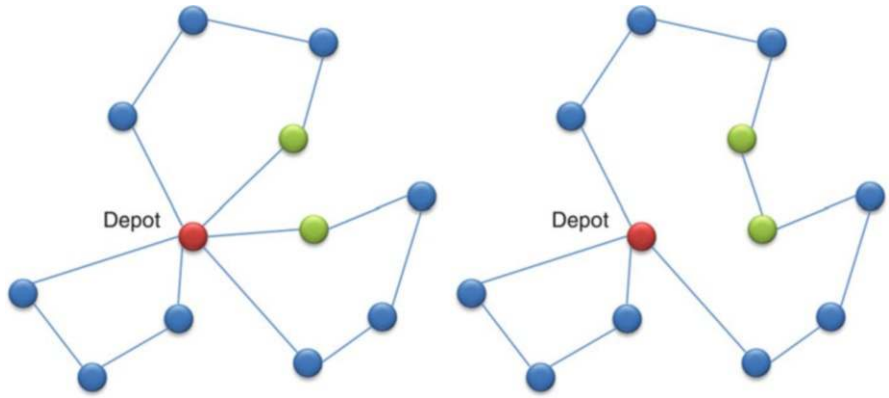
Heuristics, Fig. 4 Graph with 8 nodes and TSP tour



Heuristics, Fig. 5 Subtour and insertion candidates

some point, selecting it earlier in the construction may in fact be beneficial.

The savings heuristic is a specialization of a more general heuristic proposed by Clarke and Wright (1964). An arbitrary node is selected to play the role of the central node or depot. The method starts by creating subtours from the depot to each other node. One edge is added to go from the depot to a node and one to come back from the node to the depot. This initially creates a number of subtours that is



Heuristics, Fig. 6 Step of Clarke and Wright savings heuristic

equal to the number of nodes in the graph minus one (the depot). Then, at each step, two subtours are merged as shown in Fig. 6 (by replacing a length-2 path from one non-central node to another by a direct link), thus reducing the number of subtours by one unit. The method finishes when all the sub-tours have been successively merged into a single tour.

The Christofides (1976) procedure is another heuristic for constructing TSP tours. It is based on graph theory. It starts with a minimum spanning tree to which the number of edges is doubled to obtain an Eulerian graph (where every node has even degree). Then an Eulerian tour is found that is turn converted into a traveling salesman tour by using shortcuts. The graphical representation of this procedure is more complex than the previous ones discussed.

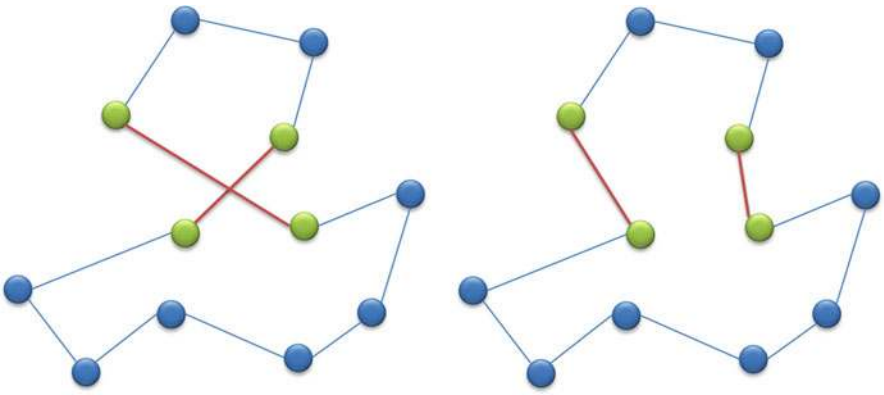
The above TSP heuristics have been applied to a set of TSPs for which the optimal answers are known. The results show that the savings and the insertion heuristics obtain the best results, with an average deviation from optimality of 9.6% and 9.9%, respectively. The nearest neighbor and Christofides heuristics have similar performance with deviations of 18.6% and 19.5%, respectively. The computational effort is similarly small for all four heuristics, making them attractive as the basis for developing more complex search procedures. While in some settings, deviations of almost 10% from optimality may be acceptable, a more precise solution may be required in others. One way of discovering solutions of higher quality is through the combination of construction and local search heuritics.

Local Search Heuristics

Local search methods are based on the notion of neighbor structures that generate changes to move from one solution to another in the solution space. Local searches perform moves as long as the current solution improves and terminate when no further improvement is possible. The resulting solution is said to be locally optimal (i.e., the solution cannot be improved within the neighbor structure under consideration). In the context of the TSP, the most popular moves are the so-called k-opt.

The 2-*opt* procedure consists of replacing two non-adjacent edges by two others that create a tour after the first two are removed. Figure 7 illustrates this move and shows that once the two edges are removed there is only one way to reconnect the two sub-paths in order to create a tour. The move value is the change in the objective function produced by the move. In the case of the TSP, it is the difference between the distances of the added edges minus the distance of the dropped ones.

A natural extension of the 2-opt heuristic is to consider three edges to drop and then relink the resulting sub-paths in the best possible way. The 3-opt heuristic results in seven possibilities for reconnecting the sub-paths, which makes it computationally more expensive than the 2-opt procedure. Several strategies have been proposed to reduce this computational effort. The most successful one consists of building, offline, a candidate subgraph that contains a reduced set of promising edges that will be considered for exchange. There are $\binom{n}{k}$ possible ways to remove k edges in



Heuristics,
Fig. 7 Illustration of a 2-opt move

a tour and $(k-1)!2^{k-1}$ ways to reconnect the tour. This is why only small values of k are usually considered in k-opt heuristics with $k = 2$ and $k = 3$ the ones most commonly used. However, in special situations of large scale TSP instances, $k = 4$ and $k = 5$ have been employed.

The TSP examples illustrate the creativity involved in the development of heuristic procedures that are designed to tackle a specific class of problems. They also show the effectiveness of combining heuristics (e.g., construction and local search), even without the addition of search strategies (e.g., memory or mechanisms to combine solutions) that are typical to metaheuristic methodologies. The combination of heuristics is the notion behind the framework known as hyperheuristics (Burke et al. 2003). While a metaheuristic searches in the solution space, a hyperheuristic is designed to search in the heuristics space. Acknowledging that all heuristics have strengths and weaknesses, the goal of a hyperheuristic is to select the right heuristic in any given situation. Hyperheuristics attempt to automate (through machine learning techniques) what a human would do when faced with a challenging problem and with the knowledge of several applicable heuristics. Additional details on heuristics and their role in solving operational research problems are found in (Silver, et al. 1980) and Silver (2004).

Hidden Markov Models

Yariv Ephraim
George Mason University, Fairfax, VA, USA

Introduction

Hidden Markov models (HMMs) constitute a family of versatile statistical models that have proven useful in many applications. HMMs were introduced in their full generality in 1966 by Baum and Petrie (1966). Baum, Petrie and other colleagues (Baum et al. 1970) at the Institute for Defense Analysis also developed and analyzed a maximum likelihood (ML) procedure for efficient estimation of the HMM parameters from a training sequence. This procedure turned out to be an instance of the now well-known EM (Expectation-Maximization) algorithm of Dempster, Laird and Rubin (1977). A form of HMM, referred to as a Markov Source, was introduced as early as 1948 by Shannon in developing a model for the English language (Shannon 1948).

Baum et al. (1970) referred to HMMs as probabilistic functions of Markov chains. Indeed, an HMM process comprises a Markov chain whose states are associated with some probability distributions. For example, the Markov states may be associated with Poisson probability distributions that differ in their means. At each time instant, a random variable with probability distribution that depends on the state in which the Markov chain lies is generated. An HMM process is thus comprised of a Markov state sequence and an associated sequence of random variables. Normally, only that sequence of random variables is observed while the corresponding sequence of Markov states is not; hence, the term hidden Markov models.

The significance of the states of an HMM varies with the application. For example, in automatic speech recognition, states may represent phonemes of the language. The probability distributions associated with the states may represent statistical variations of the acoustic signals corresponding to the different phonemes. In this application, only the acoustic signal is observed while the phonemes are estimated from the given signal during the recognition process.

Since their introduction in 1966, HMMs have been extensively studied and applied primarily to modeling of speech signals in automatic speech recognition applications. Jelinek and his group at IBM Research Labs proposed a purely statistical HMM-based speech recognition system in the early 1970s (Jelinek 1974). The models were popularized in the early 1980s primarily by Ferguson and his colleagues at the Institute for Defense Analysis (Ferguson 1980) and by Rabiner and his group at AT&T Bell Laboratories (Rabiner 1989). Since then, many advances in the theory and application of HMMs have been introduced. HMMs have been successfully used in Image Recognition, Sonar Signal Processing, Automatic Fault Detection and Monitoring, Speech Enhancement, Communication and Control, Epidemiology and Biometrics and in various Biomedical applications. An excellent survey of the field is contained in the 1996 dissertation of Couvreur. The structure and basic concepts of HMMs are first reviewed and then the Baum algorithm is presented.

Hidden Markov Models

Consider a homogeneous Markov chain of M states. Let $\boldsymbol{\pi} = (\boldsymbol{\pi}_m, m = 1, \ldots, M\}$ denote the vector of initial state probabilities and $\boldsymbol{A} = \{a_{ij}, i, j = 1, \ldots, M\}$ denote the stochastic matrix of state transition probabilities. Let $S_0^N \stackrel{\Delta}{=} \{S_0, S_1, \ldots, S_N\}$, denote the sequence of random variables representing the states of the HMM process at time instants $n = 0, \ldots, N$. A realization of the sequence S_0^N is given by $s_0^N = \{s_0, s_1, \ldots, s_N\}$, where $s_n \in \{1, 2, \ldots, M\}$ for $n = 0, \ldots, N$. The probability that the Markov chain visits state s_n at time n, given that it was in state s_{n-1} at time $n - 1$ is denoted by $a_{s_{n-1}s_n}$. For $n = 0$, $a_{s_{n-1}s_0} = \pi_{s_0}$. Thus, for example, if $s_{n-1} = i$ and $s_n = j$, $0 \le i, j \le M$, then $a_{s_{n-1}s_n} = a_{ij}$ for $n > 0$ and $a_{s_{n-1}s_n} = \pi_j$ for $n = 0$.

Let $Y_0^N \stackrel{\Delta}{=} \{Y_0, Y_1, \ldots, Y_N\}$, denote a sequence of scalar random variables observed at time instants $n = 0, \ldots, N$. The probability distribution of the random variable Y_n given that the HMM is in state S_n is denoted by $P_{Y_n|s_n}(\boldsymbol{y}_n|s_n)$ for $s_n = 1, \ldots, M$. The observable random variables $\{Y_n\}$ may be discrete, continuous or a mixture of both. Moreover, each scalar random variable Y_n may in fact be a vector $\boldsymbol{Y}_n$

of K random variables. In that case, a vector of random variables with conditional probability distribution $P_{\boldsymbol{Y}_n|s_n}(\boldsymbol{y}_n|s_n)$ is emitted whenever state s_n is visited. The vector notation will be used to cover both scalar and vector observable random variables.

The probability density function (PDF), or the probability mass function (PMF), of a sequence of observable random vectors $\boldsymbol{Y}_0^N$ from an HMM process is given next. This PDF (or PMF) is conveniently written using the sequence of states S_0^N, i.e.,

$$\begin{aligned} p_{\boldsymbol{Y}_0^N}(\boldsymbol{y}_0^N) &= \sum_{s_0^N} p_{S_0^N \boldsymbol{Y}_0^N}(S_0^N,\ \boldsymbol{y}_0^N) \\ &= \sum_{s_0^N} p_{S_0^N}(S_0^N)\, p_{\boldsymbol{Y}_0^N|S_0^N}(\boldsymbol{y}_0^N|S_0^N) \\ &= \sum_{S_0^N} \prod_{n=0}^{N} a_{S_{n-1}S_n} p_{\boldsymbol{Y}_n|S_n}(\boldsymbol{y}_n|s_n) \end{aligned} \tag{1}$$

where the Markov property has been invoked in assuming that given the state $S_n = s_n$, the observed random vector $\boldsymbol{Y}_n$ is independent of past and future states and observable random variables.

An important example for the conditional PDF $p_{\boldsymbol{Y}_n|s_n}(\boldsymbol{y}_n|s_n)$ in (1) results when a K-dimensional Gaussian observable random vector $\boldsymbol{Y}_n$ is emitted from a visited state, say $s_n = j$. In that case, $p_{\boldsymbol{Y}_n|s_n}(\boldsymbol{y}_n|s_n = j) = N(\boldsymbol{\mu}_j, \boldsymbol{R}_j)$, where $\boldsymbol{\mu}_j$ and $\boldsymbol{R}_j$ are, respectively, the mean vector and covariance matrix associated with state j. When a single PDF is not sufficient to describe the data associated with a given state, a mixture of probability distributions is useful. For example, a mixture of Gaussian PDFs may be associated with each state of the HMM.

Statistical properties of an HMM process are inherited from properties of its Markov chain (Grimmett and Stirzaker 1995). An irreducible Markov chain is said to be ergodic if all states are positive recurrent and aperiodic. An irreducible ergodic Markov chain is strongly stationary if the initial state probability distribution $\boldsymbol{\pi}$ equals the unique stationary probability distribution of the chain. This stationary probability is obtained from the unique nonnegative solution of the matrix equation $\boldsymbol{\pi} = \boldsymbol{\pi}\boldsymbol{A}$. Stationarity of the Markov chain $\{S_n\}$ implies stationarity of the observable sequence of random variables $\{\mathbf{Y}_n\}$; see Theorem 2.2 in Couvreur (1996). If $\{S_n\}$ is stationary and ergodic, then the observable sequence of random variables $\{\boldsymbol{Y}_n\}$ is ergodic; see Lemma 1 in Leroux (1992).

HMM Parameter Estimation

Modeling of a random process by an HMM involves estimation of the parameters set of the HMM from training data generated by the process. To specify the HMM, one must choose the number of states for the Markov chain, the allowable state transitions and the type of conditional probability distributions of the HMM that best fit the nature of the random process being modeled. When a Markov chain of M states is used, the parameter set of the HMM is given by $\lambda = (\boldsymbol{\pi}, \boldsymbol{A}, \boldsymbol{B})$, where $\boldsymbol{\pi}$ is the M-dimensional vector of initial state probabilities, $\boldsymbol{A}$ is the $M \times M$ matrix of state transition probabilities, and $\boldsymbol{B}$ is the set of parameters of the conditional probability distributions for the various states. If these conditional distributions are Gaussian, $\boldsymbol{B}$ consists of the set of M mean vectors and M covariance matrices.

A random process from which a training sequence $\boldsymbol{Y}_0^N$ is available by an M-state HMM with parameter set λ is shown next. The modeling is commonly performed by

$$\max_{\lambda} \frac{1}{N} \log\ p\left(\boldsymbol{y}_0^N|\lambda\right), \tag{2}$$

where $p(\boldsymbol{y}_0^N|\lambda)$, is the PDF or PMF in (1) evaluated for the training sequence $\boldsymbol{Y}_0^N$, and $\tilde{N} \triangleq K(N+1)$ is the total number of samples in the training data. Note that the subscript $\boldsymbol{Y}_0^N$ from (1) has been dropped, with the dependence of this PDF or PMF on the parameter set λ shown explicitly now. This notation will be adopted henceforth. $\tilde{N}^{-1} \log p(\boldsymbol{y}_0^N|\lambda)$ in (2) is referred to as the normalized log-likelihood function or simply the likelihood function. The estimation approach outlined by (2) is motivated by the Maximum Likelihood (ML) parameter estimation approach. Under certain conditions, the ML estimation approach has optimal asymptotic properties when the training sequence is generated by the HMM whose parameters are being estimated.

Maximization of the likelihood function in (2) is not trivial because the problem is inherently nonlinear. Furthermore, it is easy to see from (1) that evaluation

of the likelihood function requires $(2N + 1)M^{N+1}$ multiplications, since there are M^{N+1} possible state sequences $\{s_0, s_1, \ldots, s_N\}$, and summation is over products of $2(N + 1)$ terms along each such state sequence. This constitutes an exponentially growing number of multiplications as a function of the length of the training sequence. Since N is required to be large to achieve statistical consistency of the estimate of λ, any iterative maximization procedure that requires evaluation of the likelihood cost function will be prohibitively expensive. Fortunately, Baum et al. (1970) developed an efficient estimation procedure for iterative maximization of the likelihood cost function, and an efficient approach for calculating the likelihood function.

The Baum Algorithm

Suppose that an estimate λ_m of the parameter set λ is available at the end of the mth iteration of the Baum algorithm. Let $\tilde{\lambda}$ denote any other estimate of the parameter set λ. Let $L(\lambda_m) \stackrel{\Delta}{=} \tilde{N}^1 \log p\left(y_0^N|\lambda\right)$ denote the likelihood function of the training sequence under the HMM with parameter set λ_m. Then, using Jensen's inequality, Baum et al. (1970) showed that

$$L\left(\tilde{\lambda}\right) - L(\lambda_m) \geq \frac{1}{\tilde{N}}\left[Q\left(\tilde{\lambda},\ \lambda_m\right) - Q(\lambda_m,\ \lambda_m)\right], \quad (3)$$

where

$$Q\left(\tilde{\lambda},\ \lambda_m\right) \stackrel{\Delta}{=} E\left\{\log\ p\left(S_0^N,\ \mathbf{y_0^N}|\tilde{\lambda}\right)|\mathbf{y_0^N},\ \lambda_m\right\} \quad (4)$$

is called the auxiliary function. Clearly, if λ_{m+1} is chosen to be

$$\lambda_{m+1} = \arg\ \max_{\tilde{\lambda}}\ Q\left(\tilde{\lambda},\ \lambda_m\right), \quad (5)$$

then from (3), $L(\lambda_{m+1}) \geq L(\lambda_m)$, since $\tilde{\lambda}$ can always be chosen to be equal to λ_m. Thus, starting with an initial estimate λ_0, and alternating between (4) and (5) results in a sequence of estimates λ_m for the parameter set λ with non-decreasing likelihood values $L(\lambda_m)$. The iterations may be terminated if a fixed point of the algorithm is reached, that is, when $\lambda_{m+1} = \lambda_m$. In that case, $L(\lambda_{m+1}) = L(\lambda_m)$. Equations (4) and (5) constitute the Baum algorithm, or the E-step and M-step, respectively, of the EM algorithm.

It is easy to see that the ML estimate of λ is a fixed point of the algorithm. The algorithm, however, may have many other fixed points that may not even be stationary points of the likelihood function. Convergence of the sequence of estimates λ_m can be established by applying the Global Convergence Theorem to the EM algorithm (Wu 1983).

So far the discussion has focused on modeling of one random process, which is not necessarily an HMM process, by another random process in the form of an HMM. Thus, the training sequence available for estimating the parameter set of the HMM may not be generated by an HMM. In that case, no true HMM parameter set exists, and the quality of the estimate of the HMM parameter set is judged by the performance of subsequent applications. For example, if HMMs are estimated for acoustic signals from various words in a vocabulary, then the performance of a speech recognition system which relies on the estimated HMMs is measured. If, however, a training sequence generated by an HMM is available, then the goal of the estimation procedure is to provide an accurate estimate of the true parameter set of the HMM in some given sense. Thus, if the length of the training sequence is N, and the ML estimate of the parameter set λ is given by $\tilde{\lambda}(N)$, then it is desirable that $\tilde{\lambda}(N) \to \lambda$ as $N \to \infty$ with probability one. An estimator $\tilde{\lambda}(N)$ satisfying this property is called a strongly consistent estimator. One may also be interested, among other properties of the estimator, in the asymptotic distribution of $\tilde{\lambda}(N)$ as $N \to \infty$. Note that these convergence properties of the estimator $\tilde{\lambda}(N)$ are substantially different from those of an instance λ_m of the Baum algorithm. While the first case studied stochastic convergence of the estimator as more and more data become available, the second case studied deterministic convergence of an iterative algorithm for given fixed training data. Baum and colleagues have studied both aspects of convergence; Baum et al. (1970) established similar convergence properties of λ_m to those developed by Wu (1983) for two special models. Baum and Petrie (1966) verified the strong consistency and asymptotic normality of the ML sequence of estimates $\tilde{\lambda}(N)$ for HMMs with discrete observable random variables and stationary and ergodic Markov chains. Strong consistency holds for HMMs with continuous observable random variables under some additional regularity conditions (Leroux 1992). Note that ML

estimation may not be achieved by the Baum algorithm, for example, when the likelihood function has multiple local maxima.

The Re-Estimation Formulas

Maximization of the auxiliary function $Q(\tilde{\lambda}, \lambda_m)$ in (5) results in the so-called re-estimation formulas for the parameter set of the HMM, since they provide a new estimate of the parameter set in term of an old estimate of that set. These re-estimation formulas can be conveniently described using the posterior probabilities $q(s_{n-1}, s_n | \boldsymbol{y}_0^N, \lambda_m)$ of the Markov state pair (s_{n-1}, s_n) calculated from an HMM with parameter set λ_m and the training sequence $\boldsymbol{y}_0^N$. Specifically, maximization of (4) over $\tilde{\pi}$ and $\tilde{a}_{ij}$ for a given λ_m results in the following re-estimation formulas:

$$\pi_j(m+1) = q\big(s_0 = j | \boldsymbol{y}_0^N, \lambda_m\big), \tag{6}$$

$$a_{ij}(m+1) = \frac{\sum_{n=1}^{N} q\big(s_{n-1} = i,\ s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)}{\sum_{j=1}^{M}\sum_{n=1}^{N} q\big(s_{n-1} = i,\ s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)}. \tag{7}$$

For HMMs with Gaussian conditional PDFs, the re-estimation formulas for the mean vector $\boldsymbol{\mu}_j$ and the covariance matrix $\boldsymbol{R}_j$, respectively, are given by

$$\boldsymbol{\mu}_j(m+1) = \frac{\sum_{n=0}^{N} q\big(s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)\boldsymbol{y}_n}{\sum_{n=0}^{N} q\big(s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)} \tag{8}$$

and

$$\boldsymbol{R}_j(m+1) = \frac{\sum_{n=0}^{N} q\big(s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)\Big(\boldsymbol{y}_n - \boldsymbol{\mu}_j(m)\Big)\big(\boldsymbol{y}_n - \boldsymbol{\mu}_j(m)\big)^T}{\sum_{n=0}^{N} q\big(s_n = j | \boldsymbol{y}_0^N, \lambda_m\big)} \tag{9}$$

Note that the posterior probability $q(s_n | \boldsymbol{y}_0^N, \lambda)$ is obtained from summing $q(s_{n-1}, s_n | \boldsymbol{y}_0^N, \lambda)$ over all possible values of s_{n-1}. Efficient recursive calculation of $q(s_{n-1}, s_n | \boldsymbol{y}_0^N, \lambda)$ can be performed by using the forward-backward formulas as shown next.

The Forward-Backward Formulas

Let $F(s_n, \boldsymbol{y}_0^N)$ and $B(\boldsymbol{y}_{n-1}^N | s_n)$, $n = 0, 1, \ldots, N$, denote, respectively, the forward and backward probability functions. The definitions of these functions and their recursive calculation are as follows:

$$F(s_0,\ \boldsymbol{y}_0) \stackrel{\Delta}{=} p(s_0,\ \boldsymbol{y}_0 | \lambda) = \pi_{s_0} p(\boldsymbol{y}_0 | s_0) \tag{10}$$

$$\begin{aligned} F\big(s_n,\ \boldsymbol{y}_0^n\big) &\stackrel{\Delta}{=} p\big(s_n,\ \boldsymbol{y}_0^n | \lambda\big) \\ &= \sum_{s_{n-1}} F\big(s_{n-1},\ \boldsymbol{y}_0^{n-1}\big) a_{s_{n-1}s_n} p(\boldsymbol{y}_n | s_n) \\ &0 < n \le N; \end{aligned} \tag{11}$$

$$\begin{aligned} B\big(\boldsymbol{y}_{N-1}^N | s_N\big) &\stackrel{\Delta}{=} 1, \\ B\big(\boldsymbol{y}_{n-1}^N | s_n\big) &\stackrel{\Delta}{=} p\big(\boldsymbol{y}_{n-1}^N | s_n\big) \\ &= \sum_{s_{n-1}} B\big(\boldsymbol{y}_{n-2}^N | s_{n-1}\big) \alpha_{s_n s_{n-1}} p(\boldsymbol{y}_{n-1} | s_{n-1}), \\ &0 \le n < N. \end{aligned} \tag{12}$$

These relations straightforwardly result by considering the PDF or PMF $p(\boldsymbol{y}_0^N | \lambda)$ given in (1). Note that $F(s_n, \boldsymbol{y}_0^N)$ and $B(\boldsymbol{y}_{n-1}^N | s_n)$ are referred to as the forward and backward probability functions, since strictly speaking they are neither PDFs nor PMFs.

Using the forward and backward probability functions, it can be shown that the desired state posterior probabilities are given by

$$q\big(s_{n-1},\ s_n | \boldsymbol{y}_0^N,\ \lambda\big) = \frac{F\big(s_{n-1},\ \boldsymbol{y}_0^{n-1}\big) B\big(\boldsymbol{y}_{n-1}^N | s_n\big) \alpha_{s_{n-1}s_n} p(\boldsymbol{y}_n | s_n)}{\sum_{s_{n-1},\ s_n} F\big(s_{n-1},\ \boldsymbol{y}_0^{n-1}\big) B\big(\boldsymbol{y}_{n-1}^N | s_n\big) \alpha_{s_{n-1}s_n} p(\boldsymbol{y}_n | s_n)} \tag{13}$$

for $0 < n \le N$, and by

$$q(s_n | N,\ \lambda) = \frac{F\big(s_n,\ \boldsymbol{y}_0^n\big) B\big(\boldsymbol{y}_{n-1}^N | s_n\big)}{\sum_{s_n} F\big(s_n,\ \boldsymbol{y}_0^n\big) B\big(\boldsymbol{y}_{n-1}^N | s_n\big)} \tag{14}$$

for $0 \le n \le N$.

Equations (10)–(14) provide an efficient recursion for calculating the state posterior probabilities required by the re-estimation formulas (6)–(9). Moreover, by definition of the forward probability function,

$$p\left(\mathbf{y}_{\mathbf{0}}^{\boldsymbol{N}}|\lambda\right) = \sum_{s_N} F\left(s_N,\ \mathbf{y}_0^N\right). \tag{15}$$

Thus evaluation of the likelihood function using the forward formula (10) can be performed using only $2NM^2 + M$ multiplications, in contrast with the $(2N - 1)M^{N+1}$ multiplications required by direct calculation of $p(\mathbf{y}_{\boldsymbol{0}}^{\boldsymbol{N}}|\tilde{\lambda})$. Thus, the forward formula enables calculation of the likelihood function with linear rather than exponential complexity as a function of N.

Hierarchical Production Planning

Arnoldo C. Hax
Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

Production management encompasses a large number decisions that affect several organizational echelons. These decisions can be grouped into three broad categories:

1. Strategic decisions, involving policy formulation, capital investment decisions, and design of physical facilities.
2. Tactical decisions, dealing primarily with aggregate production planning.
3. Operational decisions, concerning detailed production scheduling issues.

These three categories of decisions differ markedly in terms of level of management responsibility and interaction, scope of the decision, level of detail of the required information, length of the planning horizon needed to assess the consequences of each decision, and degree of uncertainties and risks inherent in each decision. These considerations have led to the favoring of a hierarchical planning system to support production management decisions, which guarantees an appropriate coordination of the overall decision-making process but, at the same time, recognizes the intrinsic characteristics of each decision level.

Hierarchical Production Planning

The basic design of a hierarchical planning system includes the partitioning of the overall planning problem, and the linkage of the resulting subproblems.

An important input is the number of levels recognized in the product structure. Three different levels are identified:

1. *Items* are the final products to be delivered to the customers. They represent the highest degree of specificity regarding the manufactured products.

   A given product may generate a large number of items differing in characteristics such as color, packaging, labels, accessories, size, and so on.
2. *Families* are groups of items which share a common manufacturing setup cost. Economies of scale are accomplished by jointly replenishing items belonging to the same family.
3. *Types* are groups of families whose production quantities are to be determined by an aggregate production plan. Families belonging to a type normally have similar costs per unit of production time, and similar seasonal demand patterns.

These three levels are required to characterize the product structure in many batch-processing manufacturing environments. In this section, a hierarchical planning system is proposed based on these three levels of item aggregation.

The first step in the hierarchical planning approach is to allocate production capacity among product types by means of an aggregate planning model. The planning horizon of this model normally covers a full year in order to take into proper consideration the fluctuation demand requirements for the products. The use of a linear- programming model is advocated at this level.

The second step in the planning process is to allocate the production quantities for each product type among the families belonging to that type by disaggregating the results of the aggregate planning model only for the first period of the planning horizon. Thus, the required amount of data collection and data processing is reduced substantially. The disaggregation assures consistency and feasibility among the type and family production decisions and, at the same time, attempts to minimize the total setup costs incurred in the production of families. It is only at this stage that setup costs are explicitly considered.

Finally, the family production allocation is divided among the items belonging to each family. The objective of this decision is to maintain all items with inventory levels that maximize the time between family setups. Again, consistency and feasibility are the driving constraints of the disaggregation process.

Figure 1 shows the overall conceptualization of the hierarchical planning effort.

Aggregate Production Planning for Product Types

Aggregate production planning is the highest level of planning in the production system, addressed at the product-type level. Any aggregate production planning model can be used as long as it adequately represents the practical problem under consideration. The following simplified linear program is considered at this level:

Problem P

Minimize

$$\sum_{i=l}^{I}\sum_{i=l}^{T}\left(c_{it}X_{it}+h_{i,t+L}I_{i,t+L}\right)+\sum_{i=l}^{T}\left(r_lR_l+o_lO_l\right)$$

subject to

$$X_{it}-I_{i,l+L}+I_{i,l+L-1}=d_{i,t+L}\quad i=1,\ \ldots,\ I;\ t=1,\ \ldots,\ T$$

$$\sum_{i=l}^{I}m_tX_{it}=O_t+R_t\qquad t=1,\ \ldots,\ T$$

$$R_t\le(rm)_t\qquad t=1,\ \ldots,\ T$$

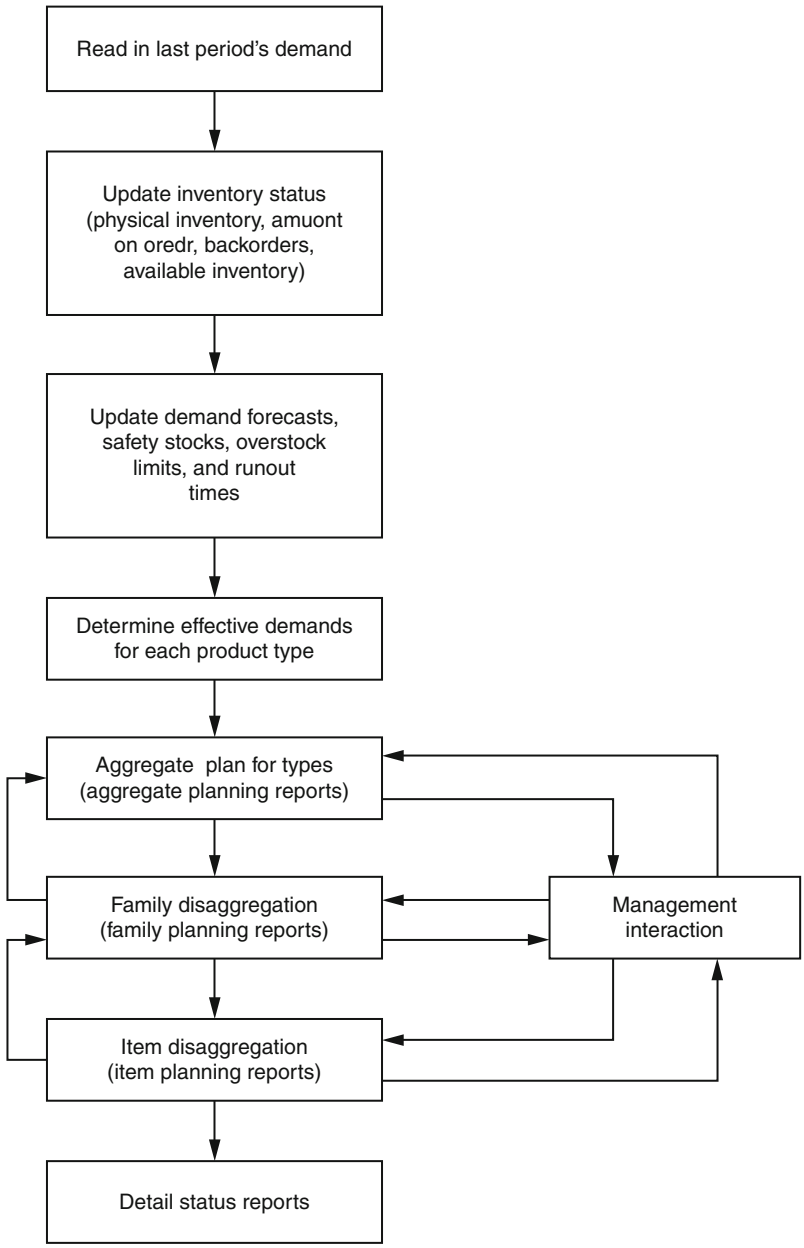
$$O_t\le(om)_t\qquad t=1,\ \ldots,\ T$$

$$X_{it}I_{i,t+L}\ge 0\qquad i=1,\ \ldots,I;\ t=1,\ \ldots,\ T$$

$$R_t,\ O_t\ge 0\qquad t=1,\ \ldots,\ T.$$

The decision variables of the model are: X_{it}, the number of units to be produced of type i during t; $I_{i,t+L}$, the number of units of inventory of type i left over at the end of period $t + L$: and R_t and O_t, the regular hours and the overtime hours used during period t, respectively.

The parameters of the model are: I, the total number of product types; T, the length of the planning horizon; L, the length of the production lead time; c_{it}, the unit production cost (excluding labor); h_{it}, the inventory carrying cost per unit per period; r_t and o_t, the cost per man-hour of regular labor and of overtime labor; $(rm)_t$ and $(om)_t$, the total availability of regular hours and of overtime hours in period t, respectively; and m_i, the inverse of the productivity rate for type i in hours/unit; $d_{i,t+L}$ is the effective demand for type i during period $t + L$.



Hierarchical Production Planning, Fig. 1 Conceptual overview of hierarchical planning system

Because of the uncertainties present in the planning process, only the first time period results of the aggregate model are implemented. At the end of every time period, new information becomes available that is used to update the model with a rolling planning horizon of length T. Therefore, the data transmitted from the type level to the family level are the resulting production and inventory quantities for the first period of the aggregate model. These quantities will be disaggregated among the families belonging to each corresponding type.

The Family Disaggregation Model

The central condition to be satisfied at this level for a coherent disaggregation is the equality between the sum of the productions of the families in a product type

and the amount dictated by the higher level for this type. This equality will assure consistency between the aggregate production plan and the family disaggregation process. This consistency is achieved by determining run quantities for each family that minimize the total setup cost among families.

Bitran and Hax (1977, 1981) proposed the following model for family disaggregation which has to be solved for every product type i and gives rise to a continuous knapsack problem:

Problem P_i

$$\begin{aligned} \text{Minimize} \quad & \sum_{j \in J^0} \left(s_j d_j | Y_j\right) \\ \text{subject to} \quad & \sum_{j \in J^0} Y_j = X_i^* \\ & lb_j \le Y_j \le ub_j \quad \left(j \in J^0\right) \end{aligned}$$

where Y_j is the number of units of family j to be produced; s_j is the setup cost for family j; d_j is the forecast demand (usually annual) for family j; lb_j and ub_j are lower and upper bounds for the quantity Y_j; and X_i^* is the total amount to be allocated among all the families belong to type i. The quantity X_i^* has been determined by the aggregate planning model and corresponds to the optimum value of the variable X_{i1} since only the first-period result of the aggregate model is to be implemented.

The lower bound lb_j, which defines the minimum production quantity for family j, is given by:

$$lb_j = \max\left[0,\ \left(d_{j,1} + d_{j,2} + \cdots + d_{j,L+1}\right) - AI_j + SS_j\right],$$

where $d_{j,1} + d_{j,2} + \ldots + d_{j,L+1}$ is the total forecast demand for family j during the production lead time plus the review period (assumed equal to one); AI_j is the current available inventory for family j (equal to the sum of the physical inventory and the amount on order minus the backorders); and SS_j is the required safety stock. The lower bound lb_j guarantees that any backorder will be caused by forecast errors beyond those absorbed by the safety stock SS_j.

The upper bound ub_j is given by:

$$ub_j = O\ S_j - AI_j,$$

where OS_j is the overstock limit of family j.

The objective function of problem P_i assumes that the family run quantities are proportional to the setup cost and the annual demand for a given family. This assumption, which is the basis of the economic order quantity formulation, tends to minimize the average annual setup cost. Notice that the total inventory carrying cost has already been established in the aggregate planning model; therefore, it does not enter into the current formulation.

The first constraint of problem P_i,

$$\sum_{j \in J^0} Y_j = X_i^*$$

assures the equality between the aggregate model input X^*_i and the sum of the family run quantities.

Initially, J^o contains only those families which trigger during the current planning period. A family is said to trigger whenever its current available inventory cannot absorb the expected demand for the family during the production lead time plus the review period, that is, those families whose current available inventory is such that

$$AI_j < \left(d_{j,1} + d_{j,2} + \cdots + d_{j,1}\right) + SS_j.$$

Equivalently, one can define J^o as containing all those families whose run out times are less than one time period, that is,

$$ROT_j = \frac{AI_j - SS_j}{\sum_{t=1}^{L+1} d_{j,t}} < 1.$$

It is necessary to start production for these families in order to avoid future backorders. All other families are put on a secondary list and will be scheduled only if extra capacity is available. Bitran and Hax (1977) proposed an efficient algorithm to solve problem through a relaxation procedure.

The Item Disaggregation Model

For the period under consideration, all the costs have already been determined in the former two levels, and any feasible disaggregation of a family run quantity has the same total cost. However, the

feasible solution chosen will establish initial conditions for the next period and will affect future costs. To save setups in future periods, one could distribute the family run quantity among its items in such a way that the run out times of the items coincide with the run out time of the family. A direct consequence is that all items of a family will trigger simultaneously. To attain this objective, the use of the following strictly convex knapsack problem is proposed for each family j.

Problem P_j

Minimize

$$\frac{1}{2}\sum_{k\in K^0}\left[\frac{Y_j^*\sum\limits_{k\in K^0}(AI_k - SS_k)}{\sum\limits_{k\in K^0}\sum\limits_{t=1}^{L+1} d_{k,l}} - \frac{Z_k + AI_k - SS_k}{\sum\limits_{t=1}^{L+1} d_{k,l}}\right]^2$$

subject to

$$\sum_{k\in K^0} Z_k = Y_j^*$$

$$Z_k \le OS_k - AI_k$$

$$Z_k \ge \max\left[0,\ \sum_{t=1}^{L+1} d_{k,l} - AI_k + SS_k\right]$$

where Z_k is the number of units to be produced of item k; AI_k , SS_k , and OS_k are, respectively, the available inventory, the safety stock, and the overstock limit of item k; $d_{k,t}$ is the forecast demand for item k in period t; $K^o = \{1, 2, \ldots, j\}$; and, Y_j^* is the total amount to be allocated for all items belong to family j. The quantity Y^* was determined by the family disaggregation model.

The first constraint of problem P_j requires consistency in the disaggregation from family to items. The last two constraints are the upper and lower bounds for the item run quantities. These bounds are similar to those defined for the family disaggregation model in the previous section.

The two terms inside the square bracket of the objective function represent, respectively, the run out time for family j and the run out time for an item k belonging to family j (assuming perfect forecast). The minimization of the square of the differences of the run out times will make those quantities as close as possible. (The term 1/2 in front of the objective function is just a computational convenience.)

For a description of the algorithm recommended to solve this problem, as well as a discussion on performance of the hierarchical production planning model, the reader is referred to Hax and Candea (1984).

Higher Education

James C. Hearn[1] and James W. Morrison[2]
[1]University of Georgia, Athens, GA, USA
[2]University of Notre Dame, Notre Dame, IN, USA

Introduction

Until the mid-1960s, rigorous planning techniques and serious attention to campus resource allocations were relatively uncommon in higher education. Expansionist institutions were flush with both students and public support. In the ensuing years, however, academic administrators' interest in better management techniques was heightened by the increasing size and complexity of academic organizations and by persuasive warnings of shrunken public financing and reduced numbers of college-going young people. By the early 1980s, college and university operations were a well-established locus of interest among OR/MS professionals.

Since that time, there has been a continued diffusion of analytic innovations and decision support systems within higher education, and operations research and management science have become increasing important in those settings. Business intelligence software, academic space planning tools, enrollment-management systems, and smart-grid technologies are just a few of the OR/MS applications enabling institutions to streamline operations and improve overall efficiency and effectiveness.

Historical Background

The earliest appearance of modern OR/MS applications in higher education came in the development of formal planning and budgeting models for institutions and systems. The first planning model, CAMPUS (Comprehensive Analytical Methods for Planning University Systems), began in 1964 at the University of Toronto. CAMPUS was part of an attempt to build a computer-based econometric model simulating cost patterns in Canadian universities. Early versions of CAMPUS required extensive data input and placed great demand on computer capacity, making widespread use by a number of colleges and universities virtually impossible. CAMPUS clearly demonstrated, however, the feasibility of developing useful planning and decision-making tools for postsecondary institutions.

Among the first budgeting processes was the planning, programming, and budgeting systems approach (PPBS). PPBS was initially developed by the RAND Corporation for use by the Department of Defense, but was adopted by many higher-education institutions in the early 1960's. The purpose of PPBS was to connect programmatic information to planning and budgetary decision making, and in higher education it represented one of the earliest efforts to tighten couplings among the academy's historically fragmented structures and processes.

In the late 1960s, planning and budgeting models began to proliferate. With funding from the U.S. Office of Education, the National Center for Higher Education Management Systems (NCHEMS) developed RRPM (the Resource Requirements Prediction Model), a computer-simulation model aimed at providing institutions detailed information on costs and resource requirements for establishing and maintaining academic programs. In Europe, two significant planning models emerged: the HIS (Hochschule Information System) in West Germany and the TUSS (Total University Simulation System) in Holland. HIS and TUSS focused mainly on the efficient use of instructional space and certain other aspects of academic operations. As such, they were less ambitious than the North American models of the time, and much less powerful than the models soon to come.

In 1977, Stanford University developed a computer-based financial planning model called TRADES to assist administrators in forecasting income and expenses. True to its name, the TRADES model focused on the trade-offs facing campus leaders. Specifically, it allowed the user to manipulate certain Primary Planning Variables (such as the number of faculty, the number of admitted students, or the level of utility rates), plus approximately 200 other variables to create what-if scenarios for any variety of campus and environmental conditions. Because it was interactive, fast, and extraordinarily comprehensive in scope, the TRADES model represented a distinct advance for the field. Soon, Stanford's Academic

Planning Office produced a generalized version for use in other institutions: GENTRA (GENeralized TRAdes). The TRADES and GENTRA models were the first to handle the large volume of tedious calculations involved in systematic, holistic financial forecasting. As a consequence, the models gave their users greater freedom to focus directly on core issues in institutional planning. In subsequent years, Stanford's pioneering models were both adapted and imitated. Perhaps the best known of the descendant models is EFPM, the EDUCOM Financial Planning Model. Developed in the late 1970s by the EDUCOM consortium of over 350 U.S. colleges and universities, EFPM provided a sophisticated financial projection system.

Beginning in the mid-1990's, developments in computing and online technologies dramatically expanded and diversified OR/MS applications within the higher-education sector (McClure 2005). Institutions' internal management systems were varied and resided on a wide assortment of hardware platforms, operating systems, and databases, however. Responding to the proliferation of incompatible homegrown systems emerging within different administrative units on campuses, universities began to adopt Enterprise Resource Planning (ERP) systems to consolidate and streamline operations and improve end-to-end connectivity (Stevens 2003). As Murphy (2004, p. 29) noted, ERP systems hold potential to "integrate disconnected business operations such as student administration, human resources, and financial systems that have been previously handled by disparate legacy systems, while satisfying the need for real-time, on-demand information.

Although OR/MS applications have been employed for over half a century in higher education, colleges and universities have generally lagged in adoptions of approaches popularized in other organizational sectors. Those lags have both been sensible and restricting. On one hand, fund accounting, systematic asset management, and other innovations have successfully been imported from business to higher education. Yet many applications have achieved only marginal success, including performance-based and zero-based budgeting, total quality management, and process reengineering. Birnbaum (2000) argue persuasively that many of these management and analytic innovations are merely fads borrowed from business or government without full consideration of their limitations within the university's distinctive organizational structures, processes, and cultures. Consequently, imported management approaches often have a limited life cycle and only brief popularity in higher education before abandonment. Inevitably, though, it seems that every failed import is soon followed by the introduction of some other idea novel to the setting.

While imported management processes and systems have had limited success in higher education, universities increasingly rely on OR/MS applications to support core operational functions. In financial and business process management, such applications aid in financial planning and modeling, budget systems, asset management, quality management, enterprise resource planning, business process design, and institutional development and fund raising. OR/MS techniques have been extensively utilized in facilities planning and management in such domains as space planning, energy management, and campus master planning. In institutional effectiveness efforts, OR/MS has been applied in institutional research and assessment, business intelligence and action analytics, strategic planning, enrollment management, and retention management. In risk management, managers have paid growing attention to crisis preparedness and business continuity. And, in research management, regulatory compliance has become a focus of systems development.

The Literature

Literature on the uses of OR/MS approaches in higher education falls into three general categories: 1) general reviews of OR/MS applications in higher education; 2) specialized essays and research reports; and 3) case studies, technical papers, and presentations produced by consultants, vendors, end users, and specialized industry associations. Selected work in each of these arenas merits attention here.

Schroeder (1973) provided an excellent early example of general reviews of OR/MS applications in higher education. The author critically surveyed work on Program Planning Budgeting Systems (PPBS); management information systems (MIS); resource-allocation models; and mathematical models for enrollment planning, faculty staffing, and optimization of resource use. Wilson (1981) provided

a less technical piece in this same vein, with eight short, well-documented articles describing actual and proposed applications. Around the same time, Hussain (1976) and Bleau, (1981b) produced thorough reviews of the packaged planning models being developed then for higher education, including CAMPUS, RRPM, HIS, TUSS, TRADES, and EFPM.

In this period, two classic, comprehensive works on OR/MS applications in higher education appeared: Halstead (1974) and Hopkins and Massy (1981). The Halstead book focused on the planning efforts of state-level postsecondary officials, and paid special attention to forecasting revenues and costs and examining alternative possible uses of scarce state resources. The Hopkins and Massy book, in contrast, addressed central financial issues facing individual institutions. The authors defined financial planning models, outline what these models could reasonably be expected to accomplish, specified how to build the necessary models, and offered historical background on Stanford University's experience in developing and applying planning models. Both of these books became widely cited in the field and are useful references.

Later in the 1980s, improvements in software-based decision-support systems (DSS) made the use of complex planning models more accessible and attractive to administrators not trained in technical applications. Rohrbaugh and McCartt (1986) presented a solid overview of the emerging uses of DSS in higher education at that time, considering such topics as Markov-based decision-support applications, formal decision models, tactical and strategic decision making, system-dynamics simulation models, and alternative approaches for evaluating decision processes. At around the same time, Yancey (1988) provided a comprehensive overview of the statistical methods then being employed by institutional research (IR) offices on campus, and White (1987) provided a useful listing of publicly known OR/MS applications in higher education, classifying extant applications along six dimensions: (1) administrative level, (2) primary purpose of the model, (3) program type, (4) techniques used, (5) resources being allocated, and (6) implementation.

Hoenack and Collins (1990) provided an important contribution focusing theoretically and practically on decision making and planning on campuses. Employing concepts from both economics and OR/MS, the book's contributing authors reviewed thinking on resource allocation, decision processes and priorities, incentive structures, fiscal environments, and cost functions. William Becker, in an especially valuable chapter in the volume, examined the extensive econometric research on students' sensitivity to institutional prices and considered the implications of that research for institutional and system-wide planning efforts. In a less ambitious but similarly framed review, Cheng (1993) explored the impacts of OR techniques on higher-education administration across a variety of functional areas, prominently including resource allocation, budgeting, registration, academic scheduling, and tuition-setting.

As technological developments of the past decade have further lowered costs and expanded information availability on campuses, numerous reviews have focused the uses and analysis of institutional data. Most prominently, McLaughlin et al. (2004) provided a comprehensive overview on the conceptual and theoretical framework for managing institutional data, including the emerging use of innovative technologies to improve data quality, streamline reporting systems, and enhance planning, assessment, and data-driven decision making processes.

Specialized essays and research reports comprise a second category of relevant OR/MS literature. Among the earliest applications of OR/MS in colleges and universities were efforts to improve facilities management, notably including increasing efficiency in buildings and grounds use and maintenance, identifying and analyzing new facility requirements, improving space utilization, examining inventory patterns, projecting demand, and decreasing energy consumption. Facilities planners have to act in the context of an institution's multiple, sometimes conflicting goals of teaching, research, and service, creating a need for sophisticated multi-objective analytic techniques (Ritzman et al. 1979).

While facilities management continues to be a major concern on campuses, it is increasingly incorporated into broader, human-resource modeling, including enrollment management. Large institutions require sophisticated models for scheduling, loading, and controlling students' course enrollments across different physical locations. Similarly, planning for short and long-term faculty and staff needs creates challenges because of ongoing changes in legal and financial conditions and changes surrounding

employment. Before the 1980s, OR/MS approaches to enrollment and employment forecasting largely extrapolated historical data into the near and long-term future (Cox and Jesse 1981), but subsequent approaches have incorporated far more variables and more advanced statistical techniques, including Markov chain methods (Bleau 1981a).

Beyond facilities and human-resource management lie OR/MS-based analyses of many topics relating to quality assessment, assurance, and improvement. Performance issues have long been prominent topics in higher education, and OR/MS work has contributed integrally to quality analysis. Dressell (1976) argued that such techniques as program budgeting, management by objectives (MBO), cost-benefit analysis, MIS, Program Evaluation Review Technique (PERT), and PPBS could provide logical, systematic, comprehensive, and, above all, rational support for evaluation and assessment processes. Although preferred techniques have evolved appreciably over the years, Dressel's early observations proved prescient. In an era in which institutions are being held to increasingly difficult accountability standards, evaluation and assessment have become central important aspects of administration on virtually every campus.

Much of the work on quality assessment, assurance, and improvement in higher education has focused on efficient and effective resource allocation and management, and on the tools needed to achieve those goals. Lee and Van Horn (1983) proposed improving institutional management through joining administration-by-objectives with goal programming, and included useful technical analyses of several resource-allocation modeling approaches. Lewis (1988) reviewed academic-program assessment efforts as of the 1980s and argued that they might be cast more productively in cost-effectiveness terms. His conceptual and empirical work provided directions for later work in that vein, as cost concerns became increasingly pressing.

In the mid-1990s, Geraint and Jill Johnes at Lancaster University's management school focused on funding, pricing, and cost issues in British higher education. G. Johnes (1996) used production theory and multiple-regression and stochastic-frontier techniques to estimate institutions' multi-product cost functions. J. Johnes (1996) explored potential ways to produce comparative indices of institutional performance taking into account substantial differences in inputs. Ryan (2004) pursued similar themes, examining relationships between inputs, in terms of expenditures on varied production factors, and outputs in degree-production terms. His results suggest that relationships between spending and outputs over time, across a wide set of institutions, are positive and merit greater attention in models of student persistence and graduation rates. Lavieri, Puterman and colleagues addressed similar issues in workforce planning: they applied linear programming to Canadian healthcare workforce data to support health human resources (HHR) planning (Lavieri et al. 2008), and used a linear-programming-based hierarchical planning model in pursuit of optimal training, promoting, and recruiting for Canadian nurses over a two-decade period (Lavieri and Puterman 2009).

Work by Welsh and Metcalf (2003) critically examined the institutional effectiveness perspective on quality. Arguing that management efforts to improve quality have consistently failed, despite increased external pressures for change and accountability, the authors maintain that the institutional-effectiveness concept holds the potential to become institutionalized within higher education, rather than another passing fad. Their empirical analysis found that faculty and administrators hold differing perceptions regarding the importance of pursuing institutional effectiveness, owing to ideological and historical factors. They nevertheless contend these resistances may be overcome through careful planning and collaboration, and suggest a variety of OR/MS-related approaches that may prove useful in improving quality assessment and achieving campus-wide support.

Much empirical OR/MS work in higher education has centered on DSS. Often, such work is not published in readily available outlets, but there are exceptions. Stallaert (1997) reported on the design and implementation of a course timetabling system for the management school at UCLA, using sophisticated integer-programming and heuristic algorithms. The author and his dean reported major scheduling efficiency improvements from the initiative (p. 81). Similarly, Darroch and Toleman (2006) explored the implementation of a learning management system in an online education environment for an Australian university. Learning management systems (LMS) are

specialized, integrated software toolsets, developed specifically for the support of online course delivery (Turban et al. 2005). Familiar examples include WebCT and Blackboard. The case-study suggests a number of lessons and recommendations for future LMS implementations. Finally, Maltz et al. (2007) found that a DSS system dramatically improved enrollment management at a small liberal arts college. Both responsiveness and real-time management improved, and knowledgability increased among key administrators, leading to attainment of several strategic enrollment objectives.

Of all the empirical work using OR/MS in higher education since the 1990s, perhaps no approach has consumed greater attention than data envelopment analysis (DEA). This is unsurprising, given the heavy attention to the topic in OR/MS more generally in the preceding years (Seiford 1997; Sarafoglou 1998). DEA is an analytical procedure for measuring the relative efficiency of decision making units performing similar functions with similar goals and objectives. Noting the special characteristics of higher-education systems, institutions, and units, Ahn et al. (1988a) and Ahn et al. (1988b) compared DEA-generated efficiency indexes across sizable samples of public and private U.S. colleges and universities. Somewhat later, Ahn and Seiford (1993) provided an especially useful examination of the history and development of the DEA approach, in the context of further analyses of inter-institutional efficiency.

Tomkins and Green (1988) provided one of the earliest efforts to examine the uses of DEA in academic departments and centers, as opposed to institutions as a whole. Focusing on university accounting departments in the U.K., they cautioned that there are inevitably concerns over data quality in such analyses, and that efforts to incorporate judgments of scholarly performance can raise concerns over subjectivity. Nevertheless, they concluded that comparable efficiency scores could be reliably and productively calculated for academic units.

Shortly after the Tomkins and Green analysis, DEA research on academic departments began to proliferate. Beasley (1990) provided a DEA model for comparing university departments in chemistry and physics departments in the U.K. Sinuany-Stern et al. (1994) produced a useful exploration of a range of academic departments in Israel, and Sarafoglou and Haynes (1996) did the same for business and economic departments in Sweden. Friedman and Sinuany-Stern (1997) added consideration of Canonical Correlation Analysis (CCA) to the use of DEA, aiming to provide full-rank scaling for all units rather than simple classification into efficient and inefficient units alone. Attempting to bridge the gap between the frontier approach of DEA and the mean-tendencies approach of econometrics, the authors noted some problems, but some promise in this approach as well.

Colbert et al. (2000) used DEA to determine the relative efficiency of 24 top ranked U.S. MBA programs. Focusing on output that measured student satisfaction, output that measured recruiter satisfaction, and output that measured both, the authors sought to compare the relative efficiency scores of certain foreign and U.S. MBA programs. The authors note numerous data issues limiting the analysis, but conclude that new rankings based on DEA would "more completely and accurately represent MBA programs [and]. . . make it possible to more fairly compare specific programs" (p. 668).

In an effort to allow effective cross-disciplinary efficiency analyses, Moreno and Tadepalli (2002) used DEA for evaluating the efficiency of a diverse sample of academic departments at a public university in the U.S. Arguing that such analyses are imperative in the increasingly accountability-driven political context of the U.S., the authors suggested that computation of a single summary measure of relative unit efficiency, across different fields, may become central in ongoing debates over resource allocation. They concluded, however, that numerous conceptual and methodological issues require attention before summary measures can be used most effectively on a given campus or across campuses.

Acknowledging such difficulties, Korhonen et al. (2001) focused on the output measurement issues that have constrained earlier work using DEA. These authors sought to combine DEA and decision maker preferences into what they term a Value Efficiency Analysis of academic research performance at universities and research institutes. The analysts suggest that their work defines the efficiency of research units "in the spirit of . . . DEA, complemented with decision maker's . . . preference information" (p. 121). Preferences were obtained by asking leaders to "locate a point on the efficient

frontier having the most preferred combination of input and output values" (p. 121). The authors conclude that this approach has real promise for addressing in difficult issues central to the further development and assessment of disciplinary units in European universities.

J. Johnes (2006) identified and attempted to resolve a methodological problem plaguing earlier DEA analyses at the unit and institutional level. Noting that prior analyses of teaching efficiency have been aggregated across students, which tends to blur individual and organizational contributions, Johnes argued that "analysis at the individual level can give institutions insight into whether it is the students' own efforts or the institution's efficiency which are a constraint on increased efficiency" (p. 443). Her empirical work on a sample of economics graduates and units in U.K. universities supports that conclusion, and casts doubt on the utility of aggregated DEA analyses, which have long been the norm in the field.

The third category of relevant OR/MS literature in higher education is case studies, technical papers, and presentations produced by consultants, vendors, end users, and specialized industry associations. This knowledge base has grown along with the rapid expansion and diversification of commercialized management tools and software. Technology companies and industry experts often produce research to differentiate themselves from their competitors, while institutional administrators increasingly become engaged in specialized learning communities to exchange information and share best practices on emerging topics in the industry. The result has been a growing literature base not reflected in traditional journal and book outlets.

Among the higher-education associations providing relevant OR/MS research and technical reports are the Web-based groups EduCause, the Society for College and University Planning (SCUP), and the Association for Institutional Research (AIR). EduCause is a nonprofit association supporting information-technology professionals in higher education. EduCause's online resource center provides an information repository concerning the use and management of information technology in higher education, including applied research and case studies on OR/MS topics. SCUP and AIR are professional associations for decision makers, planners, and management analysts in higher education. Both provide numerous online and paper resources on OR/MS uses in higher education.

Beyond the associations, individual vendors often produce reports regarding their products' performance, sometimes in conjunction with end users. Such industry-funded efforts must necessarily be evaluated with awareness of the self-interests involved, of course. Unfortunately, there are few independent and objective publicly available analyses of the performance of vendors' products (Birnbaum 2000).

The Complexity of OR/MS in Higher Education

Without question, some institutional leaders perceive OR/MS approaches to be too complex, too user-hostile, or too foreign to elements of their institutions' traditionally decentralized and participatory organizational culture. With that in mind, they resist implementations on the academic side of the business (i.e., curriculum decisions, hiring decisions, admissions decisions). Such views are in keeping with the distinctive organizational characteristics of colleges and universities (Birnbaum 1991). While virtually all large institutions have adopted OR/MS approaches in non-academic areas such as business operations and facilities management, it appears that openness to OR/MS approaches in academic decision making varies widely across institutions. This variation is unsurprising, given the long acknowledged differences among colleges and universities in organizational forms and processes. Earlier work (Baldridge et al. 1978; Baldridge and Tierney 1979) suggests that adoption of business-style techniques in the academic side of campus operations may come most easily to strongly hierarchical institutions, such as community colleges, vocational/technical institutions, and for-profit institutions. Power and control tend to be less centralized in liberal arts colleges and selective universities, and faculty leaders there may resist demands for stepped-up management systems. Pointedly, Birnbaum (2000) has suggested that faculty compliance in such settings may often be more symbolic, virtual, cynical, or self-interested than sincere. And many leaders may simply not pursue implementations of OR/MS techniques in areas touching closely on faculty domains.

But substantial OR/MS work does take place in higher education, and is simply not made widely visible to external audiences. This limited public availability of information regarding OR/MS applications and innovations in campus settings makes definitive conclusions about the state of the field difficult if not impossible. Several factors contribute to this dearth of information.

Notably, the rapid evolution and diversification of commercialized OR/MS applications and the short life-cycle of many management innovations adopted from industry limit the continuity and consistency necessary to collect data and conduct publishable research for traditional professional and academic outlets. Traditional research methodologies often do not align well to these timing constraints. What is more, the public visibility of institutional OR/MS work is constrained by 1) intense competition among vendors, each working to establish competitive advantage in a high-stakes, high-risk environment; 2) managerial and political demands on campuses, including the need to keep certain kinds of analyses in-house for competitive reasons; and 3) the limited professional rewards and outlets for publicly disseminating educationally oriented OR/MS work. The resulting invisibility unquestionably limits broader knowledge regarding the use, and usefulness, of OR/MS approaches.

Locally generated, limited-use techniques have found their way into the administrative portfolios of many institutions. Non-academic institutional units often operate with substantial autonomy under institutions' unique governance and management structures (Birnbaum 2000). Thus, much applied work is done on a small scale (e.g., at the level of a financial-aid office alone, rather than an entire campus), and much of that work remains unknown to those not directly involved. For example, decisions such as choosing among several options for meeting campus heating needs or designing an approach for using residence halls more efficiently are important and are clearly solvable in the OR/MS tradition, but are also constrained in scope. An institution's financial-aid office may choose to deploy business intelligence software as a data management and decision-support system or the university may develop an energy-management policy, but such initiatives may never become widely known on campus or have a significant impact on the institutional core.

Some of the most avid users of sophisticated, albeit localized, OR/MS applications work in offices of institutional research on campuses. Among the tools employed in many such offices are 1) enrollment-management techniques for monitoring and shaping the characteristics of student bodies; 2) models for assessing statistically the relative importance of various student characteristics in predicting whether newly admitted freshmen will register; 3) Markov projections and related predictive models for forecasting enrollments; and 4) student-flow models for analyzing the movement of students into or out of specific programs. Unfortunately, these efforts usually remain unknown to those outside of these specialized offices, unless targeted dissemination efforts are undertaken.

Thus, a variety of factors hamper efforts to estimate overall levels of OR/MS use, and indeed hamper efforts to more fully embed OR/MS in campus life. But, whatever the limitations, there can be no denying that OR/MS techniques and approaches can contribute to the effectiveness and efficiency of colleges and universities as they encounter the multiple opportunities and threats that are ongoing features of their environments. Increasingly, institutions are dependent on good information to frame and support decision making. The emergence of lower-cost computing, improved decision-support systems, expanded telecommunications, and smart-grid technologies all raise expectations that OR/MS applications will continue to play a central role in institutional adaptation and health.

Hirsch Conjecture

The Hirsch conjecture has a long history in linear programming. For a bounded ($m \times n$) linear-programming problem, the conjecture concerns how many simplex iterations (basis changes) are necessary in going from one extreme point to another. In a 1957 verbal communication with George B. Dantzig, Warren M. Hirsch (a probabilist from New York University who had worked earlier with Dantzig in the Pentagon) asked: "Does there exist a sequence of m or less pivot operations, each generating a new basic feasible solution, which starts with some given basic feasible solution and ends with some other given basic feasible solution, where m is the number of equations?" (Dantzig 1963, p. 160; Dantzig and Thapa 2003, pp. 25, 31, 33, 34). Over the years, there have been many attempts to prove or disprove the Hirsch conjecture; all of them were eventually shown to be false until Francisco Santos, University of Cantabria, Spain, announced and published his paper, "On a counterexample to the Hirsch conjecture, "(Santos 2010; also see De Loera 2011; Ziegler 2011).

In geometric terms, the Hirsch conjecture states that if a polytope (bounded polyhedron) is defined by n linear inequalities in d variables, then the length of the longest shortest path among all possible pairs of vertices (its diameter) should be at most ($n - d$). That is, any two vertices of the polytope may be connected to each other by a path of at most ($n - d$) edges (Santos 2010). Santos showed that the conjecture was false by constructing a 43-dimensional polytope with 86 facets and a diameter greater than 43.

Hit-and-Run Methods

Zelda B. Zabinsky[1] and Robert L. Smith[2]
[1]University of Washington, Seattle, WA, USA
[2]University of Michigan, Ann Arbor, MI, USA

Introduction

Hit-and-run is a Markov chain Monte Carlo (MCMC) sampling technique that iteratively generates a sequence of points in a set by taking steps of random length in randomly generated directions. Hit-and-run can be applied to virtually any bounded

region in $\Re^n$, and has nice convergence properties. Hit-and-run can generate a sequence of points that asymptotically approach a uniform distribution on open sets, and modifications of hit-and-run can approximate arbitrary multivariate distributions, including the Boltzmann distribution. The versatility of hit-and-run to approximate an arbitrary distribution makes it useful in a number of settings, including global optimization, identification of redundant constraints, simulation, volume estimation and integration estimation. In addition to converging to a target distribution, a good MCMC sampler will converge quickly from an arbitrary starting point, also known as rapid mixing. The mixing time of the original version of hit-and-run is polynomially bounded for convex sets, as opposed to an exponential mixing time for a ball walk.

Hit-and-run was introduced by Smith (1984) as a way to approximate uniformly distributed points in an open set, but many other uses emerged. Diverse applications of hit-and-run include: identifying non-redundant constraints in linear programs (Berbee et al. 1987); evaluation of multidimensional integrals (Chen and Schmeiser 1996); volume estimation of convex sets (Kannan et al. 1997); statistical model validation; construction of a confidence interval for Bayesian inference; discrete-event simulation (Rubinstein and Kroese 2008), and global optimization (Bertsimas and Vempala 2004; Kalai and Vempala 2006; Mete et al. 2011; Romeijn and Smith 1994; Shen et al. 2007; Zabinsky 2003; Zabinsky et al. 1992, 1993).

Hit-and-run in its simplest form is discussed next, followed by its convergence to a uniform distribution and its mixing time. Then a generalized form of hit-and-run that converges to an arbitrary target distribution is discussed, followed by specific variations and implementation considerations. Next, forms of hit-and-run that operate on discrete or mixed continuous/integer sets are discussed, as the previous algorithms assume that the set to be sampled from is continuous. The final section describes simulated annealing-type algorithms for global optimization that embed hit-and-run as a part of their sampling method.

Definition of Hit-and-Run

Hit-and-run, in its simplest form for a bounded open set S in $\Re^n$, makes a one-step transition from a point $x \in S \subset \Re^n$ to another point $y \in S$ by generating a direction vector uniformly distributed on the surface of a unit hypersphere centered around x, and then generating a point y uniformly distributed on the union of the line segments created by the intersection of a line along the direction vector and S. This line sampling is typically accomplished by employing a one-dimensional rejection method on the line segment intersected by an enclosing box for S.

Hit-and-run generates a sequence of points $\{X_k, k = 0, 1, \ldots\}$ in a bounded open set $S \subseteq \Re^n$ as follows.

Algorithm 1 (Hit-and-Run)

Step 0 Initialize $X_0 \in S$ and set $k = 0$

Step 1 Generate a random direction D_k uniformly distributed over the surface of a unit hypersphere centered around X_k.

Step 2 Generate a random point $X_{k+1} = X_k + \lambda D_k$ uniformly distributed over the line set $L_k = \{x : x \in S \text{ and } \mathrm{x} = \mathrm{X_k} + \lambda \mathrm{D_k}, \lambda \text{ a real-valued scalar}\}$.
If $L_k = \emptyset$, go to Step 1.

Step 3 If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

The hit-and-run chain has two distinguishing characteristics: (i) it is globally reaching, i.e., it can move from any point $x \in S \subset \Re^n$ to a neighborhood of any other point $y \in S$ in one step, and (ii) it can be implemented easily even when the feasible set S is defined by membership oracles. As Andersen and Diaconis (2007) describe, the algorithm "hits a point on the sphere and runs in that direction."

Smith (1984) proved that hit-and-run converges in total variation to a uniform distribution. Of course, a direct way to sample a point uniformly from S is to enclose it in a box and sample uniformly from the box until a point lands in S. Then this point is exactly uniformly distributed. However, the expected number of points sampled until one lands in S is exponential in dimension, so this is an impractical method for a large-dimensional set. Thus, Markov chain samplers become attractive as a means to approximately sample from a uniform distribution in much less time. Of the MCMC samplers, hit-and-run converges in polynomial time, and is considered to be the most efficient algorithm known to date for generating an

asymptotically uniform point in a convex set (Lovász 1999; Lovász and Vempala 2006).

The analysis of the mixing time of hit-and-run on a convex body in $\Re^n$ by Lovász (1999) assumed that the initial distribution of the Markov chain was not far from uniform, i.e., a 'warm-start'. This assumption was later relaxed, preserving hit-and-run's polynomial efficiency, making it the only known random walk that converges efficiently to a uniform distribution starting from any point inside a convex body (Lovász and Vempala 2006). In contrast, the ball walk takes an exponential time to get out of a corner. Moreover, hit-and-run was also shown to be polynomially efficient for sampling from log-concave distributions over convex bodies.

Some insight into hit-and-run's efficiency is presented by Ghate and Smith (2009), who showed that the network of points and arcs generated by hit-and-run is a small world network in which most nodes are not neighbors of one another, but most nodes can be reached from every other in a small number of steps. Thus another interpretation of hit-and-run is that it generates a small world on the fly.

Given hit-and-run's success at efficiently approximating a uniform distribution, many variations and generalizations have been developed.

Generalizations of Hit-and-Run

The most celebrated Markov chain sampler, introduced by Metropolis et al. (1953), used the idea of an acceptance-rejection step to act as a filter and bias the chain towards a Boltzmann distribution. The original hit-and-run algorithm was extended by Romeijn and Smith (1994) to converge to a target distribution π by adding an appropriate filter, and later further extended using a conditionalization on π to the one-dimensional line segment (Bélisle et al. 1993). Thus, hit-and-run converges to an arbitrary target distribution π in total variation.

Andersen and Diaconis (2007) proposed a generalization of hit-and-run algorithms for MCMC samplers and related it to the Gibbs sampler, Swendsen-Wang block spin dynamics, data augmentation, auxiliary variables, slice sampling, and the Burnside process under a unifying scheme. They describe choosing the point X_{k+1} according to the density π restricted to the line determined by the direction vector, as in Bélisle et al. (1993). The choice of the uniform distribution for direction is replaced by a general choice, and even the concept of a one-dimensional Euclidean line determined by the direction vector is generalized to include subsets of S.

The following algorithm generalizes hit-and-run with a general direction distribution and a Metropolis filter that converges to an arbitrary target distribution π on S, where ν is an absolutely continuous probability distribution defined on the surface of an n-dimensional unit sphere, with density bounded away from zero.

Algorithm 2 (Hit-and-Run for Target Distribution π)

Step 0 Initialize $X_0 \in S$ and set $k = 0$.

Step 1 Generate a random direction D_k from the direction distribution ν on the surface of a unit hypersphere centered around X_k.

Step 2 Generate a candidate point $Z = X_k + \lambda D_k$ uniformly distributed over the line set $L_k = \{x : x \in S \text{ and } \mathrm{x} = \mathrm{X_k} + \lambda \mathrm{D_k},$ λ a real-valued scalar$\}$

If $L_k = \emptyset$, go to Step 1.

Step 3 Accept or reject the candidate point Z with a Metropolis filter for the target distribution π,

$$X_{k+1} = \begin{cases} Z & \text{w.p. } \min\{1, \pi(\mathrm{Z})/\pi(\mathrm{X_k})\} \\ X_k & \text{otherwise.} \end{cases}$$

Step 4 If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

Note that if π is a uniform distribution, then all candidate points are accepted and Algorithm 1 is a special case of Algorithm 2.

Specific variations and implementations of hit-and-run are discussed next.

Variations and Implementations of Hit-and-Run

Several variations with specific direction distributions and candidate point sampling methods have been studied in the literature.

The most common direction distribution, and one that is readily implemented, is the uniform distribution on the surface of an n-dimensional hypersphere, termed hyperspherical direction (HD) in

Berbee et al. (1987); Zabinsky et al. (1992). It is easily implemented by generating n independent values $d_i, i = 1, 2, \ldots, n$ from a standard normal distribution, $N(0, 1)$ and scaling them to determine the unit direction vector D:

$$D = (d_1, d_2, \ldots, d_n) \left(\sum_{i=1}^{n} {d_i}^2 \right)^{-1/2}. \quad (1)$$

Another natural choice for direction distribution, termed coordinate direction (CD), is a uniform distribution over the n coordinate vectors (spanning $\Re^n$). Both HD and CD versions of direction choice were presented and applied to identifying nonredundant linear constraints in Berbee et al. (1987).

While hit-and-run is guaranteed to converge for a wide class of target distributions π when using the HD choice, the same is not true when using the CD choice. It is possible to construct situations where CD will not converge to π. For example, CD will fail to converge to a uniform distribution on disconnected regions with the property that some points cannot be reached from others along a sequence of coordinate direction moves.

Another modification of the direction choice, introduced by Romeijn et al. (1999), is called a reflection generator. The reflection generator was motivated by the problem of stalling, which may occur if the line intersects a small portion of the feasible set. For example, when the current point x is near a corner of a hypercube, there is a high probability that the next sample point is very close to x, and a very low probability that the next point generated is a substantial distance from x, especially when the number of dimensions is large. This problem is similar to jamming, a well-known problem in nonlinear programming. The reflection generator essentially lengthens the line associated with a chosen direction by reflecting it off the boundaries of the feasible region into the interior. This increases the probability of sampling a point far away from the current point. A general reflection generator is defined in Romeijn et al. (1999), with a straightforward component-by-component reflection implementation. Convergence results are preserved, and positive numerical experience was reported.

Kaufman and Smith (1998) exploited the robustness in direction distribution to accelerate the rate of convergence of hit-and-run. They derived a unique non-uniform direction distribution that optimizes the rate of convergence of hit-and-run to a uniform distribution on a convex set. They used sampled points to fit an ellipsoid to the convex set, and used the parameters of the ellipsoid as bootstrap parameters in the direction distribution to approximate the optimal direction distribution; calling the Markov chain artificial centering hit-and-run.

In addition to variations on choosing the direction distribution in Step 1, there are variations on choosing the random candidate point on the line in Step 2. Theoretically, the point could be chosen according to the target distribution π restricted to the line. However, in practice, this may be computationally difficult to implement. The line sampling is often referred to as step-size distribution. In hit-and-run as stated in Algorithm 1 and Algorithm 2, the step size λ is uniformly distributed on the intersection of the random bidirection with the feasible region. Other variations include a fixed step-size or a variable length interval that can shrink or expand.

A parametrized step-size distribution is used in Ghate and Smith (2009) for solving the Small World problem. The probability density function for the step-size λ is parametrized by a, and is roughly proportional to $(1/|\lambda|^a)$. When $a = 0$, the distribution is the familiar uniform sampling distribution. Ghate and Smith (2009) showed that the expected hitting time for the Small World problem is minimized when the parameter $a = 1$ for the step-size distribution, and that $a = 1$ is the unique choice of a that is scale invariant among all nonnegative values. This parameterized step-size distribution was further explored with hit-and-run in the context of global optimization.

Another consideration in implementing Step 2 is the difficulty in identifying the intersection of the line determined by the random direction, and the feasible set S, even when S is convex. Step 2 can be straightforward to implement if it is possible to determine the points of intersection on the line, i.e., find λ_{min} and λ_{max} such that $X_k + \lambda D_k \in S$ for $\lambda_{min} \leq \lambda \leq \lambda_{max}$. When S is defined by linear inequalities, or analytically invertible functions, the intersection points can be easily expressed (Zabinsky 2003). Then λ can be chosen uniformly over that interval, or according to the conditionalization of π, thus producing the random candidate point.

However, if the feasible region S is nonconvex, and/or the intersection points are not easily determined, then a common implementation is to enclose the feasible set S in a box B, or any regular shape that is easy to determine intersection points, and use a one-dimensional acceptance-rejection scheme to produce the random candidate point.

The following algorithm on an enclosing box B is a modification of hit-and-run with a general direction distribution, as in Bélisle et al. (1993), with details of the one-dimensional acceptance-rejection sampling, as provided in Kiatsupaibul et al. (2011).

Algorithm 3. (Hit-and-Run on a Box)

Step 1 Generate a random direction D_k with direction distribution ν and set $i = 1$.

Step 2 Generate $\lambda_{k,i}$ from the step-size (typically uniform) distribution on

$$R_k = \{r \in \Re : X_k + rD_k \in B\}.$$

Step 3 If $X_k + \lambda_{k,i}D_k$ is not in S, set $i = i + 1$ and return to Step 2. Otherwise, set $Z = X_k + \lambda_{k,i}D_k$.

Step 4 Accept or reject the candidate point Z with a Metropolis filter for the target distribution π,

$$X_{k+1}\begin{cases} Z & \text{w.p}\min\{1,\pi(\mathrm{Z})/\pi(\mathrm{X_k})\} \\ X_k & \text{otherwise} \end{cases}$$

Step 5 If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

The additional computation due to the one-dimensional acceptance-rejection has been analyzed by Kiatsupaibul et al. (2011) for the case when π is a uniform distribution. They show that the size of the box is not a critical factor to the overall computational effort. More precisely, bounds on the expected mixing time of hit-and-run on a box including all sample points increases only by a linear function of the box diameter (i.e., longest chord in the box).

Another variation to speed up the convergence rate and reduce the number of rejected sample points is to incorporate the shrinking algorithm, also known as a slice sampler, into hit-and-run. The idea is to shrink the interval for selecting λ, as follows.

Algorithm 4. (Hit-and-Run on a Box with Shrinking Step-Size)

Step 0 Initialize $X_0 \in S$ and set $k = 0$.

Step 1 Generate a random direction D_k with direction distribution ν, defining the step-size set as

$$R_k = \{r \in \Re : X_k + rD_k \in B\}.$$

Set $l_1^+ = max_r R_k$ and $l_1^- = min_r R_k$, and set $i = 1$.

Step 2 Generate $\lambda_{k,i}$ from the uniform distribution on the open interval (l_i^-, l_i^+).

Step 3 If $X_k + \lambda_{k,i}D_k$ is not in S, set l_{i+1}^+ and l_{i+1}^- as follows:
if $\lambda_{k,i} > 0$, set $l_{i+1}^+ = \lambda_{k,i}$ and keep $l_{i+1}^- = l_i^-$;
if $\lambda_{k,i} < 0$, set $l_{i+1}^- = \lambda_{k,i}$ and keep $l_{i+1}^+ = l_i^+$.
Then, set $i = i + 1$ and return to Step 2.
Otherwise, if $X_k + \lambda_{k,i}D_k$ is in S, set $Z = X_k + \lambda_{k,i}D_k$.

Step 4 Accept or reject the candidate point Z with a Metropolis filter for the target distribution π,

$$X_{k+1} = \begin{cases} Z & \text{w.p. } \min\{1, \pi(\mathrm{Z})/\pi(\mathrm{X_k})\} \\ X_k & \text{otherwise.} \end{cases}$$

Step 5 If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

Algorithm 4 differs from Algorithm 3 in that the step-size interval is shrinking. This shrinkage increases the probability of acceptance in Steps 2 and 3. Because every open subset S can still be reached in one step, the convergence property of the new Markov chain remains the same.

When S is convex, the iteration point process generated by Algorithm 4 is the same as that generated by Algorithm 3, so the mixing rate of the two processes is the same. However, when S is not convex, the iteration point processes from the two algorithms distribute differently, and, hence, the mixing rates may be different. Computational results in Kiatsupaibul et al. (2011) suggest that Algorithm 4 is faster than Algorithm 3 when S is not convex.

Other computational results are given in Chen and Schmeiser (1996), where empirical comparisons are made between variations of hit-and-run and other sampling methods including the Gibbs sampler.

Hit-and-run for Discrete and Mixed Continuous/Integer Sets

Given the exceptional performance of hit-and-run on continuous sets in $\Re^n$, it is natural to wonder if it can be extended to discrete sets, or mixed sets in $\Re^n \times Z^m$. The generalized line set in Andersen and Diaconis (2007) with conditions for convergence allows a wide variety of versions that converge to a target distribution. Baumert et al. (2009) provide a detailed definition of discrete hit-and-run (DHR) with mixing times for some specific classes of problems. Mete et al. (2011) introduces a variation on DHR, called pattern hit-and-run (PHR) that is efficiently implemented on both discrete and mixed continuous/integer sets. Both DHR and PHR, summarized next, maintain many of the nice convergence properties of hit-and-run, including polynomial mixing time for some classes of sets.

DHR defines its line set using a bidirectional random walk, called a biwalk. Whereas classical Markov chains such as the nearest neighbor random walk or the coordinate direction random walk fail to converge to a target distribution π on general discrete sets, because they can get trapped in isolated regions of the support set, DHR converges because it retains the global reaching property of hit-and-run.

Consider a finite set S with a membership oracle that is a subset of B given by a a bounded hyper-rectangle intersected with the n dimensional integer lattice $\mathbb{Z}^n$. The third step applies a Metropolis filter with respect to the target distribution to accept or π reject the candidate point and complete the transition of DHR. The DHR algorithm follows.

Discrete Hit-and-Run (DHR)

Step 0 Initialize $X_0 \in S$ and set $k = 0$.

Step 1 Generate a biwalk by generating two independent, nearest neighbor random walks in B that start at X_k and end before they step out of B. The biwalk may have loops but has finite length with probability one. The sequence of points visited by the biwalk is stored in an ordered list.

Step 2 Generate a candidate point Z by choosing a point uniformly distributed from the intersection of the list and S. Note the intersection always contains at least one point, the current point X_k.

Step 3 Accept or reject the candidate point Z with a Metropolis filter for the target distribution π,

$$X_{k+1} = \begin{cases} Z & \text{w.p. } \min\{1, \pi(\mathrm{Z})/\pi(\mathrm{X_k})\} \\ X_k & \text{otherwise.} \end{cases}$$

Step 4 If a stopping criterion is met, stop. Otherwise increment k and return to Step 1.

The reason for employing two independent nearest neighbor walks to define the line set in Step 1 instead of one walk, and for working with the ordered sequence of points in Step 2 as opposed to the set of distinct points visited, is to ensure symmetry of the candidate generator Markov chain. It is easy to construct examples where symmetry fails by employing a single nearest neighbor random walk and/or use the set of distinct points visited (Baumert et al. 2009). The Markov chain of DHR is globally reaching. The global reaching property together with symmetry and other characteristics imply that DHR converges to the target distribution π as desired.

An upper bound on the mixing time of DHR to a uniform distribution is given in Baumert et al. (2009), and polynomial upper bounds for four examples are given. The four examples include: a box within a box, a wedge inside a cube, multiple cubes inside a cube, and isolated yet aligned points within a cube. Note that conventional random walks such as the nearest neighbor random walk and the coordinate direction random walk also mix in polynomial time on the first two examples; however, both of these walks get stuck in isolated regions of S in the third and fourth examples and fail to converge to a uniform distribution. A fifth example given in Baumert et al. (2009) of diagonal points inside a cube only yields exponential bounds for the mixing time, although convergence is still maintained.

The success of discrete hit-and-run with random biwalks inspired the development of pattern hit-and-run for mixed continuous/integer domains. The biwalk in DHR is computationally expensive to implement because each move in the biwalk requires a randomization, and the list associated with the biwalk must be stored to perform the acceptance-rejection step. A more efficient implementation was introduced in Mete et al. (2011), where the biwalk is defined

with the use of patterns, visualized as a repetition of n step-sizes. An advantage to the use of a pattern-generated biwalk is that the pattern is easily generated with only n random number generations, and the acceptance-rejection on the biwalk can be performed by generating a single random number and analytically mapping it to a point on the biwalk. In Mete et al. (2011), two methods for generating patterns are defined; a sphere biwalk and a box biwalk. PHR with either sphere or box biwalk preserves the convergence properties of hit-and-run to a target distribution, and PHR with sphere biwalk converges to continuous hit-and-run as the mesh of the discretized points becomes finer, approaching a continuum. PHR with box biwalk converges to a variation of hit-and-run where the direction distribution is uniform on the surface of a box, instead of the common surface of a hypersphere.

When the feasible set S is ill-structured, the acceptance-rejection on the intersection of the biwalk and S is inevitable. However, a well-structured set of interest is an integer or mixed continuous/integer polytope, as often arises in integer programming or mixed integer linear programming feasible sets. Mete and Zabinsky (2012) remove the inefficiency that arises from rejecting infeasible points, and utilize the linearity of the constraints defining the polytope to directly sample from the intersection of the biwalk and the polytope. This provides an efficient variation of pattern hit-and-run that converges to a target distribution on a discrete or mixed continuous/discrete polytope.

Convergence to π on a general discrete polytope is not simple to attain. For example, a nearest neighbor random walk will not converge to a uniform distribution on a thin polytope that has isolated points without feasible adjacent neighbors. PHR is able to maintain the global reaching property on any polytope by determining all the feasible points on the biwalk, even though they may not be adjacent. Mete and Zabinsky (2012) derive a method to analytically generate a uniform point on the intersection of a biwalk and a discrete polytope by determining the number of feasible points on the biwalk and mapping a uniform point on $[0, 1]$ to a uniform feasible point on the biwalk. They extend the idea to a mixed continuous/discrete lattice of a polytope.

Moreover, PHR converges to a uniform distribution in polynomial time on a class of discrete polytopes; specifically, discrete polytopes that are defined by a finite number of knapsack constraints i.e., $\sum_{j=1}^{n} a_{ij}x_j \leq b_i$ where a_{ij} are nonnegative and b_i are positive for $i = 1, \ldots, m$ and the number of constraints m is independent of the number of dimensions n. This polynomial time performance and the convergence of PHR to hit-and-run on continuous sets suggests the potential efficiency for hit-and-run samplers on a broad class of sets.

Hit-and-Run for Global Optimization

Hit-and-run has been successfully applied to optimization, initially continuous problems, and expanded to mixed continuous/integer problems (Bertsimas and Vempala 2004; Kalai and Vempala 2006; Mete et al. 2011; Romeijn and Smith 1994; Shen et al. 2007; Zabinsky 2003; Zabinsky et al. 1993).

Consider the following global optimization problem:

$$\begin{aligned} &\text{minimize } f(x) \\ &\text{subject to } x \in S \subset B. \end{aligned}$$

An initial application of hit-and-run to optimization was called Improving Hit-and-Run (IHR) by Zabinsky et al. (1993), which modifies Step 3 in Algorithm 2 by simply accepting a candidate point only if it has an improving objective function value, as follows:

Step 3 Complete the transition to X_{k+1} where,

$$X_{k+1} = \begin{cases} Z & \text{if } \mathrm{f(Z)} < \mathrm{f(X_k)} \\ X_k & \text{otherwise.} \end{cases}$$

IHR has been successfully applied to realistic problems (Zabinsky et al. 1992, 2006). The complexity of IHR is, on average, of $O(n^{5/2})$ for a certain class of convex programs (Zabinsky et al. 1993). The direction distribution of IHR on elliptical programs, as defined in Zabinsky et al. (1993), is a multivariate normal distribution with mean zero and covariance matrix equal to the Hessian inverse of the objective function, H^{-1}. If the covariance matrix is the identity matrix, then the direction distribution is simply HD. Although the Hessian is not typically known, the results indicate the ability to guide the direction distribution for better performance.

Romeijn and Smith (1994) embedded hit-and-run into a simulated annealing algorithm and called it Hide-and-Seek. They added acceptance probabilities according to the Metropolis criterion with a temperature parameter T_k so that Step 3 becomes **Step 3**. Accept or reject the candidate point Z according to a Metropolis filter with temperature T_k,

$$X_{k+1} = \begin{cases} Z & \text{w.p. } \min\left\{1, e^{-(f(Z)-f(X_k))/T_k}\right\} \\ X_k & \text{otherwise.} \end{cases}$$

A property of Hide-and-Seek is that it converges to a Boltzmann T distribution, for a fixed temperature (Bélisle et al. 1993). For a general cooling schedule, Romeijn and Smith (1994) showed that if Hide-and-Seek ran long enough at each temperature value to converge to its stationary Boltzmann distribution, then the number of these temperature values would be linear in dimension. This led to an analytically derived adaptive cooling schedule, which was later extended to apply to both continuous and discrete global optimization problems (Shen et al. 2007). The analysis was motivated by the result that a sequence of such Boltzmann distributions achieves a linear complexity on the average number of function evaluations. Hit-and-run embedded as a candidate generator in simulated annealing has both analytical and numerical success.

Even though the acceptance probability for simulated annealing is interpreted as aiding the algorithm to escape local optima, simulated annealing has also been successfully applied to convex programs. Bertsimas and Vempala (2004) and Kalai and Vempala (2006) used hit-and-run as a candidate generator in a simulated annealing-type algorithm for solving convex programs with a membership oracle. In Kalai and Vempala (2006), simulated annealing is shown to converge quickly, and under certain conditions, the Boltzmann distribution is proven to be optimal for annealing on convex problems.

Simulated annealing on finite combinatorial problems has been successful; however, the candidate point generator is specifically chosen for each problem. Pattern hit-and-run, for integer or mixed continuous/integer sets, has been embedded into simulated annealing in Mete et al. (2011) and numerically shown to be very effective on many test problems.

Homogeneous Lanchester Equations

Simple Lanchester equations with one equation for each side. These equations are used when the weapons for each side are homogeneous in nature (all small-arms) or as a simplified approximation of a heterogeneous situation.

See

► Lanchester's Equations

Homogeneous Linear Equations

A set of linear equations of the form $\boldsymbol{Ax} = \boldsymbol{0}$.

Homogeneous Solution

A solution to the set of equations $\boldsymbol{Ax} = \boldsymbol{0}$. The solution $\boldsymbol{x} = \boldsymbol{0}$ is called a trivial solution, while a solution $\boldsymbol{x} \neq \boldsymbol{0}$ is called a nontrivial solution.

Horn Clause

A logical expression of the form A $\rightarrow$ C, where A (the antecedent) is a simple conjunction of basic (atomic) propositions and C (the consequent) is either null or is a single atomic proposition.

Hospitals

Yasar A. Ozcan
Virginia Commonwealth University, Richmond, VA, USA

Introduction

Hospitals represented a growing $760 billion industry in the U.S. in 2009 and were responsible at that time for about 32.6% of the nation's health care expenditures. There are 5,815 registered hospitals in U.S., and they have treated 127 million people in emergency departments, admitted 35.1 million for in patient care, and provided 642 million outpatient visits. These hospitals employ 5.4 million professionals or 34.6% of the all health care jobs in U.S. The effect of hospital expenditures on total output in U.S. economy reaches $2.5 trillion (AHA 2011).

There are several types of hospitals: acute care (i.e., defined to be those hospitals with average lengths of stay less than 30 days); psychiatric hospitals; chronic rehabilitation; nursing homes; and Federal (e.g., Veterans Administration Hospitals). The staffed hospital capacity in the U.S. is about 951 thousand beds. The majority of the hospitals are not-for-profit community hospitals (50.3%), and 17% are investor owned (for-profit) community hospitals. Fifty-seven percent of the community hospitals are part of a system, i.e., more than one hospital managed by a central organization. Almost 30% of the community hospitals are part of a network—hospitals, together with physicians and other providers including insurers, coordinate the care delivery in a given community. The major issues linked to the entire hospital industry may be summarized as access or availability, costs, and (broadly defined) quality of care. The key issues and trends associated with these concepts are the following (US Department of Labor 2010):

Access. In 1965, two government-sponsored health insurance plans were created in the U.S., Medicare and Medicaid. The Medicare program provides health insurance for people over 65, the disabled, and people with end-stage renal disease. The Medicaid program provides health insurance for people whose income and resources are below a level established by the individual state-government-sponsored health insurance programs. Despite this, there remain over 51 million uninsured people in the U.S., resulting in a large volume of uncompensated hospital care. In addition, insurance company policies on pre-existing conditions, people changing their jobs, and insurance companies deprive many people access to care. Health care reform in the U.S. has been enacted to overcome some of these access concerns. The Patient Protection and Affordable Care Act and the Health Care and Education Reconciliation Act of 2010 became law in March, 2010. Their implementation, however, will take until 2014 and beyond. By 2019, the uninsured population maybe cut in half, with other changes taking effect sooner, thus easing the access to care for families with children, individuals, people with disabilities, seniors, and young adults.

Costs. Due to spiraling health care costs over the years, cost containment policies have been a focal point for payers, including the U.S. Federal government programs. The introduction of the prospective payment system (PPS) in 1983 created strong incentives for hospitals to reduce costs. Prior to PPS, hospitals were reimbursed on the basis of actual costs plus an allowed return on equity. Following PPS, hospitals have been reimbursed by a fixed fee per patient for each diagnosis-related group (DRG). The DRG is the basic unit of analysis for inpatient hospitalization. The Federal government established DRGs as a way to pay hospitals for Medicare patients; many other payers also use DRGs. Each DRG has a numeric weight or case-severity rating reflecting the national average hospital resource consumption by patients for that DRG compared to the national average resource consumption of all patients. This has forced hospitals to adapt to a new price-competitive environment.

Quality of care. Due to the introduction of PPS, the shift to a price-competition situation, and a fear that hospitals might compromise quality of care to enhance their profitability, there was a surge in efforts to measure, monitor, and improve hospitals' delivered level of quality of care. Part of this effort was also to satisfy the employers who sought relationships with hospitals providing low cost but high quality care. The key outcome measures have typically included mortality rate, infection rate, complication rate, readmission rate (also referred to as adverse outcomes), and functional status. Much of the data analyses involved here is very similar to that used in device and system reliability analyses conducted by operations researchers (Fries 1997; Dhillon 2000).

Efforts towards quality of care created a new discipline called outcomes research. Since patients differ in the severity of their illnesses and the number and nature of medical and social problems they bring with them, there was the recognition of the need for adaptation of risk-adjustment methods (Schwartz et al. 1996). This is quite important in order that outcomes from patients with different severity of illness can be more confidently compared among hospitals.

In the past, many state agencies and private coalitions have used report cards to evaluate risk-adjusted hospital outcomes for specific conditions or procedures, while providing information that patients, employers, and health plans can use to make better decisions. In general, however, hospital leaders view quality-of-care report cards with little enthusiasm and are skeptical about their usefulness. The extent of

lack of knowledge and skepticism appears to vary by hospital size and service volume, ownership type, the method used to generate outcome information (administrative data vs. clinical data), and the time lag between submission of data and publication (Romano et al. 1999).

The U.S. Department of Health and Human Services developed a Web site, Medicare Hospital Compare, where potential patients can explore and compare quality outcomes:

1. Process of care measures in surgical care, heart attack or chest pain, pneumonia, heart failure, and children's asthma;
2. Outcome of care measures including mortality, readmission rate, use of medical imaging;
3. Survey of patients' hospital experiences; and
4. Medicare payment and volume data.

Major Trends and Issues in Hospital Industry

Strongly influenced by PPS, the hospital industry has undergone substantial transformations, most importantly from the rise of managed care plans and the concomitant rise of integrated delivery systems. These areas are of interest to the operations research field because of its ability to assist managers in analyzing systems, designing or redesigning systems, and implementing appropriate changes in systems. Also of interest are the processes that enable efficient and effective delivery modalities. These include innovations to disease management and the delivery process, as well as health information technology (HIT) implementations, of electronic health/medical records.

Innovation in Health Care Delivery. The competitive health market, national quality standards, and outcomes of some delivery processes, will challenge hospitals and health systems to self examine their service lines and redesign their processes and bring innovation and new adaptations to health care delivery. Many hospitals that belong to systems must consider health care delivery issues beyond the hospital. This includes other hospitals in the system or in the market, service line integrations, physicians, health care supply chains, and related entities. An important tool to integrating all these operations is the application of information technology. This will not only help hospital service delivery, but also help to develop a new modality termed the Medical Home—a patient centered delivery system that will coordinate and optimize the health status of each patient (Bradley et al. 2012; Rich et al. 2012).

Evidence based medicine where outcome driven best-practices surface as value to both patients and providers requires redesign of the care delivery process in health care facilities. The goals of redesign processes include elimination of variation in care delivery and produce higher quality outcomes. Hence, hospitals can employ six-sigma, reengineering or lean engineering techniques to achieve their evidence based process delivery goals (Paulus et al. 2008).

As part of redesign effort, the adaptation of Electronic Medical Records (EMR) will alleviate some of the major hospital process and quality issues. The Veterans Administration Hospitals were early adopters of complete EMR and have reaped benefits not only in outcomes, but also in efficient delivery (Ozcan and Luke 2011).

Pay for Performance. Pay-for-Performance (P4P) programs are evolving to include both quality and costs. P4P financially challenges providers to consider to increase quality and safety, thus improve patient outcomes. Accompanying this accountability, is increased transparency on public posting of quality and patient safety data. In addition to these, Accountable Care Organizations (ACOs) may become a reality to allow qualified providers to assume responsibility for overall costs and quality of care for certain populations through bundled payment structures. This may require hospitals to employ more primary care physicians to coordinate the care and enhancing the access. Altogether, the integrated models will have a major role in increasing efficiency, lowering costs, and improving outcomes (Fisher et al. 2007; Shortell et al. 2010).

Role of OR/MS

Specific problem day-to-day hospital management areas in which OR/MS techniques have had some success include: outpatient/ inpatient scheduling; service capacity planning; service demand forecasting; service system design; site location selection; health care supply chains; staffing and

scheduling; strategic planning; and service delivery (Ozcan 2009) Promising possibilities relative to the of access, cost, and quality include:

- Measuring of quality of care on the outpatient side,
- Measuring effectiveness in hospitals, including economies-of-scale and economies of scope. What causes a hospital to be evaluated as efficient—how does it apportion its resources, what procedures and processes does it employ to set itself apart from poorly performing counterparts?
- Predicting hospital risk, early disease diagnosis and treatment, and outcome prediction.
- How does the volume of services in a hospital affect cost and quantity?
- Are the current compliance measures for process of care (in surgical care, hearth attack or chest pain, pneumonia, hearth failure, and children's asthma) reasonable proxies for quality of care assessment? What other measures will are needed to form a more comprehensive outcome portfolio.
- What methods and cultural adaptations or mandates are needed to produce nationwide reports for mishaps in hospital delivery processes. e.g., medication errors, infections, patient falls?
- Measuring the effects of reform efforts.
- What are the impacts of new technologies on efficiency and outcomes?

Concluding Remarks

Only when the answers (or partial insights) to some of the above issues are available will hospital decision makers have the information and tools necessary to make informed tradeoffs and to improve operations both tactically and strategically (Ozcan 2009, Chapter 3). Probably no other area of the economy can benefit more from application of OR/MS than the health care area in general, and the hospital sector in particular.

Hundred Percent Rule

Given an optimal basic feasible solution to a linear-programming problem, this rule allows for simultaneous changes in objective function coefficients or right-hand-side values of a linear-programming problem that maintains the optimality of the current

basis. The name comes from the fact that the sum of the ratios of the proposed changes over their respective possible ranges must sum to one or less.

Hungarian Method

An algorithm for solving the assignment problem that is based on the following version of a theorem that was first stated by the Hungarian mathematician König and later generalized by the Hungarian mathematician Egerváry: if $\boldsymbol{A}$ is a matrix and m is the maximum number of independent zero elements of $\boldsymbol{A}$, then m lines can be drawn in the rows and columns of the matrix that contain all the zero elements of $\boldsymbol{A}$. (A set of elements of a matrix is said to be independent if no two elements lie in the same row or column.)

Hypercube Queueing Model

Richard C. Larson
Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

The hypercube queueing model was developed in the late 1960s and early 1970s, a period driven by a national commitment to devote scientific energies to the USA's urban ills. The initial application focus for the model was the deployment of urban police patrol cars. Issues that could be examined with the model involved determining appropriate numbers of cars to allocate in each part of the city, spatially deploying the cars to police beats or other territories, and evaluating the impact of alternative dispatch policies. Over the years, the model has been applied to a large number of police departments and ambulance services, and to other services as well, both public and private. This article reviews the history of the model's development, the key ideas of the model, and its implementation, including the evolution and framing of the model and its implementation impact.

Early Work

The hypercube model's roots started with the author's work on the Science and Technology Task Force of President Johnson's Commission on Law Enforcement and Administration of Justice (Government Printing Office 1967) and with MIT-affiliated work with the Boston Police Department. From numerous hours

riding around in the rear seats of police patrol cars and standing behind police radio dispatchers, it was clear that the fleet of police cars in an area of the city can be viewed as spatially distributed servers in a queueing system. Customer inputs to this queueing system are generated by citizens calling 911 and asking for emergency on-scene service. Unlike most multi-server queues, the police queueing system has a heterogeneous pool of servers. Each server faces their own workload situation, dependent of local geography, patterns of customer demand, and workloads of near-by servers. While writing a Ph.D. thesis in 1969, the need for a multi-server queueing model was recognized whose state space retained knowledge of which servers were available and which were busy: "If the state of a server is either 'busy' or 'idle,' then there are 2^N possible states of the system, corresponding to all possible combinations of servers busy and idle. It is convenient to represent a particular state i by a binary number, the 'ones' corresponding to the busy servers and the 'zeros' to idle servers. The state of server 1 is represented by the lth most significant digit. For instance, state $i = 01000\ldots$ corresponds to server $N - 1$ busy and all others idle. State $i = 2^N - 1$ implies that all servers are busy and that a queue may exist." (Larson 1969, p. 124). In the thesis, these hypercube issues are discussed further, and illustrated by numerical examples worked out for small N. But the algorithmic implementation for arbitrary N required further development.

Simultaneously with the thesis, the author sought to confirm the nature of the spatial queueing by conducting a two-week data gathering study in the New York Police Department (NYPD), (Larson 1971). Data were collected by the passenger officer in 54 precinct tours, where a precinct tour is defined to be a full set of operational data from one eight-hour tour or shift gathered over all police vehicles (typically 12 or less) fielded in a precinct or local area police command. While queueing in the usual sense was rare, queueing in the sense of probabilistic congestion was common.

To understand probabilistic congestion, suppose that one lives in police beat A and calls 911 requesting rapid on-scene police response. Further, suppose the police car assigned to beat A is busy with customers a fraction of time ρ_A, representing the utilization factor of the car ostensibly assigned to beat A, the so-called A car. It is assumed that the time the caller needs police service is independent of the real-time status of car A, busy or free. Thus, when calling 911, there is a probability ρ_A that the beat car is currently unavailable for immediate dispatch to the calling address. In that event, the dispatcher will select a near-by car that is available and dispatch that one. Such inter-beat dispatches are sometimes called workload sharing dispatches, because car B, say, will respond when available into beat A and, conversely, car A will occasionally respond into beat B, when needed. In that way, cars A and B share each other's workload. In general, a large number of cars share each other's workload in complex ways. Now suppose that the utilization factors of all cars A, B, C, etc. are all equal, that is, $\rho_A = \rho_B = \rho_C = \ldots = \rho$. In that case, whenever anyone in the service region calls 911, the chance that the responding car will be their beat car will be $1 - \rho$. Consequently, the fraction of dispatches that are inter-beat or workload sharing dispatches is equal to ρ. In urban America, a typical value for in the 1960s was 0.5; in the 2010's, typical values ranged from 0.5 to 0.8.

The results of checking the prediction of this simple aggregate queueing model for inter-beat dispatching for NYPD Division 16, Tour 3, Friday, February 28, 1969, were as follows:

Precinct	Percentage of time unavailable	Percentage of dispatches that are Inter-beat
103	48	55
105	59	57
107	38	48
109	38	37
111	36	48

As can be seen, the extent of inter-beat dispatching is never significantly less than the percentage of time unavailable, and it may be significantly more. There are sound theoretical arguments for suggesting that the simple Poisson model above represents a lower bound on the amount of inter-beat dispatches (Larson 1969).

The results were important for two reasons. First, the percentage of dispatches that are inter-beat dispatches is a useful performance measure of the fielded police force. The officers in each police car are, in theory, supposed to build an identity with the beat to which they are assigned, their patrol beat. This beat identity should cause the officer to feel personally responsible for public order in that beat. However, as it could have been seen empirically and argued theoretically, a patrol car is quite frequently

dispatched to incidents in beats other than its designated beat, a phenomenon known in police circles as flying. The more flying there is, the less the officer builds a strong beat identity. Prior to the research described here, police commanders, in general, had no idea that flying was as rampant as it in fact was. Later, in the 1990s, it was far worse. Second, the results, theoretical and empirical, demonstrated that the fielded police force is a complex spatially distributed queuing system, with the statuses and workloads of the various servers heavily dependent on one another.

Based on these results and the preliminary hypercube models described in Larson (1969), a more general model was developed. Prior to this work, there was very little in terms of analytical guidance for the police planner who wanted to design police beats. A common practice had been to design each beat to have equal internally generated workload. It was thought that equal internal workload would result in equal workloads experienced by the officers in the police cars. Subsequent hypercube developments and related empirical studies showed that this rule-of-thumb can be very wrong (Larson 1974b).

Central Ideas on State, Transition, and Probabilities

State — The hypercube model can be visualized as the corners and edges of a regular cube. For an $N = 3$ police car system, for example, one state of the system could be specified in words: Unit 1 is free or available; Unit 2 is busy; Unit 3 is busy. This state would be depicted by the binary set {0, 1, 1}, which is a corner of the three-dimensional cube. The state {0, 0, 0} represents the situation in which all three units are simultaneously free. The state {1, 1, 1} represents a situation is which all units are simultaneously busy and in which a queue of waiting 911 callers may exist. If there is a queue, the augmentation to the cubic state space may be thought of as an infinitely long tail emanating from state {1, 1, 1}, a situation resembling a Chinese kite.

In generalizing the three-dimensional cube, the analogous figure for an $N = 2$ unit system is a square. For $N > 3$, visualization extends into hyperspace by imagining a unit-volume cube residing in the positive orthant of an N dimensional hyperspace. This is the motivation for calling the model the hypercube model, a model having 2^N states.

Transitions — A state transition occurs whenever a server changes status from free to busy or from busy to free. Each such transition occurs only along a given edge of the hypercube. This requirement imposes the assumption that only one server (e.g., police car) is assigned to each customer, that is, there are no bulk services of customers.

Transitions occur probabilistically. Downward transitions, corresponding to completions of service on customers, occur for server j with rate μ_j. It is assumed that the service time distribution for server j is negative exponential. The rate of upward transitions from a given state to another adjacent state is determined by a complex set of dispatching rules or server assignment policies. Computation of the upward transition rates is a daunting task for a human user of a large system and has to be automated. It is assumed that from each area within the service territory, customers arrive as in a Poisson process, each process in non-overlapping neighborhoods operating independently. Thus, once the set of upward transition rates is known, the process governing upward transitions from any given state is Poisson. Hence, the entire model is a continuous-time Markov model.

State Probabilities — The system performance measures of the hypercube model can be obtained once the limiting probabilistic behavior is determined. To do this requires the computation of the limiting or steady-state probability that the system is operating in some state, $i = 0,1,\ldots, 2^N - 1$, where the hypercube vertices are indexed in some convenient way. This is simply done by employing a balance of flow argument: In the steady state, the probability that the system will enter state i in any small interval of time Δt must equal the probability that the system will exit that state in a time interval of length Δt. That is, inward and outward probability fluxes must be equal. Iif they were not, then there would be a net buildup or builddown of probability in state i, a contradiction to the steady-state hypothesis. The balance-of-flow equations are generated by constructing an N-dimensional sphere around each hypercube vertex, and then equating outward flow to inward flow. In general, there are 2^N equations to solve, with one being redundant and replaced by the condition that the sum of all probabilities must equal unity.

Campbell was the first to create a general computer code for the N-server hypercube model (Campbell 1972). Larson generalized that code, a program written in PL/1, and released it into the public domain in 1975 (Larson 1975b). That version contained several algorithms that sped up the execution time of the model, including an enhanced Gauss-Seidel procedure, a general method for performing a complete unit step tour of the hypercube and more. The code implemented all of the ideas discussed in the first journal paper describing the model (Larson 1974a).

The Physical Assumptions of the Original Model

The original model, called the basic hypercube model, required the following assumptions (Larson 1978; Larson and Odoni 1981):

1. *Geographical atoms*. The area in which the system provides service can be broken down into a number N_A of statistical reporting areas or geographical atoms. These might correspond, for instance, to census blocks, small collections of city blocks, or police reporting areas. In the model, each atom is modeled as a single point located in the center of the atom. Each can also be viewed as a node or vertex of a transportation network over which the servers operate.
2. *Independent Poisson Arrivals*. Each atom is viewed as an independent Poisson generator of customers requiring on-scene service, with the rate λ_j being the Poisson arrival rate from atom j.
3. *Travel times*. Data are available to estimate the mean travel time t_{ij} from each atom i to each atom j. In the absence of such data, plausible approximations for travel times can be made using analytical models and/or transportation network algorithms.
4. *Servers*. There are N spatially distributed servers or response units, each of which can travel to any geographical atom in the service region.
5. *Server locations*. The server location methodology includes both the probabilistic locations of patrolling police cars and the deterministic locations of ambulances. Define a probability l_{nj} = probability that server n is located in atom j at a random time during which server n is known to be free or idle. For an ambulance n with a known fixed location (when idle), there is one l_{nj} having value unity and all other $\{l_{nj}\}$ (for fixed n) equal to zero. For a police car, which may have to patrol several atoms, several $l_{nj} \neq 0$ are assigned, corresponding to the atoms in which the car patrols.
6. *Server assignment*. In response to each customer call, exactly one server is dispatched to the customer, assuming that at least one server is currently available in the service region. If no unit is currently available, there are options of queueing or forwarding the customer to some backup service, for example, a private ambulance service.
7. *Fixed preference dispatching*. Server assignment takes place according to a fixed preference procedure. That is, for each atom there is an ordered list of preferred servers to dispatch to that atom. The dispatcher will search that list in order and always dispatch the first idle server. Usually the list is generated by concerns of geography, such as travel time minimization, but on occasion other concerns such as assigning bilingual personnel could be important.
8. *Service times*. The service time associated with servicing a customer, including travel time, on-scene time, and possible related follow-up time, has a known average value. In general, each server may have its individualized average value. Service-time distribution, as discussed above, is assumed to be negative exponential, an obvious crude approximation in some cases.
9. *Service-time dependence on travel time*. Variations in service times that are due solely to variations in travel time are assumed to be second order compared to variations of on-scene time and related off-scene time.

Given the assumptions above, the model is used to generate a variety of useful performance measures related to server workloads, travel times throughout the service region and disparities among neighborhoods in quality of service received (Larson 1974a, b).

In practice, no actual system will ever conform exactly to all the model's assumptions. There is always a balance to be struck between modeling simplicity and operational reality, with the determining factor being the quality of decisions that can be derived from the model with limited expenditure of effort.

Approximations

In 1973, the author received a telephone call from the New Haven, Connecticut police department. The planners there wanted to use the hypercube model. This was an exciting offer as it was likely to be the first real test-bed application. The hypercube model had been programmed in PL/1 to accommodate up to 15 servers, a limit imposed at the time by the number of bits in a computer word. If New Haven were like New York City or Boston, it would be divided into a number of independently operating precincts or commands, with typically 8 to 12 servers (police cars) in each. In New York City and in many other large U.S. cities, police cars do not routinely cross over precinct boundary lines, so each precinct can be modeled independently with the hypercube model.

For New Haven, however, any police car could be assigned to virtually any address in the city. In fact, for the hypercube model, all of New Haven was one big precinct, with $N = 48$ police cars. This would result in a computational problem of note—an $N = 48$ hypercube model would require the solution to 2^{48} simultaneous linear equations! The curse of dimensionality imposed by the state-space structure of the hypercube model doubled the size of the state space with each additional server.

Motivated to solve the New Haven problem, a simple idea was resorted to: the equations used to compute performance measures suggested that it was not necessary to compute the fine grain 2^N state probabilities in order to evaluate the system performance measures. All that was really needed were the workloads (utilization factors) of the respective units and the dispatch frequencies in the form of the fraction of dispatches that send unit n to atom j. However, the logic behind this sort of argument was wrong because there is an implicit assumption that the units operate independently.

But, in 1975, a probabilistically valid way of dealing with this lack-of-independence problem was derived (Larson 1975a). Using an M/M/N queueing model to represent the aggregate probabilistic behavior of the system, a set of correction factors were developed to make the prior approximation precisely correct for an M/M/N system having a homogeneous pool of servers with a random dispatch policy, and approximately correct for the heterogeneous server system that had to be resolved by the hypercube model.

Armed with the correction factors, one can write a set of N simultaneous nonlinear equations whose solution provides the (approximate) utilization factors of all the N units. The nonlinear equations have a nice geometrically decreasing quality that results in solutions usually within three or four Gauss-Seidel type iterations. From this result, using the correction factors again, the fraction of dispatches that send server n to atom j can be computed. From that, the problem is solved and all required performance measures can be found. For a period of two years, the exact hypercube and the approximate models were run concurrently with numerous different data sets. In almost all of the runs, the approximate model was within about 2% of the exact model's results. This accuracy was judged to be within the modeling accuracy of the exact model. From that point on, It was decided to proceed only with the approximate model in implementations. The results of the use of the approximate model in New Haven were documented in Chelst (1975).

Additional Hypercube Model Applications

Emergency medical services. In Brazil, the hypercube model has been applied and developed further in a number of areas. A key focus has been on the configuration and operation of the emergency medical services on highways, which operate with dispatching policies somewhat different from police and ambulance services in urban settings, (Iannoni and Morabito 2007; Morabito et al. 2008; Iannoni et al. 2009). Their work includes heuristic-based location optimization, dispatch of multiple units, back-up units, non-homogeneous units, plus implementation issues.

Ambulance Location and Relocation. A significant amount of research has been developed using the hypercube model as the physics of the system, while attempting to optimize, usually with respect to home locations of dispatchable servers. Because how busy a server is depends on where the server is located, and location of an ambulance is a decision variable, finding the busy probability of each individual server a priori becomes virtually impossible. Embedding the hypercube model or its approximations in meta-heuristic search methods enables the estimation of individual server busy-probabilities at run time, thereby greatly increasing the location models' realism.

In an effort to increase the accuracy and realism of the Daskin (1983) maximum expected coverage location model (MEXCLP) that uses a system-wide ambulance busy probability (estimated a priori), Saydam and Aytug (2003) developed a genetic algorithm (GA) that combined MEXCLP with an efficient approximation of the hypercube model. Instead of using a system-wide busy probability, this approach enabled location-specific ambulance busy probability estimates. They showed that locations prescribed by the MEXCLP were generally robust, but the corresponding predicted expected coverage could be significantly off. Their hypercube embedded GA model yielded the same solutions as did the MEXCLP for 17 problems, found better solutions for 51 problems, and, for only four of the 72 problems, they were off by a very small margin.

Rajagopalan, Saydam and Xiao (2008) developed the Dynamic Available Coverage Location Problem (DACL), where DACL minimizes the number of ambulances required to cover a city over multiple time periods when demand is fluctuating. The DACL takes into account redeployment of ambulances within a city. It uses the Jarvis (1985) approximation of the hypercube model inside a Reactive Tabu-Search-based Incremental Search Algorithm to calculate the individual server busy probabilities at run time and, thus, ensures that coverage constraints are not violated.

The Minimum Expected Response Location Problem (MERLP) minimizes the expected response time while maintaining coverage requirements (Rajagopalan and Saydam 2009). Minimizing expected response times saves lives, prevents permanent injuries and reduces suffering. In this model, the Jarvis approximation of the hypercube model is embedded in a greedy search algorithm to calculate the expected coverage and to calculate the expected response time using individual server busy probabilities (Jarvis 1985).

Implementations

The hypercube decision technology has been tested extensively (Chelst and Barlach 1981) and generalized over the years, with almost all upgrades due to implementation experience and suggestions; see Larson (1979) for an early detailed technical description. Among notable improvements is inclusion of GPS (Global Positioning Satellite) information or other vehicle locator technologies, supported by a new hypercube dispatch algorithm that assigns the closest real-time available response unit (Larson and Franck 1978).

The hypercube model has been implemented by police departments in many cities, including Hartford, Connecticut; Orlando, Florida (Sacks and Grief 1994); Rotterdam, the Netherlands (Larson and McEwen 1974); Chapel Hill, North Carolina; Dallas, Texas; New York City (Larson and Rich 1987; Larson 1979); and Cambridge, Massachusetts. In Hartford, for instance, the focus was to redesign the spatial deployment of the police cars so that a number of them could be freed from the usual 911 responding force and reassigned to special drug fighting units; this was successfully done in 1991. Using the model, the Orlando Police Department in 1992 essentially redesigned the deployment of its entire force within a project that implemented a new down-town police precinct. The Cambridge, Massachusetts Police Department used the model to demonstrate to city management the deleterious consequences of reducing the size of the force in response to the tax cutting required from Massachusetts Proposition 2 1/2.

The hypercube model has also been implemented by ambulance services in Boston (Brandeau and Larson 1986; Hill et al. 1981; Larson 1982) and New York City. In ambulance deployments, finding nearly optimal locations for the ambulances was a major task. The ambulance services coauthors cited here found the locate-allocate heuristic described in Larson (1979) extremely robust and useful for this task.

Hyperexponential Distribution

A continuous random variable is said to be hyperexponential (or mixed exponential) when its probability density function is the convex sum of exponential density functions. The term hyperexponential is due to always having a coefficient of variation greater than 1, which is the coefficient of variation for an exponentially distributed random variable.

► Queueing Theory

Hypergame Analysis

A problem structuring method which addresses situations of conflict and cooperation between the independent actors. A key feature is its ability to represent differing perceptions of the situation which may be held by different actors.

See

► Problem Structuring Methods

Hyperplane

A hyperplane in n-dimensional space is defined by the set of vectors $\boldsymbol{X} = (x_1,\ldots, x_n)$ that satisfy a linear function of the form $a_1\, x_1 + \ldots + a_n\, x_n = \boldsymbol{b}$ for given numbers a_j and b. This can be written as $\boldsymbol{ax} = \boldsymbol{b}$, $\boldsymbol{a} = (a_1,\ldots, a_n)$. For $n = 2$, the function defines a line, and for $n = 3$, the function defines a plane.

Identity Matrix

A square matrix $\boldsymbol{A} = a_{ij}$ with $a_{ii} = 1$ and all $a_{ij} = 0$ for $i = j$.

Imbedded Markov Chain

An analysis technique used to analyze a queueing system that is not a continuous-time Markov chain. It appraises the system at selected time points which allow the system to be analyzed via a discrete-parameter Markov chain. The queue length process in the M/G/1 queueing system is not Markovian, but can be analyzed via a Markov chain at service completion time points.

The Watch It and Model It Approach

The primary assumption of this approach to OR Implementation is that if the OR/MS person is

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

sufficiently educated in the theoretical constructs and methodology that only minimum exposure to the actual situation is required. This assumption often works startlingly well in practice because the graduates of such programs are customarily drawn from the already rich and/or extremely bright quartile of the population. In short, entrance to these schools requires either massive amounts of money or outstanding academic performance which generates a scholarship. The argument is as follows. The product of this approach, when confronted with a real-world problem, could do a memory search from their conceptual education and unerringly choose the proper model for the solution of the problem. It is often implied that the rest is dog work which can be safely handed to others.

The good news about this approach is that if the OR/MS person is quite bright, quick and politically aware, excellent results usually obtain in spite of lack of knowledge of the system. Any tailoring of the process again is accomplished quickly due to the acuteness of the intellect of the person. It must also be pointed out that the customer is often sufficiently in awe of the educational, cultural, and economic background of the consultant that Gestalt psychology plays no small part in acceptance of models. This approach has been found to be particularly effective in strategic and high-level corporate planning with correspondingly high acceptance by top management. Another way to characterize situations where this approach does well is to say that the less measurable the results, the better the acceptance.

The bad news about this approach is that it almost uniformly fails in the tactical world. Manufacturing managers are justly famous for having little time for academic experts with no shop floor experience. This often supports the argument about how little OR/MS has actually been used in the manufacturing workplace as opposed to the corporate levels mentioned above. The time it takes to accomplish a Ph.D. militates strongly against a person having also the shop floor experience in a manufacturing situation. A story going the rounds of the profession is of interest here. It is alleged that a Lanchester Prize winner for nonlinear optimization was suddenly thrown out of work by the Army pulling the monetary plug on his particular Beltway Bandit employer. He well knew that refineries had a multitude of nonlinear problems in the production of hydrocarbons. He therefore hide himself off to the nearest refinery and offered his services to the refinery manager to solve his nonlinear refinery optimization problems. He named a price for his services, and the refinery manager then asked him how much he knew about chemical engineering. When he confessed his total ignorance in this area, the refinery manager politely asked him how much he was prepared to pay the oil company for him to learn enough about chemical engineering to help them! With this cautionary tale, the difference between conceptual excellence and practical reality is addressed next.

The principal reason for failure at the tactical level is that the customer must perceive that the consultant knows enough about their area so that the consultant

(a) Understands that politics wins over optimality all the time and
(b) That such knowledge will create respect for what they have to put up with

Further, people at the tactical level of companies are not impressed by anyone unless the latter have gone through the same boot camp learning process that they have. In short, the author believes that an education from an eminent institution may be actually more of something to be overcome than an asset in the milieu of tactics.

The Get Down and Do It Approach

It is the author's custom to encourage implementation in OR by attending conventions and asking the presenters the following questions.

1. Did you know what was happening on the project before you modeled it?
   If the answer is yes, they are then politely asked:
2. How do you know?
   The only acceptable answer is that the presenter found out by doing the work being modeled under the conditions of the people who are presently doing it until they had enough confidence in the presenter to take a day off and let the presenter do it alone. Anyone that believes that one can learn enough by watching should be treated with the amusement they deserve.
   The next question is:
3. Did they accept and use your model?
   If the answer is yes, the author proceeds to the last question which is:

4. Do you have measurable results in, for example, dollars at present worth, after tax, adjusted for inflation?

It is the author's opinion that people who answer no to any of the above questions have failed the test of operations research implementation.

Implementation of OR/MS in the Public Sector

Kenneth Chelst
Wayne State University, Detroit, MI, USA

Introduction

The successful use and impact of OR/MS in the public sector varies by domain. Areas of continuing operational and policy impact include the military, energy administration, and environmental quality. With forest land management, OR/MS successes extend to all corners of the globe: U.S., Chile, and New Zealand. When policies are debated with regard to illicit drugs, prison populations, homeland security, or air traffic safety, the leading experts are operations researchers who have made a long-term commitment to studying the issues. In contrast, the growing list of city government success stories of the 1970s has now become an infrequent event. With regard to social welfare and educational policy, there are no significant successes to speak of in the U.S. in part because operations researchers have not even attempted to penetrate these areas.

The OR/MS literature of the 1960s and 70s began to document a growing concern about implementation failure of many OR/MS models and studies in business. The primary goal of these papers was to raise the level of awareness of practitioners and cause them to think beyond the technical validity and sophistication of their models. They needed to recognize that OR/MS model implementation often engenders organizational change. OR/MS practitioners were encouraged to view factors affecting model implementation as part of the broader framework of the difficulty of change management. In this article, even more complex implementation challenges faced by OR/MS modelers in the public sector will be explored.

In the context of this article, the term public sector covers primarily governmental agencies and services at every level from local to federal. The focus is mainly on the U.S. perspective, but also includes the greater role OR/MS has played in Great Britain and in the developing world. The term public sector can also be applied to hospitals, health insurance, other health care providers, as well as public utilities. The services provided are of such public importance that in many countries these organizations and systems are government run. For example, in Great Britain, there is one health care system that provides and pays for services. It was then possible for an OR/MS team to plan and help successfully launch a medical assistance hotline called National Health Service (NHS) Direct (Royston et al. 2003). In the U.S., health care providers, insurance companies, and power generators are quasi-public and in some cases regulated monopolies that receive special oversight from all levels of governmental. Thus, the factors that affect implementation are not significantly different from that of the private sector. If anything, legal and regulatory restrictions on major decisions encourage the use of quantitative analysis and models. For example, major power plant location decisions and related rate increases require formal analysis and hearings to justify and assess the impact of these decisions. Similarly, hospital capacity expansion in the U.S. has long been governed by a requirement to prove a need. OR/MS models with explicit assumptions and logic can be valuable tools in these public presentations.

Public Sector Implementation: Definition

OR/MS models play three distinct roles in the public sector and successful implementation has a different meaning in each context. These are:

1. Operating efficiency and effectiveness,
2. Evaluating major policy initiatives, and
3. Public debates

In the first category, successful implementation has the same goal as in the private sector. Do managers of the governmental agency use the model to make decisions or manage and improve operations? In the second category, agencies such as the Federal Energy Agency, U.S. Forestry Service, or the Environmental Protection Agency are charged with assessing the impact of changes in policy, budgeting, regulation, and law. Successful model implementation means that as issues arise and alternatives are considered, models are run and their results play an important part in the internal and external discussions. In essence, model implementation means the OR/MS study fits Little's characterization of model success as "updating the intuition of decision makers," (Little 1970), or agrees with Murphy's goal of "communicate core insights," (Murphy 1991). The fact that politicians may choose to override the results of the analysis is not necessarily reflective of a poorly designed OR/MS model.

The last category is unique to public decisions. For macro policy decisions, there is often extensive public data available for analysis. An OR/MS analyst can build a model and explore the issue. Successful modeling is reflected in the OR/MS researcher playing the role of expert in public testimony before legislative bodies or being interviewed and quoted in the mass media. In this role, the OR/MS researcher may face an ethical dilemma. At what point, if any, as the public debate evolves, does the researcher move from the role of analyst, who simply presents findings and assumptions, to the role of an advocate vigorously supporting and defending positions.

Governmental Operations

Many of the barriers to the implementation of OR/MS models to improve governmental operations in the U.S. are the same as those reported in the Total Quality Management (TQM) experience (Radin and Coffee 1993). The areas in which OR/MS has had limited success have many of the following characteristics:

- Measurement – hard to measure outputs of messy systems
- Accountability – little or none
- Lack of pressure to improve – no crisis
- Fragmentation of governmental systems
- Multiple interest groups with conflicting objectives
- Leadership – top executives and managers are political appointees that often change
- Weak management skills of core organization especially with regard to analysis
- Unstable budgeting and accompanying uncertainty and
- Extensive demagoguery

Conversely, the likelihood of success is greater in organizations with clearly defined measures for which leaders are held accountable, and that are facing major budget crises that demand improved efficiency. Thus, OR/MS had an opportunity to facilitate more effective collection of state taxes in New York (Miller et al. 2012). Similarly, areas not prone to demagoguery, such as allocating resources and scheduling road repaving, have led to OR/MS modeling successes (Feunekes et al. 2011).

The factors listed above are often interrelated. Measurement, accountability, and pressure are obviously linked. Without measures, an agency cannot be held accountable. Where will pressure come from to improve service performance? For example, what is the output of a department of social services or an unemployment agency? It would be absurd to hold any one governmental agency accountable for the number of broken families or unemployed workers. How do you measure the performance of a fire department? Can you blame the fire service for an increase in fires or fire damage? Thus, the agency can sidestep most attempts at accountability. Without total system performance accountability, it would be rare for a political leader to feel any pressure to improve services except in response to a highly publicized mishandled event.

In the 1990s, the federal government launched an initiative to use performance based budgeting to encourage more accountability and continuous improvement. It was also hoped that the federal example would lead to parallel efforts at the state level. There have been sporadic success stories at the federal level and even fewer at the state level (Jordan and Hackbart 1999). These were not enough to create a culture of measurement that might have spurred the greater use of OR/MS to make resource allocation decisions or improve processes. In contrast, in Great Britain, an OR/MS group is an integral part of the Prime Minister's Delivery Unit in the Cabinet Office that has overall responsibility for improving the operation of all government agencies (Turner 2008). In areas in which ultimate outputs cannot be measured,

OR/MS studies have successfully improved operational efficiency. One study, for example, improved the process of managing children who are placed in foster care or put up for adoption.

Even when society has a measure, there is often little known about the measure's link to the operations of relevant agencies. There is ample data on reported crime and victimization studies to monitor crime trends. The success of COMPSTAT in New York City has created a culture of precinct commander accountability for crime levels. Other large cities have attempted to copy New York's usage of crime data analytics to continually refine strategies to suppress and deter crime. However, without research that defines relationships between inputs and outputs, there is little chance for OR/MS to contribute to increased crime fighting efficiency and effectiveness.

The vertical and horizontal fragmentation of governmental systems in the U.S. adds another barrier to implementation. Local, county, state and federal agencies often play complex interrelated roles that impact the ultimate service. Although state and federal agencies assert regulatory and budgetary control, the vast majority of services are provided by an enormously diverse set of independent and relatively small jurisdictions. For example, there are more than 16,000 local area police forces in the U.S., as compared to approximately 50 in Great Britain. For the vast majority of U.S. cities, their size makes it impossible to justify the development of internal operations research groups. Also, the relative scarcity of funds and lack of accountability has discouraged the development of a critical mass of consultants to fill this technical gap. In contrast, the State of Israel has a national police force that has an internal operations research group. Great Britain has highly regarded OR/MS groups deployed broadly in government agencies that carry out operational studies and contribute to policy analysis. They assist in technology transfer and provide analytic support for local jurisdictions. Operations researchers seem to be most effective when they are embedded in interdisciplinary teams. In addition laws that require formal analysis as part of an approval process, as in the case of land use planning, also contribute to OR/MS's success. Table 1 provides 2005 data on the number of OR/MS professionals in various departments of the British government. These totals are double the number in the Civil Service 10 years earlier (Turner 2008).

Implementation of OR/MS in the Public Sector, Table 1 Government operational research services staff by department (Turner 2008)

Department	Headcount	Per cent
Department for work & pensions	89	27
HM revenue & customs	66	20
Department for education & skills	41	12
Home office	40	12
Department of health	35	11
Export credit guarantees department	18	5
Department for trade & industry	13	4
Department for transport	8	2
Office of the Deputy Prime Minister	6	2
Cabinet Office	4	1
Others	9	3

One exception to this lack of critical mass in the U.S. occurred in the 1970s when the federal government helped fund a joint venture between New York City and the RAND Corporation, the New York City-RAND Institute. This organization and its affiliated researchers at MIT developed mathematical models that continue to form the basis for analyzing the deployment of emergency services. These researcher and consultants provided the technical support needed for OR/MS model transfer to other jurisdictions. This organization, however, disappeared before the decade ended as a result of political changes in New York City. With its demise, there was a dramatic decline in the implementation of OR/MS models in city government (Green and Kolesar 2004). Now, when model implementation is attempted, it is generally a story of one or two dedicated academics and their students working with a local agency. These individuals occasionally succeed by force of will and persistence in overcoming the barriers listed above. Rarely can they provide the continuity of support necessary to institutionalize the use of an OR/MS model. One promising development has been due to the International City/County Managers Association (ICMA). In 2007, the ICMA organized an analytic public safety consulting group to help small and medium sized cities. In 2011, this group completed an average of two public safety studies a month.

In addition to fragmentation, the U.S. system of government at every level has built in checks and balances that limit the power and ability of any agency to work with a consistent vision. This dispersion of roles and responsibilities compounds the problem of accountability. For example, state legislation on prison

sentencing and state budgets for corrections may run up against court orders resulting from prison and jail overcrowding.

Public sector OR/MS studies face an added complexity in that public agencies serve multiple interest groups, all of which have a legitimate voice in the operation of government. Almost every change in operation or policy will have winners and losers. The differential impact may vary by geography and social class. Equity and efficiency measures may conflict. As a result, most public sector analyses that use models are descriptive tools for evaluating the impact of a policy or operational change on diverse segments. OR/MS models by their nature explicitly quantify the overall impact of change and identify the winners and losers. This is not necessarily a blessing for the politically appointed managers operating under freedom of information acts and sunshine meeting laws. The political clout of a small group, or in some cases a single individual, can overwhelm the analysis that supports seemingly superior solutions. The political clout could reside with the government workers themselves who might impede changes that would benefit the public, but which they perceive as negatively impacting their jobs. For example, the adamant and militant opposition of firefighters to police-fire mergers has discouraged almost all city officials from proceeding with a change that OR/MS models have shown can save money and improve performance (Matarese and Chelst 1991). As a result, the natural instincts of survival of top political appointees can lead to decisions that are not in the broad public interest and undermine the value of an OR/MS study. OR/MS procedures have been shown to facilitate a negotiated agreement among multiple interest groups with divergent objectives. OR/MS helped design an agreement on water release polices for the Delaware River by clarifying the benefits and minor risks of proposed policies on each constituency (Kolesar and Serio 2011). Similarly, OR models help competitive airlines deal with major weather related schedule disruptions and negotiate equitable allocations of landing slots that enable them to efficiently return to their daily schedule (Sud et al. 2009).

Multi-criteria decision analysis (MCDA) is one set of modeling tools that offers the greatest potential for addressing concerns of multiple interest groups with conflicting objectives. Different perspectives can be reflected in the weights assigned to the various objectives and measures. MCDA can determine whether or not these different weights affect the overall rankings of the alternatives. If they do, the discussion can focus on reasons for the differences in an attempt to identify an alternative that best balances the competing visions (Kersten 2003; Danielson et al. 2008). It is especially useful in an open participatory budget process that has been used in hundreds of municipalities around the world (Cabannes 2004).

Perhaps it could be argued that the models are often at fault because they do not adequately reflect political realities. However, is it appropriate for an operations researcher to design a model that addresses the concern articulated by a well-traveled police chief? "Why can't your model maximize the chance that the police chief will keep his job?" It is similarly inappropriate for an optimal location model to give greater weight to a neighborhood of a wealthy contributor to a recent political campaign or automatically assign a governmental office to the congressional district of a powerful House of Representative committee chairman. This dominance of politics over analysis discourages operations researchers from investing the time and energy needed to bring models to bear on local government decisions.

British OR/MS researchers have developed a structured analysis approach, termed Soft OR (soft systems methodology) that is designed to help analyze the complex multi-stakeholder real-world problems such as those encountered in the public sector, as well as in other areas (Cooper et al. 2006). Soft OR contrasts to the standard mathematical analysis approach that is basic to OR/MS, that is, Hard OR. The latter emphasizes formal data analysis and building and applying OR/MS models. Soft OR assists in structuring the problem context by incorporating the values and perceptions of the multiple stakeholders early in the identification of project goals and viable alternatives. Soft OR is process oriented and may involve workshops designed to integrate competing perspectives. It facilitates successful implementation by explicitly incorporating the views of the stakeholders in the model development and application.

The OR/MS analyst working with local and state government managers quickly notices their weak analytic skills. Many government services are case or incident driven. Promotions tend to be based more on people skills than analysis. The educational experiences of these managers also tend to minimize analysis. In addition, their case or incident based data systems rarely provide good system statistics that would be important for analysis. Thus, the OR/MS analyst is

working against the grain of the organization when attempting to bring in sophisticated mathematical models that are data driven. Interestingly, these perceived weaknesses are considered an important factor in the growth of government OR/MS groups in Great Britain, as they provide the otherwise missing quantitative analysis requested by federal authorities.

In the U.S., federal departments, agencies, and centers have a decided advantage over state and local agencies when it comes to using analysis techniques. These organizations are usually large enough to support a core group of quantitative analysts. Even when top leadership is transient and politicized, these professionals have the long-term stability to integrate OR/MS models into the decision making process. In addition, Congress routinely asks for studies and data when making policy decisions. These are some of the factors that have contributed to the use of OR/MS type models, for example, in the Department of Energy, the Federal Aviation Administration, U.S. Army Core of Engineers, U.S. Forest Service, Environmental Protection Agency, and the Centers for Disease Control and Prevention.

Further, the bizarre political budgeting process that occurs annually at every level of government discourages long-term planning that might warrant the development of OR/MS models. When faced with a sudden budget or personnel cutback, the public agency manager may decide that the wisest course is to maximize the damage caused by the cutback rather than efficiently use the resources that are left. The goal is to maximize the public outcry against the pain caused by the cutbacks so as to generate political support for restoring the lost funds as soon as possible. Needless to say, OR/MS tools are not generally intended for this type of counter-productive decisions. However, the recession of 2007–2009 and accompanying decline in property values in many locales has forced many city officials to take a closer look at the high cost of emergency services. This has contributed to the demand for studies from the ICMA public safety consulting group. Continuing deficits in the U.S. Postal Service have led the leadership of this independent agency to embrace OR/MS models to improve efficiencies (Chakravarthy et al. 2009). However, when it comes to closing local post offices or distribution centers that provide jobs, politics can undermine analysis.

The military is unique in that all of the barriers listed above are not found in most military operations decisions. All aspects of military operations can be measured in terms of effectiveness. Battles are won and lost, air-to-air combat has winners and losers, and all weapons systems have measures of effectiveness. There is also a long tradition on accountability in the military. The next war is always more or less a decade away and the military must constantly update and adjust to the pressure. The overwhelming majority of standard military operations do not run into fragmented government systems and multiple interest groups. Politics become an issue only on big decisions and interest group pressures arise only when economics come into play. Although the top defense department officials are civilian political appointees, few operational decisions get to that level. The education of the military leadership is rooted in the military academies where analytic skills are nurtured. OR/MS research has a proven track record in the military where staff personnel are often experts in military OR/MS. As a result, the military has been and will continue to be a fertile area for successful application of OR/MS.

Major Policy Initiatives and Public Debates

The same barriers discussed earlier apply to most major policy questions at both the local and state level. In addition, it is even harder to validate models at the policy level, which reduces the credibility of the analysis. OR/MS has not been a significant factor in decision making at the state level with one major exception. OR/MS models are used in many states to evaluate legislative actions and policy decisions that affect prison populations. Blumstein (2007) and others were modeling crime and prison populations for more than a decade when the crisis in prison population arose in the 1980s. The problem was clearly measurable; prison populations more than doubled, quickly outstripping available capacity and budgeted resources. The easy solutions disappeared very quickly. Overloading the prisons was prohibited be federal courts. Letting prisoners go early was politically unacceptable after several highly publicized murders. Even a strategy of building more prisons required a model to forecast growth. Some states were adding one new prison each month and watched almost helplessly as corrections' spending on buildings and operations overwhelmed almost every other state budget category. There was an

obvious link between legislative actions on sentence length and policies regarding parole eligibility. Thus, there were a number of elements that facilitated the adoption of OR/MS models to forecast prison populations. In addition, once a model was structured to meet the needs of one state, it did not require major modifications to adopt it to other states.

At the federal level, OR/MS models have played a significant role in policy analysis in a number of areas. Congressional debaters often request the respective agencies provide detailed analysis of policy and budgetary changes. In the area of economic policy, economic model forecasts are a prerequisite for political debate since the early 1970s. This has set a tone for the use of mathematical models in other aspects of federal policy and legislation. The less politicized the debate is, the greater the role of models. The U.S. Forest Service began developing and using OR/MS models in the 1970s at a time when citizens were uninterested in the issues debated by the federal government and the timber interests. As environmentalism became a factor, there was time to revamp the models to make them multi-dimensional and keep them as viable contributors to congressional debate. Models in the area of energy policy, air and water quality, and controlling reservoirs have had an analogous successful implementation experiences. In each of the agencies, the model outputs were variables that were easily measured, although relationships and assumptions may have been hard to validate.

The development of think tanks has also played an important role in the success of OR/MS models at the federal level. These organizations have the critical mass and stability needed for the development and continued refinement of models. The most noted is the RAND Corporation. Initially, it carried out national defense studies and later extended its skills to other policy areas such as health care and criminal justice. Its European division has brought those same analytic modeling skills to address critical questions of water management in the Netherlands (Walker et al., 1994).

OR/MS researchers who have made long-term commitments to a particular problem area are the key to OR/MS's contribution to debates in areas such as criminal justice, aviation safety, and health care. OR/MS models have provided these nationally recognized experts a unique perspective, but their knowledge of the issues extends far beyond just modeling. It is this breadth of knowledge that is critical to achieving credibility in the public debate. Typically, these OR/MS subject area experts head up a group of researchers either at a university or think tank. This has enabled them to maintain a long-term focus as the important topics develop and evolve.

Implicit Enumeration

A process for solving integer-programming problems in which all possible integer solutions need not be investigated (enumerated) due to information obtained in the process that relates to problem feasibility and value of the objective function. That is, certain solutions need not be pursued as it can be shown that they would lead to infeasible solutions or values of the objective function that are worse than those that are known to be possible.

Implicit Price

► Marginal Value

Importance Sampling

In stochastic or Monte Carlo simulation, a variance reduction technique whereby the underlying probability distribution is altered to increase the probability of (1) simulating events of highest interest, such as rare events, or (2) sampling from regions that have a larger effect on the quantity being estimated, such as a high-dimensional integral.

Independent Private Values Bidding Model

A bidding model in which a bidder's estimate of value for what is being auctioned is statistically independent of the value estimate for any other bidder. In such a model, no bidder has any reason to adjust an estimate of value upon learning the information of any other bidder.

See

► Bidding Models

Indirect Costs

In the simplex method, the indirect costs are found by taking the inner products of the multiplier (pricing) vector with each column of the problem's defining $\boldsymbol{A}$ matrix. This product, for a column j, is usually denoted by z_j. For c_j, the original objective function coefficient for column j, the term $(z_j - c_j)$ or $(c_j - z_j)$ is used to determine if the associated variable is a candidate to enter the basic feasible solution. For any basic variable x_k, $(z_k - c_k) = 0$. The $(z_j - c_j)$ terms are called relative costs (relative to the basis) or reduced costs.

Introduction

Although this article is based largely on some of the authors' experiences and views of European OR/MS, it is of direct importance to the worldwide OR/MS community. The field is better known in Europe as Operational Research or OR, and it occupies itself with quantitative methods for the analysis and solution of management problems. Its origins lie in military organizations during World War II: first the Royal Air Force (U.K.) preparing for the Battle of Britain and later on the U.S. Navy fighting German U-Boote (submarines). After the war, there was a general feeling that OR/MS could also be helpful to managers in industry, government, public services, and financial institutions. The logic was obvious: industrial activities such as production planning, inventory control, and physical distribution were quite suitable for model building and other forms of abstraction that lead to challenging mathematical problems, and trained OR workers (analysts) were available. But soon it became evident that solutions capable of being applied in practice were not as numerous as expected. Causes for this phenomenon can be traced to the following.

On the one hand, models running on the then available computers were so strongly a simplification of reality that managers did not recognize their problems any longer. On the other hand, OR researchers in academia moved their attention to the basics of the discipline. Their theoretical results were very impressive, especially in the field of mathematical programming, combinatorial analysis, and queueing theory. But for managerial problems of daily life, these OR researchers tended to have little interest. Consequently, decision makers felt disappointed and lost their confidence in OR/MS and returned to simple, often too simple, rules of thumb. In this way, a practicality gap came into existence, a gap between the managers with real, urgent decision problems demanding simple solutions, and the OR/MS scientists who strived for elegant solutions to abstract problems of their own invention. For a discipline founded on solving real-world problems, as OR claimed to be, the gap caused a highly unsatisfactory situation. Hence, after a while, professional journals tried remedy the situation, while an outstanding cadre of OR/MS analysts attempted to regain managers' interest for management science. But all efforts seemed in vain. One of the gurus of OR/MS even concluded that "The future of OR is past" (Ackoff 1979).

This is how OR/MS lost the good reputation earned during the war. Even OR analysts in staff departments of industrial companies had to fight for their existence and often lost their jobs. Many departments were dissolved or put at work on other tasks, for example, on automation projects. Mainly, the so-called loners, working in decentralized positions, continued to do OR/MS work (see Fortuin and Lootsma 1985).

But OR/MS analysts never lost faith in their discipline. Gradually they improved their position by

rediscovering real-world problems. In the 1980, two developments fostered this process: the availability of low-cost and versatile computer power (PCs) and the establishment of special university chairs for OR/MS and other quantitative methods. Ten years after Ackoff, a completely different sound could be heard: "The future of OR is bright?" (Rinnooy Kan 1989).

The Faces of OR/MS

OR/MS has two faces: on the one hand it concentrates on operations and as such it tries to be practical and to provide solutions to real-world problems; on the other hand, OR/MS means research, involving theoretical studies of problems that at best may be regarded as abstract version of problems that actually exist in the real world. These two faces of OR/MS have brought into existence two types of OR/MS workers: the practitioners and the theoreticians. The practitioners are to be found primarily in consultancies, but also at universities, for example in departments such as industrial engineering and industrial mathematics. In large companies, loners can still be found. As for the theoreticians, they tend to work only at universities and related institutions.

The two types of OR/MS workers are carrying out their tasks independently, but contact between them is improving, with exchange of ideas at conferences and seminars, and bilaterally. This situation originated in a natural way:

- Most consultants graduated from a university. They maintain their university network to learn about theoretical breakthroughs. In return, they inform their fellow OR/MS analysts in academia about the problems their clients in industry are grappling with.
- Many consultants are working as part-time professors at universities. They use their experiences to keep their teaching up-to-date and use the results of their academic studies to support their consultancy work.

In this way, opportunities for OR/MS have improved considerably. Other factors have enhanced this process:

- Modern managers in industry have an academic background. During their studies, they have become acquainted with the basics of OR/MS and, thus, they are easier to convince that OR/MS can help them. As most managers no longer have OR/MS staff departments in their organizations, they become clients of OR/MS consultants.
- Universities have discovered the importance of good relations with business companies:
  1. It makes academic OR/MS workers more practical and teaches them to cooperate with managers.
  2. It enhances their cash flow by doing contract research in OR/MS.
  3. It offers students an opportunity for working temporarily in an industry as part of their program, to the benefit of the quality of their education.
  4. It helps universities to assign priorities to the items on their research program.
- The pure theoreticians less often select in isolation the subjects of their investigations. Instead, they have opportunities to pay attention to the signals that reach them from their colleagues operating with their students in industry.
- Information technology has produced powerful computer software and hardware. Consequently, model building has become very realistic; all relevant details are taken into account, and animated graphics convince managers more easily than words that indeed their problems are being analyzed.

This improvement process is reflected in professional journals on OR/MS. Many successful applications of OR/MS in practice have been reported in the literature. These case studies usually have following sequence: (1) the problem and its environment; (2) the OR/MS approach towards a solution; (3) results of the OR/MS analysis; (4) selection by management of a solution from a set of alternatives; (5) implementation of the solution; and (6) results in terms of improvements with respect to the situation before the OR/MS intervention. Examples can be found in (Bell 1985; Lootsma 1991; Fortuin and Korsten 1988).

There will always be managers who have to make decisions in complex and complicated situations, each with far-reaching consequences. They are obliged, mostly under time pressure, to select the best solution. Here they can be supported with OR/MS in its modern version, given that they are aware of the powerful methods and tools that OR/MS practitioners have at hand and the impact that OR/MS has had in

solving real-world problems; see (Fortuin et al. 1992; Davenport 2006; Liberatore and Luo 2010).

The main problem lies in gaining the confidence of managers so that they are prepared to give OR/MS a chance. The practicality gap has been narrowing, and there exist opportunities to enhance engagement between research and practice (Corbett and van Wassenhove 1993; Sodhi and Tang 2008). To bridge the gap, OR consultants and academic OR workers have to act as missionaries to the benefit of their profession, to their career perspectives, and to help managers trying desperately to improve their business in the face of an ever increasing global competition.

OR/MS In Industry: Where And What?

Fortuin and Zijlstra (1989) reported on the experiences of an OR group within Philips Electronics, a multinational company producing consumer products (e.g., domestic appliances, lighting, television sets, high-fidelity consumer electronics, and razors) and professional products (e.g., medical systems, telephone exchanges, and lighting systems). They analyzed over 200 projects in OR/MS and showed which areas were most important for OR/MS application in industry and which OR/MS tools were most frequently used. A 1992 update of these investigations confirmed these results. Apparently, the most frequently occurring projects were the ones on the design of a production systems, whereby discrete computer simulation is the OR/MS tool employed to take complex interactions into account (Tables 1 and 2). This conclusion holds for a large multi-national company in Europe. In the U.S., the picture seems to be slightly different. A longitudinal survey in the journal *Interfaces*, for instance, mentions statistics, linear programming, and discrete simulation as the top three OR tools, in that order (Harpell et al. 1989).

Industrial Applications, Table 1 Application areas for OR/MS in industry

Areas of application	Number of applications
Design of production systems	95
Production	86
Transport and storage	35
Training and courses	16
Design of systems for transport and storage	13
Performance of systems	11
Miscellaneous such as portfolio analysis, measuring the quality of information systems, and performance indicators	20

Industrial Applications, Table 2 OR/MS tools applied in industry

OR/MS tools	Number of applications
Discrete event simulation	95
Waiting theory models	82
Combinatorial analysis	48
Inventory models	46
Mathematical programming with emphasis on linear programming	23
Miscellaneous such as the structuring of facts and figures (many projects start with this type of OR), which is sometimes is all that the client desires	29

Model Building

In most OR/MS projects in industry, an important part of the work is model building. A model is the description of a piece of reality that has to be analyzed in the course of the project, leaving out all irrelevant details while maintaining essential characteristics. This gives model building the character of an art rather than of a science.

Model building plays an important part in modern OR/MS projects, often in combination with discrete simulation and optimization. Models offer insights and the possibility to compare decision scenarios in both the qualitative and the quantitative senses. The computer is almost always an indispensable tool in this pursuit. The driving force exerted by development in informatics cannot easily be overestimated. A large part of the arsenal of OR techniques can be used on a PC, thanks to software that is becoming more and more user-friendly and cheaper. The ease with which a problem area can be represented by a model that the problem owners consider sufficiently realistic has grown enormously. Large quantities of data can easily be stored in databases that are simple to access. The opportunities

are great for OR/MS to really contribute to the reduction of uncertainty in complex industrial situations and to increasing control of business processes. But, there still are managers who are unaware of the help they can get from OR/MS: quickly calculating the consequences of decision variants, the preparation of decisions, and decision support. These managers are unaware that they can save considerable amounts of money and improve effectiveness of their decisions.

The Position of OR/MS in Industry

Times have changed. In the 1980s, OR/MS was primarily in the hands of a company's staff department. Since then, many companies have reorganized about their core business. Consequently, staff departments were reduced to a bare minimum, if not completely eliminated. Also, many were disconnected from their original company. For instance, the OR/MS department discussed in Fortuin and Zijlstra (1989) became an independent consultancy with, not surprisingly, Philips Electronics as its main client. Such reorganizations also occurred in many industrial companies in Europe, as well as in North America.

In Europe, OR/MS support is offered to industry from two sources. First, there are the consultancies. They usually follow the project approach, according to which the work is done in phases. To a certain extent, they have to compete with the second source, that is, OR/MS university departments whose study program includes real-world student-oriented projects that stem from companies willing to invest in such OR/MS projects. Both parties profit from this alliance: the students learn to practice the profession, while the company obtains a relatively inexpensive solution to a problem or, at least, begins to explore it by using the experience and talents of both professors and students. These academic OR activities are an important means for showing managers how advantageous the support of external consultants can be.

The Project Management Approach

Table 3 gives an overview of the OR/MS project approach. A contract between the client (company) and the OR/MS consultancy is agree to, with the contract stating what problem will be studied, and possibly solved, at what cost, and the study time interval. The contract also states the contributions the client and company's staff are obligated to contribute, and indicates what deliverables the client may expect. More details can be found in Fortuin et al. (1992). This approach has proven to be very successful, for two reasons:

- The preliminary phase is usually short. Its aim is reconnaissance of the problem area and a problem description that the problem owner (manager) can agree with. Costs are relatively modest so that financial risk is low. This facilitates the process of making the manager confident that the consultancy is indeed able to help solve the problem.

Industrial Applications, Table 3 Summary of the steps in an OR/MS project: In phases 1 and 2, the consultant is heavily involved in the project. Usually, Phase 3 is carried out by the client and/or staff

	Activities	Details
Phase 1	General survey	Discussions with client and staff
		Interviews, study of document
		Global problem description
		Generation of ideas for a possible approach
	Reporting	Outline of results to be expected
		Proposal for Phase 2
Phase 2	Model building	Systematic description of the problem area. In order not to make the model too complicated, only the most relevant factors are taken into account
	Verification	Discussions with client and staff: Is the model correctly presenting the problem area, the organization, the methods, processes, and procedures?
	Experiments	Translation of the model into computer program
		Calculations under various circumstances
	Analysis	Investigation of results
	Reporting	Presentation of the most important results, conclusions, and recommendations. A proposal for Phase 3
Phase 3	Implementation	Working out and implementation of recommendations
		Teaching client and/or staff to work with the new method

- It may happen, that during the preliminary phase, the problem becomes so transparent that a solution can be seen immediately. Then a follow-up phase is not necessary.

Concluding Remarks

The prospects for the continued application of OR/MS in industry are excellent:

1. Managing an industrial company is becoming ever more complicated. Global competition, globalization of the economy, demanding customers, decreasing profit margins, new markets, and fluctuating exchange rates are just a few of the causes. The time for simple solutions is over, and only fundamental and theoretically sound analyses can justify management decisions. Managers lack the time and the expertise for such analyses.
2. Practitioners now working in independent consultancy units can make their own business plans and follow their own strategy when promoting OR/MS, rather than being ruled, or overruled, by a general company policy.
3. Computer power is widespread in industry, which facilitates the implementation of OR/MS solutions, even if the problems are complex and their resolution requires large and diverse data bases.

Industrial Dynamics

► System Dynamics

Infeasible Solution

In general, a proposed solution to an optimization problem that does not satisfy all the constraints. For the linear-programming problem $\boldsymbol{Ax} = \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}$, a vector $\boldsymbol{x}^0$ is an infeasible solution if it does not fully satisy the equations or the nonnegativity condition.

See

► Feasible Solution

Inference Engine

A piece of software or a computational strategy that is based on a problem statement from the user, uses reasoning knowledge about the problem area in attempting to derive a solution, gathers needed problem-specific information (e.g., from the user) in the course of reasoning, explains why it needs this

added information, presents the solution to the user, and explains the line of reasoning used in reaching the solution.

Influence Diagrams

James E. Matheson
SmartOrg, Inc., Menlo Park, CA, USA

Introduction

Before influence diagrams were developed, describing and solving decision problems under uncertainty was quite difficult. The first difficulty was determining the probabilistic relationship among uncertain variables, because it is easy to model many variables as jointly related, but extremely difficult to assess their probabilistic relationship. An experienced decision analyst can reasonably assess the uncertainty in a single variable (Spetzler and Staël von Holstein 1975), but more than two variables make the task almost impossible. A better way was needed to understand the relationship among uncertain variables. The second difficulty was understanding and describing the relationship between decisions and uncertainties, particularly indicating which uncertainties would be revealed before which decisions and then transforming the probabilistic descriptions to condition the probabilities in the proper order of information revelation, using Bayes' Rule. The usual, but very awkward, method was to describe the uncertainties in a possibly very large probability tree, called nature's tree, and to describe the sequence of revelation of uncertainties and decisions in a decision tree, followed by the calculations necessary to transform the probabilities into the sequence needed for the decision tree (Howard 1965). Only an expert could hope to deploy these methods, both to think through and describe the problem and to do the complex assessments and computations involved. Then, communicating what had been done, especially to decision makers, was also a daunting task.

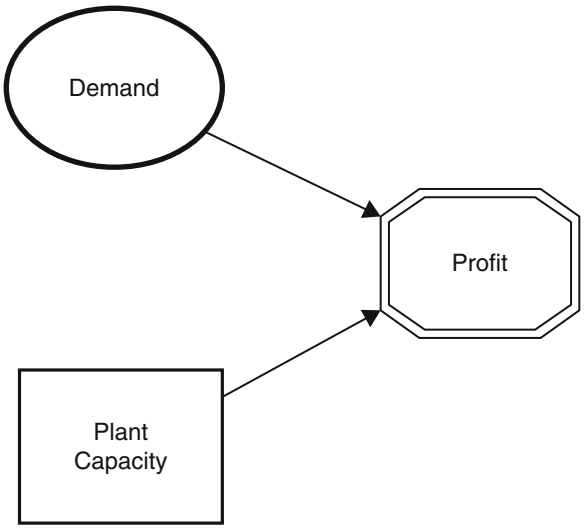
The SRI International Decision Analysis Group was highly active from about 1968 to the early1980's. This group comprised many motivated individuals doing pioneering applications and research on decision analysis, largely defining the Stanford School approach to decision analysis. It included several award-winning individuals: Ronald A. Howard, James E. Matheson, D. Warner North, and Carl S Spetzler. These individuals, along with several others, Miley W. (Lee) Merkhofer and Allen C. Miller, were engaged in many problems of probabilistic inference, especially on a project initiated in 1973 for the Defense Intelligence Agency, and a previous project on space-mission planning. Motivated by the need to efficiently assess highly-dependent information regarding the conflict in the Persian Gulf, the group tried many methods, such as coalesced decision trees – ones having repetitive structures – to capture that information. Ultimately, this exploration developed methods for graphically mapping probabilistic dependence and produced a signal flow graph method for treating states of information, termed "influence diagrams". These formed a directed graph showing the relationships (arrows) among both decisions and uncertainties (nodes) that became simultaneously a presentational device and a computational tool. A Defense Projects Research Agency project followed, where these ideas were solidified and fully described in Howard et al., (1976). This seminal paper was published privately and became one of the most-referenced works in the field. It was reprinted in a special issue of the *Decision Analysis Journal* about 30 years later (Howard et al. 1976; Howard and Matheson 1983, 2005a, b).

The Nature of Influence Diagrams

Influence diagrams represent both uncertainties and decisions in a single compact graph. They contain both the nature's tree and the decision tree of the older cumbersome method, showing the probabilistic relationships among the uncertainties, the sequencing of the decisions, and the information revealed before each decision is taken. These relationships are shown by a set of decision and chance nodes with arrows connecting them in an acyclic graph. The graphical relationships are easy to comprehend so that influence diagrams have become a standard method for describing decision problems and explaining them to subject-matter experts and to decision makers. In addition, the nodes of the influence diagram capture the numerical data describing the situation and the whole diagram may be processed to solve the decision problem, to do probabilistic inference, and to make many different insightful derivative graphs and calculations. One potential output of an influence diagram processor would be a decision tree describing all or a reduced portion of the decision situation. Decision trees have shifted from a computational one to more of a presentation role, and are easily derived as a byproduct of influence diagram representations.

About a decade later, a parallel development arose in the statistics and artificial intelligence communities, called Belief Nets or Bayesian Networks, that are roughly equivalent to influence diagrams, but with no decision nodes. The focus of work in this area has been in treating complex probabilistic inference problems and causality issues (Pearl 1986, 2005; Neapolitan 2004). In contrast, the development of influence diagrams has focused on decision making under uncertainty.

An influence diagram for a typical real problem is shown in Fig. 1. The decision nodes are represented by squares or rectangles, while chance nodes are represented by circles or ovals. It has become a common convention to use a double border, especially on chance nodes, to indicate that the node contains only deterministic relationships, such as equations or data tables. Also, often a payoff or profit node is included, usually as a deterministic function (which might be as complex as a large Excel spreadsheet), usually indicated by an octagon, representing a stop sign, which sometimes degenerates into a hexagon for easier graphics.

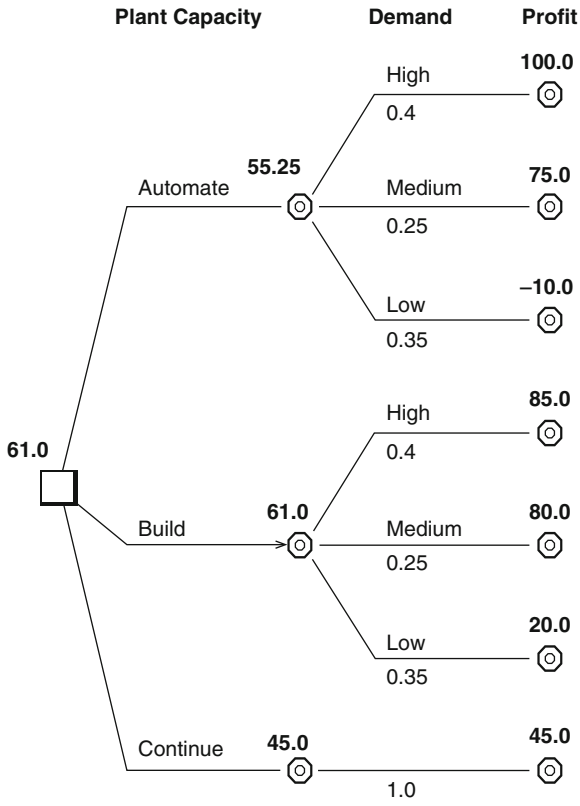


Influence Diagrams, Fig. 1 Influence Diagram for the Capacity Example

A Straightforward Example

The following simplified example is from Matheson and Matheson, (2005). A company is expanding an old plant and wants to decide on how much and how to expand. Their only uncertainty is what the demand will be, because they do not want to over-build the plant and pay for unneeded capacity or under-build and lose profit opportunities from insufficient production. Figure 1 is an influence diagram for this problem, which has three kinds of nodes, a decision node, representing the Plant Capacity; a chance node, representing Demand; and a value, or in this case, a Profit node, that contains the calculation needed to determine profit. The double outline on the profit node means that at present the information inside the node is a deterministic function of its inputs. (During processing of the diagram the uncertainty in the Demand node could be pushed into the Profit node, at which point the Profit node would become uncertain and have a single border).

Using a computer interface analogy, inside each of these nodes is embedded information describing that node. Inside the Plant Capacity node is a list of possible alternatives under consideration, in this case Continue as is, with no increase in capacity; Build a conventional expansion; or retrofit, and fully Automate an expanded plant. In each case, expansion plans and schedules have been specified, but are characterized by only



Influence Diagrams, Fig. 2 The Solved Decision Tree for the Capacity Example

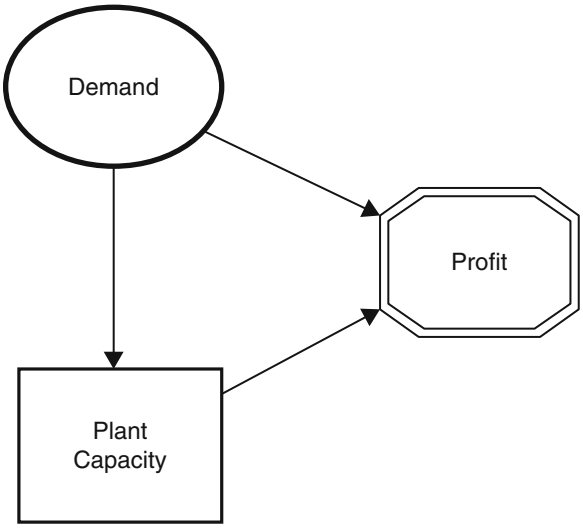
one word for convenience. Similarly, there are three well-specified potential demand scenarios: Low, Medium and High; with probabilities carefully assessed as 0.35, 0.25, and 0.40. Again, this information can be thought of as inside the node. It is critical to note that this demand probability assessment does not depend upon the plant capacity selected, which is indicated structurally by the absence of an arrow from Plan Capacity to Demand. Lastly, a financial value model has been developed for this decision situation which projects cash flows for each combination of decision (Capacity) and uncertain outcome (Demand) and reduces each set of cash flows to a Net Present Value (NPV). This model can be thought of as residing inside the Profit node.

Because this example is so limited, the influence diagram can be solved by using it to generate the decision tree of Fig. 2. It shows that the best decision is to Build an expanded conventional plant and make an expected profit of 61.0. For simplicity, assume that the company desires to maximize expected value, but the influence diagram can also treat risk aversion, for example, by using certain equivalents in place of expected values. While this result solves the primary decision problem, many further analyses are possible to gain insight into the situation. Decision analysis often asks hypothetical questions about modifying the original problem before making the primary decision. Influence diagrams are ideal for clearly specifying the nature of these hypothetical interventions, see Matheson, (1990). Two interventions to be considered are gathering more information and gaining control over demand. Assume that these hypothetical interventions can be made without disturbing the rest of the problem structure. In other words, there are no unintended consequences. If some of these idealized interventions look valuable, then real interventions with all of their potential interactions should be investigated.

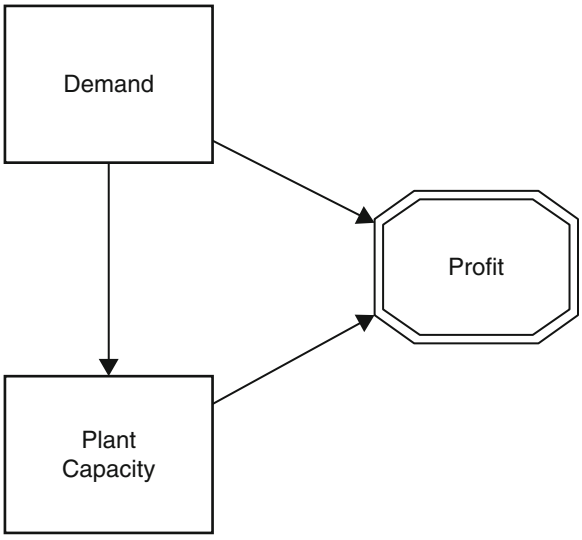
Valuing Interventions

The first intervention to consider is gathering perfect information on Demand before making the original primary decision. This intervention is incorporated into the structure of the influence diagram by adding an arrow from the Demand node into the Plant Capacity node, which indicates that the decision maker will know demand (e.g. the demand will be revealed by a clairvoyant) before the capacity is selected, as shown in Fig. 3. A new decision tree could be generated from this diagram, using the new ordering, but this problem can be solved by just inspecting Fig. 2. If the decision maker knows the demand is going to be Low, the decision maker makes a maximum of 45.0 by choosing Continue as is; if the demand will be Medium, value is maximized with Build for 80.0; if the demand will be High, the maximum value is achieved by Automate for 100.0. Since a true clairvoyant will report each of these forecasts with the same probabilities that have already been assessed, these numbers are weighted by those probabilities to get an expected value of 75.75 and subtracting the value of the original situation of 61 to give an expected value of (free) perfect information of 14.75, sometimes called EVPI.

Another basic intervention is perfect control. If the decision maker could somehow set a specific demand of interest (e.g. employing a wizard), before deciding

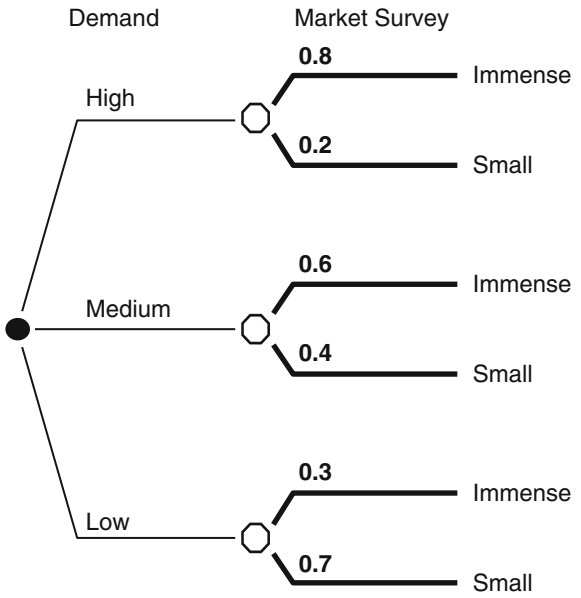


Influence Diagrams, Fig. 3 The Capacity Example with Perfect Information on Demand



Influence Diagrams, Fig. 4 The Capacity Example with Perfect Control of Demand

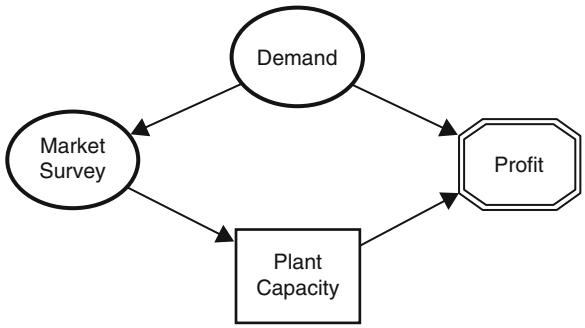
on capacity, the decision maker could pick the best of all possible worlds. In Fig. 4, the Demand node has been changed to a decision node representing what to ask of the wizard, with an arrow to indicate the demand choice is made before selecting the Plant Capacity. Again, inspecting the earlier tree determines that it would be best to chose the High demand and Automate the plant leading to a profit value of 100,



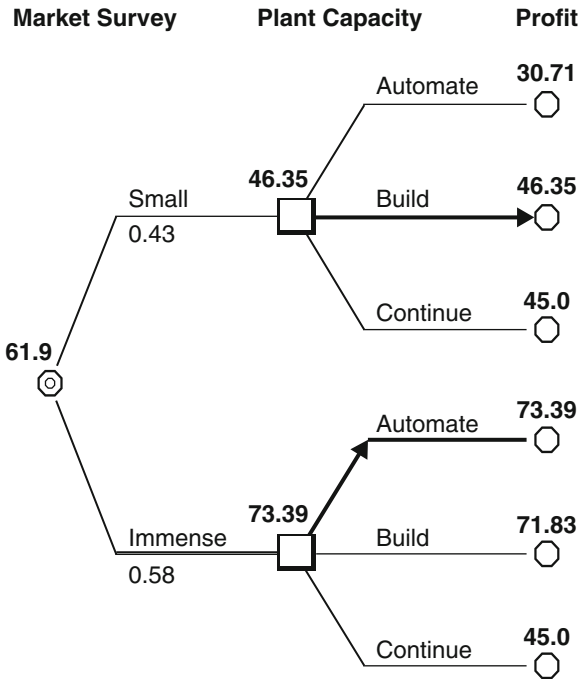
Influence Diagrams, Fig. 5 The Conditional Distribution of the Market Survey

which subtracting the original 61.0 lead to a value of perfect control of 39.0.

The analyst and the decision maker now look for more realistic interventions that maybe undertaken. Assume they cannot find a legal means to control demand, but they do have a proposal to undertake a market survey, that can report that the market will be either Immense or Small. Such a report is usually modeled by assigning a probability of each report conditional on each case of what the market might actually be, as shown if Fig. 5. This information is captured by inserting a new chance node into the original influence diagram for the result of the Market Survey, drawing an arrow from the Demand node to that node, indicating the functional dependence or probabilistic relevance, and drawing another arrow from the Market Survey node to the Plant Capacity decision node indicating that the decision maker will know the market survey results when making the primary decision, as shown in Fig. 6. Now there is a problem of how to draw a proper decision tree to solve this influence diagram, as simply following the arrows will not lead to the correct tree. Most readers will recognize that what is needed is the application of Bayes' Rule to reverse the arrow between the Demand node and the Market Survey node. In an influence diagram, an arrow can



Influence Diagrams, Fig. 6 Influence Diagram for the Capacity Example with a Market Survey



Influence Diagrams, Fig. 7 Abbreviated Solved Decision Tree for the Capacity Example with a Market Survey

always be reversed (by Bayes' Rule) if both nodes have the same arrows into them, except for the arrow between them, because this means both nodes are conditioned on the same state of information. New arrows may be added to create this condition, but only if they do not create directed loops in the diagram. In the original paper (Howard et al. 1976), a valid influence diagram describing a decision was called a decision diagram, and one with all nodes reversed so that a tree could be drawn by simply following the arrows is called a decision tree diagram. The ability to express the complete problem the way it is assessed, and then do this kind of manipulation, is a unique advantage of influence diagrams.

Prior to influence diagrams, a decision analyst used two separate constructs, the decision tree (to state the sequential nature of the problem) and nature's tree (to state the original probability assessments), and then manipulated nature's tree into the sequence needed for inserting revised probabilities into the decision tree. Influence diagrams allow both the problem statement and solution to be captured and treated in the same structure. Since trees expand exponentially as nodes are added, only the first two levels in the solution of Fig. 7 are shown, followed by their expected values. Here, the real market survey raises the value of the original problem by only 1.9 compared to the value of perfect information of 14.7 or only about 11.5%. Perfect information is often not a good guide to the value of real information, see Matheson and Matheson, (2005). Influence diagrams can be used to explore similar questions in much more complex situations. An elaborate example, that illustrates a sequence of more complex but useful influence diagram models of a space program decision, including dealing with perplexing counter-factual probability assessments, appears in Matheson, (1990). Formulating and solving general interventions to observe or control decision situations are also discussed in Matheson and Matheson, (2005).

While influence diagrams can grow large, they usually can be constructed so they fit onto one sheet of paper. A corresponding decision tree, however, would be very unwieldy (it might wrap around the room!) and be difficult to manipulate. Fortunately, methods have been developed for solving influence diagrams directly, without building large trees, making solutions of large influence diagrams practical, see (Olmsted 1983; Shachter 1986, 1988).

Summary of Rules, Conventions, and Issues

The references show many rules for constructing and manipulating influence diagrams, including manipulations that constitute formal proofs, with no

numbers involved. Some rules and terminology are provided here.

An influence diagram usually represents the state of information of an author. In the graphical representation, the author is making assertions about the structure of the problem, usually before assigning the functions and numbers inside the nodes. If information is supplied by several parties, a single author should first review and accept it, then consolidate that information into the influence diagram. Large organizations sometimes designate individual information certifiers, or a small group to perform these functions, who sign off on the content of the influence diagrams, much like an architect or engineer signs blueprints.

One can think of a decision node as a node where the decision maker specifies a choice by a usually degenerate probability distribution. The node could represent a randomized strategy in a gaming context, so the whole diagram can be viewed as one joint probability assignment of the decision maker that has been simplified and specified using the influence diagram structure. Thus, influence diagrams represent a conditioning order for representing a joint probability distribution; they are always directed graphs indicating a particular conditioning order and cannot have directed loops.

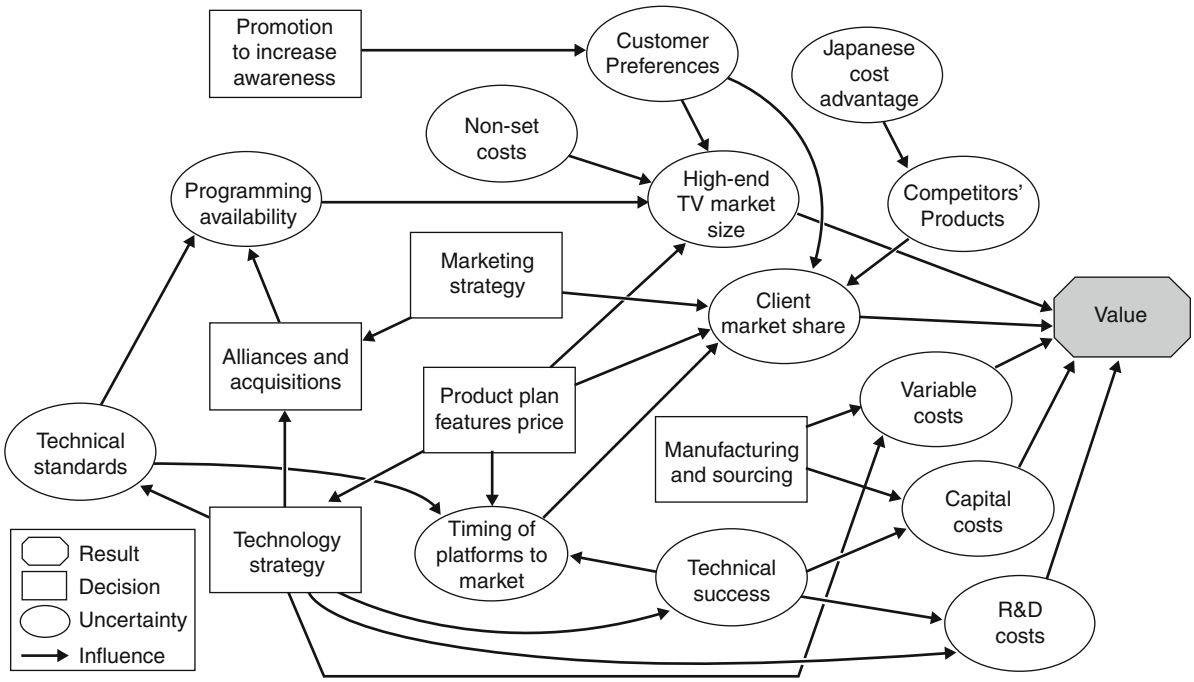
Influence diagrams usually describe a single decision maker who remembers previous decisions. This no forgetting condition means that the decision nodes should be directly ordered by arrows from all preceding decisions, although sometimes implied arrows are left off of the diagram to eliminate clutter. Arrows into decision nodes are informational influences. Arrows into chance nodes are conditioning influences.

The original influence diagram paper did not insist upon having an explicit value node, essentially considering it to be deterministic and in another dimension. But in practice, value nodes are normally used to show what is being maximized, creating what are called decision diagrams. Also, in practice, many deterministic chance nodes surround the value node to link value from various parts of the problem; for example, stating that profit is revenue less cost or revenue is sales volume multiplied by price. Influence diagrams containing a value node and other deterministic relationships are sometimes referred to as value maps. These help to put the main features of the entire decision model into one diagram that can be readily explained and understood. A diagram with only chance nodes is sometimes called a knowledge map with the arrows relevance arrows, see Howard, (1990).

The most important assertions in an influence diagram are given by the lack of possible arrows, as this lack asserts that the author believes that there are structural reasons for a lack of influence (or relevance), and that any subsequent assessment of actual functions or numbers will preserve this property. This feature allows graphical dialog and reasoning about issues that are separate from the particular assessments that might be made later or by different authors who all agree on the structure represented by the diagram. They also allow graphical proofs about features of the diagram that are true no matter what numerical assessments are made. For example, an influence diagram that is a chain of nodes and arrows between each successive node, having no arrows bypassing other nodes, can easily shown to be reversible into the opposite order, while retaining the same features, regardless of what assessments are put into the nodes themselves.

Influence diagrams are often constructed top down. After establishing a value node, the assessor asks the subject, “if you wanted to eliminate some of your uncertainty about value, what question might you ask (of a clairvoyant)?” The subject might answer, “our revenue,” which further breaks down into “the amount sold” and “our realized price.” Asked what information would help reduce those uncertainties, the subject might say, “time of entry of foreign competition” and “U.S. tariff barrier level.” The cost side might be broken into capital cost and variable cost. The process continues until the influence diagram becomes an adequate description of the problem for assessment and analysis.

Influence diagrams can interconnect many decisions and uncertainties to express highly complex problems that would be very difficult to treat with decision trees. A virtual tree always exists as a hypothetical construct, but may be too large to be useful. Decision trees, however, can be useful to display parts of the diagram or the nature of solutions. There are many solution methods that do



Influence Diagrams, Fig. 8 Complex Industrial Influence Diagram

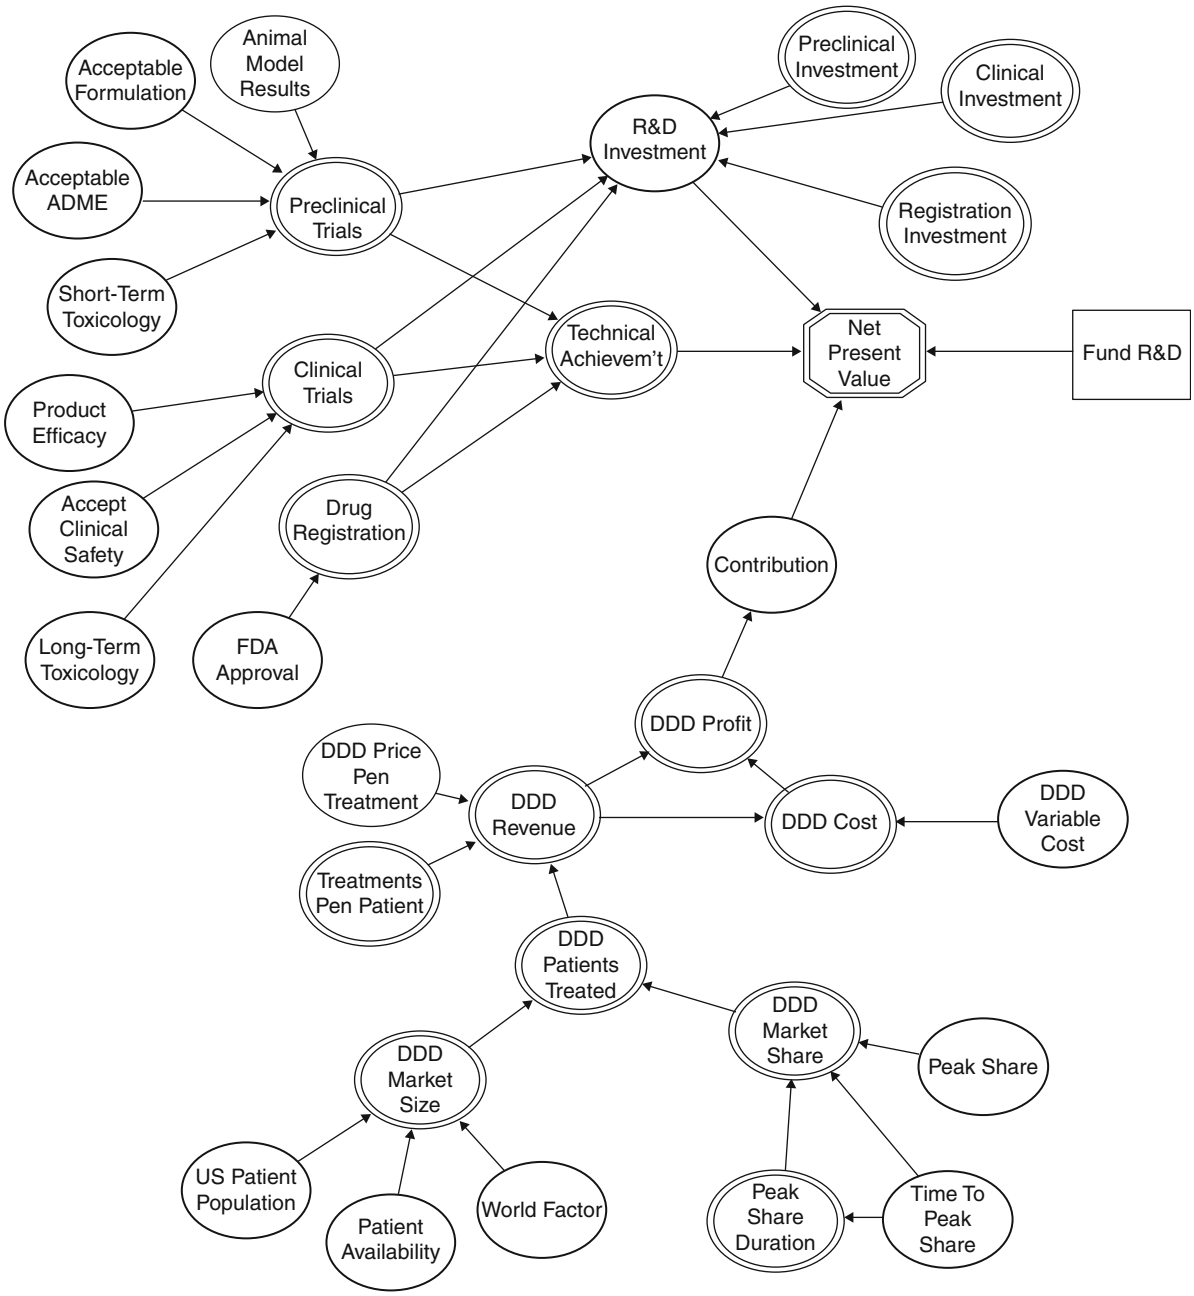
not require developing trees, some for solving decision problems and others specialized to limited situations, such as propagating the impact of information on marginal probabilities.

Adding Complexity: Real-World Influence Diagrams

An example of an influence diagram use to capture and treat a real-world industrial problem is illustrated in Fig. 8. A major international electronics company was concerned about slipping behind in their television and related electronics strategy as the era of HDTV was approaching. The Japanese were already using an early version of HDTV, and an international standards battle was brewing. These standards would influence the strategic position of the company. The company also needed to determine what areas they would keep in-house as proprietary. For example, design and manufacturing technologies, and in what areas they would partner or outsource. In this instance, all of the decision nodes are simultaneous, and the arrows among them have been left off to eliminate clutter. The diagram shows how the company perceived their decisions and the influences on the development of the markets for HDTV and their own participation in it. This work ultimately set their strategy for the following decade. (See Matheson and Matheson 1998) for further discussion).

Another real-world influence diagram, shown here for illustrative purposes is that of a typical drug development, Fig. 9 (SmartOrg 2005). The diagram splits into two: an upper portion that deals with R&D, and a lower portion that deals with the commercial contribution that might accrue if the drug is successfully developed and approved by the FDA for marketing. This diagram is typical of research or development problems, including projects such as oil exploration, or litigation. These problems are all characterized by a development phase, that determines whether the project is commercially feasible, followed by a commercialization phase, that determines the project's contribution if it is commercialized.

Some companies find that parts of an influence diagram repeat themselves in many problems. For example, an oil company investment may often have a portion of the influence diagram representing oil-price economics. This allows the company to do



Influence Diagrams, Fig. 9 A typical Drug Development

a careful assessment once and to distribute the assessed influence diagram to its decision analysts as a starting point for many situations. This process clearly saves labor and assures consistency. But beyond that, most of these companies have a portfolio of investments to make involving the same assessments. In this case the common influence diagram insures consistency and conveys the information needed to determine dependency among the investments, permitting analysis of risk concentration and risk compensation, and providing the analytics needed for diversification and hedging (Matheson 1983).

Information Systems and Database Design in OR/MS

Heiner Müller-Merbach
Technische Universität Kaiserslautern, Kaiserslautern, Germany

Introduction

There are many close relations between information systems, database structures, and operations research (OR). The models and algorithmic procedures of OR are becoming more integrated parts of information systems. The task of OR may continually shift towards the comprehensive design of information systems, database structures included.

Architechture of Comprehensive Information Systems

Traditional data processing was based on collections of individual programs, separated from one another, each with its own individual data organization. Similarly, the characteristic OR packages were stand-alone solutions for singular types of problems, be it mathematical programming, network analysis, and simulation or even more specialized packages for the knapsack problem, traveling salesman problem, set covering problem, etc.

Future information systems, in contrast, will have a comprehensive architecture. The vast majority of data will be stored and maintained centrally, on a data management computer, or on a network of such computers. Most of the programs will mainly process such centralized data and the programs themselves will be available from the comprehensive information system.

A particular feature of the comprehensive information systems is the client–server structure, that is, a network with a huge number of clients (client computers) being provided with data and programs from a server (server computer) or networks of servers.

Relational Databases

The design of such comprehensive information systems and their databases requires standards, in particular those for data structures. A quite common standard today is that of relational databases, such as designed by Codd (1970). The main principles of relational databases are (in non-technical terms):

- All the information is organized in terms of attributes to entity sets. Entity sets are collections of entities with identical attributes — but individual attribute values.
- There is no hierarchy between the entity sets. All the entity sets are at the same level and allow for immediate access. However, it is sometimes advantageous to distinguish between elementary and connecting entity sets. The first ones are self-contained, while the latter ones connect other entity sets and, therefore, depend partly on them.
- Any information is only stored once and no redundancy is allowed. Any attribute, therefore, has to be attached to its corresponding (elementary or connecting) entity set. This is the essence of the normalization concept of relational database structures.

Models and Databases

There exists a narrow correspondence between mathematical models and relational database structures. Indices of a mathematical model indicate the individual entities of an entity set, single indices those of elementary, multiple indices those of connecting entity sets. The constants and variables of a mathematical model correspond with the attributes of the entity sets (Müller-Merbach 1983, 1989; Geoffrion 1989).

This correspondence can easily be shown by a production function that connects the quantities of production factors with the quantities of products:

$$r_j = \sum_k a_{jk}\, x_k$$

with j and k indicating the entities of the entity sets **FACTOR**(j) and **PRODUCT**(k), respectively, and

r_j = quantity of production factor j required

x_k = quantity of product k to be produced

a_{jk} = production coefficient, representing the quantity of factor j required per unit of product k.

The relational database structure corresponding with the production function is given in Fig. 1. There are the elementary entity sets **FACTOR**(j) and **PRODUCT**(k), as well as the connecting entity set $\mathbf{F} \times \mathbf{P}(j, k)$. This database structure is to be considered as a subset of the comprehensive database of the corresponding enterprise with many more entity sets and many more attributes to the entity sets.

Any mathematical model (be it from OR, statistics, etc.) should have such an immediate correspondence with the database. The entity sets correspond with the mathematical indices and the attributes to the entity sets correspond with the constants and variables of the model.

Therefore, model design and database design follows the same logical structure. Either one can proceed the other. However, normally database design is prior to model design and the attributes required for a model can be derived from the data-base. Should, however, the attributes required for a model not be available in the database, an appropriate extension of the database may become necessary.

Mnemonic Notation

Large-scale mathematical models and — even more so — databases in general tend to cover huge numbers of entity sets and attributes. In order to cope with them, a mnemonic notation of the attributes is useful.

The notation should (i) refer to the entity set, (ii) specify the content of the attribute, and (iii) indicate the formal property of the attribute.

Considered be a two-stage production and cost function, respectively, connecting the three elementary entity sets **LABOR**, **MACHINE**, and **PRODUCT** (Fig. 2). The indices indicate the qualification class of labor (i), the machines (j) and the products (k). All the attributes of the entity set **LABOR** start with an L, the others with an M or a P, respectively, referring to the entity sets. The content is represented by a Q (quantity), a T (time required), or a C (cost) in the second position. The third letter indicates constants (C), variables (V) and other formal properties such as discrete variables (D), Boolean variables (B), etc.

Thus, the constants vector PQC_k represents the known (therefore, C) quantities (Q) of the single products (P). The variables vector MTV_j represents the times (T) of the machines (M) required for producing the given quantities of the products. The variables vector LQV_i stands for the quantity (Q) of labor (L) necessary for running the machines.

In addition, the production coefficients have to be introduced. They are attributes of the dependent entity sets, connecting the elementary entity sets **MACHINE** and **PRODUCT** as well as **LABOR** and **MACHINE**. It is convenient that the attributes of the dependent entity sets refer immediately to the attributes of the elementary entity sets. Thus, the constants matrix $MTPQC_{jk}$ represents the machine time (MT) per unit of the product quantities (PQ). This leads immediately to the production function for the machine times required for the given product quantities:

$$MTV_j = \sum_k MTPQC_{jk} PQC_K.$$

In a similar way, the quantity of labor hours (LQ) per unit of the machine times (MT) is represented by the constants matrix $LQMTC_{ij}$, the basis for the production function for the labor quantities required for the computed machine times:

$$LQV_i = \sum_j LQMTC_{ij} MTV_j.$$

The cost functions (here only labor costs) are dual to the production functions. They use the same production coefficients matrices as the production functions, but the attributes of the elementary entity sets are different:

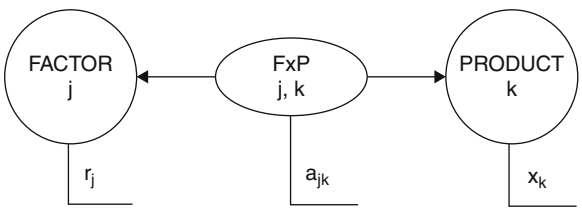
LCC_i = cost of quantity unit of labor (qualification class i)

MCV_j = labor cost per time unit of machine j

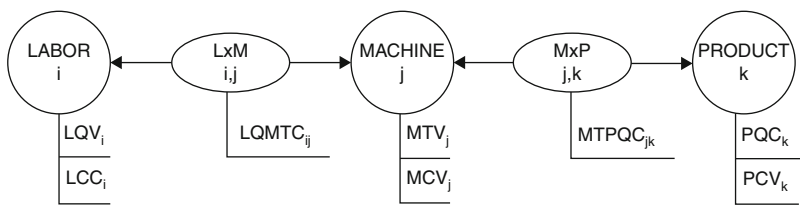
PCV_k = labor cost per quantity unit of product k.

By the first cost function, the labor costs are assigned to the machines:

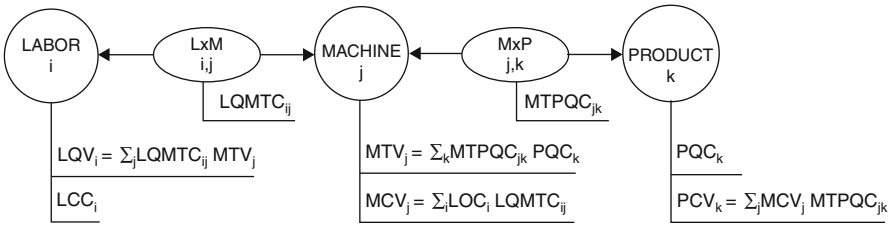
$$MCV_j = \sum_i LCC_i LQMTC_{ij}.$$



Information Systems and Database Design in OR/MS, Fig. 1 Relational database structure for a production function (The attributes are attached to the entity sets **FACTOR**, **PRODUCT**, and **F** × **P**.)



Information Systems and Database Design in OR/MS, Fig. 2 Relational database structure for a two-stage production function and cost function (The mnemonic attributes are attached to the elementary entity sets **LABOR**, **MACHINE**, and **PRODUCT**, as well as to the dependent entity sets **L** × **M** and **M** × **P**.)



Information Systems and Database Design in OR/MS, Fig. 3 Object-oriented database structure for two-stage production function and cost-function (The mnemonic attributes and the functions for the variables are attached to the elementary entity sets **LABOR**, **MACHINE**, and **PRODUCT**, as well as to the dependent entity sets **L** × **M** and **M** × **P**.)

By the second cost function, the resulting labor costs per machine time unit are assigned to the products:

$$PCV_k = \sum_j MCV_j MTPQC_{jk}.$$

Object-Oriented Modeling

There is a tendency from relational databases and modeling towards object-oriented databases and modeling. One of the object-oriented features is the integration of functions and data. Even if there is no unique standard as yet for object-oriented databases, the idea of object-oriented mathematical models can be presented (Fig. 3), with all the production functions integrated into the database structure.

Advantage of Integration

The integration of models and algorithmic procedures of OR into comprehensive information systems has many convenient properties. The main advantage is: the data required for a model can immediately be taken from the centralized database. The results derived from the model can immediately be transferred back to the database and is then available to other users.

Information Technology Benefits

Douglas A. Samuelson
Infologix, Inc., Annandale, VA, USA

Many companies and other organizations have adopted new information technology, expending considerable effort and resources to do so. Understandably, managers wish to evaluate whether the organization's benefits from these new technologies exceeded the cost of acquisition and adoption. What was in 2000 a large and growing literature on this subject seems to have reached a plateau, as early studies questioning the value of information technology collided with the reality of growth and profitability for companies that employed information technology heavily. Methods to evaluate utility and appropriateness of information technology have not kept pace with the technological advances. Good methods of evaluation do exist, but they are not prominent in the literature. Using such methods and developing new ones represent an important challenge and opportunity for OR/MS analysts.

Much of the earlier published work on the subject, especially in business journals, focused on examining whether firms' profits, typically reported quarterly, rose substantially in a fairly short time after adoption of new information technology. This approach proved uninformative and often misleading, as corporate tax accounting practices tend to strive for smallish, level net profits. Hence, the profits metric obscures the true value of information technology investments.

The high-tech boom and bust of 1999–2000 raised awareness of the disparities between the claims and reality for many such investments. Perceptive analysts began to ask not whether information technology pays off in general, but what factors most influence whether it pays off in particular cases. This area of study, most prominently in the software engineering literature, as typified and summarized by Gilb (1988), had been ongoing for some time, but remained unfamiliar many business analysts. Gilb emphasized the need to develop quantified requirements, that is, clear objectives that could be measured numerically and unambiguously, and to monitor continuously whether the project met intermediate milestones as captured by the metrics. Gilb (2005) expanded on these principles, summarizing additional lessons learned and elaborating on the method and some case studies to support his assessment, with little change in the fundamental ideas.

Strassmann (1990) asserted that growth of assets and return on investment, that are more promising measures of benefit, also have drawbacks: return on investment is hard to define precisely and, in most organizations, hard to obtain; growth of assets is also subject to problems of definition, although not to the same extent. Instead, he suggested computing the total expenditure on all forms of management, which in his view includes most support services of any kind, and computing the company's return on management. This is usually not possible without extensive internal auditing of the company; in some cases, Strassmann reported, he arrived at a first approximation of the percentage of total company expenditures devoted to management by counting the number of windows in the company's headquarters that correspond to employees involved in some level of management and support.

Brynjolfsson and Hitt (1998) and Brynjolfsson and Yang (1996, 1996) approached the conceptualization somewhat differently, asserting that information technology and the attendant restructuring of organizational processes create a valuable intangible asset. The resources expended to maintain and protect this asset — or by competitors to diminish its value or duplicate it — can then be used as an indication of its perceived value. This approach has the additional advantage of being applicable to non-profit organizations, rather than just corporations.

Shapiro and Varian (1999) gave a considerably more thorough discussion of the economics of value of information. They argued strongly that accurate and timely information has value which may be considerably greater than one's first attempts at measurement would suggest. If a company uses its information advantage to achieve customer lock-in and, thereby, enables itself to price its products and services, within selected market niches at a high profit margin, it obtains a large return on its information investment — a return which would escape many approaches to measurement, as the benefit is confounded with that of general marketing. Similarly, accumulating know-how which reduces costs of production is confounded with other aspects of cost control.

Another apparently popular method of evaluation is to survey users of the technology. These surveys need not and, in fact, should not be restricted to simple "Do you like it?" items. Subject only to the respondents' limits on the time they are willing to spend, analysts can ask numerous specific questions about how certain tasks, such as disseminating background materials for an important decision, are performed before and after the introduction of new information technology.

Unfortunately, even the best of these surveys are of limited value. Respondents asked how much time they spend finding lost information, for example, may not know, as many of them delegate such tasks to others. Individuals, regardless of level, rarely see group costs. Even more fundamental is the Baywatch Syndrome, which is that people do not realize what they know. That is, in the few years after the show left the air in the U.S., many people who claimed to be unfamiliar with the television series Baywatch were nevertheless able to identify readily a still photograph from the show, rated as the most widely watched show in the world for several years in the mid-1990s. What happened, however, is that much of the exposure took place via channel surfing, or in some other rather haphazard fashion, or via promotions for the show during other programs. For many people, the viewing experience never entered

into their central, attention-directing mental activity, so they did not recall it without specific prompting.

A similar phenomenon occurs when people adopt new information technology. Like a manual gearshift in a car, the information technology slips out of the person's central mental activity and into semi-automatic behavior — and such slippage precisely defines adoption. Once this has occurred, the respondent is less and less likely to recall specifics of use and value of the information technology, as the person is using it with less and less conscious, directed thought about it.

This change in attention and in involvement of higher-order thinking also helps to explain a phenomenon commonly encountered in surveys: respondents state that the new technology is of little value, and one of the primary reasons they give — often with some irritation — is that it breaks too often. Upon closer examination, these responses are contradictory: if the technology is truly of little value, one would not care how often it breaks. Such responses should be interpreted as positive with regard to the perceived value (or at least potential value) of the technology, though clearly not positive with regard to satisfaction and ease of use.

The most useful approach in evaluation, therefore, is to utilize the technology itself to make unobtrusive measurements of actual usage and patterns of use. Most Web servers can readily accommodate software which measures numbers of hits on various resources, numbers of logins and duration of sessions (for systems which have a formal login and logout as part of their access protocols), and similar statistics. With more effort, and custom software, one can also track discussion threads by topic, which makes it possible to answer such questions as how long it takes to get a specific type of order filled, a specific type of question answered, or a specific directive carried out and verified as done. If these measures then change shortly after additions or modifications to the information system, association is easy to identify, and the causal connection is easier to assert.

Finally, some organizations genuinely experience disappointing results with new information technology because they do not change their work processes to take advantage of it. Attempting to maintain hierarchical structures and traditional controls greatly reduces the organization's ability to use the information technology to support coherent, simultaneous activities which do not require direct coordination — the types of activity for which enriched information systems are most critical. As Arquilla and Ronfeldt (1997) pointed out in their review of military information warfare, "The information revolution favors and strengthens networks, while it erodes hierarchies.... Hierarchies have a difficult time fighting networks."

An organization, therefore, which adopts new information technology but does not have clear, measurable objectives and the commitment to change its work processes, will be highly unlikely either to achieve significant benefits or to be able to measure the effects accurately. The proper evaluation of the benefits of information technology requires not only assessment of use of the technology, but also a clear statement of the organization's objectives, realistic appraisal of how well those objectives are being met before and after the technology is introduced, and unflinching accounting for the extent to which organizational, structural, and political resistance to change are affecting the results.

Hubbard (2010) gave a number of good examples of better ways to measure seemingly intangible aspects of organizational performance, some drawn from experience with information technology projects. Hubbard (2009) also noted explicitly the tendency of managers to over-value some techniques for decision-making. According to surveys he conducted, some popular methods, such as balanced scorecards and some applications of the Analytic Hierarchy Process (AHP), consistently did better at raising managers' confidence in decisions than in improving outcomes. He concluded that methods of decision making should be subjected to the same rigorous quantitative evaluation as other subject areas – if anything, even more so – with the purpose of driving out underperforming methods.

Hubbard also noted that metrics' value is not inherent, but depends on what is already known. An approach he invented (or at least stated cogently and named), Applied Information Economics, addresses this valuation by calculating the Expected Value of Perfect Information (EVPI), that is, the risk associated with the decision if a selected data element were known with certainty, and devoting resources to those areas of uncertainty (regarding data elements) in which more information would most decrease the decision risk. For example, in information technology investments, his studies indicated that managers generally knew the

costs of information projects much better than the benefits. Hence, they tended to underestimate one of the biggest risks: cancellation of the project partway through because of some combination of changing management objectives, changing perception of requirements, and frustration with the lack of tangible progress. Thus, Hubbard arguing from probabilistic-decision making, reinforces Gilb's emphasis on the importance of well-defined quantitative metrics that are systematically and periodically reviewed throughout the project's life.

Initial Feasible Solution

▶ First Feasible Solution

Input Process

The stochastic point process representing some aspect of customers actually entering a queueing system (or nodal part of one) or some aspect of the state of the node at the instant of input, with points representing the instants of entrance. For example, in finite capacity queues, and $(\boldsymbol{X}^a, \boldsymbol{T}^a)$ process has the $\boldsymbol{X}^a$ process as a sequence of 1s and 0s representing whether the queue is full or not at an arrival and the $\boldsymbol{T}^a$ process represents the times of arrivals. The subset of the $\boldsymbol{T}^a$ process for which $\boldsymbol{X}^a = 0$ represents the set of arrival epochs at which a customer actually enters the node, while the $\boldsymbol{T}^a$ for which $\boldsymbol{X}^a = 1$ represents the set of arrival times at which customers do not gain access to the node but overflow.

See

- ▶ Arrival Process

- ▶ Queueing Theory

Input–Output Analysis

The economic theory developed by the economist W.W. Leontief to study a national economy. The approach requires the development of an input–output table (matrix) in which the coefficients in a row indicate how much of the industry designated by that row is required to produce a unit of output for itself and all other industries, and the coefficients in

a column represent the amounts of each industry required to produce one unit of output for the industry designated by that column. Under the assumption that the input–output coefficients are stable over the near future and reflect a constant return to scale (linear) relationship, a square set of equations can be established to determine production levels for the industries that meets projected demand.

See

► Input–Output Coefficients

Input–Output Coefficients

For some linear programming and other production problems, the $\boldsymbol{A} = (a_{ij})$ coefficients of the constraints $\boldsymbol{Ax} = \boldsymbol{b}$ can be interpreted as the amount of resource i required (input) to produce one unit of product j (output). More generally, an input–output matrix of American industries formed the bases of the economist Leontief's contribution to economic theory.

► Activity-Analysis Problem
► Input–Output Analysis

Insensitivity

A property of queueing systems wherein some measure of effectiveness does not depend on a particular distribution assumption except through its mean value. The classical example is the Erlang loss call formula in the multi-server M/G/c/c queue that depends on the service-time process only through its mean value.

Institute for Operations Research and the Management Sciences (INFORMS)

The main organization for operations research and the management sciences in the United States begun officially on January 1, 1995 upon the merger of the Operations Research Society of America (ORSA) and The Institute of Management Sciences (TIMS).

Integer and Combinatorial Optimization

Karla L. Hoffman[1] and Ted K. Ralphs[2]
[1]George Mason University, Fairfax, VA, USA
[2]Lehigh University, Bethlehem, PA, USA

Introduction

Integer optimization problems are concerned with the efficient allocation of limited resources to meet a desired objective when some of the resources in question can only be divided into discrete parts. In such cases, the divisibility constraints on these resources, which may be people, machines, or other discrete inputs, may restrict the possible alternatives to a finite set. Nevertheless, there are usually too many alternatives to make complete enumeration a viable option for instances of realistic size. For example, an airline may need to determine crew schedules that minimize the total operating cost, an automotive manufacturer may want to determine the optimal mix of models to produce in order to maximize profit, or a flexible manufacturing facility may want to schedule production for a plant without knowing precisely what parts will be needed in future periods. In today's changing and competitive industrial environment, the difference between ad hoc planning methods and those that use sophisticated mathematical models to determine an optimal course of action can determine whether or not a company survives.

A common approach to modeling optimization problems with discrete decisions is to formulate them as mixed integer optimization problems. This entry focuses on problems in which the functions required to represent the objective and constraints are additive, i.e., linear functions. Such a problem is called a mixed

integer linear optimization problem (MILP) and its general form is

$$\max \sum_{j\in B} c_j x_j + \sum_{j\in I} c_j x_j + \sum_{j\in C} c_j x_j \tag{1}$$

$$\text{subject to } \sum_{j\in B} a_{ij} x_j + \sum_{j\in I} a_{ij} x_j + \sum_{j\in C} a_{ij} x_j \begin{Bmatrix} \le \\ = \\ \ge \end{Bmatrix} b_i \quad \forall i \in M, \tag{2}$$

$$l_j \le x_j \le u_j \quad \forall j \in N = B \cup I \cup C, \tag{3}$$

$$x_j \in \{0, 1\} \quad \forall j \in B, \tag{4}$$

$$x_j \in \mathbb{Z} \quad \forall j \in I, \text{and} \tag{5}$$

$$x_j \in \mathbb{R} \quad \forall j \in C. \tag{6}$$

A solution to (1)–(6) is a set of values assigned to the variables $x_j, j \in N$. The objective is to find a solution that maximizes the weighted sum (1), where the coefficients c_j, $j \in N$ are given. B is the set of indices of binary variables (those that can take on only values 0 or 1), I is the set of indices of integer variables (those that can take on any integer value), and C is the set of indices of continuous variables. As indicated above, each of the first set of constraints (2) can be either an inequality constraint ("$\le$" or "$\ge$") or an equality constraint ("$=$"). The data l_j and u_j are the lower- and upper-bound values, respectively, for variable $x_j, j \in N$.

This general class of problems has many important special cases. $B = I = \emptyset$ gives what is known as a linear optimization problem (LP). If $C = I = \emptyset$, then the problem is referred to as a (pure) binary integer linear optimization problem (BILP). Finally, if $C = \emptyset$, the problem is called a (pure) integer linear optimization problem (ILP). Otherwise, the problem is simply a MILP. Throughout this discussion, refer to the set of points satisfying (1)–(6) as $\mathcal{S}$, and the set of points satisfying all but the integrality restrictions (4)–(5) as $\mathcal{P}$. The problem of optimizing over $\mathcal{P}$ with the same objective function as the original MILP is called the LP relaxation and arises frequently in algorithms for solving MILPs.

A class of problems closely related to BILPs are the combinatorial optimization problems (COPs). A COP is defined by a ground set $\mathcal{E}$, a set $\mathcal{F}$ of subsets of ε that are called the feasible subsets, and a cost c_e associated with each element $e \in \mathcal{E}$. Each feasible subset $F \in \mathcal{F}$ has an associated (additive) cost taken to be $\Sigma_{e \in F} c_e$. The goal of a COP is find the subset $F \in \mathcal{F}$ of minimum cost. The set $\mathcal{F}$ can often be described as the set of solutions to a BILP by associating a binary variable x_e with each member e of the ground set, indicating whether or not to include it in the selected subset. For this reason, combinatorial optimization and integer optimization are closely related and COPs are sometimes informally treated as being a subclass of MILPs, though there are COPs that cannot be formulated as MILPs.

Solution of an MILP involves finding one or more best (optimal) solutions from the set $\mathcal{S}$. Such problems occur in almost all fields of management (e.g., finance, marketing, production, scheduling, inventory control, facility location and layout, supply chain management), as well as in many engineering disciplines (e.g., optimal design of transportation networks, integrated circuit design, design and analysis of data networks, production and distribution of electrical power, collection and management of solid waste, determination of minimum energy states for alloy construction, planning for energy resource problems, scheduling of lines in flexible manufacturing facilities, and design of experiments in crystallography).

This entry gives a brief overview of the related fields of integer and combinatorial optimization. These fields have by now accumulated a rich history and a rich mathematical theory. Texts covering the theory of linear and integer linear optimization include those of Bertsimas and Weismantel (2005), Chvátal (1983), Nemhauser and Wolsey (1988), Parker and Rardin (1988), Schrijver (1986), and Wolsey (1998). Overviews of combinatorial optimization are provided by Papadimitriou and Steiglitz (1982) and Schrijver (2003). Jünger et al. (2010) have produced a marvelous and comprehensive volume containing an overview of both the history and current state of the art in integer and combinatorial optimization.

Applications

This section describes some classical integer and combinatorial optimization models to provide an overview of the diversity and versatility of this field.

Knapsack Problems

Suppose one wants to fill a knapsack that has a weight capacity limit of W with some combination of items from a list of n candidates, each with weight w_i and value v_i, in such a way that the value of the items packed into the knapsack is maximized. This problem has a single linear constraint (that the weight of the items selected not exceed W), a linear objective function (to maximize the sum of the values of the items in the knapsack), and the added restriction that each item either be in the knapsack or not—it is not possible to select a fractional portion of an item. For solution approaches specific to the knapsack problem, see Martello and Toth (1990).

Although this problem might seem too simplistic to have many practical applications, the knapsack problem arises in a surprisingly wide variety of fields. For example, one implementation of the public-key cryptography systems that are pervasive in security applications depends on the solution of knapsack problems to determine the cryptographic keys (Odlyzko 1990). The system depends on the fact that, despite their simplicity, some knapsack problems are extremely difficult to solve.

More importantly, however, the knapsack problem arises as a substructure in many other important combinatorial problems. For example, machine-scheduling problems involve restrictions on the capacities of the machines to be scheduled (in addition to other constraints). Such a problem involves assigning a set of jobs to a machine in such a way that the capacity constraint is not violated. It is easy to see that such a constraint is of the same form as that of a knapsack problem. Often, a component of the solution method for problems with knapsack constraints involves solving the knapsack problem itself, in isolation from the original problem (see Savelsbergh (1997)). Another important example in which knapsack problems arise is the capital budgeting problem. This problem involves finding a subset of the set of (possibly) thousands of capital projects under consideration that will yield the greatest return on investment, while satisfying specified financial, regulatory, and project relationship requirements (Markowitz and Manne 1957; Weingartner 1963). Here also, the budget constraint takes the same form as that of the knapsack problem.

Network and Graph Problems

Many optimization problems can be represented by a network, formally defined as a set of nodes and a set of arcs (unidirectional connections specified as ordered pairs of nodes) or edges (bidirectional connections specified as unordered pairs of nodes) connecting those nodes, along with auxiliary data such as costs and capacities on the arcs (the nodes and arcs together *without* the auxiliary data form a graph). Solving such network problems involves determining an optimal strategy for routing certain commodities through the network. This class of problems is thus known as network flow problems. Many practical problems arising from physical networks, such as city streets, highways, rail systems, communication networks, and integrated circuits, can be modeled as network flow problems. In addition, there are many problems that can be modeled as network flow problems even when there is no underlying physical network. For example, in the assignment problem, one wishes to assign people to jobs in a way that minimizes the cost of the assignment. This can be modeled as a network flow problem by creating a network in which one set of nodes represents the people to be assigned, and another set of nodes represents the possible jobs, with an arc connecting a person to a job if that person is capable of performing that job. A general survey of applications and solution procedures for network flow problems is given by Ahuja et al. (1993).

Space-time networks are often used in scheduling applications. Here, one wishes to meet specific demands at different points in time. To model this problem, different nodes represent the same entity at different points in time. An example of the many scheduling problems that can be represented as a space-time network is the airline fleet assignment problem, which requires that one assign specific planes to prescheduled flights at minimum cost (Abara 1989; Hane et al. 1995). Each flight must have one and only one plane assigned to it, and

a plane can be assigned to a flight only if it is large enough to service that flight and only if it is on the ground at the appropriate airport, serviced and ready to depart when the flight is scheduled for takeoff. The nodes represent specific airports at various points in time and the arcs represent the flow of aircraft of a variety of types into and out of each airport. There are layover arcs that permit a plane to stay on the ground from one time period to the next, service arcs that force a plane to be out of duty for a specified amount of time, and connecting arcs that allow a plane to fly from one airport to another without passengers.

A variety of important combinatorial problems are graph-based, but do not involve flows. Such graph-based combinatorial problems include the node-coloring problem, the objective of which is to determine the minimum number of colors needed to color each node of a graph in order that no pair of adjacent nodes (nodes connected by an edge) share the same color; the matching problem, the objective of which is to find a maximum weight collection of edges such that each node is incident to at most one edge; the maximum clique problem, the objective of which is to find the largest subgraph of the original graph such that every node is connected to every other node in the subgraph; and the minimum cut problem, the objective of which is to find a minimum weight collection of edges that (if removed) would disconnect a set of nodes s from a set of nodes t.

Although these graph-based combinatorial optimization problems might appear, at first glance, to be interesting only from a mathematical perspective and to have little application to the decision-making that occurs in management or engineering, their domain of application is extraordinarily broad. The four-color problem, e.g., which is the question of whether a map can be colored with four colors or less, is a special case of the node-coloring problem. The maximum clique problem has important implications in the growing field of social network analysis. The minimum cut problem is used in analyzing the properties of real-world networks, such as those arising in communications and logistics applications.

Location, Routing, and Scheduling Problems

Many network-based combinatorial problems involve finding a route through a given graph satisfying specific requirements. In the Chinese postman problem, one wishes to find a shortest walk (a connected sequence of arcs) through a network such that the walk starts and ends at the same node and traverses every arc at least once (Edmonds and Johnson 1973). This models the problem faced by a postal delivery worker attempting to minimize the number of traversals of each road segment on a given postal route. If one instead requires that each node be visited exactly once, the problem becomes the notoriously difficult traveling salesman problem (Applegate et al. 2006). The traveling salesman problem has numerous applications within the routing and scheduling realm, as well as in other areas, such as genome sequencing (Avner 2001), the routing of SONET rings (Shah 1998), and the manufacturing of large-scale circuits (Barahona et al. 1988; Ravikumar 1996). The well-known vehicle routing problem is a generalization in which multiple vehicles must each follow optimal routes subject to capacity constraints in order to jointly service a set of customers (Golden et al. 2010).

A typical scheduling problem involves determining the optimal sequence in which to execute a set of jobs subject to certain constraints, such as a limited set of machines on which the jobs must be executed or a set of precedence constraints restricting the job order (see Applegate and Cook (1991)). The literature on scheduling problems is extremely rich and many variants of the basic problem have been suggested (Pinedo 2008). Location problems involve choosing the optimal set of locations from a set of candidates, perhaps represented as the nodes of a graph, subject to certain requirements, such as the satisfaction of given customer demands or the provision of emergency services to dispersed populations (Drezner and Hamacher 2004). Location, routing, and scheduling problems all arise in the design of logistics systems, i.e., systems linking production facilities to end-user demand points through the use of warehouses, transportation facilities, and retail outlets. Thus, it is easy to envision combinations of these classes of problems into even more complex combinatorial problems and much work has been in this direction.

Packing, Partitioning, and Covering Problems

Many practical optimization problems involve choosing a set of activities that must either cover certain requirements or must be packed together so as

not to exceed certain limits on the number of activities selected. The airline crew scheduling problem, e.g., is a covering problem in which one must choose a set of pairings (a set of flight legs that can be flown consecutively by a single crew) that cover all required routes (Hoffman and Padberg 1993; Vance et al. 1997). Alternatively, an example of a set packing problem is a combinatorial auction (Cramton et al. 2006). The problem is to select subsets of a given set of items that are up for auction in such a way that each item is included in at most one subset. This is the problem faced by an auctioneer in an auction in which bidders can bid on sets of items rather than just single items. If one requires that all items be sold, then the auctioneer's problem becomes a partitioning problem. There are a variety of languages that allow users to express the interrelationship among their bids. Such languages (e.g., "OR," "XOR," "ORofXOR," "XORofOR") create a somewhat different structure to the combinatorial problem.

In the above examples, the coefficients in constraints (2) are either zero or one and all variables are binary. The variables represent the choice of activities, while each constraint represents either a covering ("$\geq$"), packing ("$\leq$"), or partitioning ("$=$") requirement. In many cases, these problems can be easily interpreted by thinking of the rows as a set of items to be allocated or a set of activities to be undertaken and the columns as subsets of those items/activities. The optimization problem is then to find the best collection of subsets of the activities/items (columns) in order to cover/partition/pack the row set. Surveys on set partitioning, covering, and packing are given in Balas and Padberg (1976), Borndörfer and Weismantel (2000), Hoffman and Padberg (1993), and Padberg (1979b).

Other Nonconvex Problems

The versatility of the integer optimization model (1)–(6) might best be exemplified by the fact that many nonlinear/nonconvex optimization problems can be reformulated as MILPs. For example, one reformulation technique for representing nonlinear functions is to find a piecewise linear approximation and to represent the function by adding a binary variable corresponding to each piece of the approximation. The simplest example of such a transformation is the fixed-charge problem in which the cost function has both a fixed charge for initiating a given activity, as well as marginal costs associated with continued operation. One example of a fixed-charge problem is the facility location problem in which one wishes to locate facilities in such a way that the combined cost of building the facility (a onetime fixed cost) and producing and shipping to customers (marginal costs based on the amount shipped and produced) is minimized (see Drezner and Hamacher (2004)). The fact that nothing can be produced in the facility unless the facility exists creates a discontinuity in the cost function. This function can be transformed to a linear function by the introduction of additional variables that take on only the values 0 or 1. Similar transformations allow one to model separable nonlinear functions as integer (linear) optimization problems.

Solution Methods

Solving integer optimization problems (finding an optimal solution), can be a difficult task. The difficulty arises from the fact that unlike (continuous) linear optimization problems, for which the feasible region is convex, the feasible regions of integer optimization problems consists of either a discrete set of points or, in the case of general MILP, a set of disjoint polyhedra. In solving a linear optimization problem, one can exploit the fact that, due to the convexity of the feasible region, any locally optimal solution is a global optimum. In finding global optima for integer optimization problems, on the other hand, one is required to prove that a particular solution dominates all others by arguments other than the calculus-based approaches of convex optimization. The situation is further complicated by the fact that the description of the feasible region is implicit. In other words, the formulation (1)–(6) does not provide a computationally useful geometric description of the set $\mathcal{S}$. A more useful description can be obtained in one of two ways described next.

The first approach is to apply the powerful machinery of polyhedral theory. Weyl (1935) established the fact that a polyhedron can either be defined as the intersection of finitely many half-spaces, i.e., as a set of points satisfying inequalities of the form (2) and (3), or as the convex hull of a finite set of extreme points plus the conical hull of a finite set of extreme rays. If the data describing the original problem formulation are rational

numbers, then Weyl's theorem implies the existence of a finite system of linear inequalities describing the convex hull of $\mathcal{S}$, denoted by conv($\mathcal{S}$) (Nemhauser and Wolsey 1988). Optimization of a linear function over conv($\mathcal{S}$) is precisely equivalent to optimization over $\mathcal{S}$, but optimizing over conv($\mathcal{S}$) is a convex optimization problem. Thus, if it were possible to enumerate the set of inequalities in Weyl's description, one could solve the integer optimization problem using methods for convex optimization, in principle. The difficulty with this method, however, is that the number of linear inequalities required is too large to construct explicitly, so this does not lead directly to a practical method of solution.

A second approach is to describe the feasible set in terms of logical disjunction. For example, if $j \in B$, then either $x_j = 0$ or $x_j = 1$. This means that, in principle, the set $\mathcal{S}$ can be described by replacing constraints (4)–(5) with a set of appropriately chosen disjunctions. In fact, it is known that any MILP can be described as a set of linear inequalities of the form (2) and (3), plus a finite set of logical disjunctions (Balas 1998). Similarly, however, the number of such disjunctions would be too large to enumerate explicitly and so this does not lead directly to a practical method of solution either.

Although neither of the above methods for obtaining a more useful description of $\mathcal{S}$ leads directly to an efficient methodology because they both produce descriptions of impractical size, most solution techniques are nonetheless based on generating partial descriptions of $\mathcal{S}$ in one of the above forms (or a combination of both). The general outline of such a method is as follows:

1. Identify a (tractable) convex relaxation of the problem and solve it to either
   - Obtain a valid upper bound on the optimal solution value; or
   - Prove that the relaxation is infeasible or unbounded (and thus, the original MILP is also infeasible or unbounded)
2. If solving the relaxation produces a solution $\hat{x} \in \mathbb{R}^N$ that is feasible to the MILP, then this solution must also be optimal to the MILP.
3. Otherwise, either
   - Identify a logical disjunction satisfied by all members of $\mathcal{S}$, but not by $\hat{x}$ and add it to the description of $\mathcal{P}$ (more on how this is done below); or
   - Identify an implied linear constraint (called a valid inequality or a cutting plane) satisfied by all members of $\mathcal{S}$, but not by $\hat{x}$ and add it to the description of $\mathcal{P}$

In Step 1, the LP relaxation obtained by dropping the integrality conditions on the variables and optimizing over $\mathcal{P}$ is commonly used. Other possible relaxations include Lagrangian relaxations (Fisher 1981; Geoffrion 1974), semi-definite programming relaxations (Rendl 2010), and combinatorial relaxations, e.g., the one-tree relaxation for the traveling salesman problem Held and Karp (1970). This discussion initially considers use of the LP relaxation, since this is the simplest one and the one used in state-of-the-art software. Additional relaxations are considered in more detail in section "Advanced Procedures."

By recursively applying the basic strategy outlined above, a wide variety of convergent methods that generate partial descriptions of $\mathcal{S}$ can be obtained. These methods can be broadly classified as either implicit enumeration methods (employing the use of logical disjunction in Step 3) or cutting plane methods (based on the generation of valid inequalities in Step 3), though these are frequently combined into hybrid solution procedures in computational practice. In the next two sections, more details about these two classes of methods are given.

Enumerative Algorithms

The simplest approach to solving a pure integer optimization problem is to enumerate all finitely many possibilities (as long as the problem is bounded). However, due to the combinatorial explosion resulting from the fact that the size of the set $\mathcal{S}$ is generally exponential in the number of variables, only the smallest instances can be solved by such an approach. A more efficient approach is to only implicitly enumerate the possibilities by eliminating large classes of solutions using domination or feasibility arguments. Besides straightforward or implicit enumeration, the most commonly used enumerative approach is called branch and bound.

The branch-and-bound method was first proposed by Land and Doig (1960) and consists of generating disjunctions satisfied by points in $\mathcal{S}$ and using them to partition the feasible region into smaller subsets. Some variant of the technique is used by practically all state-of-the-art solvers. An LP-based

branch-and-bound method consists of solving the LP relaxation as in Step 1 above to either obtain a solution and an associated upper bound or to prove infeasibility or unboundedness. If the generated solution $\hat{x} \in \mathbb{R}^N$ to the relaxation is infeasible to the original MILP, then $\hat{x}_j \notin \mathbb{Z}$ for some $j \in B \cup I$. However, $x_j \in \mathbb{Z}$ for all $x \in \mathcal{S}$. Therefore, the logical disjunction

$$x_j \leq \lfloor \hat{x}_j \rfloor \text{ OR } x_j \geq \lceil \hat{x}_j \rceil \tag{7}$$

is satisfied by all $x \in \mathcal{S}$, but not by $\hat{x}$. In this case, one can impose the disjunction implicitly by branching, i.e., creating two subproblems, one associated with each of the terms of the disjunction (7).

The branch-and-bound method consists of applying this same method to each of the resulting subproblems recursively. Note that the optimal solution to a subproblem may or may not be the global optimal solution. Each time a new solution is found, it is checked to determine whether it is the best seen so far and if so, it is recorded and becomes the current incumbent. The true power of this method comes from the fact that if the upper bound obtained by solving the LP relaxation is smaller than the value of the current incumbent, the node can be discarded. Mitten (1970) provided the first description of a general algorithmic framework for branch and bound. Hoffman and Padberg (1985) provided an overview of LP-based branch-and-bound techniques. Linderoth and Savelsbergh (1999) reported on a computational study of search strategies used within branch and bound.

Cutting Plane Algorithms

Gomory (1958, 1960) was the first to derive a cutting plane algorithm following the basic outline above for integer optimization problems. His algorithm can be viewed, in some sense, as a constructive proof of Weyl's theorem. Although Gomory's algorithm converges to an optimal solution in a finite number of steps (in the case of pure integer optimization problems), the convergence to an optimum may be extraordinarily slow due to the fact that these algebraically derived valid inequalities are weak—they may not even support conv($\mathcal{S}$) and are hence dominated by stronger (but undiscovered) valid inequalities. Since the smallest possible description of conv($\mathcal{S}$) is desired, one would like to generate only the strongest valid inequalities, i.e., those that are part of some minimal description of conv($\mathcal{S}$). Such inequalities are called facets. In general, knowing all facets of conv($\mathcal{S}$) is enough to solve the MILP (though this set would still be very large in most cases).

A general cutting plane approach relaxes the integrality restrictions on the variables and solves the resulting LP relaxation over the set $\mathcal{P}$. If the LP is unbounded or infeasible, so is the MILP. If the solution to the LP is integer, i.e., satisfies constraints (4) and (5), then one has solved the MILP. If not, then one solves a separation problem whose objective is to find a valid inequality that cuts off the fractional solution to the LP relaxation while assuring that all feasible integer points satisfy the inequality—i.e., an inequality that separates the fractional point from the polyhedron conv($\mathcal{S}$). Such an inequality is called a cut for short. The algorithm continues until termination in one of two ways: either an integer solution is found (the problem has been solved successfully) or the LP relaxation is infeasible and therefore the integer problem is infeasible.

For ILPs, there are versions of Gomory's method that yield cutting plane algorithms that will produce a solution in a finite number of iterations, at least with the use of exact rational arithmetic. In practice, however, the algorithm could terminate in a third way—it may not be possible to identify a new cut even though the optimal solution has not been found either due to numerical difficulties arising from accumulated round-off error or because procedures used to generate the cuts are unable to guarantee the generation of a violated inequality, even when one exists. If one terminates the cutting plane procedure because of this third possibility, then, in general, the process has still improved the original formulation and the bound resulting from solving the LP relaxation is closer to the optimal value. By then switching to an implicit enumeration strategy, one may still be able to solve the problem. This hybrid strategy, known as branch and cut, is discussed in the next section.

Advanced Procedures

Branch and Cut

The two basic methods described above can be hybridized into a single algorithm that combines the

power of the polyhedral and disjunctive approaches. This method is called branch and cut. A rather sizable literature has sprung up around these methods. Papers describing the basic framework include those of Hoffman and Padberg (1991) and Padberg and Rinaldi (1991). Surveys of the computational issues and components of a modern branch-and-cut solver include Atamtürk and Savelsbergh (2005), Linderoth and Ralphs (2005), and Martin (2001). The major components of the algorithm consist of automatic reformulation and preprocessing procedures (see next section), heuristics that provide good feasible integer solutions, procedures for generating valid inequalities, and procedures for branching. All of these are embedded into a disjunctive search framework, as in the branch-and-bound approach. These components are combined so as to guarantee optimality of the solution obtained at the end of the calculation. The algorithm may also be stopped early to produce a feasible solution along with a bound on the relative distance of the current solution from optimality. This hybrid approach has evolved to be an extremely effective way of solving general MILPs. It is the basic approach taken by all state-of-the-art solvers for MILP.

Ideally, the cutting planes generated during the course of the algorithm would be facets of conv($\mathcal{S}$). In the early years of integer optimization, considerable research activity was focused on identifying part (or all) of the list of facets for specific combinatorial optimization problems by exploiting the special structure of conv($\mathcal{S}$) (Balas and Padberg 1972; Balas 1975; Bauer et al. 2002; Hammer et al. 1975; Nemhauser and Sigismondi 1992; Nemhauser and Trotter 1974; Nemhauser and Vance 1994; Padberg 1973, 1974, 1979a; Pochet and Wolsey 1991; Wolsey 1975, 1976). This led to a wide variety of problem-dependent algorithms that are nevertheless based on the underlying principle embodied in Weyl's theorem. An extensive survey of the use of these techniques in combinatorial optimization is given by Aardal and van Hoesel (1996a, b).

Research on integer optimization is increasingly focused on methods for generating inequalities based purely on the disjunctive structure of the problem and not on properties of a particular class of problems. Part of the reason for this is the need to be able to solve more general MILPs for which even the dimension of conv($\mathcal{S}$) is not known. With this approach, it is not possible to guarantee the generation of facets in every iteration, but theoretical advances have resulted in vast improvements in the ability to solve general unstructured integer optimization problems using off-the-shelf software. A survey of cutting plane methods for general MILPs is provided by (Cornuéjols 2008). Other papers on techniques for generating valid inequalities for general MILPs include Balas et al. (1993, 1996, 1999), Gu et al. (1998, 1999, 2000), Nemhauser and Wolsey (1990), Marchand and Wolsey (2001), and Wolsey (1990).

Equally as important as cutting plane generation techniques are branching schemes, though these methods have received far less attention in the literature. Branching methods are generally based on some method of estimating the impact of a given branching disjunction and trying to choose the best one according to certain criteria. Papers discussing branching methods include Achterberg et al. (2005), Fischetti and Lodi (2002), Karamanov and Cornuéjols (2009), and Owen and Mehrotra (2001).

There has been a surge in research on the use of heuristic methods within the branch-cut-cut framework in order to generate good solutions and improve bounds as the search progresses. Many search methods are based on limited versions of the same search procedures used to find globally optimal solutions. The development of such methods has led to marked improvements in the performance of exact algorithms (Balas and Martin 1980; Balas et al. 2004; Fischetti and Lodi 2002; Nediak and Eckstein 2001). In current state-of-the-art software, multiple heuristics are used because they are likely to produce feasible solutions more quickly than tree search, which helps both to eliminate unproductive subtrees and to calculate improved variable bounds that result in a tighter description of the problem. These heuristics include techniques for searching within the local neighborhood of a given linear feasible solutions for integer solutions using various forms of local search. Achtenberg and Berthold (2007), Danna et al. (2005), Fischetti et al. (2009), and Rothberg (2007) provide descriptions of heuristics built into current packages.

Automatic Reformulation

Before solving an integer optimization problem, the first step is that of formulation, in which a conceptual model is translated into the form (1)–(6). There are often different ways of mathematically representing the same problem, both because different systems of

the form (1)–(6) may define precisely the same set $\mathcal{S}$ and because it may be possible to represent the same conceptual problem using different sets of variables. There are a number of different ways in which the conceptual model can be translated into a mathematical model, but the most common is to use an algebraic modeling language, such as AIMMS, AMPL (Fourer et al. 1993), GAMS (Brooke et al. 1988), MPL, or OPL Studio.

The time required to obtain an optimal solution to a large integer optimization problem usually depends strongly on the way it is formulated, so much research has been directed toward the effective automatic reformulation techniques. Unlike linear optimization problems, the number of variables and constraints representing an integer optimization problem may not be indicative of its difficulty. In this regard, it is sometimes advantageous to use a model with a larger number of integer variables, a larger number of constraints, or both. Discussions of alternative formulation approaches are given in Guignard and Spielberg (1981) and Williams (1985), and a description of approaches to automatic reformulation or preprocessing is given in Anderson and Anderson (1995), Atamturk and Savelsbergh (2000), Brearley et al. (1975), Hoffman and Padberg (1991), Roy and Wolsey (1987), and Savelsbergh (1994).

A variety of difficult problems have been solved by reformulating them as either set-covering or set-partitioning problems having an extraordinary number of variables. Because for even small instances, such reformulations may be too large to solve directly, a technique known as column generation, which began with the seminal work of Gilmore and Gomory (1961) on the cutting stock problem, is employed. An overview of such transformation methods can be found in Barnhart et al. (1998). For specific implementations, for the vehicle routing problem, see Chabrier (2006), for the bandwidth packing problem, see Hoffman and Villa (2007) and Parker and Ryan (1995), for the generalized assignment problem, see Savelsbergh (1997), and for alternative column-generation strategies for solving the cutting stock problem see Vance et al. (1994). Bramel and Simchi-Levi (1997) have shown that the set-partitioning formulation for the vehicle routing problem with time windows is very effective in practice—that is, the relative gap between the fractional linear optimization solutions and the global integer solution is small. Similar results have been obtained for the bin-packing problem (Chan et al. 1998a) and for the machine-scheduling problem (Chan et al. 1998b).

Decomposition Methods

Relaxing the integrality restriction is not the only approach to relaxing the problem. An alternative approach to the solution to integer optimization problems is to relax a set of complicating constraints in order to obtain a more tractable model. This technique is effective when the problem to be solved is obtained by taking a well-solved base problem and adding constraints specific to a particular application. By capitalizing on the ability to solve the base problem, one can obtain bounds that are improved over those obtained by solving the LP relaxation. These bounding methods can then be used to drive a branch-and-bound algorithm, as described earlier. Such bounding methods are called constraint decomposition methods or simply decomposition methods, since they involve decomposing the set of constraints. By removing the complicating constraints from the constraint set, the resulting subproblem is frequently considerably easier to solve. The latter is necessary for the approach to work because the subproblems must be solved repeatedly. The bound found by decomposition can be tighter than that found by linear optimization, but only at the expense of solving subproblems that are themselves integer optimization problems. Decomposition requires that one understand the structure of the problem being solved in order to then relax the constraints that are complicating.

The bound resulting from a particular decomposition can be computed using two different computational techniques—Dantzig-Wolfe decomposition (Dantzig and Wolfe 1960; Vanderbeck 2000) (column generation) and Lagrangian relaxation (Fisher 1981; Geoffrion 1974; Held and Karp 1970). In the former case, solutions to the base problem are generated dynamically and combined in an attempt to obtain a solution satisfying the complicating constraints. In the latter case, the complicating constraints are enforced implicitly by penalizing their violation in the objective function. Overviews of the theory and methodology behind decomposition methods and how they are used in integer programming can be found in Ralphs and Galati (2005) and Vanderbeck and Wolsey (2010).

A related approach is that of Lagrangian decomposition (Guignard and Kim 1987), which consists of isolating sets of constraints so as to obtain multiple, separate, easy-to-solve subproblems. The dimension of the problem is increased by creating copies of variables that link the subsets and adding constraints that require these copies to have the same value as the original in any feasible solution. When these constraints are relaxed in a Lagrangian fashion, the problem decomposes into blocks that can be treated separately.

Most decomposition-based strategies involve decomposition of constraints, but there are cases in which it may make sense to decompose the variables. These techniques work well in the case when fixing some subset of the variables (the complicating variables) to specific values reduces the problem to one that is easy to solve. Benders' decomposition algorithm projects the problem into the space of these complicating variables and treats the remaining variables implicitly by adding so-called Benders cuts violated by solutions that do not have a feasible completion and adding a term to the objective function representing the cost of completion for any given set of value of the complicating variables (Benders 1962). For a survey on Benders cuts, see Hooker (2002).

Concluding Remarks

There are a number of topics related to combinatorial and integer optimization that have not been covered here. One such topic is the complexity of integer optimization problems (Garey and Johnson 1979), an area of theoretical study that has increased understanding of the implicit difficulty of integer optimization dramatically. Another important topic is that of heuristic solution approaches—that is, techniques for obtaining good but not necessarily optimal solutions to integer optimization problems quickly. In general, heuristics do not provide any guarantee as to the quality of the solutions they produce, but are very important in practice for a variety of reasons. Primarily, they may provide the only usable solution to very difficult optimization problems for which the current exact algorithms fail to produce one. Research into heuristic algorithms has applied techniques from the physical sciences to the approximate solution of combinatorial problems. For surveys of research in simulated annealing (based on the physical properties of heat), genetic algorithms (based on properties of natural mutation), and neural networks (models of brain function) see Hansen (1986), Goldberg (1989), and Zhang (2010), respectively. Glover and Laguna (1998) have generalized some of the attributes of these methods into a method called tabu search. Worst-case and probabilistic analysis of heuristics are discussed in Cornuejols et al. (1980), Karp (1976), and Kan (1986).

Another developing trend is the use of approaches from other disciplines in which optimization problems also arise. In some cases, multiple approaches can be used to handle difficult optimization problems by merging alternative strategies into a single algorithm (the so-called algorithm portfolio approach). As an example, constraint-logic programming was developed by computer scientists in order to work on problems of finding feasible solutions to a set of constraints. During the last decade, many of the advances of constraint-logic programming have been embedded into mathematical programming algorithms in order to handle some of the difficult challenges of combinatorial optimization such as those related to scheduling where there is often significant symmetry. For example, see Hooker (2007) and Rasmussen and Trick (2007) for some applications that use both Benders decomposition and constraint programming to handle difficult scheduling problems. For research that relates issues in computational logic to those associated with combinatorial optimization see McAloon and Tretkoff (1996).

Integer Goal Programming

A goal-programming methodology that generates an integer solution for decision variables.

See

► Goal Programming

Integer-Programming Problem

A mathematical-programming problem in which some or all of its variables are restricted to integer values.

See

► Integer and Combinatorial Optimization

Intelligent Manufacturing Systems

Automated processing systems for manufacturing operations that include intelligent machines, advanced sensors for real-time-in-process measurements, software for precision control of machine tools, and information technology for integrating all elements of a product's life cycle.

See

► Automation in Manufacturing and Services
► Flexible Manufacturing Systems
► Industrial Applications
► Operations Management
► Production Management

Intelligent Transportation Systems

Systems in which synergistic communication and information technologies are combined with operations research methodologies such as simulation and optimization to improve transportation systems of all modes, from road and rail to air and water, including their interfaces. Problems addressed span the spectrum from system design to real-time control and management of operations, e.g., traffic management and mobility management, and encompass infrastructure, vehicles and users.

University of Central Florida, Orlando, FL, USA

Introduction

Decision making typically involves a decision maker selecting a course of action that optimizes some criterion while respecting the resources and other conditions that must be satisfied. When multiple criteria are involved, this class of problems is generally referred to as multiple criteria decision problems. In some circumstances, the number of alternatives is limited and the decision maker identifies a number of (multiple) desirable measureable attributes. Each of the alternatives is assessed with respect to each of the attributes to provide information to the decision maker to aid in selecting the desired alternative. This type of problem is generally termed a multiple attribute decision problem. In other situations, the set of alternatives may be very large and represented as various types and levels of particular actions. The decision maker may be able to determine how various combinations of these alternatives contribute to a particular objective (e.g., completion time, cost, profit). When decision problems involve multiple objectives, the challenge is to select a set of alternatives (and values) that best satisfy (optimize) those objectives while respecting resources and other required conditions. This type of decision problem is generally referred to as a multiple objective decision problem. When the multiple objective problems are expressible in a mathematical structure, the problems are referred to as multiple

objective mathematical programming (optimization) problems. When a mathematical programming formulation exists, there is typically an analyst involved in the decision process to support the decision maker.

The literature on multiple objective decision making is extensive. White (1990) identified over 500 methods and applications published between 1955 and 1986. Detailed treatments of multiple objective optimization methods are available in Chankong and Haimes (1983) and Steuer (1986), the latter of which provides extensive treatment of linear multiple objective optimization methods. The text by Miettinen (1999) is a comprehensive treatment of nonlinear multiple objective optimization that includes the essential theory, detailed descriptions of multiple methods, and over 700 references that address all aspects of the problem. Branke, Deb, Miettinen, and Slowiński, (2008) provide basics on multiple objective optimization including noninteractive and interactive approaches, a description of recent interactive and preference-based approaches including evolutionary methods, and chapters on visualization, modeling, implementation and applications. Finally, Zopounidis and Pardalos (2010) provide a compilation of methods that includes chapters on interactive and evolutionary approaches for multiple objective optimization problems.

In general, a multiple objective mathematical programming problem can be expressed as follows:

$$\begin{aligned} &\text{Minimize } \{f_1(\boldsymbol{x}), f_2(\boldsymbol{x}), \ldots, f_p(\boldsymbol{x})\} \\ &\text{Subject to } g_j(\boldsymbol{x}) \leq 0 \; j = 1, 2, \ldots, m \end{aligned} \tag{1}$$

where $\boldsymbol{x}$ is an n-dimensional vector of decision variables, $f_i(\boldsymbol{x})$, $i = 1, 2, \ldots, p$, are p distinct objective functions, and $g_i(\boldsymbol{x})$, $j = 1, 2, \ldots, m$, are m distinct constraint functions.

Based on the classification given in Evans (1984), almost all methods for solving multiple objective problems involve two general sub-processes: (1) articulation of the decision maker's preference structure, and (2) optimization over the preference structure. The various methods for solving multiple objective problems have been categorized into three types according to the timing of these sub-processes: (1) prior articulation of preferences where the preference structure is obtained prior to the optimization process (a priori), (2) posterior articulation of preferences where the decision maker's preference is elicited after the generation of a candidate solution set (a posteriori), and (3) progressive articulation of preferences where the elicitation of information about the preference structure is interspersed with optimization processes (interactive). With a priori methods, the decision maker acts first and explicitly expresses his or her preferences and then the analyst generates the best solution consistent with the decision maker's preferences. With a posteriori methods, the analyst acts first to generate a number of alternative solutions and then the decision maker applies his or her preference structure (perhaps implicit) to select the best solution. With interactive methods, there is a back and forth exchange between the decision maker and the analyst that continues until the decision maker is satisfied that no significantly better solution exists or can easily be found.

Most multiple objective mathematical programming methods require the generation of nondominated solutions. Let $\mathbf{X}$ be the set of all feasible solutions to problem (1). An efficient (nondominated, Pareto optimal) solution is a feasible solution $\boldsymbol{x}* \in X$, for which there does not exist any other feasible solution, $\boldsymbol{x} \in \boldsymbol{X}$, that is the same or better in each of the objectives. In other words, you cannot find another solution $\boldsymbol{x}$, where $f_i(\boldsymbol{x}) \leq f_i(\boldsymbol{x}*)$ for $i = 1, 2, \ldots, p$, and for at least one $i, f_i(\boldsymbol{x}) < f_i(\boldsymbol{x}*)$. (Note that this definition assumes that smaller values of $f_i(\boldsymbol{x})$ are preferred.) Moving from one Pareto optimal solution to another requires some sort of trade-off reflecting the value equivalence in improving one objective relative to degrading another objective.

In some cases, a decision maker does not have any particular preferences with respect to the values of the objective functions. In these cases, a method that can identify a single Pareto optimal point may suffice. Miettinen (1999) identifies the global criterion method and the multiobjective proximal bundle method as two viable approaches. In the global criterion method, a reference point is selected and a chosen metric is used to minimize the distance to the reference point. In this case, all objective functions

are assumed to be equally important. When the L_p-metric ($1 \leq p < \infty$) is used, the solution is Pareto optimal. When $p = \infty$, the metric is called the Tchebycheff metric. Objective function scaling can influence the relative importance of particular objectives in the optimization. Another approach is the multiobjective proximal bundle (MPB) method that seeks to move in a direction where the values of all of the objective functions improve simultaneously. Unlike other approaches, MPB does not transform the problem into one with a single objective function. Rather, its scalarization takes place inside a special (nondifferentiable) optimizer. The method is described in detail in Mäkelä (1993).

When a decision maker does have preferences with respect to the values of the objective functions, it is necessary to be able to evaluate sets of nondominated solutions. The following two methods are common approaches for generating nondominated solutions. Clearly, the two methods can serve as a posteriori methods since a decision maker can use the set of solutions to select the one that best satisfies his or her preferences. However, many of the interactive solution methods incorporate either or both of these two basic approaches.

A Weighting (Scalarization) Approach for Generating Nondominated Solutions. A common approach to finding nondominated solutions to a multiple objective mathematical programming problem is to convert the set of multiple objectives into a single objective through the use of weights. The weighting technique transforms problem (1) into a single objective problem given in (2):

$$\begin{aligned} \text{Minimize} \quad & f(\boldsymbol{x}) = w_1 f_1(\boldsymbol{x}) + w_2 f_2(\boldsymbol{x}) + \ldots + w_p f_p(\boldsymbol{x}) \\ \text{Subject to} \quad & g_j(\boldsymbol{x}) \leq 0 \; j = 1, 2, \ldots, m \\ & w_1 + w_2 + \ldots + w_p = 1 \\ & w_i > 0, i = 1, 2, \ldots, p \end{aligned} \tag{2}$$

Given a set of weights that are nonnegative and that sum to one, the solution to problem (2) is a nondominated solution. This means that the weighting approach is guaranteed to generate at least some of the possible nondominated solutions if the weights are varied. If the problem is also convex, then the weighting approach is guaranteed to generate all of the nondominated solutions if all possible weights are explored, see Chankong and Haimes (1983). Of course, there is an infinite number of possible weights that can be assigned and there could be an infinite number of nondominated solutions.

ε-Constraint-Based Approach for Generating Nondominated Solutions. Another approach to finding nondominated solutions to a multiple objective mathematical programming problem is to convert the set of multiple objectives into a single objective by treating all but one of the objectives as inequality constraints. In this approach, one primary objective, $f_k(\boldsymbol{x})$, is selected to be minimized while the remaining objectives are converted into inequality constraints. Consider the following multiple objective programming problem:

$$\begin{aligned} \text{Minimize} \quad & f_k(\boldsymbol{x}) \\ \text{Subject to} \quad & g_j(\boldsymbol{x}) \leq 0 \; j = 1, 2, \ldots, m \\ & f_j(\boldsymbol{x}) \leq \varepsilon_i \; j = 1, 2, \ldots, p, i \neq k \end{aligned} \tag{3}$$

If the values of ε_i are chosen so that problem (3) has feasible solutions, then the solution is guaranteed to be nondominated. This means that at least some of the nondominated solutions can be discovered by solving problem (3) for specific feasible values for ε_i. In fact, unlike the weighting approach, it turns out that all of the nondominated solutions can be generated if the ε_i are varied over all possible feasible values, even for problems that are not convex.

Interactive Methods

The techniques that rely on a progressive articulation of preferences (interactive methods) follow a common pattern. The decision maker is presented with a subset of the non-dominated alternatives and is asked to provide some local preference information on these alternatives. This information allows the formulation of a single criterion subproblem, which is then solved. The new nondominated solution and the outcome are then presented to the decision maker to provide new local preference information. This process is repeated until the decision maker either converges toward a best-compromise solution, or terminates the process prior to reaching this point. The objective of these approaches is to find a satisfactory solution after

a reasonable number of iterations and within a reasonable amount of time.

Interactive methods differ in how the single objective optimization problem is formed, how the preference information is incorporated and obtained from the decision maker, and how information is provided to the decision maker. Interactive methods may involve direct interaction with an analyst or with a computer program with appropriate interface for the decision maker. In interactive methods, the decision maker may be required to provide one of the following types of information regarding the nondominated solutions or criteria, (Evans, Stuckman, & Mollaghasemi, 1991):

1. A ranking of nondominated solutions in the outcome space,
2. A readjustment of aspiration levels from one iteration to the next, or
3. Marginal rates of substitution between various criteria.

Interactive methods may be based on the existence of an underlying value function for the decision maker (often implicit), the ability to create reference points on which the algorithms can operate, the ability to classify objectives, or a combination of these approaches. The value function allows a decision maker to identify trade-off values and generate marginal rates of substitution. The following methods are representative of the kinds of interactive approaches that have been developed for multiple objective optimization. The first four assume the existence of a value function and the remaining methods use reference points and classification. The following paragraphs provide very brief, high level descriptions of the various approaches. Mollaghasemi and Pet-Edwards (1997) provide additional descriptions. Miettinen (1999) includes a much more detailed treatment of the methods and provides much of the background for the following descriptions.

Interactive Surrogate Worth Trade-off (ISWT) Method. The basic idea of the interactive surrogate worth trade-off (ISWT) method (Chankong & Haimes, 1978) is to maximize an underlying value function that is known implicitly. The algorithm begins with the ε-constraint method by having the analyst select one objective to optimize and provide bounds on the other objectives. The problem is solved and a Pareto optimal solution is presented to the decision maker. The opinions of the decision maker regarding the trade-off rates at the current solution are used to determine a new search direction. Specifically, the decision maker conducts a worth assessment using a specified worth scale to determine how (much) the decision maker would like to make a trade-off between the primary response and each secondary response, where the value of the primary response decreases by the value of the Lagrange Multiplier for a one unit increase in value of the secondary response. The worth values are used to update the right-hand-side of the secondary response and then the problem is re-optimized. The process continues until the decision maker is satisfied with the solution.

Geoffrion-Dyer-Feinberg (GDF) Method. The Geoffrion-Dyer-Feinberg (GDF) method (Geoffrion, Dyer, & Feinberg, 1972) also assumes the existence of a decision maker value function and the process of the method is similar to the ISWT method, although the computational approach is different. The GDF method maximizes a value function and requires the decision maker to identify the reference function and then specify marginal rates of substitution between this function and the other objectives at the current solution point. The marginal rates of substitution are used to specify the direction of steepest ascent for the value function. The decision maker also helps to determine the step size. The optimization is conducted iteratively with the decision maker choosing the preferred solution among each set of solutions until the decision maker chooses to stop. The GDF method is one of the most well-known interactive methods.

Sequential Proxy Optimization Technique (SPOT) Method. The sequential proxy optimization technique (SPOT) method (Sakawa, 1982) is also based on maximizing the decision maker's underlying value function. SPOT includes some of the ideas of ISWT and GDF. The algorithm begins with the ε-constraint method like the ISWT method. With that solution, like the GDF method, the decision maker must specify the marginal rates of substitution. Then, unlike GDF where the decision maker is involved in determining a step size for the next iteration, a proxy function is generated by solving a series of ε-constraint problems and step size is determined from those results. The optimization is conducted iteratively until the decision maker is satisfied.

Interactive Goal Programming. Dyer (1972) introduced the concept of interactive goal

programming to provide a linkage between goal programming and interactive strategies that had been suggested for the optimization of multiple criteria optimization problems. The method assumes that the decision maker can specify a goal for each objective. It further assumes that the decision maker has an underlying utility function and can provide appropriate trade-off weights. These weights are used in a one-sided goal-programming problem to generate a new solution. The optimization is conducted iteratively until the decision maker chooses to stop.

Tchebycheff Method. The Tchebycheff method (Steuer & Choo, 1983) does not assume the existence of a decision maker value function and requires much less information from the decision maker. The algorithm starts by computing the utopian objective vector, an infeasible point that is slightly perturbed from the ideal objective vector that corresponds to the point where all objectives are at their minimum value. The algorithm proceeds by minimizing the maximum weighted distance of the function from the utopian objective vector using the weighted Tchebycheff metric. The bounds on the weights are tightened to reduce the number of Pareto optimal solutions generated. The decision maker chooses a most preferred objective vector among a subset of the generated ones at each iteration until a final solution is chosen.

STEM (Step Method). The step method (STEM) (Benayoun, de Montgolfier, Tergny, & Laritchev, 1971) is one of the first interactive methods developed for multiple objective optimization. While STEM has some elements similar to the Tchebycheff method, it focuses on identifying satisfactory solutions rather than optimizing an underlying value function. The method is described in more detail below, but follows the following framework. The decision maker must be able to indicate functions that have acceptable values and those that have values that are too high. The weighted Tchebycheff metric is used to generate solutions. Then the decision maker is asked to determine which of the objectives are satisfactory and relax the upper bounds on those objectives. The method repeats until the decision maker is satisfied for all objectives.

Reference Point Method. The reference point method (Wierzbicki, 1982) is based on the decision maker specifying a reference point of aspiration levels that are reasonable or desirable to the decision maker. The reference point method begins by providing the decision maker with some information that provides a range of the Pareto optimal set based on lower and upper bounds on the objectives. The decision maker specifies a reference point from which the achievement function is minimized. The solutions are provided to the decision maker and if one of the solutions is satisfactory, the process stops. If not, a new reference point is determined and the process continues. The reference point idea has been subsequently incorporated in other interactive methods. For example, the reference direction approach (Korhonen & Laasko, 1986) projects the vector from the current iteration point to the reference point. This provides the decision maker with more information to determine the next direction and also provides a wider part of the weakly Pareto optimal set to review. The reference direction method minimizes the computational effort by having the decision maker determine the number of steps to be taken in the reference direction, minimizing the number of alternatives that the decision maker will review. This method may be facilitated by computer graphic representations of the Pareto optimal curve. Korhonen (1987) developed a general software package to apply this visual interactive graphic technique to multiple criteria problems in general.

GUESS Method. The GUESS method (Buchanan, 1997) is a relatively simple method that assumes that lower bounds (ideal objective vector) and upper bounds (nadir objective vector) can be computed and are available. The decision maker specifies a reference point (a guess) as well as any additional upper or lower bounds to the objective functions. Then a function representing the maximum weighted deviation from the nadir objective vector is optimized with equal proportional achievement and the solution is presented to the decision maker. If the solution is satisfactory the process stops otherwise it is repeated with the decision maker specifying new bounds and reference points.

Satisficing Trade-Off Method (STOM). The satisficing trade-off method (STOM), based on satisficing decision making, incorporates ideas from STEM, the reference point method, and GUESS (Nakayama, 1989). STOM begins by optimizing a scalarizing function and providing the solution to the decision maker. Different kinds of scalarizing functions (and weighting schemes) can be used, but require that the utopian objective vector is known and

available. The decision maker reviews each objective and labels them as unacceptable, acceptable with the ability to relax, or acceptable as is. The decision maker provides aspiration levels for the objectives to be improved. Then the modified scalarizing function is minimized and the process is repeated.

Light Beam Search Method. The light beam search method has the decision maker identify bounds for each objective, as well as to specify indifference thresholds (Jaszkiewicz & Slowiński, 1994). This incorporates features and reference point methods with concepts from multiple attribute decision analysis. The decision maker is asked to specify indifference thresholds and preference thresholds that are used to establish preference relations between alternative pairs of objective vectors. The achievement function is minimized and the solution, as well as Pareto optimal neighbors, are presented to the decision maker. If one of the alternatives is satisfactory, then the process is stopped. Otherwise, the decision maker can revise reference points or thresholds and the function is re-optimized. This method allows the decision maker to save preferred solutions, explore other directions, and then select among the preferred solutions.

The preceding general descriptions of the interactive methods have not rigorously described the assumptions and characteristics for the objectives and constraint functions in the multiple objective problem. The methods described above were developed for cases where the functions were differentiable and many required other kinds of smooth properties. In real-world optimization problems, one may encounter nondifferentiable functions. For noninteractive approaches, use of some smoothing approaches may make a nondifferentiable problem solvable. For interactive approaches, however, there are limits since trade-off weights, for example, require twice continuous differentiability.

NIMBUS. To address these complicated real-world problems, Miettinen (1994) developed the Nondifferentiable Interactive Bundle-based optimization System (NIMBUS). The NIMBUS algorithm includes two versions: one uses a vector subproblem, and the other uses a scalar subproblem. They differ with respect to the handling of the information provided by the decision maker. The NIMBUS method requires that at each solution point the decision maker determines whether each objective should be decreased freely, decreased to a certain bound, satisfactory, increased to a certain bound, or changed freely. These classifications provide more freedom in developing subsequent solutions. The function is minimized and the process repeats with input from the decision maker until the decision maker chooses a preferred solution. When the vector version is used, the multiobjective proximal bundle (MPB) method is required for the optimization. For the scalar version, any efficient nondifferentiable optimization approach may be used.

NIMBUS is suitable for both differentiable and nondifferentiable multiple objective and single objective optimization problems subject to both linear and nonlinear constraints with bounds on the variables. Miettinen and Mäkelä (2006) have developed a Web-based computer implementation of the method. See Table 1 for a summary of representative interactive methods.

STEM (Step Method)

The following description of STEM, the step method, serves to illustrate an interactive method in more detail. See Benayoun et al. (1971) for a more complete description of this method. The original formulation of the method was designed for maximizing Multiple Objective Linear Programming problems. Although the method has been generalized for nonlinear problems, the original intent is illustrated with an MLOP problem in the following description that is based on Mollaghasemi and Pet-Edwards (1997).

STEM, the step method, is an interactive method that can be used to identify the best compromise solution for multiple objective mathematical programming problems. STEM starts by converting the multiple objective problem into a series of single objective problems. Assume, without loss of generality, that it is desirable to maximize p separate linear objective functions, $f_1(\boldsymbol{x}), f_2(\boldsymbol{x}), \ldots, f_p(\boldsymbol{x})$, where $\boldsymbol{x}$ is an n-dimensional vector of decision variables and

$$f_k(\boldsymbol{x}) = \sum_{j=1}^{n} c_{jk} x_j \tag{4}$$

Suppose also that the decision variable values are constrained by $\boldsymbol{x} \in \boldsymbol{X}$, where $\boldsymbol{X}$ is a set of feasible solutions.

Interactive Multiple Objective Mathematical Programming, Table 1 Summary of representative interactive methods

Interactive method	Features	User inputs and actions
Interactive Surrogate Worth Tradeoff Method (ISWT)	Assumed underlying utility function; ε-constraint based approach	Primary objective and limits on other objectives; worth function; trade-off rates
Geoffrion-Dyer-Feinberg (GDF)	Assumed underlying utility function; Frank and Wolfe gradient method	Reference function; trade-off values among objectives; step size; best local solution
Sequential Proxy Optimization Technique (SPOT) Method	Assumed underlying utility function; ε-constraint based approach	Marginal rates of substitution; best local solution
Interactive Goal Programming	Assumed underlying utility function; scalar optimization	Target values on the goals (aspiration levels); Marginal rates of substitution
Tchebycheff Method	Computed weighting vector; weighting method	Best local solution at each iteration
STEM (Step Method)	Classification of objectives (2 classes); weighting method	Objectives to relax and amount of acceptable relaxation
Reference Point Method	Reference point; aspiration levels; perturbation of reference points	Reference point; assess perturbed solutions
Reference Direction Approach	Reference point; works best for MOLP problems	Reference point; most preferred solutions
GUESS Method	Reference point; maximize minimum distance from nadir (weighted)	Reference point (guess); assessment of solution and adjustment of reference point
Satisficing Trade-Off Method (STOM)	Classification of objectives (3 classes); weighting method	Classification of objectives; aspiration levels
Light Beam Search Method	Reference point; outranking	Best and worst values of objectives; indifference, preference, and veto thresholds
Nondifferentiable Interactive BUndle-based optimization System (NIMBUS)	Classification of objectives (5 classes); bundle method	Classification of objectives; aspiration levels

STEM begins by solving p single objective problems separately, as shown in (5):

$$\begin{aligned} &\text{Maximize } f_k(\boldsymbol{x}) = \sum_{j=1}^{n} c_{jk} x_j \\ &\text{Subject to } \boldsymbol{x} \in \boldsymbol{X} \text{ for } k = 1, 2, \ldots, p \end{aligned} \tag{5}$$

The solution to problem (5), $\boldsymbol{x}^k$, results in the maximum value of $f_k(\boldsymbol{x})$ which is represented by $f_k^M(\boldsymbol{x}^k)$. Note that this solution is always a nondominated solution. The values of the remaining objectives at $\boldsymbol{x}^k$ are denoted by $f_k^i(\boldsymbol{x}^k)$ for $i = 1, 2, \ldots, p$ and $k \neq i$. By solving the p optimization problems, a $p \times p$ payoff matrix is then constructed. The objective function values associated with the solutions to problem (5), $f_k^M(\boldsymbol{x}^k)$, represent the ideal solutions. They are placed as the diagonal elements of the payoff matrix and the remaining elements of the payoff matrix, $f_k^i(\boldsymbol{x}^k)$, correspond to the values of the remaining objective functions when the optimal solution, $\boldsymbol{x}^k$, to problem (5), is substituted into the objective functions.

The diagonal elements of the matrix give an outcome associated with an ideal solution. Unfortunately, due to the conflicting nature of the objectives, an ideal solution usually does not exist. However, the payoff matrix provides the decision maker with a better understanding of the system's multiple response surface.

The next step involves identifying the nondominated solution with the least deviation from the ideal solution. This is accomplished by solving the following problem:

$$\begin{aligned} &\text{Minimize} && d \\ &\text{Subject to} && \pi_k\left(f_k^M - f_k(\boldsymbol{x})\right) \leq d, \quad k = 1, 2, \ldots, p \\ &&& \boldsymbol{x} \in \boldsymbol{X}, \quad d > 0 \end{aligned} \tag{6}$$

where

d = maximum deviation of an objective from the ideal solution, and

π_k = relative weight of deviation defined as

$$\pi_k = \left(\frac{a_k}{\sum_{i=1}^{p} a_i} \right)$$

with

$$a_k = \begin{cases} \left[\frac{f_k^M - f_k^m}{f_k^M} \right] \sqrt{\sum_{j=1}^{n} C_{jk}^2} & \text{if } f_k > 0 \\ \left[\frac{f_k^m - f_k^M}{f_k^m} \right] \sqrt{\sum_{j=1}^{n} C_{jk}^2} & \text{if } f_k \leq 0 \end{cases}$$

And $f_k^M (f_k^m)$ is the maximum (minimum) of each column in the payoff matrix. It is evident that the value of a given weight, π_k, is dependent upon the deviation of the objective from its ideal solution. That is, the greater this deviation, the larger the magnitude of π_k.

The decision maker is then presented with the solution to problem (6) (i.e., the solution that results in the least deviation from the ideal solution.) The decision maker must then identify the satisfactory and unsatisfactory objectives and also indicate which objectives in the current solution can be decreased to achieve an improvement in the unsatisfactory objectives. The constraint set in problem (5) is then modified using this information generating a new ideal point and the iterations continue until the decision maker is satisfied with a solution.

STEM has been successfully used in a number of practical applications. For example, Loucks (1977) described how the method was used in a water resources planning project in North Africa. The aim of the project was to aid government officials in choosing the best compromise among three conflicting objectives: maximize water yield, maximize yield reliability, and minimize total cost. The solution yielded a single plan for each irrigation area.

► Network Planning

Interior Point

In a constrained optimization problem, an interior point is a solution point that is not on the boundary of the solution space S. If S is defined by the set of constraints $\{g_i(\boldsymbol{x}) \leq 0\}$, then $\boldsymbol{x}^0$ in S is an interior point if $g_i(\boldsymbol{x}) < 0$ for all i.

Interior-Point Methods for Conic-Linear Optimization

Tamás Terlaky[1] and Paul T. Boggs[2,3]

[3]National Institute of Standards and Technology, Gaithersburg, MD, USA

Introduction

Even with the success of the simplex method for linear programming (LP), there was from the earliest days of operations research a desire to create an algorithm for solving LP problems that proceeded on a path through the polytope rather than around its perimeter. Interior point methods (IPMs) were first developed in 1950s, analyzed and first implemented in the 1960s. At that time the conclusion was made that IPMs were not competitive with other algorithms, especially with simplex methods. The continuous effort to find a polynomial algorithm for LP problems led to the revitalization of IPMs. In 1984 Karmarkar first proved the polynomial complexity of an IPM, which led to the "Interior Point Revolution" (Wright 2004) in mathematical programming. In this article the motivation for desiring an interior path, the concept of the complexity of solving LP problems, a brief history of the developments in the area, and the research state of the art are discussed, including generalizations to nonlinear problems.

Background

The LP problem in standard form is

$$\begin{array}{ll} \text{minimiz e}_x & \boldsymbol{c}^T\boldsymbol{x} \\ \text{subject to} & \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}, \\ & \boldsymbol{x} \geq \boldsymbol{0}, \end{array} \qquad (\boldsymbol{LP})$$

where $\boldsymbol{c}, \boldsymbol{x} \in R^n$, $\boldsymbol{b} \in R^m$, and $\boldsymbol{A} \in R^{m \times n}$. It will be assumed that the feasible region for the problem **(LP)** has a strictly feasible point, that is, a point $\boldsymbol{x}^0$ such that $\boldsymbol{A}\boldsymbol{x}^0 = \boldsymbol{b}$ and $\boldsymbol{x}^0 > 0$ (i.e., each component of $\boldsymbol{x}^0$ is strictly positive). The simplex method proceeds on a path from vertex to vertex on the boundary of this region, a process that could require many steps to go around a multifaceted feasible region, although in actual practice the method is generally quite efficient. Intuitively, however, a more direct path through the interior of the region is appealing since there exists the possibility of moving through the polytope in very few steps.

A formal analysis of the complexity of the simplex method remained elusive until the famous result of Klee and Minty (1972), who showed with a simple example that the worst case complexity of some variants of the simplex method is exponential. Their example is a slightly out-of-kilter cube (in n dimensions) in which all $2n$ vertices can be visited by a simplex method, i.e., starting at the origin, there is a path through all of the vertices such that the objective function is decreased at each step. It was immediately recognized, however, that no practical simplex method would use this path; thus there was a desire to explain the efficiency of practical simplex methods. Later analyses showed that a simplex method could expect linear performance, thus partially explaining its behavior (Borgwardt 1987; Goldfarb and Todd 1989).

The first algorithm for LP that was proven to have a worst-case polynomial complexity is the ellipsoid algorithm of Khachiyan (1979). Assuming that the optimal set is nonempty, Khachiyan's algorithm first constructs an ellipsoid that is large enough to contain the optimal set. At subsequent iterations, that ellipsoid is shrunk so that the center of the ellipsoid is the solution to the problem **(LP)**, or after a polynomial number of steps, evidence for the nonexistence of optimal solution is derived. For his method, Khachiyan proved that the complexity is $O(n^4L)$, where L is the number of bits necessary to specify the problem. Unfortunately, the algorithm also seemed to have an expected performance of similar complexity, and was quickly shown to be noncompetitive in practice. Note that Khachiyan's algorithm is not an interior-point method.

Interior-point methods (IPMs) seek to approach the optimal solution through a sequence of points that are always strictly feasible. Such methods have been known for a long time, but for reasons explained below were not considered to be effective. One of the earliest IPMs is the barrier method originally proposed in the 1950s by Frish (1954). When applied to problems with only inequality constraints, it is typically used in conjunction with the sequential unconstrained minimization technique that is described more generally in Fiacco and McCormick (1968). In the primal barrier method for problem **(LP)**, the following log-barrier function problem with equality constraints is formed:

$$\begin{array}{ll} B(\boldsymbol{x}, \mu) = & \boldsymbol{c}^T\boldsymbol{x} - \mu \sum_{i=1}^{m} \log x_i \\ \text{subject to} & \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b} \end{array}$$

where μ is a positive parameter. Given a positive value of μ and a strictly feasible point $\boldsymbol{x}^0$, the equality constrained barrier problem

$$\begin{array}{ll} \text{minimize}_x & B(\boldsymbol{x}, \mu) \\ \text{subject to} & \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b} \end{array} \qquad (\textbf{BP})$$

is solved approximately, i.e., a vector $\boldsymbol{x}^1$ is calculated that satisfies the equality constraints and is close to the true minimum of the barrier function. (Note that minimizing a strictly convex function with linear equality constraints is not difficult). Clearly, $\boldsymbol{x}^1$ will remain strictly feasible since the log-barrier function becomes infinite at the boundary of the feasible region. The parameter μ is reduced and **(BP)** is solved again using $\boldsymbol{x}^1$ as the initial starting point. It can be shown that if μ is reduced to zero, for example, by setting $\mu = \frac{\mu}{2}$ at the beginning of each iteration, the resulting sequence $\{\boldsymbol{x}^i\}$ will converge to $\boldsymbol{x}^*$, an optimal solution to **(LP)**. The set of the minimizers $\{\boldsymbol{x}(\mu) \mid \mu > 0\}$ of the barrier function $B(\boldsymbol{x}, \mu)$ gives a smooth analytic curve, the so-called central path (Sonnevend 1985).

Another interior-point approach, called the method of centers was suggested by Huard (1967). This method is initiated with a strictly feasible point $\boldsymbol{x}^0$

and computes the so-called analytic center of the polytope formed by the intersection of the original polytope and the half space of points corresponding to an objective function value less than $\boldsymbol{c}^T\boldsymbol{x}^0$. The analytic center of this bounded polytope is defined to be the maximum of the function

$$C(\boldsymbol{x}, \boldsymbol{c}^T\boldsymbol{x}^0) = (\boldsymbol{c}^T\boldsymbol{x}^0 - \boldsymbol{c}^T\boldsymbol{x}) \prod_{i=0}^{n} \boldsymbol{x}_i.$$

The function $C(\boldsymbol{x}, \boldsymbol{c}^T\boldsymbol{x}^0)$ is clearly zero on the boundary and positive in that part of the interior of the polytope that corresponds to lower values than $\boldsymbol{c}^T\boldsymbol{x}^0$ of $\boldsymbol{c}^T\boldsymbol{x}$, and thus has a maximum, say $\boldsymbol{x}^1$. The level set is then redefined using $\boldsymbol{x}^1$ in place of $\boldsymbol{x}^0$, and the process repeated. It can be shown that the sequence $\{\boldsymbol{x}^i\}$ converges to an optimal solution $\boldsymbol{x}^*$. Moreover, the set of the minimizers $\{\boldsymbol{x}(\gamma)\}$ of the function $C(\boldsymbol{x}, \gamma)$, where γ runs from the maximum until the minimum of $\boldsymbol{c}^T\boldsymbol{x}$ on the feasible set coincides with the central path.

Early IPMs also include that of Dikin (1967). This method begins each iteration by scaling the variables so that the current, strictly feasible point is transformed to the vector of all ones, a point well away from the boundary in the affinely scaled space. A steepest descent step is then applied to this scaled problem, and the resulting point is transformed back to the original space to obtain the next iterate. The advantage of this idea is that the steepest descent step in the original space can be extremely short if the current iterate is close to the boundary, whereas long steps are always possible in the transformed space. This method is known as the affine scaling algorithm. Modern variants of log-barrier methods and the methods of centers enjoy polynomial complexity, while the polynomiality of Dikin's affine scaling method is still open. There is strong belief that primal or dual affine scaling methods are not polynomial, but variants of primal-dual affine scaling methods enjoy polynomial complexity.

All these early methods relate to Karmarkar's method, as discussed below. All of them were tried and compared with the simplex method in the 1970s, but none was seen to be competitive for two principal reasons. First, almost all IPMs (see the next section) require at each step the solution to a linear system of equations of the form

$$\boldsymbol{A}^{\mathrm{T}}\boldsymbol{D}\boldsymbol{A}\boldsymbol{u} = \boldsymbol{r}, \tag{1}$$

where $\boldsymbol{u}$ and $\boldsymbol{r}$ are n-vectors and $\boldsymbol{D}$ is an appropriate positive definite diagonal matrix. It was not until the 1970s that there were sufficiently powerful linear algebra routines that were able to explore the sparsity structure of $\boldsymbol{A}^T\boldsymbol{D}\boldsymbol{A}$ to solve such systems efficiently. Second, IPMs tend to outperform simplex methods on large problems that were well beyond the capabilities of the computers of the 1960s. Third, IPMs typically need more memory and need better floating point calculations than simplex methods. While IPMs were put aside in the 1970s, significant advances in numerical linear algebra were made and, of course, in computational capacity and speed. Interest in IPMs was then revitalized by the announcement of Karmarkar (1984) that he had developed an IPM that had provable polynomial complexity and was competitive with the simplex method. In fact he claimed a factor of 100 speed-up, compared with the state-of-the-art simplex solver MPSX. Karmarkar's procedure begins with a strictly feasible point and then embeds the problem **(LP)** in a space of one dimension higher, in which the feasible point is the center of the higher dimensional polytope. As in the affine scaling algorithm, a "good" step can then be taken in this space and the new point projected back to the original space to obtain the next iterate. Karmarkar's method and its relatives, including the affine scaling algorithm and barrier methods, were studied intensively. Since then, thousands of papers have been written on both the theoretical and computational aspects of IPMs for LP and on the extension of these ideas to quadratic and more general nonlinear programming problems. IPMs opened a new age in the theory, implementations and applications of mathematical optimization, mathematical programming.

IPMs for LP

In the theoretical arena, there has been considerable interest in improving the bound on the number of iterations required to solve an LP problem. It was observed early that IPMs could be cast in such a way as they follow a continuous path, or trajectory, the central path from an initial interior feasible point to

an optimal solution. The central path enjoys many appealing properties. Much analysis of these trajectories and of algorithms based on following the central trajectory has been performed. Several versions of the algorithms described below have also been extensively analyzed. The best theoretical results for these methods demonstrate a complexity that is $O(\sqrt{n}L)$ steps with a quadratic asymptotic rate of convergence. The computationally most successful IPMs for solving an LP problem are based on using a primal-dual formulation and applying Newton's method to the system of equations arising from the barrier method, i.e., by perturbing the optimality conditions. Specifically, the dual problem to **(LP)** is

$$\begin{aligned} \text{maximize}_{y,s} \quad & \boldsymbol{b}^T\boldsymbol{y} \\ \text{subject to } & \boldsymbol{A}^{\mathrm{T}}\boldsymbol{y} + \boldsymbol{s} = \boldsymbol{c} \qquad (\mathbf{DP}) \\ & \boldsymbol{s} \geq 0, \end{aligned}$$

where $\boldsymbol{y} \in R^m$ and $\boldsymbol{s} \in R^n$. By the duality theorem of **LP**, at an optimal solution pair the duality gap is zero, thus

$$\boldsymbol{x}|^T\boldsymbol{s} = \boldsymbol{c}^T\boldsymbol{x} - \boldsymbol{b}^T\boldsymbol{y} = 0.$$

The optimality conditions for the primal-dual problem can thus be formulated as

$$\begin{aligned} \boldsymbol{A}\boldsymbol{x} \quad & = \boldsymbol{b}, \quad \boldsymbol{x} \geq 0, \\ \boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{s} \quad & = \boldsymbol{c}, \quad \boldsymbol{s} \geq 0, \\ \boldsymbol{X}\boldsymbol{S}\boldsymbol{e} \quad & = 0, \end{aligned}$$

where $\boldsymbol{X}$ denotes the diagonal matrix with x_i as its i^{th} diagonal element. The last conditions are called the complementarity conditions, because they require that at least one of the complementary pair of variables (x_i, s_i) be zero. By perturbing the complementarity conditions, the system

$$\begin{aligned} \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}, \quad & \boldsymbol{x} \geq 0, \\ \boldsymbol{A}^T\boldsymbol{y} + \boldsymbol{s} = \boldsymbol{c}, \quad & \boldsymbol{s} \geq 0, \qquad (\mathbf{CP}) \\ \boldsymbol{X}\boldsymbol{S}\boldsymbol{e} = \mu\boldsymbol{e}, & \end{aligned}$$

is obtained, where $\boldsymbol{e}$ denotes the vector with all coordinates equal to one. This perturbed system **(CP)** coincides with the Karush-Kuhn-Tucker (first order) optimality conditions of the primal $\mathrm{B}(\boldsymbol{x}, \mu)$, the dual $\boldsymbol{b}^{\mathrm{T}}\boldsymbol{y} + \mu\sum_{\mathrm{i}=1}^{\mathrm{n}} \log \mathrm{s_i}$ and the primal-dual $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{s} - \mu\sum_{\mathrm{i}=1}^{\mathrm{n}} \log \mathrm{x_i s_i}$ barrier functions as well, so it can be concluded that the set of solutions $\{\boldsymbol{x}(\mu)|\mu > 0\}$ and $\{(\boldsymbol{y}(\mu), \boldsymbol{s}(\mu))|\mu > 0\}$ is the primal and dual central path, respectively.

The Newton Step

Given an interior feasible point $\boldsymbol{x} > 0, \boldsymbol{y}, \boldsymbol{s} > 0$, a Newton step can be made to solve the system **(CP)**. The goal is to compute the displacements $(\Delta\boldsymbol{x}, \Delta\boldsymbol{y}, \Delta\boldsymbol{s})$ such that

$$\begin{aligned} \boldsymbol{A}(\boldsymbol{x} + \Delta\boldsymbol{x}) &= \boldsymbol{b}, \\ \boldsymbol{A}^T(\boldsymbol{y} + \Delta\boldsymbol{y}) + (\boldsymbol{s} + \Delta\boldsymbol{s}) &= \boldsymbol{c}, \\ (\boldsymbol{X} + \Delta\boldsymbol{X})(\boldsymbol{S} + \Delta\boldsymbol{S})\boldsymbol{e} &= \mu\boldsymbol{e}. \end{aligned}$$

By neglecting the second-order term in the last set of equations and using that $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s})$ is interior feasible, the Newton equation system is obtained:

$$\begin{aligned} &\boldsymbol{A}\Delta\boldsymbol{x} = 0, \\ &\boldsymbol{A}^T\Delta\boldsymbol{y} + \Delta\boldsymbol{s} = 0, \\ &\boldsymbol{X}\Delta\boldsymbol{S}\boldsymbol{e} + \boldsymbol{S}\Delta\boldsymbol{X}\boldsymbol{e} = \mu\boldsymbol{e} - \boldsymbol{X}\boldsymbol{S}\boldsymbol{e}. \end{aligned}$$

Since the matrix $\boldsymbol{A}$ has full rank, the Newton system has a unique solution, which can be obtained by first expressing

$$\begin{aligned} \Delta\boldsymbol{s} &= \boldsymbol{X}^{-1}(\mu\boldsymbol{e} - \boldsymbol{X}\boldsymbol{S}\boldsymbol{e}) - \boldsymbol{X}^{-1}\boldsymbol{S}\Delta\boldsymbol{X}\boldsymbol{e} \\ &= \mu\boldsymbol{X}^{-1}\boldsymbol{e} - \boldsymbol{S}\boldsymbol{e} - \boldsymbol{X}^{-1}\boldsymbol{S}\Delta\boldsymbol{X}\boldsymbol{e} \end{aligned}$$

from the last equations, which leads to the so-called augmented system:

$$\begin{pmatrix} 0 & \boldsymbol{A} \\ \boldsymbol{A}^T & -\boldsymbol{X}^{-1}\boldsymbol{S} \end{pmatrix} \begin{pmatrix} \Delta\boldsymbol{y} \\ \Delta\boldsymbol{x} \end{pmatrix} = \begin{pmatrix} 0 \\ \boldsymbol{S}\boldsymbol{e} - \mu\boldsymbol{X}^{-1}\boldsymbol{e} \end{pmatrix}.$$

This system has a symmetric indefinite coefficient matrix. Expressing Δx as a function of Δy

$$\Delta\boldsymbol{x} = \boldsymbol{S}^{-1}\boldsymbol{X}\boldsymbol{A}^T\Delta\boldsymbol{y} + \boldsymbol{x} - \mu\boldsymbol{S}^{-1}\boldsymbol{e},$$

then the so-called normal equation system

$$(\boldsymbol{AXS}^{-1}\boldsymbol{A}^T)\Delta\boldsymbol{y} = \boldsymbol{x} - \mu\boldsymbol{S}^{-1}\boldsymbol{e}$$

is obtained, where the coefficient matrix is symmetric and positive definite. Highly efficient sparse matrix techniques are available to solve either the augmented or the normal equation system. Having the displacement vectors, an appropriate step-length $\alpha > 0$ needs to be determined to get the new iterates:

$$\begin{aligned}\boldsymbol{x} &:= \boldsymbol{x} + \alpha\Delta\boldsymbol{x},\\ \boldsymbol{y} &:= \boldsymbol{y} + \alpha\Delta\boldsymbol{y},\\ \boldsymbol{s} &:= \boldsymbol{s} + \alpha\Delta\boldsymbol{s}.\end{aligned}$$

Centrality Measures

To determine the appropriate step-size, the deviation of the iterates from the central path needs to be measured. Besides the barrier functions themselves, various centrality measures have been developed. Two such measures are presented here.

Observe that on the central path all the coordinates of the vector $\boldsymbol{XSe}$ are equal. This observation indicates that the proximity measure

$$\Delta_c(\boldsymbol{x},\boldsymbol{s}) := \frac{\max_i(\boldsymbol{x}_i,\boldsymbol{s}_i)}{\min_i(\boldsymbol{x}_i,\boldsymbol{s}_i)},$$

which equals to one on the central path, is an appropriate measure of centrality. The use of this simple measure leads to $O(nL)$ complexity, what is $O(\sqrt{n})$ worse than the best known iteration complexity to date. Due to its simplicity, this centrality measure is frequently used in practice. Another proximity measure can be defined as follows:

$$\delta_0(\boldsymbol{x},\boldsymbol{s},\mu) := \frac{1}{2}\left\|\left(\frac{\boldsymbol{XS}}{\mu}\right)^{\frac{1}{2}}\boldsymbol{e} - \left(\frac{\boldsymbol{XS}}{\mu}\right)^{-\frac{1}{2}}\boldsymbol{e}\right\|.$$

This centrality measure assumes the value zero on the central path. By using this proximity, polynomial IPMs are designed with iteration complexity $O(nL)$ and $O(\sqrt{n}L)$ as well.

Generic Interior Point Newton Algorithm.
Inputs:
proximity parameter κ;
accuracy parameter $\varepsilon > 0$;
variable damping factor α;
update parameter $0 < \theta < 1$;
$(\boldsymbol{x}^0,\boldsymbol{y}^0,\boldsymbol{s}^0)$, $\mu^0 \le 1$ subject to $(\boldsymbol{x}^0,\boldsymbol{s}^0) > 0$ and $\delta(\boldsymbol{x}^0,\boldsymbol{s}^0;\mu^0) \le \kappa$.
begin
  $\boldsymbol{x} := \boldsymbol{x}^0$; $\boldsymbol{y} := \boldsymbol{y}^0$; $\boldsymbol{s} := \boldsymbol{s}^0$; $\mu := \mu^0$;
  while $n\mu \ge \varepsilon$ **do**
  begin
    $\mu := (1-\theta)\mu$;
    while $\delta(\boldsymbol{x},\boldsymbol{s};\mu) \ge \kappa$
      $\boldsymbol{x} := \boldsymbol{x} + \alpha\Delta\boldsymbol{x}$;
      $\boldsymbol{y} := \boldsymbol{y} + \alpha\Delta\boldsymbol{y}$;
      $\boldsymbol{s} := \boldsymbol{s} + \alpha\Delta\boldsymbol{s}$;
    end
  end
end

The following crucial issues remain: How to get an initial interior point that satisfies the initialization requirements; how to choose the centrality parameter κ; how to update μ; and how to damp the Newton step, when needed. Initialization strategies will be discussed in the next section; at this moment it is assumed that an initial interior point, with $\mu = 1$, on the central path is given. The following two parameter choices allow polynomial complexity proof.

(1) **primal-dual log-barrier algorithm with full Newton steps**

This IPM enjoys the best complexity known to date. The following parameter choices are made:

- $\delta(\boldsymbol{x},\boldsymbol{s},\mu) := \delta_0(\boldsymbol{x},\boldsymbol{s},\mu)$;
- $\mu^0 := 1$;
- $\theta := \frac{1}{2\sqrt{n}}$;
- $\kappa = \frac{1}{\sqrt{2}}$;
- $(\Delta\boldsymbol{x},\Delta\boldsymbol{y},\Delta\boldsymbol{s})$ is the Newton step;
- $\alpha = 1$.

Theorem 1. Theorem II.52 in Roos, Terlaky and Vial (1997) *With the given parameter set, the full Newton step algorithm requires not more than*

$$\left\lceil 2\sqrt{n}\log\frac{n}{\varepsilon}\right\rceil$$

iterations to produce a feasible solution $(\boldsymbol{x},\boldsymbol{y},\boldsymbol{s})$ *such that* $\Delta_0(\boldsymbol{x},\boldsymbol{s},\mu) \le \kappa$ *and* $n\mu \le \varepsilon$.

(2) **large-update primal-dual log-barrier algorithm**

The following parameter choices are made:

- $\delta(\boldsymbol{x},\boldsymbol{s},\mu) := \delta_0(\boldsymbol{x},\boldsymbol{s},\mu)$;

- $\mu^0 := 1$;
- $0 < \theta < \frac{n}{n+\sqrt{n}}$;
- $\kappa = \frac{\sqrt{R}}{2\sqrt{1+\sqrt{R}}}$, where $R = \frac{\theta\sqrt{n}}{1-\theta}$;
- $(\Delta \boldsymbol{x}, \Delta \boldsymbol{y}, \Delta \boldsymbol{s})$ is the Newton step;
- α is the result of a line search, when along the search direction the primal-dual log-barrier function

$$\boldsymbol{x}^T \boldsymbol{s} - n \sum_{i=1}^{n} \log \boldsymbol{x}_i \boldsymbol{s}_i$$

is minimized.

Theorem 2. Theorem II.74 in Roos, Terlaky and Vial (1997) *With the given parameter set, the large update primal-dual log-barrier algorithm requires not more than*

$$\left\lceil \frac{1}{\theta} \left\lceil 2 \left(1 + \sqrt{\frac{\theta\sqrt{n}}{1-\theta}} \right)^4 \right\rceil \log \frac{n}{\varepsilon} \right\rceil$$

iterations to produce a feasible solution $(\boldsymbol{x}, \boldsymbol{y}, \boldsymbol{s})$ *such that* $\delta_0(\boldsymbol{x}, \boldsymbol{s}, \mu) \leq \kappa$ *and* $n\mu \leq \varepsilon$.

With the choice $\theta = \frac{1}{2}$, the total complexity becomes $O\left(n \log \frac{n}{\varepsilon}\right)$, while the choice $\theta = \frac{K}{\sqrt{n}}$, with any fixed positive value K gives $O\left(\sqrt{n} \log \frac{n}{\varepsilon}\right)$ complexity.

Hundreds of polynomial time IPMs have been developed since 1984, including projective methods; predictor-corrector methods; small- and large-update methods; higher-order methods that are based on higher than first-order approximation of the central path, volumetric barrier methods, self-regular IPMs. Several variants enjoy quadratic or superlinear convergence to an optimal solution.

On Finding an Exact Solution

IPMs follow the central path, and the iterates converge to a maximally complementary solution. However, IPMs not only converge to a solution but also allow identification of exact solutions after a finite number of iterations. This is because the size of the variables can be bounded along, or close to, the central path. An absolute lower bound can be given for the variables that converge to a positive value, while an upper bound, depending on the parameter μ, can be given for the variables that converge to zero. If μ is small enough, then the algorithm stops. The "small" variables can be rounded-off to zero, while the "large" variables can be modified to to get an an exact strictly complementary solution pair. This is a strongly polynomial rounding procedure, see Roos, Terlaky and Vial (1997) and Ye (1997).

The rounding procedure provides an exact strictly complementary solution. When an optimal basis is needed then from an optimal solution pair, an optimal basis can be obtained in strongly polynomial time. The optimal basis identification procedure is due to Megiddo; it can be found in the books by Terlaky (1996) and Roos, Terlaky and Vial (1997). This basis identification algorithm is successfully implemented in various commercial packages.

Initialization

IPMs need an interior feasible point to start with. "Interior" essentially means that having a feasible solution for which all the inequalities hold with strict inequality. Further, in the polynomial IPM variants given above, it is required that the initial solution is close to the central path. To find such solutions the following two methods were developed.

Infeasible IPMs: An infeasible interior point for both the primal and dual LP problem can easily be selected. Choose $\boldsymbol{x}^0 = \boldsymbol{e}$, $\boldsymbol{y}^0 = 0$ and $\boldsymbol{s}^0 = \boldsymbol{e}$, where $\boldsymbol{e}^T = (1, \cdots, 1)$. Then clearly $\boldsymbol{x} > 0$ and $\boldsymbol{s} > 0$, i.e., they are interior points of the positive orthant, but they are infeasible, because usually the primal $\boldsymbol{r}_p = \boldsymbol{b} - \boldsymbol{A}\boldsymbol{x}^0 = \boldsymbol{b} - \boldsymbol{A}\boldsymbol{e}$ and dual $\boldsymbol{r}_d = \boldsymbol{c} - \boldsymbol{s}^0 - \boldsymbol{A}^T\boldsymbol{y}^0 = \boldsymbol{c} - \boldsymbol{e} - \boldsymbol{A}^T 0 \neq 0$ residuals are not zero. Nevertheless, starting from such an infeasible interior point, the working horse of IPMs, the Newton process, can be launched. In this case the Newton system becomes

$$\begin{aligned} \boldsymbol{A}\Delta\boldsymbol{x} &= \boldsymbol{r}_p, \\ \boldsymbol{A}^T\Delta\boldsymbol{y} + \Delta\boldsymbol{s} &= \boldsymbol{r}_d, \\ \boldsymbol{X}\Delta\boldsymbol{S}\boldsymbol{e} + \boldsymbol{S}\Delta\boldsymbol{X}\boldsymbol{e} &= \mu\boldsymbol{e} - \boldsymbol{X}\boldsymbol{S}\boldsymbol{e}. \end{aligned}$$

This differs from the original Newton system just in the right hand side of the first two equations. Since the coefficient matrix remains the same, the new Newton system can be solved the same way as in the feasible case. During infeasible IPMs the primal and dual residual and the complementarity gap is reduced to

zero simultaneously. Infeasible IPMs allow polynomial complexity proofs. However, the worst case complexity of infeasible IPMs is $O(nL)$ iterations, a factor of $O(\sqrt{n})$ worse than the complexity of feasible IPMs.

Initialization by embedding: Another theoretically and for infeasible or unbounded problems also practically more sound initialization procedure is the self-dual embedding strategy, originally proposed by Ye, Todd and Mizuno (see the books Ye 1997; Jansen 1997; and Roos, Terlaky and Vial, 1997). The roots of this approach can be recognized in Goldman and Tucker's homogeneous self-dual model. By putting the primal and dual constraints together, requiring that the dual objective value be at least as large as the primal one, and finally by homogenizing the system, the Goldman–Tucker model is obtained:

$$\begin{array}{rrrrl} \boldsymbol{A}\boldsymbol{x} & & -\boldsymbol{b}\tau & = 0, & \boldsymbol{x} \geq 0, \quad \tau \geq 0, \\ -\boldsymbol{A}^T\boldsymbol{y} & -\boldsymbol{s} & +\boldsymbol{c}\tau & = 0, & \boldsymbol{s} \geq 0, \\ +\boldsymbol{b}^T\boldsymbol{y} & -\boldsymbol{c}^T\boldsymbol{x} & & -\rho = 0, & \rho \geq 0. \end{array}$$

Any solution of this system where $\tau > 1$ gives an optimal solution to the LP problem; moreover if this system has no solution with $\tau > 0$, then either the primal or the dual LP is infeasible. Due to the Weak Duality Theorem, this problem cannot have an interior feasible solution, but allows the following embedding with a perfectly centered interior feasible solution.

Let $\boldsymbol{y}^0 = 0, \boldsymbol{x}^0 = \boldsymbol{e}, \boldsymbol{s}^0 = \boldsymbol{e}, \tau^0 = 1, \rho^0 = 1, \ \vartheta^0 = 1$ be the initial value of the variables and let $\bar{\boldsymbol{b}} = \boldsymbol{b} - \boldsymbol{A}\boldsymbol{e}$, $\bar{\boldsymbol{c}} = \boldsymbol{c} - \boldsymbol{e}$, $\gamma = \boldsymbol{c}^T\boldsymbol{e} + 1$, $\beta = \gamma - \bar{\boldsymbol{c}}^T\boldsymbol{e} = \boldsymbol{e}^T\boldsymbol{e} + 1$. For the embedding problem **(SP)**

$$\begin{array}{l} \min \beta\vartheta \\ \text{Subject to} \\ \begin{array}{rrrrrl} \boldsymbol{A}\boldsymbol{x} & & -\boldsymbol{b}\tau & +\bar{\boldsymbol{b}}\vartheta & & = 0, \boldsymbol{x} \geq 0, \quad \tau \geq 0, \\ -\boldsymbol{A}^T\boldsymbol{y} & -\boldsymbol{s} & +\boldsymbol{c}\tau & -\bar{\boldsymbol{c}}\vartheta & & = 0, \boldsymbol{s} \geq 0 \\ +\boldsymbol{b}^T\boldsymbol{y} & -\boldsymbol{c}^T\boldsymbol{x} & & +\gamma\vartheta & -\rho & = 0, \rho \geq 0, \\ -\bar{\boldsymbol{b}}^T\boldsymbol{y} & +\bar{\boldsymbol{c}}^T\boldsymbol{x} & -\gamma\vartheta & & & = -\beta, \end{array} \end{array}$$

the following statements hold:

- the given initial point is interior feasible;
- it is on the central path of the embedding problem with $\mu = 1$;
- this the embedding problem can be solved by any feasible IPM;
- **(SP)** is self dual, thus its optimal value is zero, hence at optimum $\vartheta = 0$;
- a solution of **(SP)** with $\vartheta = 0, \tau > 0$ gives an optimal solution pair for LP;
- a solution of **(SP)** with $\vartheta = 0, \rho > 0$ gives evidence of primal or dual infeasibility of LP.

When problem **(SP)** is solved by any feasible IPM, the linear algebra can be organized so that an iteration costs hardly any more computational effort than an iteration at the original problem. Further, IPMs provide a strictly complementary solution, thus $\tau\rho = 0$ and $\tau + \rho > 0$ holds for the solution produced by IPMs. As a consequence, it suffices to solve **(SP)** to solve the original problem **LP**. Finally, note that the worst case complexity of IPMs applied to **(SP)** is the same as their complexity when applied to the original problem, because the embedding problem has $m + 2n + 3$ variables, thus the iteration complexity is $O(\sqrt{m + 2n + 3}L = O(\sqrt{n}L)$.

Initialization by embedding not only allows initializing IPMs while preserving the best worse-case complexity, but also provides the most robust method to detect infeasibility of either the primal or the dual LP problem. This is due to the fact that infeasiblity is detected by convergence to an optimal solution of the embedding problem **(SP)**. This is in sharp contrast to the divergence of the iterates when an infeasible IPM is applied to an infeasible or unbounded problem.

Barrier Approaches

Various extensions of interior point methods were developed in the past decades. It is natural to replace the logarithmic barrier $(-\ln t)$ by other barrier functions. Nesterov and Nemirovskii (1994) introduced the so-called universal barrier function that allows solution of any smooth convex optimization problem in a polynomial number of iterations. However, such an algorithm is not necessarily polynomial time, because the iterations might not be possible to compute in polynomial time. Copositive optimization (see Bomze et al. 2000), where a linear objective function is optimized over the intersection of an affine subspace and the cone of copositive matrices is a convex optimization problem where the universal barrier approach yields an algorithm for which the number of iterations is polynomial, but a single Newton step cannot be made in polynomial time. Nesterov and Nemirovskii (1994) have also

developed the theory of self-concordant barrier functions that allowed development of polynomial time algorithms for large classes of convex optimization problems.

Other approaches include the volumetric barrier method that in a cutting plane framework allows solution of LP problems in polynomial time. When a polynomial time separation oracle is available, the complexity of the volumetric barrier cutting plane IPM is independent of the number of constraints, its complexity depending only on the dimension of the problem. The significance of this result is that a large set of combinatorial optimization problems, previously solvable in polynomial time only by the ellipsoid method, can be solved with better complexity, and so IPMs completely supersede the ellipsoid method.

Self-regular barrier functions, by Peng, Roos and Terlaky (2002), allow design of IPMs that operate in a large neighborhood of the central path, while having almost the same complexity as small-update IPMs.

IPMs Versus Simplex Methods

An extensive comparison of IPMs and simplex methods can be found in Illés and Terlaky (2002). Some important aspects are reviewed here.

Efficiency: IPMs have been extremely successful in solving some very large linear programs, but they do not completely replace the simplex method. The best algorithm is, of course, problem-dependent, but generally speaking the IPMs perform better on larger problems and on problems that allow efficient exploitation of the numerical linear algebra. Specifically, as noted above, if the structure of $\boldsymbol{A}^T\boldsymbol{D}^2\boldsymbol{A}$ can be exploited to solve either the augmented or the normal equation system quickly, then IPMs have an advantage. An example of such an $\boldsymbol{A}$ matrix arises in multi-period resource planning problems where $\boldsymbol{A}$ has a staircase structure. The matrix $\boldsymbol{A}^T\boldsymbol{D}^2\boldsymbol{A}$ is then block diagonal and can usually be factored efficiently. IPMs also perform better on (highly) degenerate problems that often arise in large-scale applications, because degeneracy hardly effects the performance of IPMs.

Basic solution versus strictly complementary solution: IPMs by nature generate a maximally complementary optimal solution pair, while simplex-based solvers generate an optimal basis. Although users are used to basic solutions, there are many practical situations when a strictly complementary solution is desirable. In these situations simplex methods are clearly outperformed by IPMs, because finding a strictly complementary solution from an optimal basis solution is not easier than solving the original problem.

On the other hand, when an optimal basis is needed, then as discussed earlier, the identification of an optimal basis can be made in strongly polynomial time. Such algorithms are efficiently implemented in state-of-the-art software packages. So it can be concluded, that even in this case, the choice between IPMs and simplex methods should be made on the basis of their ability to solve the original problem efficiently, i.e., on the basis of which is better able to exploit the sparsity structure of the problem.

Sensitivity analysis: Post-optimality analysis has tremendous importance in practice. Linear programming software reports sensitivity analysis based on the obtained optimal basis, which answers the questions:

Over what range of the parameter values does the obtained optimal basis remain optimal, and how does the optimal function value change with this optimal basis solution?

However, typically the user would prefer to know the answers to the following questions:

What is the rate of change (shadow price, reduced cost) of the optimal objective value when a parameter changes, and for what intervals does this rate remain valid?

To answer this question correctly requires finding the possibly different left- and right-hand derivatives of the optimal value function. For this purpose the solution of some smaller linear problems is needed. Both an optimal basic solution and a strictly complementary solution are appropriate to set up those subproblems, which can again be solved either by simplex or IPM solvers. A thorough treatment of correct sensitivity analysis can be found in Jansen (1997) and in Roos, Terlaky and Vial (1997).

IPMs, Klee-Minty Examples and Complexity Bounds

This section reviews some cases when the central path exhibits extreme behavior.

Klee-Minty Examples for IPMs

The Klee-Minty cube (1972) for which simplex algorithms may take an exponential number,

i.e., $2^n - 1$ pivot steps, is given in the following form, where the convention $x_0 = 0$ is used, and τ is a small positive factor by which the unit cube $[0,1]^n$ is perturbed.

$$\min \; x_n$$

$$\text{s.t. } \tau x_{k-1} \le x_k \le 1 - \tau x_{k-1} \text{ for } k = 1, \ldots, n.$$

This optimization problem has $N = 2n$ constraints and n variables. The set of feasible solutions is a perturbed n-dimensional cube. Starting from the vertex $(0, \ldots, 0, 1)^T$, simplex methods may visit all the vertices of the feasible set.

Although IPMs are polynomial time algorithms, the complexity of central-path following IPMs depend on the number of inequalities in the problem and the condition number, or input length, see e.g., Roos, Terlaky and Vial (2006). Deza et al. (2006) show that in any dimension, the central path of an LP problem, where the feasible set is the Klee-Minty cube, follows the simplex path. More precisely, by adding exponentially many redundant constraints that are parallel to the facets passing through the optimal vertex of the Klee-Minty cube, the central path can be forced to visit a predefined arbitrary small neighborhood of all the vertices of the Klee-Minty cube in the same order as simplex methods do. In other words, this central path has $2^n - 2$ almost-90° turns. All redundant hyperplanes are at the same distance from the Klee-Minty cube, and the number of inequalities in dimension n is $N = O(n^2 2^{6n})$. In subsequent papers the number of redundant inequalities are reduced significantly. By decaying geometrically the distances of the redundant constraints to the corresponding facets, Deza, Nematollahi and Terlaky (2008) show that the number of the inequalities N can be reduced to $O(n^3 2^{2n})$ and that after $O(\sqrt{N}n)$ iterations, a standard rounding procedure allows identification of the optimal solution. This results tighten the gap between iteration-complexity lower and upper bounds.

The tightest result is given by Nematollahi and Terlaky (2008). The redundant constraints are placed parallel to the coordinate hyperplanes at geometrically decaying distances, so only $N = O(n2^{2n})$ redundant inequalities are needed to force the central path to follow the simplex path of the n-dimensional Klee-Minty cube, yielding an $O(n\frac{3}{2}2^n)$ iteration-complexity upper bound. The iteration complexity lower bound remains $\Omega(2^n)$, which follows from the fact that the central path follows the simplex path arbitrarily close. As a result, the gap between the iteration complexity upper and lower bounds is almost closed, because the lower bound for the number of iterations is $\Omega(\sqrt{\frac{N}{\ln N}})$, while the upper bound is $O(\sqrt{N}\ln N)$.

The Tight Klee-Minty Construction and Complexity Bounds

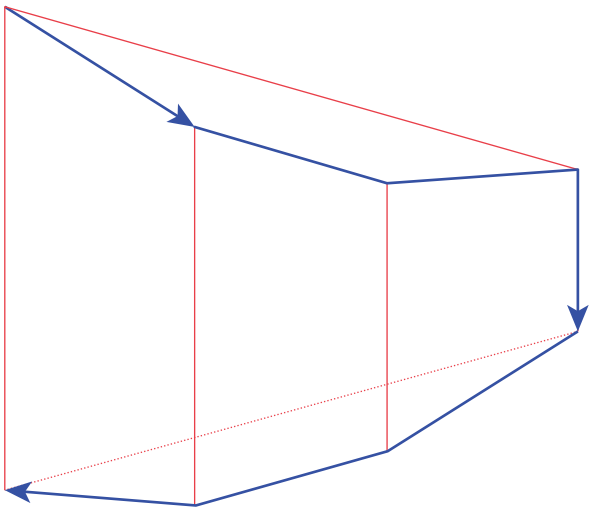
To force the central path to follow the simplex path, redundant constraints are introduced that are given by the inequalities $d_k + x_k \ge 0\}$, for $k = 1, \ldots, n$, where d_k is the distance to the respective coordinate plane. These redundant constraints are repeated h_k times, where the specific values of h_k are given in the sequel. While adding redundant constraints do not change the set of feasible solutions, the analytic center and the central path change. The redundant Klee-Minty example of Nematollahi and Terlaky (2008) is given as:

$$\begin{aligned} &\min && x_n \\ &\text{s.t.} \\ &&& \tau x_{k-1} \le x_k \le 1 - \tau x_{k-1} \text{ for k} = 1, \ldots, \text{n}, \\ &0 \le d_k + x_k \text{ repeated h}_\text{k} \text{ times, for k} = 1, \ldots, \text{n}. \end{aligned}$$

For this example the following parameters are chosen (Fig. 1):

$$\begin{aligned} &\tau = \tfrac{n}{2(n+1)}, \; \delta \le \tfrac{1}{4(n+1)}, \\ &d = \left(\tfrac{1}{\sqrt{\tau^{n-1}}}, \tfrac{1}{\sqrt{\tau^{n-2}}}, \ldots, \tfrac{1}{\sqrt{\tau}}, 0\right), \\ &h = \left(\left\lfloor \tfrac{4(1+\sqrt{\tau^{n-1}})}{\sqrt{\tau^{n-1}}\delta} \right\rfloor, \left\lfloor \tfrac{4(1+\sqrt{\tau^{n-2}})(2+\sqrt{\tau^{n-1}})}{\tau\sqrt{\tau^{n-2}}\delta} \right\rfloor, \right. \\ &\qquad \left. \ldots, \left\lfloor \tfrac{4(1+\sqrt{\tau})\prod_{i=2}^{n-1}(2+\sqrt{\tau^i})}{\tau^{n-2}\sqrt{\tau}\delta} \right\rfloor, \left\lfloor \tfrac{4\prod_{i=1}^{n-1}(2+\sqrt{\tau^i})}{\tau^{n-1}\delta} \right\rfloor \right). \end{aligned}$$

Theorem 3. *For the given redundant Klee-Minty example, the iteration-complexity lower and upper bounds for central-path-following interior point methods are* $O(2^n)$ *and* $O(n\frac{3}{2}2^n)$, *respectively. These bounds expressed in terms of the number of inequalities are* $O(\sqrt{\frac{N}{\ln N}})$ *and* $O(\sqrt{N}\ln N)$, *respectively. The gap between the lower and upper bounds is* $O(\ln^2 \text{N})$.



Interior-Point Methods for Conic-Linear Optimization, Fig. 1 The Klee-Minty 3-cube and the simplex path that is traced by the central path

Curvature and Conjectures

Deza, Terlaky and Zinchenko (2008, 2009) present a construction where all the N constraints are non-redundant, and the central path makes $N-4$ sharp turns. For this non-redundant example, the input length and the condition number of the problem grow as the number of inequalities grows. They also relate IPMs to the Hirsch Conjecture, a claim presented by W.M. Hirsch to Dantzig in a letter in 1957 (cf. Dantzig 1963), which asserts a linear upper bound for the diameter of polytopes. Although the conjecture in its original form was disproved by Santos (2010), its weaker variants are still open. Analogous conjectures for the central path curvature are presented by Deza, Terlaky and Zinchenko (2008, 2009), substantiating the relationships and presenting partial results.

Extensions

IPMs were designed for nonlinear problems already in the sixties, see e.g., Fiacco and McCormick (1968). Since then, IPMs have been generalized to large classes of smooth, convex optimization problems. Some polynomially solvable classes are summarize here.

QP, LCP

Convex quadratic optimization problems are solvable in polynomial time by IPMs. The complexity results are analogous to the case of LP. There are two differences: typically the step length is shorter in QP than in LP, but this just adds a constant factor in the complexity estimates. The other, more important difference is that no strictly complementary solution exists in general for QP problems. The consequence is that identifying an exact solution needs more computational effort, and the analysis gets also significantly more involved (see Illés et al. 2000).

Linear complementarity problems (LCPs) are natural generalizations of LP and QP. The solvability of an LCP

$$-\boldsymbol{M}\boldsymbol{x}+\boldsymbol{s}=\boldsymbol{q}, \qquad \boldsymbol{x}\geq 0, \boldsymbol{s}\geq 0, \qquad x_i s_i = 0\ \forall i$$

depends on the properties of the coefficient matrix $\boldsymbol{M}$. The largest polynomially solvable class is the class of LCPs with $P_*(\kappa)$ matrices, for all $\kappa \geq 0$. A matrix is $\boldsymbol{M}$ is a $P_*(\kappa)$ matrix if for all $x \in R^n$ the inequality

$$(1+4\kappa)\sum_{\boldsymbol{x}_i(M\boldsymbol{x})_i>0}\boldsymbol{x}_i(M\boldsymbol{x})_i+\sum_{\boldsymbol{x}_i(M\boldsymbol{x})_i<0}\boldsymbol{x}_i(M\boldsymbol{x})_i\geq 0$$

holds. Clearly $P_*(0)$ matrices are positive semidefinite. The union of the classes $P_*(\kappa)$ for all $\kappa \geq 0$ is the class of P_* matrices, which coincides with the class of sufficient matrices. It is known that LCPs with sufficient matrices are solvable with pivoting methods, thus there is no discrepancy (except worst-case complexity) between the solvability of LCPs by pivot and IPMs. The book of Kojima, Megiddo, Noma and Yoshise (1991) is devoted to IPMs for LCPs.

Conic Linear Optimization Problems

Conic linear optimization (CLO) problems are obtained when the nonnegativity constraints, i.e., the requirement that the variables of an LP problem are in the polyhedral cone of the nonnegative vectors, are replaced by the requirement that the variables belong to a convex cone. A primal-dual pair of CLO problems is given as:

$$\begin{array}{llll} (P)\ \min & \boldsymbol{c}^T\boldsymbol{x} & (D)\ \max & \boldsymbol{b}^T\boldsymbol{y} \\ \text{s.t.} & \boldsymbol{A}\boldsymbol{x}-\boldsymbol{b} \in \mathcal{C}_1 & \text{s.t.} & \boldsymbol{c}-\boldsymbol{A}^T\boldsymbol{y} \in \mathcal{C}_\in^* \\ & \boldsymbol{x} \in \mathcal{C}_2 & & \boldsymbol{y} \in \mathcal{C}_\infty^*, \end{array}$$

where $\boldsymbol{b}, \boldsymbol{y} \in R^m$, $\boldsymbol{c}, \boldsymbol{x} \in R^n$, $\boldsymbol{A}: m \times n$ matrix, C_1, C_2 are convex cones and $C_i^* = \{\boldsymbol{s} \in R^n : \boldsymbol{x}^T\boldsymbol{s} \geq 0, \forall \boldsymbol{x} \in C_i\}$ are the dual cones for $i = 1, 2$.

Large classes of CLO problems are solvable by IPMs in polynomial time. The best known classes of CLO problems are the classes of second-order cone optimization and semidefinite optimization problems. In a second-order cone optimization problem the cones $\mathcal{C}_1$ and $\mathcal{C}_2$ are direct products of second order and linear cones. The second order cone, or ice cream cone, in dimension n is given by

$$S_2^n := \left\{ \boldsymbol{x} \in R^n \; : \; \sqrt{\sum_{i=1}^{n-1} x_i^2} \leq x_n \right\}.$$

Second-order cone optimization problems are studied in Nesterov and Nemirovskii (1994); Vandenberghe and Boyd (1996); and Andersen, Roos, and T. Terlaky (2003).

Another important class of CLO problems, semidefinite optimization (SDO), which has numerous important applications, particularly in control and combinatorics, is discussed in more detail here (see e.g., Nesterov and Nemirovskii 1994; Vandenberghe and Boyd 1996; de Klerk 2002). Let $C, \boldsymbol{A}_i$ for $i = 1, \ldots, n$ be given symmetric matrices and $\boldsymbol{b} \in R^m$. Let X be denote the symmetric matrix of variables. The primal problem of semidefinite optimization can be given as

$$\begin{array}{lll} \text{minimize}_{\,X} & \mathbf{Tr}(CX) & \\ \text{subject to} & \mathbf{Tr}(\boldsymbol{A}_i X) = \boldsymbol{b}_i, & i = 1, \ldots, n, \quad \text{(CLP)} \\ & \boldsymbol{X} \succcurlyeq 0, & \end{array}$$

where $\mathbf{Tr}(\cdot)$ indicates the trace of the given matrix and the positive semidefiniteness of the matrix $\boldsymbol{X}$ is denoted by $\boldsymbol{X} \succcurlyeq 0$. Analogous to LP, the dual problem can be given as

$$\begin{array}{lll} \text{maximize}_{(y,S)} & \boldsymbol{b}^{\mathrm{T}} \boldsymbol{y} & \\ \text{subject to} & \sum_{\mathrm{i}=1}^{\mathrm{n}} \boldsymbol{A}_{\mathrm{i}} \boldsymbol{y}_{\mathrm{i}} + \boldsymbol{S} = \boldsymbol{C}, & \quad \text{(CLD)} \\ & \boldsymbol{S} \succcurlyeq 0. & \end{array}$$

The interior point condition for SDO reads as follows: a feasible solution $\boldsymbol{X}$ and $(\boldsymbol{y}, \boldsymbol{S})$ exists where the matrices $\boldsymbol{X}$ and $\boldsymbol{S}$ are positive definite. The design and analysis of IPMs for SDO are analogous to the case of LP, with two major differences.

First, the duality theory of SDO is weaker. There are SDO problems where both the primal and the dual problem admit an optimal solution, but the duality gap is nonzero; or where the optimal value either from the primal or from the dual side is not attained; or where either of the problems is weakly infeasible. Special techniques have been developed to deal with these pathological cases, see Wolkowicz, Saigal, and Vandenberghe (2000).

The second difference comes from the calculation of the search direction. When the interior point condition holds, the central path is well defined. Again, it is defined as the set of solutions of the perturbed optimality conditions:

$$\begin{array}{lll} \mathbf{Tr}(\boldsymbol{A}_{\mathbf{i}} \boldsymbol{X}) & = \boldsymbol{b}_{\mathbf{i}}, & i = 1, \ldots, n, \boldsymbol{X} \succcurlyeq 0, \\ \sum_{i=1}^{n} \boldsymbol{A}_i \boldsymbol{y}_i + \boldsymbol{S} & = \boldsymbol{C}, & \boldsymbol{S} \succcurlyeq 0, \quad \text{(CCP)} \\ \boldsymbol{X}\boldsymbol{S} & = \mu \boldsymbol{I}. & \end{array}$$

When Newton's method is applied to this system to calculate the search directions, the system

$$\begin{array}{ll} \mathbf{Tr}(\boldsymbol{A}_i \Delta \boldsymbol{X}) & = 0, \quad i = 1, \ldots, n, \\ \sum_{i=1}^{n} \boldsymbol{A}_i \Delta \boldsymbol{y}_i + \Delta \boldsymbol{S} & = 0, \\ \boldsymbol{X}\Delta \boldsymbol{S} + (\Delta \boldsymbol{X})\boldsymbol{S} & = \mu \boldsymbol{I} - \boldsymbol{X}\boldsymbol{S} \end{array}$$

is obtained. When $(\Delta \boldsymbol{X}, \Delta \boldsymbol{y}, \Delta \boldsymbol{S})$ is the solution of this Newton system, then $\Delta \boldsymbol{S}$ is symmetric; however $\Delta \boldsymbol{X}$ is symmetric if and only if $\boldsymbol{X}\boldsymbol{S}$ is a multiple of the unit matrix. As a consequence, additional tools are needed to symmetrize the Newton system. For details the reader is referred to Wolkowicz, Saigal, and Vandenberghe (2000), and Todd (1999).

Several codes have been developed to solve SDO problems. Traditionally nonlinear optimization software has required a functional description of the set of feasible solution, hence not allowing incorporation of conic constraints.

Smooth Structured Nonlinear Programming Problems

Smooth nonlinear programming (NLP) problems are also solvable in polynomial time by using IPMs when a smoothness condition is satisfied. Let a set of convex

functions $f_0(\boldsymbol{x}), f_1(\boldsymbol{x}), \ldots, f_m(\boldsymbol{x}) : R^n \to R$ be given. Further, assume that the NLP problem

$$\begin{aligned} &\text{minimize}_{\mathrm{x}} \quad \mathrm{f}_0(\boldsymbol{x}) \\ &\text{subject to} \quad \mathrm{f}_{\mathrm{i}}(\boldsymbol{x}) \leq 0, \qquad \mathrm{i} = 1, \ldots, \mathrm{n}, \end{aligned}$$

satisfies the interior point condition, i.e., admits a solution for which all constraints hold with strict inequality and its level sets are bounded. Let

$$\phi_\mu(\boldsymbol{x}) := f_0(\boldsymbol{x}) - \mu \sum_{i=1}^{m} \log(-f_i(\boldsymbol{x}))$$

be the log-barrier function. The NLP problem satisfies the smoothness condition – called κ self-concordant – if there exists a $\kappa \geq 0$ for which the inequality

$$|\nabla^3 \phi_\mu(\boldsymbol{x})[h,h,h]| \leq 2\kappa \left\{\nabla^2 \phi_\mu(\boldsymbol{x})[h,h]\right\}^{\frac{3}{2}}$$

holds for any $\boldsymbol{x}$ in the domain of ϕ_μ and for any $h \in R^n$. Here $\nabla^2 \phi_\mu(\boldsymbol{x})[h,h]$ and $\nabla^3 \phi_\mu(\boldsymbol{x})[h,h,h]$ denote the second- and third-order directional derivatives of $\phi_\mu(\boldsymbol{x})$ in the direction $h \in R^n$, respectively.

When the self-concordancy condition is satisfied, IPMs applied to NLP admit polynomial complexity proofs (see den Hertog 1994; Nesterov and Nemirovskii 1994). Implementations of IPMs for NLP problems include the KNITRO package Byrd, Nocedal, and Waltz (2006), and the IPOPT package Wächter (2002).

Concluding Remarks

IPMs allow polynomial-time solution of large classes of smooth convex optimization problems, where new efficiently solvable problem classes such as semidefinite programming and second-order cone optimization have been identified. IPMs are efficient not only in theory, but also in computational practice, often being the only option for solving large-scale structured problems. This has contributed heavily to efficiency improvements in optimization software on the order of 10^6 or more (Bixby 2002). Core theory, such as duality theory and sensitivity analysis, has been rejuvenated (Roos et al. 2006; Koltai and Terlaky 2000; Ghaffari Hadigheh et al. 2007).

IPMs have spread to all areas of optimization. For example, novel robust optimization methodology developed by Ben-Tal and Nemirovskii (2001) has opened new opportunities to solve important problem classes, including problems in truss-topology design, signal processing, VLSI design and robust and intensity modulated radiation therapy treatment (Chu et al. 2008; Craig et al. 2008).

More details on IPMs for LP problems can be found in Gonzaga (1991a,1991b,1992), Goldfarb and Todd (1989), Roos and Terlaky (1997), Roos, Terlaky and Vial (1997), Terlaky (1996), Ye (1997), Wright (1996) and Wright (2004); for more general convex and nonlinear problems, see den Hertog (1994), Nesterov and Nemirovskii (1994), and Wolkowicz, Saigal, and Vandenberghe (2000).

International Federation of Operational Research Societies (IFORS)

Graham K. Rand
Lancaster University, Lancaster, UK

IFORS, the International Federation of Operational Research Societies, is an international society whose members are national operational research societies. IFORS was founded in 1959 following the first international OR conference that was held in Oxford, 1957 (Rand 2000).

IFORS was formed by three societies: The U.S. Operations Research Society of America (ORSA), the U.K. Operational Research Society (ORS), and the French Société Française de Recherche Opérationelle (SOFRO). The Statutes of IFORS (Anonymous 1959) set out the purpose of the Federation: "The development of operational research as a unified science and its advancement in all nations of the world." Perhaps the most striking aspect of the Statutes is the provision that in all formal votes taken by the IFORS Board, the voting strength of each member society is in proportion to the square root of its membership. As of this writing, 50 national societies belong to IFORS, with a collective individual membership of about 30,000. See Rand (2001) and del Rosario and Rand (2010) for fuller information about IFORS' history.

IFORS publications includes the proceedings of its triennial conferences from 1957 to 1990; the abstracting journal, *International Abstracts in Operations Research* (*IAOR*), started in 1961 and now published on the Internet as well as in print; and, since 1993, the journal, *International Transactions in Operational Research* (*ITOR*), that publishes selected conference papers, special issues focused on current OR topics, as well as international perspectives of OR.

Discussions at the sixth IFORS Conference in Dublin in 1972 led to the creation, in 1976, of EURO, The Association of European Operational Research Societies within IFORS; there are now 31 member societies in EURO, including South Africa, Egypt and Israel. In 1982, the Association of Latin American OR Societies (ALIO) was established; there are now eight member societies in ALIO, including two members of EURO: Spain and Portugal. The Association of Asian-Pacific OR Societies within IFORS (APORS) came into being in 1985; there are now 10 member societies in APORS. When, in 1987, the IFORS constitution was changed, NORAM, the Association of North American OR Societies within IFORS, composed of the OR Societies in Canada and the USA, was created solely so that a Vice-President would be able to represent North America.

International Institute for Applied Systems Analysis (IIASA)

The International Institute of Applied Systems Analysis (IIASA) is a nongovernmental research institution located in Laxenburg, Austria. IIASA was founded in 1972 on the initiative of the academies of science or equivalent institutions of 12 nations. As of 2012, the following countries are national member organizations:

Austria, Brazil, China, Egypt, Finland, Finland, Germany, India, Japan, Republic of Korea, Malaysia, Netherlands, Norway, Pakistan, Russian Federation, South Africa, Sweden, Ukraine and United States of America. The original motivation for the establishment of IIASA was to enable scientists from East and West to work together on problems of common concern. Although this is still an objective of the Institute, it has been broadened to encompass joint work by scientists from most countries. The goal of IIASA is "To conduct international and interdisciplinary scientific studies to provide timely and relevant information and options, addressing critical issues of global environmental, economic, and social change, for the benefit of the public, the scientific community, and national and international institutions" (IIASA *Agenda for the Third Decade*). Resident scientists at IIASA coordinate research projects, working in collaboration with worldwide networks of researchers, policymakers, and research organizations. IIASA has been instrumental in the development of global (world) models that are concerned with environmental, energy and other resource, economic and population issues.

Inventory Modeling

Edward A. Silver[1] and David F. Pyke[2]
[1]University of Calgary, Calgary, Alberta, Canada
[2]University of San Diego, San Diego, CA, USA

Introduction

Supply chains have simultaneously become increasingly globalized and lean. As a result, costs have often decreased dramatically, but at the expense of increased complexity and risk. A virus outbreak in Asia can shut down a factory in Cleveland, and a volcano in Iceland can shutter automotive factories in Spain and Germany. These developments suggest that excellent inventory management and control are critical to effective management of supply chains. Managers need to understand the optimal amount of inventory to hold in stable situations, as well as in highly dynamic and uncertain environments. The tendency is often to hold too much inventory, and thus to avoid stockouts and the resulting fallout that lands on inventory managers. Companies, however, are also confronted with the cost of inventory in the form of reduced working capital that could be used for other profitable activities such as new product innovation or paying down debt. How should managers handle this tradeoff? This article provides an introduction to the answer to this question.

Standard inventory models, of the type introduced here, add significant value to many organizations. In a number of cases, however, the basic models must be adjusted to account for the complexities of the situation (Silver 2008). Tiwari and Gavirneni (2007) argue that inventory researchers should seek close connections with companies facing these complexities so that their research will address actual company needs. This is clearly true. Nevertheless, there are excellent examples of successful implementation of challenging inventory models, including:

i) A major appliance manufacturer demonstrates that it could reduce its service parts inventory stocked in service vehicles from $7 million to $3 million (Gorman and Ahire 2006).
ii) A division of John Deere with sales of $3 billion improved on-time shipments from 63% to 92%

while reducing or avoiding inventory costs by $890 million (Troyer et al. 2005).

Inventory decisions can often interact with decisions in other areas of the organization. Examples include: i) preventive maintenance (determination of inventory levels of spare parts); ii) marketing (effects of pricing and promotion on demand, hence stock requirements and, in the opposite direction, more effective inventory management can reduce customer response time, hence stimulating increased demand), iii) quality assurance (higher quality levels reduce the need for buffer or safety stocks), iv) production scheduling (provision of supporting raw materials and supplies), and v) finance (interest rates that vary with the level of assets held by the firm (Buzacott and Zhang 2004). The models that deal with these complexities are not explicitly presented here. Rather, the intention is to provide an introduction to inventory models per se, thus providing the reader with an overview of the general subject area.

In the next section a listing is provided of the generic reasons why organizations carry inventories. This is followed by a discussion of the types of costs that are relevant in the development and use of inventory models. Then, the subsequent four sections deal with illustrative models. These are followed by a general classification scheme. The coverage of the topic area concludes with a discussion of the important possibility of changing some of the parameters or constraints (givens) in inventory models. More detailed treatments of inventory modeling include Graves, Rinnooy Kan and Zipkin (1993), Silver, Pyke, and Peterson (1998), Zipkin (2000), and Axsäter (2010).

Reasons for Carrying Inventories

There are six generic reasons for organizations to carry inventories. Most situations involve a mix of these reasons, but each is discussed separately to emphasize the associated rationale:

i) *Cycle stock* — when the demand pattern is level and known and there is no uncertainty in supply it still may make sense to not have the replenishment inflow precisely match the steady outflow. There may be physical limits on replenishment sizes (e.g., batch container sizes in chemical processes), major fixed costs associated with each replenishment action, or quantity discounts on purchase price and/or transportation costs. Full truck load shipments, for example, are significantly less expensive than less-than-truckload shipments. Each of these reasons leads to the repeated (or cyclic) use of a significant replenishment size.

ii) *Congestion stock* — even when the reasons for holding cycle stock are not present and there is still no uncertainty in supply or demand, it may be necessary to have inventories of items when they are produced on the same piece of equipment and it takes an appreciable amount of time to change over from production of one item to another. One has to produce more than the immediate needs of an item because the congestion on the equipment prevents producing that item again for an appreciable amount of time.

iii) *Buffer or safety stock* — when there is uncertainty in demand and/or supply and the required customer response time is lower than the time necessary to acquire/produce the demanded goods, it is necessary to have extra stock on hand to ensure an adequate level of customer service. Note that the customer can be internal to the organization; for example, spare parts needed to repair equipment.

iv) *Pipeline stock* — if an item has to be moved an appreciable distance before being delivered to the customer, then there will be stock in the pipeline. More generally, if units must go through a process (transportation is a special case) that requires a non-negligible amount of time, then there will be associated pipeline stock equal to the throughput rate multiplied by the process time per unit.

v) *Anticipation stock* — where factors such as demand levels, raw material availability or raw material prices are expected to change appreciably with time it may make sense to build up (and deplete) inventory levels in anticipation of these changes.

vi) *Decoupling stock* — in a multi-echelon situation (or multistage process) stock may be used to permit the separation of decision making at the different levels or echelons. For example, decoupling inventory allows decentralized decision making at branch warehouses without every decision at a branch having an immediate impact on, say, the central warehouse or factory.

I

As discussed below, it may be more appropriate to eliminate the underlying causes or reasons for carrying inventories, rather than simply accepting them within the modeling and inventory control environment.

The Categories of Inventory: Related Costs

The costs associated with inventory management are often not easy to estimate in practice. Moreover, only so-called relevant costs, that is, those that can be influenced by inventory management decisions, should be considered. In particular, care must be taken with respect to overhead costs that are often not affected by inventory decisions., see (Silver et al. 1998).

Five different categories of costs are considered.

a) *Costs of the Material Itself*: This so-called unit variable cost (raw material plus any value added or material handling) is denoted by v, with dimension of dollars/unit. These costs are relevant only insofar as they are affected by the size of the replenishments used. If there are no quantity discounts in acquisition cost (including the transportation component), then over a given time period (such as a year), the costs of the material will be a constant, independent of the replenishment sizes used. Specifically, if the unit variable cost is independent of the replenishment sizes used, then the total cost of the material is Dv per year, where D is the demand (or usage) rate in units/year.

b) *Fixed Cost of Each Replenishment Action*: The fixed cost of a replenishment action is denoted by A, that is, the cost component that is independent of the size of the replenishment. In a production context, A is often referred to as the setup or change-over cost. In a retail or distribution environment, A includes the costs of order forms, postage, authorization, receiving, inspection, and handling of vendor invoices.

c) *The Costs of Having Material in Inventory (Inventory Carrying Costs)*: The common way of modeling the costs of having material in inventory is as

$$\text{Cost/year} = \bar{I}vr \tag{1}$$

where $\bar{I}$ is the *average* inventory, in convenient units of the item under consideration, v is the unit variable cost in \$/unit, and the carrying charge, r, is the cost in dollars of carrying one dollar of inventory for one year. The latter encompasses out-of-pocket expenses (e.g., insurance, taxes, operating the warehouse, etc.) and the lost opportunity of having capital tied up in the stock (e.g., it could be invested elsewhere or used to pay off debt). Some models use the symbol $h = vr$ to represent the cost per unit in inventory per year.

d) *The Costs of Insufficient Stock in the Short Run*: If the stock is inadequate to meet pending demand, then two types of costs may be incurred – those associated with stockouts (lost sales, backorders, loss of goodwill, downtime of equipment, etc.) and those of emergency actions to avoid stockouts (e.g., expediting, use of an emergency high-cost supplier, etc.). There is no universally appropriate way of modeling such costs as a function of the occurrence and magnitude of the shortage. Possibilities include a fixed cost per stockout occasion, a cost proportional to the number of units short, and so on.

In lieu of assigning a cost of insufficient stock, many organizations impose a service constraint on the inventory policy. Again, there are a wide variety of possible service measures. Two of the more common ones are a specified probability of no stockout prior to the receipt of each replenishment, and a specified fraction of the demand to be routinely met from stock. The latter is known as the fill rate.

e) *The Costs of the Inventory Control System*: Many models are concerned with minimizing the total of two or more of the preceding four cost categories. There is a fifth category, however, that should be considered in selecting among different inventory control systems, namely the costs of administering the system itself. These include the costs of acquiring and updating the data (e.g., demand rate, measure of demand variability, cost parameters, etc.) required for the operation of the system and its associated decision rules. They also include the cost of numerical calculations, although these are likely quite low in most instances, and the cost training and other aspects of implementation.

The Economic Order Quantity (Wilson Lot-Size)

The Economic Order Quantity (EOQ) is one of the earliest results developed in inventory modeling

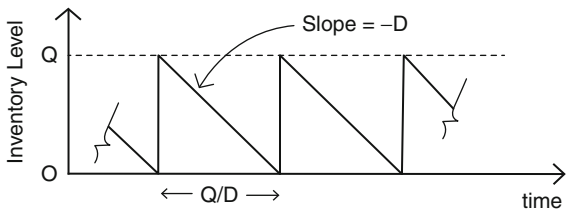
(*Harris* 1913). It addresses the issue of how much inventory to replenish under very stable conditions where there is a significant fixed cost (A) per replenishment. Thus, the economic order quantity (EOQ) is concerned with cycle stock. Strictly speaking, it is based on a number of rather severe assumptions, but it is still an important result for two reasons: (1) the costs tend to be insensitive to some of the assumptions; and (2) many of the assumptions can be relaxed leading to somewhat more complicated results, but the EOQ or an obvious variation thereof often still plays a central role.

Assumptions — There are nine underlying assumptions:

1. the demand rate is constant and known,
2. there are no restrictions on the size of the replenishment quantity (including that it need not be an integer number of units),
3. there are no quantity discounts,
4. the cost factors do not change appreciably with time,
5. each inventory item is treated independently of others (i.e., it is chosen to ignore any possible benefits of coordination),
6. the replenishment lead time (the time interval from when it is decided to place a replenishment order until the moment that the associated material is on the shelf ready to satisfy demand) has a known value,
7. the entire replenishment arrives at the same time (unlike in a production context where there may be a gradual buildup of stock),
8. no shortages are permitted,
9. the planning horizon is very long; that is, the parameters will continue at the current values well into the future.

Derivation of the EOQ — Under the above set of assumptions, there is no uncertainty and no parameters change appreciably with time. Therefore, it is appropriate to restrict attention to a policy of ordering the same quantity Q (in units) over and over again with each replenishment arriving just as the on-hand inventory goes to zero. Thus, each order is placed exactly a lead time before the replenishment arrives. The resulting pattern of inventory versus time is shown in Fig. 1, where the slope is the negative of the demand rate, D, in units/year.

From the set of assumptions it follows that there are only two categories of relevant costs (relevant



Inventory Modeling, Fig. 1 Inventory Level Versus Time

in the sense that they will be affected by the choice of Q), namely the fixed costs of replenishments and the inventory carrying costs. The total relevant costs per year as a function of the order quantity are given by

$$TRC(Q) = \frac{AD}{Q} + \frac{Qvr}{2}. \tag{2}$$

The first term is the product of the fixed cost per replenishment and the number of replenishments per year, while the second term comes from Equation (1) and the fact that $\bar{I}$ for the triangles of Fig. 1 is $Q/2$.

Setting $dTRC(Q)/dQ = 0$ leads to the optimum Q-value as

$$\text{EOQ} = \sqrt{\frac{2AD}{vr}}. \tag{3}$$

Moreover,

$$\frac{d^2TRC(Q) =}{d^2Q} = \frac{2AD}{Q^3} > 0$$

for any $Q > 0$, so that the minimizing value of Q is indeed found.

Remarks

i) At the EOQ value, one can show that the two components of $TRC(Q)$ in Equation (2) are equal. (This is a very special property of the nature of these two components. In general, when one is minimizing the sum of two cost functions of a variable, the two cost functions are not equal at the minimizing value of the controllable variable, but at that point it is known that the slopes of the two component functions are equal and opposite in sign.)

ii) The EOQ expressed as a time supply is

$$\frac{EOQ}{D} = \sqrt{\frac{2A}{Dvr}}. \tag{4}$$

Many organizations have tended to use a very simple decision rule, namely the same time supply replenishment quantity for a broad range of items. For example, they may set Q = six weeks of supply for all items. Equation (4) shows that this is inappropriate in that any of A, D and v are likely to vary between items.

iii) An important relaxation of the EOQ model is to permit quantity discounts.

As an example, the so-called all units discount situation is where the unit variable cost

$$v = \begin{cases} v_0 & \text{if } Q < Q_b \\ v_1 & \text{if } Q \geq Q_b \end{cases}$$

where Q_b is the breakpoint order quantity and $v_1 < v_0$. Under such circumstances, it can be shown that the best order quantity must be at one of three positions: the EOQ using v_0, Q_b, or the EOQ using v_1 (Silver et al. 1998).

iv) Another important extension is where the demand pattern is still known but varies with time. Trended demand would be an example. In addition, with the use of Manufacturing Resources Planning (MRP), the demand pattern may be lumpy. In these situations, it no longer follows that repetitive use of the same Q value is appropriate; hence it is inadequate to look at average costs in a typical year and an exact analysis becomes much more complicated. There is an extensive literature on this so-called lot-sizing problem, see (Silver et al. 1998).

An Illustrative Model for the Case of Congestion Stock

Here, a group of n items (numbered $i = 1, 2, \ldots, n$) satisfying all but two of the EOQ assumptions is considered. Specifically the items are produced on the same piece of equipment (i.e., coordination is necessary) and there is a gradual buildup of the stock of the item being replenished (m_i units/year for item i). Furthermore, it is assumed that a so-called cyclic production schedule is used, that is, item 1, then item 2 are produced,. . ., then item n and returned to item 1 to begin a new cycle. There may be idle time in each cycle, as appropriate. Item i has parameters D_i, A_i, v_i and m_i and Q_i is defined to be its replenishment quantity. Moreover, assume that there is a setup time of τ_i at the beginning of the replenishment of item i. The single decision variable is the duration of each cycle, T, in years. The associated replenishment quantities are given by

$$Q_i = D_i T \quad i = 1,\ 2,\ \ldots,\ n. \tag{5}$$

Production of item i begins just as its inventory level is depleted, that is, the setup must be commenced τ_i before that moment. Production of i continues for $D_i\, T/m_i$ units of time and the inventory reaches a maximum level of $Q_i\,(1 - D_i/m_i)$, not Q_i, because usage at rate D_i continues during the production. Thus the average inventory level of item i is

$$\bar{I}_i = \frac{D_i T}{2}(1 - D_i/m_i) \tag{6}$$

The total relevant costs per year are

$$TRC(T) = \sum_{i=1}^{n} \frac{A_i}{T} + \sum_{i=1}^{n} \frac{D_i T}{2}(1 - D_i/m_i)v_i r. \tag{7}$$

One wishes to minimize this expression but subject to having adequate capacity, namely

$$\sum_{i=1}^{n} \left(\tau_i + \frac{D_i T}{m_i}\right) \leq T$$

or

$$T \geq \frac{\Sigma \tau_i}{1 - \Sigma D_i/m_i}. \tag{8}$$

Again, one can show that $\mathrm{d}^2\, TRC(T)/\mathrm{d}T^{\,2} > 0$, so that setting $\mathrm{d}TRC(T)/\mathrm{d}T = 0$ will give a minimum of $TRC(T)$. This turns out to be where

$$T_{\text{opt}} = \sqrt{\frac{2\Sigma A_i}{r\Sigma D_i v_i (1 - D_i/m_i)}}. \tag{9}$$

Because of the convexity of $TRC(T)$, T_{opt} is used if it satisfies condition (8), otherwise T is set equal to the right-hand side of (8).

A more complicated problem to analyze is where not every item is produced on each cycle. Rather, now let $Q_i = k_i D_i T$ where $k_i = 1, 2, 3, \ldots$, see Chapter 11 in Silver, Pyke and Peterson (1998).

The Newsvendor (or Single-Period) Problem

The Newsvendor problem applies to situations in which the selling season is quite brief relative to the replenishment lead time. Therefore, there is only one opportunity to purchase the item in advance of actual demand. Seasonal goods, holiday items, newspapers, fashion apparel, and even consumer electronics fit in this category. Indeed, in today's world, more and more products share the characteristics that demand a newsvendor solution. Typically, some type of forecasting model is used to forecast demand in the period of interest, and there is an associated probability distribution of forecast errors or equivalently of actual demand that will result. Let the continuous probability distribution of demand x in the period of interest be denoted by $f(x)$ with a cumulative distribution

$$F(x) = \int_0^x f(y)dy. \tag{10}$$

The decision to be made is how large a quantity, Q, of the item to have available to meet demand in the period. Suppose that there is a shortage (or underage) cost of c_u for each unit of demand not satisfied (i.e., when $Q < x$), and an overage cost of c_o for each unit of stock that is not demanded, that is, remaining at the end of the period (when $Q > x$).

A marginal is used, as opposed to a total, cost argument. Specifically consider the Qth unit made available. It will save an underage cost anytime $x \geq Q$. The probability of this event is $1 - F(Q)$. Hence, the expected marginal cost savings of the Qth unit are

$$EMS(Q) = c_u[1 - F(Q)]. \tag{11}$$

The Qth unit will incur an avoidable cost of c_o if demand turns out to be less than Q. Therefore, the expected marginal cost increase of the Qth unit is

$$EMI(Q) = c_o F(Q) \tag{12}$$

It can be argued, that for optimality, one would want to stop with the Q value where

$$EMS(Q) = EMI(Q)$$

or, using Equations (11) and (12), the best Q, denoted by Q^*, must satisfy

$$F(Q^*) = \frac{c_u}{c_u + c_o}. \tag{13}$$

Note that (13) is a general result for any continuous distribution of demand.

Many extensions of this problem have been solved. A multi–item version with a budget constraint on the total amount that can be spent on the set of items can be found in Silver, Pyke and Peterson (1998, pp. 393–396. Pricing and quantity decisions are reviewed and extended in Petruzzi and Dada (1999), and situations with demand substitution are analyzed in Netessine and Rudi (2003). Numerous additional extensions exist.

An Illustration of Dealing with Uncertain Demand in an On-Going Situation

In contrast with the previous section, consider the case where demand continues on indefinitely so that unused material can be kept in stock until it is used up by future demand. Examples include apparel that is not fashion-oriented and non-perishable staple food items. These items typically have a non-zero replenishment lead time. The combination of random demand and a non-zero lead time forces a more careful definition on what is meant by inventory level. In fact, there are at least four different definitions:

i) On-hand stock — material physically present.
ii) Backorders — unsatisfied demand that will be met when stock becomes available.
iii) Net stock = (On-hand) — (Backorders)
iv) Inventory position = (On-hand)

$$+\begin{pmatrix}\text{On-order}\\ \text{from supplier}\end{pmatrix} - \begin{pmatrix}\text{Backordered}\\ \text{customer demands}\end{pmatrix}$$

Reordering decisions are based on this last quantity.

Common Individual Item Control Systems: When demand is uncertain, there are really three decision variables regarding the inventory management of a particular item at a specific location, namely,

i) how often to review the status of the item (continuous review, sometimes called transactions reporting, versus periodic review and, if the latter, what review interval (R) to use),
ii) when to initiate a replenishment, and
iii) how much to replenish.

The three most common individual item control policies are

i) (s, Q) — continuous review ($R = 0$) with an order for a fixed quantity Q being placed when the inventory position drops to the reorder point s or lower,
ii) (R, S) — every R units of time enough is ordered to raise the inventory position to the order–up–to–level S, and
iii) (R, s, S) — every R units of time a review is made. If the inventory position is at s or lower, enough is ordered to raise it to S.

It should be emphasized that here one deals with a so-called independent demand situation, where the demand for the item under consideration is not a function of replenishment decisions for other items. In particular, where an item is a component of another item, its demand is dependent on the demand for the latter item, and the control procedures of MRP may be more appropriate than any of the above control policies. Furthermore, if the item shares a common resource, such as a transportation container or production equipment, it cannot be considered in isolation of the other items that share the resource.

Selecting s in an (s, Q) System: In an (s, Q) system, the order quantity, Q, is often chosen using the EOQ or perhaps a constrained order quantity, such as a truckload. Here it is focused on choosing the reorder point, s. It is illustrated for the case of normally distributed demand during a constant lead time (of duration L) and for a particular service constraint, namely, where there is a specified probability P of no stockout during each lead time. [A variety of other combinations of control policy, demand distribution and service measure/shortage costing method can be treated (Brown 1982; Hax and Candea 1984; Nahmias 2008; Silver et al. 1998; Zipkin 2000; *Axsäter* 2010)].

It is assumed that each replenishment is triggered when the inventory position is exactly at the level of s. (If the inventory position falls below s before a replenishment is triggered, due to large transactions, the amount below the reorder point is called an undershoot, and the mathematics becomes substantially more complex). Letting $f(x)$ be the general probability distribution of the lead time demand x, then the probability of no stockout must satisfy

$$P = \int_{-\infty}^{s} f(x)dx \tag{14}$$

For the special case of $f(x)$ being normally distributed (with mean μ_L and standard deviation σ_L), letting

$$s = \mu_L + k\sigma_L, \tag{15}$$

then a substitution of $u = (x - \mu_L)/\sigma_L$ in Equation (14) leads to

$$P = \Phi(k) \tag{16}$$

where $\Phi(k) = \int_{-\infty}^{k} \phi(u)du$ is the unit normal distribution function and $\phi(u)$ is the probability density function of that distribution.

In summary, the procedure is as follows: The specified value of P gives $\Phi(k)$ from (16). Then using the Excel function NORMSINV($\Phi(k)$), or a table lookup, find the associated k value. Then s is determined from equation (15).

The above analysis was based on a constant lead time L. If the lead time is variable, a more refined analysis is required. For example, if one can assume that L and D are independent random variables, then it can be shown that $E(x) = E(L)E(D)$ and $\sigma_x = \sqrt{E(L)\,\mathrm{var}(D) + [E(D)]^2\,\mathrm{var}(L)}$, where x, with mean $E(x)$ and standard deviation σ_x, is the total demand in a replenishment lead time, in units; L, with mean $E(L)$ and variance var (L), is the length of a lead time (L is the number of unit time periods, that is, just a dimensionless number); and D, with mean $E(D)$ and variance var (D), is the demand, in units,

in a unit time period. In this case, the $E(x)$ and σ_x quantities found here should be used in place of μ_L and σ_L in the above decision rule.

Note that the above choice of s is independent of Q. Other service measures/shortage costing methods lead to a decision rule for s that depends upon Q. Such a dependence was ignored in the derivation of the EOQ. There are optimization procedures for *simultaneously* choosing values of Q and s (Hadley and Whitin 1963; Naddor 1966; Nahmias 2008; Silver et al. 1998).

The Wide Variety of Possible Inventory Models

There are a large number of structural parameters that can take on two or more values in actual inventory systems. In principle, each combination of these parameters leads to a different inventory model. In this section, most of the important parameters are listed (many of the possible combinations have been modeled in the literature but often tailor–made adaptations or approximations are needed to accurately model the inventory problem of a given organization (Silver 1981; Silver 2008; Tiwari and Gavirneni 2007):

Nature of Demand

- deterministic vs. probabilistic (in the latter case, known versus uncertain probability distribution)
- stationary vs. varying with time (e.g., seasonality)
- influenced by on–hand inventory or not
- consumables vs returnables/repairables
- independent of, vs. dependent on, replenishment decisions of other items

Time Horizon

- single period vs. multiperiod
- discrete vs. continuous time
- use of discounting or not

Supply Issues

- quantity discounts (economies of scale)
- minimum order size or fixed batch size
- supply available or not in certain periods
- fixed or random lead time
- orders can cross in time or not
- random yield (acceptable quantity received is not the same as that ordered)
- capacity restrictions
- two or more suppliers used for the same item (i.e., possible order-splitting to help cope with either random lead times or random yield)

Time-Dependent Parameters (Other than Demand)

- inflation
- one-time special prices
- lead time varies with time
- capacity varies with time

What Happens Under a Stockout Situation

- lost sales vs. backorders vs mix of these

Shelf-Life Considerations

- obsolescence
- perishability (deteriorating inventory)

Single vs. Multiple Items

- group budget or space constraint
- coordinated control (or joint replenishment) because of common supplier, mode of transport or production equipment
- substitutable or complementary items

Single vs. Multiechelon

- in multiechelon (multistage) (Schwarz 1981; Sherbrooke 2004), serial vs. convergent (e.g., assembly) vs. divergent (e.g., distribution)

Knowledge of Status of Stock (and Other Parameter Values)

- known exactly or not
- continuously vs. at discrete points in time

Challenging the Underlying Assumptions and Parameter Values

Traditionally, the underlying assumptions and the values of the parameters, discussed earlier, have been accepted as givens in inventory modeling and associated inventory control. There are a number of

innovations that challenge this perspective. First, the philosophy of continuous improvement (an aspect of the philosophy of Just-in-Time, or JIT) argues that parameters such as the setup cost, the replenishment lead time and so on can be changed, often with much more substantial benefits than simply optimizing subject to the given parameter values. Another way of saying this is that it may be better to at least partially eliminate the causes of inventories rather than just choosing the best inventory level (Silver 1992). Second, the Theory of Constraints perspective is that one should identify the key constraint (e.g., a bottleneck operation) that is preventing better performance and concentrate improvement efforts on reducing the impact of this constraint (Goldratt and Cox 1986). Third, the spread of electronic and internet ordering has significantly reduced both the cost of communication and the fixed cost of orders, although substantial costs remain. Fourth, globalization has encouraged companies to consider moving operations across the world, sometimes increasing the replenishment lead time from, say, one week to eight weeks. Fluctuations in oil prices and currency exchange rates have caused companies to reconsider offshoring, moving their sources of supply back to their domestic markets. Finally, other innovations in supply chain management, such as vendor managed inventory (VMI), have improved communications and therefore forecast accuracy. These changes do not necessarily change the appropriate choice of models, but they do demand that managers should update model parameters and re-optimize, or even change models to more accurately capture the new situation.

Inverse Matrix

For a square $m \times m$ matrix $\boldsymbol{A}$, the inverse matrix $\boldsymbol{A}^{-1}$ is also an $m \times m$ matrix such that $\boldsymbol{A}^{-1}\boldsymbol{A} = \boldsymbol{I} = \boldsymbol{A}\boldsymbol{A}^{-1}$, where $\boldsymbol{I}$ is the identity matrix. If a matrix has an inverse, then its inverse is unique and the matrix is said to be nonsingular. If an inverse does not exist, the matrix is said to be singular. A nonsingular matrix has a nonzero value for its determinant; a singular matrix has a determinant value equal to zero.

Isoquant

For a function $f(x)$, the graph or contour $f(x) = C$, where C is a constant, is called an isoquant. If $f(x)$ is a profit (cost) function, then the isoquant is termed an isoprofit (isocost) line.

Iteration

The cycle of steps of an algorithm is called an iteration. For example, in the simplex algorithm for solving linear-programming problems, one iteration is given concisely by the steps: (1) select a nonbasic variable to replace a basic variable, (2) determine the inverse of the new feasible basis, and (3) determine if the new basic feasible solution is optimal.

Jackson Network

A collection of multi-server queueing systems or nodes with exponential service and Markovian or memoryless probabilistic routing of departures from one node to the others. If there are customers arriving from outside the network to individual nodes in Poisson streams, the network is said to open; otherwise it is closed. All customers who arrive from outside to an open network must eventually leave after receiving service at one or more systems within the network.

Job Shop Scheduling

Luis C. Rabelo[1] and Albert Jones[2]
[1]University of Central Florida, Orlando, FL, USA

Introduction

In the United States there are approximately 62,000 factories producing metal fabricated parts. These parts end up in a wide variety of products sold here and abroad. These factories employ roughly 1.5 million people and ship close to $247 billion worth of products every year. The vast majority of these factories are what are called job shops, meaning that the flow of raw and unfinished goods through them is completely random. Over the years, the behavior and performance of these job shops have been the focus of considerable attention in the operations research (OR) literature. Research papers on topics such as factory layout, inventory control, process control, production scheduling, and resource utilization can be found in almost every issue of every OR journal. The most popular of these topics is production (often referred to as job shop) scheduling. Job shop scheduling can be thought of as the allocation of resources over a specified time to perform a predetermined collection of tasks. Job shop scheduling has received this large amount of attention, because it has the potential to dramatically decrease costs and increase throughput, thereby, profits.

A large number of approaches to the modeling and solution of these job shop scheduling problems have been reported in the OR literature, with varying degrees of success. These approaches revolve around a series of technological advances that have occurred mainly since the 1960s. These include mathematical programming, dispatching rules, expert systems, neural networks, support vector machines, agents, genetic algorithms, particle warm optimization, and inductive learning. In this article, an evolutionary view is taken in describing how these technologies have been applied to job shop scheduling problems. To do this, a few of the most important contributions in each of these technology areas and trends are discussed.

Mathematical Techniques

Mathematical programming has been applied extensively to job shop scheduling problems. Problems have been formulated using integer programming (Balas 1965, 1967), mixed-integer programming (Balas 1969, 1970), and dynamic programming (Srinivasan 1971). Until recently, the use of these approaches has been limited because scheduling problems belong to the class of *NP*-complete problems. To overcome these deficiencies, a group of researchers began to decompose the scheduling problem into a number of subproblems, proposing a number of techniques to solve them. In addition, new solution techniques, more powerful heuristics, and the computational power of modern computers have enabled these approaches to be used on larger problems. Still, difficulties in the formulation of material flow constraints as mathematical inequalities and the development of generalized software solutions have limited the use of these approaches.

Decomposition strategies—Davis and Jones (1988) proposed a methodology based on the decomposition of mathematical programming problems that used both Benders-type (Benders 1960) and Dantzig/Wolfe-type (Dantzig and Wolfe 1960) decompositions. The methodology was part of closed-loop, real-time, two-level hierarchical shop floor control system. The top-level scheduler (i.e., the supremal) specified the earliest start time and the latest finish time for each job. The lower level scheduling modules (i.e., the infimals) would refine these limit times for each job by detailed sequencing of all operations. A multicriteria objective function was specified that included tardiness, throughput, and process utilization costs. The decomposition was achieved by first reordering the constraints of the original problem to generate a block angular form, then transforming that block angular form into a hierarchical tree structure. In general, *N* subproblems would result plus a constraint set that contained partial members of each of the subproblems. The latter are termed coupling constraints, and included precedence relations and material handling. The supremal unit explicitly considered the coupling constraints, while the infimal units considered their individual decoupled constraint sets. The authors pointed out that the inherent stochastic nature of job shops and the presence of multiple, but often conflicting, objectives made it difficult to express the coupling constraints using exact mathematical relationships. This made it almost impossible to develop a general solution methodology. To overcome this, a real-time simulation methodology was proposed by Davis and Jones (1988) to solve the supremal and infimal problems.

Gershwin (1989) used the notion of temporal decomposition to propose a mathematical programming framework for analysis of production planning and scheduling. This framework can be characterized as hierarchical and multi-layer. The problem formulations to control events at higher layers ignored the details of the variations of events occurring at lower layers. The problem formulations at the lower layers view the events at the higher layers as static, discrete events. Scheduling is actually carried out in bottom three layers so that the production requirements imposed by the planning layers can be met. First, a hedging point is found by solving a dynamic programming problem. This hedging point is the number of excess goods that should be produced to compensate for future equipment failures. This hedging point is used to formulate a linear-programming problem to determine instantaneous production rates. These rates are then used to determine the actual schedule (which parts to make and when). Other approaches have been proposed for generating schedules.

Enumerative techniques and Lagrangian relaxation—Two popular solution techniques for integer-programming problems are branch-and-bound and Lagrangian relaxation. Branch-and-bound is an enumerative technique (Agin 1966; Lawler and Wood 1966). A summary of branching is as follows, (Morton and Pentico 1993): "The basic idea of branching is to conceptualize the problem as a decision tree. Each decision choice point–a node-corresponds to a partial solution. From each node, there grow a number of new branches, one for each possible decision. This branching process continues until leaf nodes, that cannot branch any further, are reached. These leaf nodes are solutions to the scheduling problem."

Although efficient bounding and pruning procedures have been developed to speed up the search, this is still a very computational intensive procedure for solving large scheduling problems. If the integer constraint is the main problem, then why not remove that constraint? A technique called

Lagrangian relaxation, does just that (Shapiro 1979). Lagrangian relaxation solves integer-programming problems by omitting specific integer-valued constraints and adding the corresponding costs (due to these omissions and/or relaxations) to the objective function. As with branch and bound, Lagrangian relaxation is computationally expensive for large scheduling problems.

Model-Based Optimization—Model-Based Optimization (MBO) is an optimization approach that uses mathematical expressions (e.g., constraints and inequalities) to model scheduling problems as mixed integer (non) linear programs (MINLP), (Zentner et al. 1994). A set of methods such as linear programming, branch-and-bound, and decomposition techniques are used to search the scenario space of solutions. Due to the advances in computer technologies, the computation times are becoming very practical. These approaches are being enhanced by the development of English-like scheduling and high-level graphical interfaces. The scheduling languages support the developing of the mathematical formulations with minimum intervention from the user.

Dispatching rules—Dispatching rules have been applied consistently to scheduling problems. They are procedures designed to provide good solutions to complex problems in real-time. The term dispatching rule, scheduling rule, sequencing rule, or heuristic are often used synonymously (Panwalker and Iskander 1977; Blackstone et al. 1982; Baker 1974). Dispatching rules have been classified mainly according to the performance criteria for which they have been developed. Wu (1987) categorized dispatching rules into several classes. Class 1 contains simple priority rules, which are based on information related to the jobs. Sub-classes are based on the particular piece of information used. Example classes include those based on processing times (such as shortest processing time, SPT), due dates (such as earliest due date, EDD), slack (such as minimum slack, MINSLACK), and arrival times (such as first-in first-out, FIFO). Class 2 consists of combinations of rules from class one. The particular rule that is implemented can now depend on the situation that exists on the shop floor. A typical example of a rule in this class is, for example, SPT until the queue length exceeds 5, then switch to FIFO. This prohibits jobs with large processing times from staying in the queue for long periods. Class 3 contains rules that are commonly referred to as Weight Priority Indexes. The idea here is to use more than one piece of information about the jobs to determine the schedule. Pieces of information are assigned weights to reflect their relative importance. Usually, an objective function $f(x)$ is defined. For example,

$$f(x) = \mathbf{weight}_1 * \mathbf{Processing\ Time\ of\ Job}\,(x) + \mathbf{weight}_2 * (\mathbf{Current\ Time} - \mathbf{Due\ Date\ of\ Job}(x)).$$

Then, any time a new sequence is needed, the function f(x) is evaluated for each job x in the queue. The jobs are ranked based on this evaluation.

The performance of a large number of these rules has been studied extensively using simulation techniques (Montazer and Van Wassenhove 1990). These studies have been aimed at answering the question: If you want to optimize a particular performance criterion, which rule should you choose? Most of the early work concentrated on the shortest processing time rule (SPT). Conway and Maxwell (1967) were the first to study the SPT rule and its variations. They found that, although some individual jobs could experience prohibitively long flow times, the SPT rule minimized the mean flow time for all jobs. They also showed that SPT was the best choice for optimizing the mean value of other basic measures such as waiting time and system utilization. Many similar investigations have been carried out to determine the dispatching rule which optimizes a wide range of job-related (such as due date and tardiness) and shop-related (such as throughput and utilization) performance measures. This problem of selecting the best dispatching rule for a given performance measure has been a very active area of research. The research, however, has been expanded to include the possibility of switching rules to address an important problem: error recovery. Two early efforts to address error recovery were conducted by Bean and Birge (1986) and Saleh (1988). Both developed heuristic rules to smooth-out disruptions to the original schedule, thereby creating a match-up with that schedule. Bean and Birge (1986) based their heuristic on Turnpike Theory (McKenzie 1976) to optimize a generalized cost function. Saleh showed how to minimize duration of the disruption by switching the objective function from mean flow time to makespan based on disjunctive graphs (Adams et al. 1988).

Composite dispatching rules are found to be performing much better than simple dispatching rules (Binh and Cing 2005). In addition, their performance depends on the state of the system. Data mining has been used as a to find these composite dispatching rules. For instance, Shahzad and Mebarki (2008) have provide a methodology using data mining to identify a rule-set by exploring the patterns in the solution set obtained by an optimization module based on Tabu Search, a very efficient meta-heuristic. The rule-set approximates the output of the optimization module when incorporated in a simulation model of the system. The C5.0 algorithm (Quinlan 1992) is used as a data mining algorithm for the induction of rule-set.

Artificial Intelligence (AI) Techniques

Starting in the early 1980s, a series of new technologies were applied to job shop scheduling problems. They fall under the general title of artificial intelligence (AI) techniques and include expert systems, knowledge-based systems, and several search techniques. Expert and knowledge-based systems were quite prevalent in the early and mid-1980s. They have four main advantages. First, and perhaps most important, they use both quantitative and qualitative knowledge in the decision-making process. Second, they are capable of generating heuristics that are significantly more complex than the simple dispatching rules described above. Third, the selection of the best heuristic can be based on information about the entire job shop including the current jobs, expected new jobs, and the current status of resources, material transporters, inventory, and personnel. Fourth, they capture complex relationships in elegant new data structures and contain special techniques for powerful manipulation of the information in these data structures. There are, however, serious disadvantages. They can be time consuming to build and verify, as well as difficult to maintain and change. Moreover, since they generate only feasible solutions, it is rarely possible to tell how close that solution is to the optimal solution. Finally, since they are tied directly to the system they were built to manage, there is no such thing as a generic AI system.

Expert/knowledge-based systems—Expert and knowledge-based systems consist of two parts: a knowledge base and inference engine to operate on that knowledge base. Formalizations of the knowledge that human experts use — rules, procedures, heuristics, and other types of abstractions — are captured in the knowledge base. Three types of knowledge are usually included: procedural, declarative, and meta. Procedural knowledge is domain specific problem solving knowledge. Declarative knowledge provides the input data defining the problem domain. Meta knowledge is knowledge about how to use the procedural and declarative knowledge to actually solve the problem. Several data structures have been utilized to represent the knowledge in the knowledge base including semantic nets, frames, scripts, predicate calculus, and production rules. The inference engine selects a strategy to apply to the knowledge bases to solve the problem at hand. It can be forward chaining (data driven) or backward chaining (goal driven).

ISIS (Fox 1983) was the first major expert system aimed specifically at job shop scheduling problems. ISIS used a constraint-directed reasoning approach with three constraint categories: organizational goals, physical limitations, and causal restrictions. Organizational goals considered objective functions based on due-date and work-in-progress. Physical limitations referred to situations where a resource had limited processing capability. Procedural constraints and resource requirements were typical examples of the third category. Several issues with respect to constraints were considered, such as constraints in conflict, importance of a constraint, interactions of constraints, constraint generation and constraint obligation. ISIS used a three level, hierarchical, constraint-directed search. Orders were selected at level 1. A capacity analysis was performed at level 2 to determine the availability of the resources required by the order. Detailed scheduling was performed at level 3. ISIS also provided for the capability to interactively construct and alter schedules. In this capacity, ISIS utilized its constraint knowledge to maintain the consistency of the schedule and to identify scheduling decisions that would result in poorly satisfied constraints. Other examples of expert/knowledge-based scheduling systems developed are MPECS (Multi-Pass Expert Control System, Wysk et al. 1986) and OPIS (Opportunistic Intelligent Scheduler, Smith 1995).

Distributed AI: *Agents*—Due to the limited knowledge and the problem solving ability of a single expert or knowledge based system, these AI

approaches have difficulty solving large scheduling problems, as well. To address this, AI researchers have developed distributed scheduling system approaches (Parunak et al. 1985). They have done this by an application of the well-known divide and conquer approach. This requires a problem decomposition technique, such as those described above, and the development of different expert/knowledge-based systems that can cooperate to solve the overall problem (Zhang and Zhang 1995). The AI community's answer is the agent paradigm. An agent is a unique software process operating asynchronously with other agents. Agents are complete knowledge-based systems by themselves. The set of agents in a system may be heterogeneous with respect to long-term knowledge, solution/evaluation criteria, or goals, as well as languages, algorithms, hardware requirements. Integrating agents selected from a library creates a multi-agent system.

For example, one such multi-agent system could involve two types of agents: tasks and resources. Each task agent might be responsible for scheduling a certain class of tasks such as material handling, machining, or inspection on those resources capable of performing those tasks. This can be done using any performance measure related to tasks, such as minimize tardiness, and any solution technique. Each resource agent might be responsible for a single resource or a class of resources. Task agents must send their resource requests to the appropriate resource agent, along with the set of operations to be performed by that resource (Daouas et al. 1995). Upon receipt of such a request, the resource agent must generate a new schedule using its own performance measures, such as maximize utilization, which includes this request. The resource agent will use the results to decide whether to accept this new request or not. To avoid the situation, where no resource will accept a request, coordination mechanisms need to be developed. No general guidelines for the design and implementation of this coordination are available. Thus, the debates (pros and cons) about centralized vs. decentralized approaches to job shop scheduling continue. The agents formalism may provide an answer to these debates.

Artificial neural networks — Neural networks, also called connectionist or distributed parallel processing models, have been studied for many years in an attempt to mirror the learning and prediction abilities of human beings. Neural network models are distinguished by network topology, node characteristics, and training or learning rules. An example of a three-layer, feed-forward neural network is shown in Fig. 1.

Supervised learning neural networks—Through exposure to historical data, supervised learning neural networks attempt to capture the desired relationships between inputs and the outputs. Back-propagation is the most popular and widely used supervised training procedure. Back-propagation (Rumelhart et al. 1986; Werbos 1995) applies the gradient-descent technique in the feed-forward network to change a collection of weights so that some cost function can be minimized. The cost function, which is only dependent on weights ($\boldsymbol{W}$) and training patterns, is defined by:

$$C(W) = \frac{1}{2}\sum_{ij}(T_{ij} - O_{ij}) \tag{1}$$

where $\boldsymbol{T}$ is the target value, $\boldsymbol{O}$ is the output of the network, i is an output node, and j is the training pattern.

After the network propagates the input values to the output layer, the error between the desired output and actual output will be back-propagated to the previous layer. In the hidden layers, the error for each node is computed by the weighted sum of errors in the next layer's nodes. In a three-layered network, the next layer means the output layer. The activation function is usually a sigmoid function with the weights modified according to

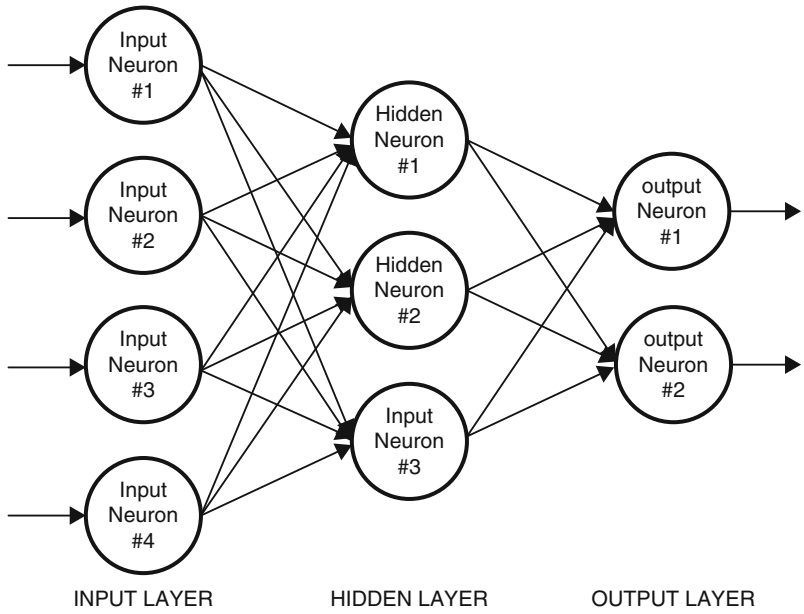
$$\Delta W_{ij} = \eta X_j(1 - X_j)(T_j - X_j)X_i \tag{2}$$

or

$$\Delta W_{ij} = \eta X_j(1 - X_j)\left(\sum_k \delta_\kappa\ W_{jk}\right)X_i \tag{3}$$

where W_{ij} is weight from node i to node j (e.g., neuron), η is the learning rate, X_j is the output of node j, T_j is the target value of node j, and δ_k is the error function of node k.

If j is in the output layer, Equation (2) is used; if j is the hidden layers, (3) is used. The weights are updated to reduce the cost function at each step. The Job shop scheduling temporal reinforcement learning in process continues until the error between



Job Shop Scheduling, Fig. 1 An example of a three-layer, feed-forward neural network

the predicted and the actual outputs is smaller than some predetermined tolerance.

Rabelo (1990) was the first to use back propagation neural nets to solve temporal reinforcement learning, in job shop scheduling problems with several job types, exhibiting different arrival patterns, process plans, precedence sequences and batch sizes. Training examples were generated to train the neural network to select the correct characterization of the manufacturing environments suitable for various scheduling policies and the chosen performance criteria. In order to generate training samples, a performance simulation of the dispatching rules available for the manufacturing system was carried out. The neural networks were trained for problems involving 3, 4, 5, 8, 10, and 20 machines. To carry out this training, a special, input-feature space was developed. This space contained both job characteristics (such as types, number of jobs in each type, routings, due dates, and processing times) and shop characteristics (such as number of machines and their capacities). The output of the neural network represented the relative ranking of the available dispatching rules for that specific scheduling problem and the selected performance criteria. The neural networks were tested in numerous problems and their performance (in terms of minimizing Mean Tardiness) was always better than each single dispatching rule (25% to 50%).

Relaxation models — Neural networks based on job shop scheduling relaxation models in are defined by energy functions. They are preassembled systems that relax from input to output along a predefined energy contour. Hopfield neural networks (Hopfield and Tank 1985) are a classical example of a relaxation model that has been used to solve some classic, textbook scheduling problems (Foo and Takefuji 1988). Two-dimensional Hopfield networks were used to solve 4-job, 3-machine problems and 10-job, 10-machine problems (*Zhou et al.* 1990). They were extended in (Lo and Bavarian 1991) to 3 dimensions to represent jobs ($i = 1, \ldots, I$), machines $j = 1, \ldots, J$), and time ($m = 1, \ldots, M$). In each case, the objective was to minimize the makespan, total time to complete all jobs, which is defined as

$$E = \frac{1}{2} \sum_{j=1} \sum_{i=l} \sum_{m=l} (v_{ijm})(m + T_{ij} - 1) \qquad (4)$$

where v_{ijm} is the output (1 or 0) of neuron ijm, and T_{ij} is the time required by the jth resource (e.g., machine) to complete the ith job.

Due to a large number of variables involved in generating a feasible schedule, these approaches tend to be computationally inefficient and frequently generate infeasible solutions. Consequently, they have not been used to solve realistic scheduling problems.

Temporal reinforcement learning — It was noted above that supervised learning neural networks attempt to capture the desired relationships between inputs and the outputs through exposure to training patterns. However, for some problems, the desired response may not always be available during the time of learning. When, the desired response is obtained, changes to the neural network are performed by assessing penalties for the scheduling actions previously decided by the neural network. As summarized by Tesauro (1992), "In the simplest form of this paradigm, the learning system passively observes a temporal sequence of input states that eventually leads to a final reinforcement or reward signal (usually a scalar). The learning system's task in this case is to predict expected reward given an observation of an input state or sequence of input states. The system may also be set up so that it can generate control signals that influence the sequence of states."

For scheduling, the learning task is to produce a scheduling action that will lead to minimizing (or maximizing) the performance measure (e.g., makespan, tardiness) based on the state of the system (e.g., inventories, machine status, routings, due dates, layouts). Several procedures have been developed to train neural networks when the desired response is not available during the time of learning. Rabelo et al. (1994) utilized a procedure developed by Watkins (1989), denominated Q-learning, to implement a scheduling system to solve dynamic job shop scheduling problems. The scheduling system was able to follow trends in the shop floor and select a dispatching rule that provided the maximum reward according to performance measures based on tardiness and flow time.

Support Vector Machines – Support Vector Machines (SVMs) are algorithms in machine learning based on advances in statistical learning theory. Advances in statistical learning theory, Vapnik-Chervonenkis (VC) theory, (Vapnik 1994; Vapnik 1995) explain that it is critical to constrain the class of functions that the learning machine can generate to one with a capacity that is appropriate for the available training data. Burges (1998) states, "There is a remarkable family of bounds governing the relation between the capacity of a learning machine and its performance. The theory grew out of considerations of under what circumstances, and how quickly, the mean of some empirical quantity converges uniformly, as the number of data points increases, to the true mean (that which would be calculated from an infinite amount of data)." Therefore, to design efficient learning algorithms, a class of functions whose capacity can be computed is essential. SVMs are based on the class of hyperplanes

$$\langle \boldsymbol{w} \cdot \boldsymbol{x} \rangle + \boldsymbol{b} = 0$$

where $\boldsymbol{w}$ are the weights, $\boldsymbol{x}$ is an N-dimensional input vector, and $\boldsymbol{b}$ is a numeric parameter. This class of hyperplanes corresponds to decision functions of the

$$f_{\omega,b}(\boldsymbol{x}) = \text{sign}(\langle \boldsymbol{w} \cdot \boldsymbol{x} \rangle + b)$$

The maximum margin hyperplane is defined as the one with the maximal margin of separation between the classes has the lowest capacity. The instances that are closest to the maximum margin hyperplane are called support vectors (SVs). Points that are not SVs have no influence (Burges 1998) and they may be eliminated without affecting the decision function. SVMs has been applied for the dynamic dispatching rule selection classifier (Shiuea 2009). The proposed SVM classifier using the data-mining-based approach yields a better system performance than heuristic individual dispatching rules under various performance criteria over a long period.

Neighborhood search methods—Neighborhood search methods are very popular. Neighborhood search methods provide good solutions and offer possibilities to be enhanced when combined with other heuristics. Wilkerson and Irwin (1971) developed one of the first neighborhood procedures. This method iteratively added small changes (perturbations) to an initial schedule, that is obtained by any heuristic. Conceptually similar to hill climbing, these techniques continue to perturb and evaluate schedules until there is no improvement in the objective function. When this happens, the procedure is ended. Popular techniques that belong to this family include tabu search, simulated annealing, and genetic algorithms. Each of these has its own perturbation methods, stopping rules, and methods for avoiding local optimum.

Tabu search—The basic idea of Tabu search (Glover 1989, 1990) is to explore the search space of all feasible scheduling solutions by a sequence of

moves. A move from one schedule to another schedule is made by evaluating all candidates and choosing the best available, just like gradient-based techniques. Some moves are classified as tabu, i.e., they are forbidden, because they either trap the search at a local optimum, or they lead to cycling (repeating part of the search). These moves are put onto the tabu list, which is built up from the history of moves used during the search. These tabu moves force exploration of the search space until the old solution area (e.g., local optimum) is left behind. Another key element is that of freeing the search by a short term memory function that provides strategic forgetting. Tabu search methods have been evolving to more advanced frameworks that includes longer term memory mechanisms. These advanced frameworks are sometimes referred as Adaptive Memory Programming (AMP), (Glover 1996).

Tabu search methods have been applied successfully to scheduling problems and as solvers of mixed integer-programming problems. Glover (1996) showed some specialized implementations of tabu search methods for job shop and flow shop scheduling problems, including a number of important cases where tabu search methods are superior to other approaches such as simulated annealing, genetic algorithms, and neural networks.

Simulated annealing — Simulated annealing is based on the analogy to the physical process of cooling and recrystallization of metals. The current state of the thermodynamic system is analogous to the current scheduling solution, the energy equation for the thermodynamic system is analogous to the objective function, and the ground state is analogous to the global optimum. In addition to the global energy J, there is a global temperature T, which is lowered as the iterations progress. Using this analogy, the technique randomly generates new schedules by sampling the probability distribution of the system (Kirkpatrick et al. 1983),

$$p_j \mu \ \exp[-T(\Delta J_{\text{best}} - \Delta J_j)/K], \tag{5}$$

where p_j represents the probability of making move j from among the neighborhood choices, ΔJ_{best} represents the improvement of the objective function for the best choice, and ΔJ_j represents the improvement for choice j, while K is a normalization factor. Since increases of energy can be accepted, the algorithm is able to escape local minima.

Simulated annealing has been applied effectively to job shop scheduling problems. Vakharia and Chang (1990) developed a scheduling system based on simulated annealing for manufacturing cells. Jeffcoat and Bulfin (1993) applied simulated annealing to a resource-constrained scheduling problem. Their computational results indicated that the simulated annealing procedure provided the best results in comparison with other neighborhood search procedures.

Variable Neighborhood Search – Variable Neighborhood Search (VNS) has shown an excellent capability to solve scheduling problems to optimal or near-optimal schedules. VNS can be categorized as a local search-based algorithm, armed with systematic neighborhood search structures. Roshanaei et al. (2009) introduced implementations of VNS that improve the notorious myopic behavior of local search-based metaheuristic algorithms by the means of several systematic insertion neighborhood search structures. Roshanaei et al. (2009) uses the Taillard's benchmark to evaluate the efficiency and effectiveness of their proposed VNS approach against some effective algorithms. The obtained results strongly support the high performance of VNS with respect to other well-known heuristic and metaheuristic algorithms.

Genetic algorithms — Genetic algorithms (GAs) are an optimization methodology based on a direct analogy to Darwinian natural selection and mutations in biological reproduction. In principle, genetic algorithms encode a parallel search through concept space, with each process attempting coarse-grain hill climbing (Goldberg 1988). Instances of a concept correspond to individuals of a species. Induced changes and recombinations of these concepts are tested against an evaluation function to see which ones will survive to the next generation.

Starkweather et al. (1993) were the first to use genetic algorithms to solve a dual-criterion job shop scheduling problem in a real production facility. The criteria were the minimization of average inventory in the plant and the minimization of the average waiting time for an order to be selected. These criteria are negatively correlated (the larger the inventory, the shorter the wait; the smaller the inventory, the longer the wait). To represent the production/shipping

optimization problem, a symbolic coding was used for each member (chromosome) of the population. In this scheme, customer orders are represented by discrete integers. Therefore, each member of the population is a permutation of customer orders. The GA used to solve this problem was based on blind recombinant operators. This recombination operator emphasizes information about the relative order of the elements in the permutation, because this impacts both inventory and waiting time. A single evaluation function (a weighted sum of the two criteria) was utilized to rank each member of the population. That ranking was based on an on-line simulation of the plant operations. This approach generated schedules that produced inventory levels and waiting times that were acceptable to the plant manager. In addition, the integration of the genetic algorithm with the on-line simulation made it possible to react to system dynamics.

The utilization of GA has become very dominant in job shop scheduling. As noted by Fan and Zhang (2010), 22% of the journal articles from 2000 to 2009 in job shop scheduling proposed the utilization of GAs. Another dimension of this use of GAs is the combination of GAs with other methodologies to improve performance. For instance, Thamilselvan and Balasubramanie (2009) produced very good results with GAs combined with TS to create a combinational heuristic denominated Genetic Tabu Search Algorithm (GTA). In general, GTA follows the traditional GA. for the selection process, however, GTA uses tabu search. In several problems with combinations of 5 jobs and 5 machines, GTA outperformed GAs and TSs. Even chaos theory has been used to help GAs to find optimal solutions. For example, Zhou et al. (2009) utilized chaos theory to support the development of a mechanism to avoid local minima.

Fuzzy logic — Fuzzy set theory has been utilized to develop hybrid scheduling approaches. Fuzzy set theory can be useful in modeling and solving job shop scheduling problems with uncertain processing times, constraints, and set-up times. These uncertainties can be represented by fuzzy numbers that are described by using the concept of an interval of confidence. These approaches are usually integrated with other methodologies (e.g., search procedures, constraint relaxation). For example, Slany (1994) stressed the imprecision of straightforward methods presented in the mathematical approaches and introduces a method known as fuzzy constraint relaxation, that is integrated with a knowledge-based scheduling system. This system was applied to a steel manufacturing plant. Grabot and Geneste (1994) used fuzzy logic principles to combine dispatching rules for multi-criteria problems. On the other hand, Krucky (1994) addressed the problem of minimizing setup times of a medium-to-high product mix production line using fuzzy logic. The heuristic, fuzzy logic based algorithm helps to determine how to minimize setup time by clustering assemblies into families of products that share the same setup by balancing a product's placement time between multiple-high-speed placement process steps. Tsujimura et al. (1993) presented a hybrid system that uses fuzzy set theory to model the processing times of a flow shop scheduling facility. Triangular Fuzzy Numbers (TFNs) are used to represent these processing times. Each job is defined by two TFNs, a lower bound and an upper bound. A branch and bound procedure is utilized to minimize makespan.

Particle Swarm Optimization–Particle Swarm Optimization (PSO) was invented in the mid-1990s by Kennedy and Eberhart (1995) as an alternative to genetic algorithms for solving job shop scheduling problems. PSO is based on a social simulation of the movement of flocks of birds. PSO performs a population-based search to optimize the objective function. The population is composed by a swarm of particles that represent potential solutions to the problem. These particles, that are a metaphor of birds in flocks, fly through the search space updating their positions and velocities based on the best experience of their own and the swarm. The swarm moves in the direction of "the region with the higher objective function value, and eventually all particles will gather around the point with the highest objective value" (Jones 2005). There are many application of PSO to job shop scheduling. One of the most prominent ones is the approach presented by Yen and Ivers (2009) that uses space division techniques.

Reactive Scheduling — Reactive scheduling is generally defined as the ability to revise or repair a complete schedule that has been overtaken by events on the shop floor (Zweben et al. 1995). Such events include rush orders, excessive delays, and broken resources. There are two approaches: reactive repair and the proactive adjustment. In reactive repair,

the scheduling system waits until an event has occurred before it attempts to recover from that event. The match-up techniques described earlier fall into this category. Proactive adjustment requires a capability to monitor the system continuously, predict the future evolution of the system, do contingency planning for likely events, and generate new schedules, all during the execution time of the current schedule. The work of Wysk et al. (1986) and Davis and Jones (1988) fall into this category. Other approaches utilize artificial intelligence and knowledge-based methodologies (Smith 1995). Most AI approaches propose a quasi-deterministic view of the system, that is, a stochastic system featuring implicit and/or explicit causal rules. The problem formulation used does not recognize the physical environment of the shop floor domain where interference not only leads to readjustment of schedules but also imposes physical actions to minimize them.

Learning in Scheduling — The first step in developing a knowledge base is knowledge acquisition. This in itself is a two-step process: get the knowledge from knowledge sources and store that knowledge in digital form. To extract knowledge from these two sources, the machine learning technique that learns from examples (data) becomes a promising tool. Inductive learning is a state classification process. If the state space is viewed as a hyperplane, the training data (consisting of conditions and decisions) can be represented as points on the hyperplane. The inductive learning algorithm seeks to draw lines on the hyperplane based on the training data to divide the plane into several areas within which the same decision (conclusion) will be made.

An algorithm that has been implemented in inductive aids and expert system shells is that developed by *Quinlan* (1986), called Iterative Dichotomister 3 or ID3. ID3 uses examples to induce production rules (e.g. IF ... THEN ...), which form a simple decision tree. Decision trees are one way to represent knowledge for the purpose of classification. The nodes in a decision tree correspond to attributes of the objects to be classified, and the arcs are alternative values for these attributes. The end nodes of the tree (leaves) indicate classes to which groups of objects belong. Each example is described by attributes and a resulting decision. To determine a good attribute to partition the objects into classes, entropy is employed to measure the information content of each attribute, and then rules are derived through a repetitive decomposition process that minimizes the overall entropy. The entropy value of attribute A_k can be defined as

$$H(A_k) = \sum_{j=l}^{M_k} P(a_{kj}) \left\{ - \sum_{i=1}^{N} P(c_i|a_{kj}) \log_2 P(c_i|a_{kj}) \right\} \tag{6}$$

where $H(A_k)$ is the entropy value of attribute A_k;$P(a_{kj})$ is the probability of attribute k being at its jth value; $P(c_i \mid a_{kj})$ is the probability that the class value is c_i when attribute k is at its jth value; M_k is the total number of values for attribute A_k; and N is the total number of different classes (outcomes).

The attribute with the minimum entropy value will be selected as a node in the decision tree to partition the objects. The arcs out of this node represent different values of this attribute. If all the objects in an arc belong to one class, the partition process stops. Otherwise, another attribute will be identified using entropy values to further partition the objects that belong to this arc. This partition process continues until all the objects in an arc are in the same class. Before applying this algorithm, all attributes that have continuous values need to be transformed to discrete values.

In the context of job shop scheduling, the attributes represent system status and the classes represent the dispatching rules. Very often, the attribute values are continuous. Yih (1990) proposed a trace-driven knowledge acquisition (TDKA) methodology to deal with continuous data and to avoid the problems occurring in verbally interviewing human experts. TDKA learns scheduling knowledge from expert schedulers without a dialogue with them. There are three steps in this approach. Step 1, an interactive simulator is developed to mimic the system of interest. The expert will interact with this simulator and make decisions. The entire decision-making process will be recorded in the simulator and can be repeated for later analysis. The series of system information and the corresponding decision collected is called a trace. Step 2 analyzes the trace and forms classification rules to partition the trace into groups. The partition process stops when most of the cases in

each group use the same dispatching rule (error rate is below the threshold defined by the knowledge engineer). Then, the decision rules are formed. Step 3 is to verify the generated rules. The resulting rule base is used to schedule jobs in the simulator. If it performs as well as or better than the expert, the process stops. Otherwise, the threshold value is increased, and the process returns to Step 2.

As the job shop operates over time, it is important to be able to modify the knowledge contained in these rule bases. Chiu (1994) looks at knowledge modification for job shop scheduling problems by a framework of dynamic scheduling schemes that explores routing flexibility and handles uncertainties. The proposed methodology includes three modules: discrete-event simulation, instance generation, and incremental induction. First, a simulation module is developed to implement the dynamic scheduling scheme, to generate training examples, and to evaluate the methodology. Second, in an instance-generation module, the searching of good training examples is successfully fulfilled by a genetic algorithm. Finally, in an incremental-induction module, a tolerance-based incremental learning algorithm is pro-posed to allow continuous learning and facilitate knowledge modification. This algorithm uses entropy values to select attributes to partition the examples where the attribute values are continuous. The tolerance is used to maintain the stability of the existing knowledge while the new example is introduced. The decision tree will not be reconstructed unless there is enough momentum from the new data, that is, the change of the entropy value becomes significant. The experimental results showed that the tolerance-based incremental learning algorithm cannot only reduce the frequency of modifications, but also enhances the generalization ability of the resulting decision tree in a distributed job shop environment.

Theory of Constraints

The Theory of Constraints (TOC) developed by Eliyahu Goldratt (1990, 1992) is the underlying philosophy for synchronized manufacturing. Goldratt (1990) defined synchronized manufacturing as any systematic method that attempts to move material quickly and smoothly through the production process in concert with market demand. A core concept of TOC is the idea that a few critical constraints exist. Goldratt contends that there is only one constraint in a system at any given time. As defined by Dettmer (1997), a constraint is "any element of a system or its environment that limits the output of the system." A constraint will prevent increases in throughput regardless of improvements made to the system. The best schedule is obtained by focusing on the planning and scheduling of these constraint operations. In essence, the constraint operations become the basis from which the entire schedule is derived. TOC has several important concepts and principles. Among them (Goldratt 1990; Goldratt 1992):

1. Systems function like chains.
2. The system optimum is not the sum of the local optima.
3. The effect-cause-effect method identifies constraints.
4. System constraints can be either physically or policy.
5. Inertia is the worst enemy of a process of ongoing improvement.
6. Throughput is the rate at which the entire system generates money through sales.
7. Inventory is all the money the system invests in things it intends to sell.
8. Operating expense is all the money the system spends turning inventory into throughput.

The general process of TOC is as follows (Goldratt 1990):

1. Identify the system's constraints.
2. Decide how to exploit the system's constraints.
3. Subordinate everything else to the above decision.
4. Elevate the system's constraints.
5. If in the previous steps a constraint have been broken, go back to Step 1, but do not allow inertia to cause a system constraint.

TOC has been successfully applied to scheduling problems. Its tools comprise five distinct logic trees, (see Dettmer 1997), are the Current Reality Tree, the Evaporating Cloud Diagram, the Future Reality Tree, the Prerequisite Tree, and the Transition Tree. These trees are tied to the Categories of Legitimate Reservation (that provide the logic to guide the construction of the trees). These tools have not only been used in production scheduling, but also in other enterprise functions such as marketing and sales.

Human-Guided Search

An approach to job shop scheduling is to leverage people's abilities in areas in which they currently outperform computers, Lesh et al. (2003). This will allow human guidance to steer a computer towards effective job shop schedules based on their knowledge of real-world constraints. Furthermore, users can better understand, justify, and modify schedules if they participate in their construction. Lesh et al. (2003) developed a prototype which "allows users to manually modify the current schedule, backtrack to previous schedules, and invoke, monitor, and halt a variety of search algorithms to find better schedules." This interactive scheduling approach provides solutions with the potential to revolutionize the utilization of optimization in actual production environments.

Concluding Remarks

Job shop scheduling problems fall into the class of *NP*-complete problems. They are most difficult to formulate and solve. Operations Research analysts have been pursuing solutions to these problems for many years, with varying degrees of success.

Job shop scheduling problems are among the most important found in manufacturing; they impact the ability of manufacturers to meet customer demands in an effective and profitable manner. They also impact the ability of autonomous systems to optimize their operations, the deployment of intelligent systems, the development of software, and the optimization of communications systems.

Just-in-Time (JIT) Manufacturing

A manufacturing philosophy focusing on the elimination of waste (non-value added activities) in the manufacturing process by the more timely sequencing of operations.

Most of the early ideas originated from work at Toyota Motor Company in Japan, with the kanban system being the most well-known innovation.

Karmarkar's Algorithm

An algorithm devised by N. Karmarkar (1984) for solving a linear-programming problem by generating a sequence of points lying in the strict interior of the problem's solution space which converges to an optimal solution. Karmarkar's algorithm, and its many variations, have been shown to be polynomial-time algorithms that solve large-scale linear-programming problems in a computationally efficient manner.

Karush-Kuhn-Tucker (KKT) Conditions

The Karush-Kuhn-Tucker (KKT) conditions are necessary conditions that a solution to a general nonlinear-programming problem must satisfy, provided that the problem constraints satisfy a regularity condition called constraint qualification. If the problem is one in which the constraint set (i.e., solution space) is convex and the maximizing (minimizing) objective function is concave (convex), the KKT conditions are sufficient. Applied to a linear-programming problem, the KKT conditions yield the complementary slackness conditions of the primal and dual problems.

Kendall's Notation

A shorthand notation of the form $A/S/c/K/Q$ used to describe queueing systems. The A refers to an acronym for the interarrival-time distribution, S the service-time distribution, c the number of parallel servers, $K(\geq c)$ the maximum allowable system size (assumed infinite if omitted), and Q the queue discipline. Common designations for A and S include: M for Markovian or exponential; E_k for k-Erlang; D for deterministic or constant; H_k for hyperexponential of order k; PH for phase-type; G for general. Common queue disciplines include first-in, first-out (FIFO), first-come, first-served (FCFS), last-come, first-served (LCFS), and processor sharing (PS). Sometimes another parameters is included between K and Q that gives the arrival population size, which is assumed infinite otherwise. For example, an $M/M/1$ queue generally refers to a FCFS single-server queue with a Poisson arrival process and i.i.d. exponentially distributed service times.

Klee-Minty Problem

The Klee-Minty problem is a linear-programming problem designed to demonstrate that a problem exists that would require the simplex algorithm to generate all extreme point solutions before finding the optimal. This problem demonstrated that, although the simplex algorithm (under a nondegeneracy assumption) would find an optimal solution in a finite number of iterations, the number of iterations can increase exponentially. Thus, the simplex method is not a polynomially bounded algorithm. One form of the Klee-Minty problem, which defines a slightly perturbed hypercube, is the following:

$$\begin{aligned}
&\text{Minimixe } -x_d \\
&\text{subject to } x_1 \geq 0 \\
&x_1 \leq 1 \\
&-\varepsilon x_1 + x_2 \geq 0 \\
&\varepsilon x_1 + x_2 \leq 1 \\
&\vdots \\
&-\varepsilon x_{d-1} + x_d \geq 0 \\
&\varepsilon x_{d-1} + x_d \leq 1 \\
&x_j \geq 0
\end{aligned}$$

with $0 < \varepsilon < 1/2$.

Knapsack Problem

The following optimization problem is called the knapsack problem:

$$\begin{aligned} \text{Maximize} \quad & c_1x_1 + c_2x_2 + \cdots + c_nx_n \\ \text{subject to} \quad & a_1x_1 + a_2x_2 + \cdots + a_nx_n \le b \end{aligned}$$

with each x_j equal to 0 or 1, with all (a_j, c_j, b) usually taken to be positive integers. The name is due to interpreting the problem as one in which a camper has a knapsack that can carry up to b pounds. The camper has a choice of packing up to n items, with $x_j = 1$ if the item is packed and $x_j = 0$ if the item is not packed. Item j weighs a_j pounds. Each item has a value c_j to the camper if it is packed. The camper wishes to choose that collection of items having the greatest total value subject to the weight condition. The knapsack problem arises in many applications such as selecting a set of projects and as a subproblem of other problems. It can be solved by dynamic programming or by integer-programming methods. If the x_j are ordered such that $c_1/a_1 \ge c_2/a_2 \ge \ldots \ge c_n/a_n$ and the integer restrictions on the variables are replaced by $0 \le x_j \le 1$, then an optimal solution to the relaxed problem is to just pack all the items starting with the first until the weight restriction is violated. The item that caused the violation is then chosen at a fractional value so that the total weight of the selected set is equal to b.

Knapsack Problems with Nonlinearities

Kurt M. Bretthauer[1,2] and Bala Shetty[1]
[1]Texas A&M University, College Station, TX, USA
[2]Indiana University Bloomington, Bloomington, IN, USA

Introduction

Nonlinear optimization problems with a single constraint are known as nonlinear knapsack problems or nonlinear resource allocation problems, and will be formulated as follows:

$$\begin{aligned} \text{Minimize} \quad & \sum_{i=1}^{n} f_i(x_i) \qquad \text{(IP)} \\ \text{s.t.} \quad & \sum_{i=1}^{n} g_i(x_i) \le b \\ & l_i \le x_i \le u_i, \quad i = 1, \ldots, n \\ & x_i \text{ integer}, \; i = 1, \ldots, n \end{aligned}$$

The continuous variable version of the problem also will be considered, and will be denoted as problem (CP). Assume $x_i \varepsilon \Re$ for $i = 1, \ldots, n$; $f_i(x_i)$ and $g_i(x_i)$ for $i = 1, \ldots, n$ are differentiable functions on $\Re$; b is a constant; l_i and u_i for $i = 1, \ldots, n$ are lower and upper bounds on the variables; and the feasible region is nonempty and bounded.

Practical applications of the nonlinear knapsack problem abound in financial models (Mathur et al. 1983), production and inventory management (Bretthauer et al. 1994), stratified sampling (Bretthauer et al. 1999; Cochran 1963), and the optimal design of queueing network models in manufacturing (Bitran and Tirupati 1989; Bretthauer 1996), health care, and computer systems (Gerla and Kleinrock 1977). The fact that the problem has one constraint allows efficient solution methods to be developed that take advantage of its special structure. Solution methods have been developed for the following versions of the problem: (1) continuous and integer variables, (2) constraints of the form $\sum_{i=1}^{n} x_i = b$ and $\sum_{i=1}^{n} g_i(x_i) = b$, (3) convex and nonconvex functions, and (4) additional specially structured constraints.

Continuous Convex Problems

Two basic approaches for solving the continuous problem (CP) are multiplier search methods and relaxation or variable pegging methods. Assume all objective and constraint functions are convex. Bretthauer and Shetty (1995) presented a multiplier search algorithm that solves the problem via a one-dimensional search for the optimal Lagrange multiplier of the single constraint. Let λ denote the Lagrange multiplier for $\sum_{i=1}^{n} g_i(x_i) \le b$, let v_i

denote the multiplier for $l_i \le x_i$, and let w_i denote the multiplier for $x_i \le u_i$. Also, let f_i' denote the derivative of $f_i(x_i)$ with respect to x_i and let g_i' denote the derivative of $g_i(x_i)$ with respect to x_i. Assume that a solution $\bar{x}_i(\lambda)$ exists to the nonlinear equation $f_i' + g_i' = 0$ as a function of λ for $i = 1, \ldots, n$. Consider the following expressions:

$$x_i(\lambda) = \begin{cases} l_i & \text{if } \bar{x}_i(\lambda) \le l_i \\ \bar{x}_i(\lambda) & \text{if } l_i < \bar{x}_i(\lambda) < u_i \\ u_i & \text{if } \bar{x}_i(\lambda) \ge u_i \end{cases}$$

$$v_i(\lambda) = \begin{cases} f_i'(l_i) + \lambda g_i'(l_i) & \text{if } \bar{x}_i(\lambda) \le l_i \\ 0 & \text{if } \bar{x}_i(\lambda) > l_i \end{cases}$$

$$w_i(\lambda) = \begin{cases} 0 & \text{if } \bar{x}_i(\lambda) < u_i \\ f_i'(l_i) + \lambda g_i'(l_i) & \text{if } \bar{x}_i(\lambda) \ge u_i \end{cases}$$

It can be shown that these equations for $x_i(\lambda), v_i(\lambda)$, and $w_i(\lambda)$ satisfy all the Karush-Kuhn-Tucker (KKT) conditions of problem (CP) except $\sum_{i=1}^{n} g_i(x_i) \le b$ and $\lambda(\sum_{i=1}^{n} g_i(x_i) - b) = 0$ for every $\lambda \ge 0$. Problem (CP) is solved by searching for the optimal λ value such that these two remaining KKT conditions are also satisfied. This search requires finding the root of one nonlinear equation if $\bar{x}_i(\lambda)$ can be written in closed form as a function of λ, or finding the root of one nonlinear equation several times if $\bar{x}_i(\lambda)$ cannot be written in closed form as a function of λ. The optimal solution to problem (CP) is obtained by substituting the optimal λ value into the equations for $x_i(\lambda), v_i(\lambda)$, and $w_i(\lambda)$.

Relaxation or variable pegging algorithms have been developed by Kodialam and Luss (1998) for the problem with nonnegativity conditions and Bretthauer and Shetty (1990) for the general problem (CP) with lower and upper bounds on the variables. See Bitran and Hax (1981), Ibaraki and Katoh (1988), and Robinson, Jiang, and Lerme (1992) for pegging algorithms for more specialized versions of the problem. These algorithms are based on the observation that if the bounds on the variables are ignored, then the resulting relaxed problem is generally easier to solve than problem (CP) and often has a simple closed form solution. Each iteration of this class of algorithms solves a relaxed subproblem of this type and then fixes (or pegs) a subset of the variables not satisfying their bounds at either their lower or upper bounds. Pegging variables reduces the size of the relaxed subproblem that must be solved in the next iteration. The algorithm terminates in a finite number of iterations when all unpegged variables in the solution to a relaxed subproblem satisfy their bounds.

Special versions of the problem where all terms in the objective function are convex and the single constraint is a simple sum of the variables of the form $\sum_{i=1}^{n} x_i = b$ have been widely studied. Ibaraki and Katoh (1988) provide an excellent discussion of methods for solving both continuous and integer variable versions of this special class of nonlinear knapsack problems. A related version of the problem with a strictly convex quadratic objective and a linear constraint is discussed in (Bretthauer et al. 1995; Brucker 1984; Helgason et al. 1980; Pardalos and Kovoor 1990; Robinson et al. 1992; Shetty and Muthukrishnan 1990). Nielsen and Zenios (1992) addressed the convex objective and linear constraint problem.

Integer Convex Problems

Of special interest is the nonlinear knapsack problem (IP) with integer variables and all functions assumed convex. The most common methods for solving the integer convex version of the problem include branch and bound (Bretthauer and Shetty 1995, 1998); (0, 1) linearization (Hochbaum 1995; Mathur et al. 1986); and dynamic programming (Denardo 1982). In addition, Lawler (1979) describes an approximation algorithm for problem (IP).

Branch and bound algorithms for solving the integer problem (IP) solve a series of continuous subproblems of the form of (CP) using the algorithms discussed in the previous section. Bretthauer and Shetty (1995) show how the performance of the branch and bound algorithm can be improved via reoptimization procedures that reduce the time spent solving each subproblem and by heuristically generating feasible integer solutions to problem (IP) from the fractional subproblem solutions.

Hochbaum (1995) and Mathur, Salkin, and Mohanty (1986) present a method for solving problem (IP) that first converts it to an equivalent linear (0, 1) knapsack problem with a larger number of variables, and then solves the resulting (0, 1) knapsack problem. Hochbaum assumes the objective is the sum of

nonincreasing convex functions and the single constraint is the sum of nondecreasing convex functions. Mathur, Salkin, and Mohanty assumes the objective is the sum of decreasing convex functions and the single constraint is the sum of increasing convex functions. Problem (IP) can be converted to an equivalent linear (0, 1) knapsack problem as follows. For $i = 1, \ldots, n$ let $p_{ij} = f_i(l_i + j) - f_i(l_i + j + 1)$ and $q_{ij} = g_i(l_i + j) - g_i(l_i - j - 1)$ for $j = 1, \ldots, u_i - l_i$. Using these coefficients, problem (IP) is equivalent to the following linear knapsack problem:

$$\text{Minimize} \quad \sum_{i=1}^{n} \sum_{j=1}^{u_i - l_i} p_{ij} x_{ij} + \sum_{i=1}^{n} f_i(l_i)$$

$$\text{s.t.} \quad \sum_{i=1}^{n} \sum_{j=1}^{u_i - l_i} q_{ij} x_{ij} \leq b - \sum_{i=1}^{n} g_i(l_i)$$

$$x_{ij} \varepsilon \{0, 1\}, \; i = 1, \ldots, n; \; j = 1, \ldots, u_i - l_i$$

The solution to problem (IP) is obtained from the solution to the above problem using $x_i = l_i + \sum_{j-1}^{u_i - l_i} x_{ij}$ for $i = 1, \ldots, n$.

Nonconvex Problems

Assume that any of the functions $f_i(x_i)$ and $g_i(x_i)$ for all i may be nonconvex. This modification makes the continuous problem much more difficult to solve because a locally optimal solution may not be globally optimal. However, nonconvex functions often arise in practice, in particular concave functions. For example, fixed charges and costs exhibiting economies of scale can be modeled with a concave function.

Branch and bound methods for solving continuous and integer nonconvex optimization problems typically use convex underestimating functions to the nonconvex functions for lower bounding purposes in each subproblem of the search tree. This approach results in continuous convex subproblems that can be solved with the methods previously discussed. The convex envelope is commonly used as an underestimating function to a nonconvex function. Simply stated, the convex envelope is the highest possible convex function that underestimates the nonconvex function over a given set (see Horst and Tuy 1990, for a formal definition). Let $f_i^c(x_i)$ denote the convex envelope of $f_i(x_i)$ over $l_i \leq x_i \leq u_i$ and let $g_i^c(x_i)$ denote the convex envelope of $g_i(x_i)$ over $l_i \leq x_i \leq u_i$. The convex envelope is particularly attractive as an underestimating function to a separable concave function because then it is easy to construct and linear.

A continuous convex underestimating subproblem of the form

$$\text{Minimize} \quad \sum_{i=1}^{n} f_i^c(x_i)$$

$$\text{s.t.} \quad \sum_{i=1}^{n} g_i^c(x_i) \leq b$$

$$l_i \leq x_i \leq u_i, \quad i = 1, \ldots, n$$

is solved at every node in the branch-and-bound tree using the results discussed in the section on continuous convex problems. The lower and upper bounds on the variables will change at the nodes as branching is performed. *See* Horst and Tuy (1990) for further details on algorithms for solving continuous nonconvex problems and convergence results. Incorporating the above subproblem within the prototype branch and bound framework for discrete global optimization developed by Benson, Erenguc, and Horst (1990) yields a globally optimal solution to the integer nonconvex problem (IP) in a finite number of iterations.

Handling Additional Specially Structured Constraints

It is also possible to develop efficient algorithms for solving problems that include additional specially structured constraints. For example, consider the continuous convex problem with a type of block diagonal or angular structure in the constraints (Bretthauer and Shetty 1997; Federgruen and Zipkin 1983; Hochbaum 1994):

$$\text{Minimize} \quad \sum_{i \varepsilon S}^{n} f_i(x_i)$$

$$\text{s.t.} \quad \sum_{i \varepsilon S} g_i(x_i) \leq b$$

$$\sum_{i \varepsilon S_k} h_i(x_i) \leq c_k, \quad k = 1, \ldots, K$$

$$l_i \leq x_i \leq u_i, \quad i \varepsilon S$$

In this problem, S is the index set of the variables; $S_1, S_2, \ldots, S_K$ are disjoint subsets of S; the objective

function is assumed convex; the single constraint $\sum_{i \varepsilon S} g_i(x_i) \leq b$ involving all the variables is convex; and the K constraints $\sum_{i \varepsilon S_k} h_i(x_i) \leq c_k$ involving disjoint subsets of the variables are convex.

To solve the above problem, first form a Lagrangian relaxation with respect to the one constraint $\sum_{i \varepsilon S} g_i(x_i) \leq b$. The resulting Lagrangian subproblem then decomposes into K singly constrained convex problems. These singly constrained problems can be solved with the previously discussed methods. A one-dimensional search must be performed to identify the optimal value of the single Lagrange multiplier.

Knowledge Management

Heiner Müller-Merbach
Technische Universität Kaiserslautern,
Kaiserslautern, Germany

Introduction

Knowledge management (KM) is a modern term based on old philosophical insights, such as:

- "All I know is that I know nothing." (Socrates, 490-399 BC).
- "Knowledge itself is power." (Francis Bacon, 1561-1626).
- "Cogito ergo sum." ("I think, therefore I am.") (René Descartes, 1596-1650).
- "Where is the wisdom we have lost in knowledge? Where is the knowledge we have lost in information?" (T. S. Eliot, 1888-1965; in: *The Rock*, 1934).

Two views of knowledge management: In most publications on knowledge management, only one of two aspects of KM is emphasized: Either (i) management, leadership, learning, group organization, i.e. human aspects, or (ii) information systems, i.e. technical aspects. Or as Begona Lloria (2003, pp. 77, 88) put it in her extended review: "... managing knowledge (either with greater emphasis on the human factor or on information technologies)."

Since (i) most of the information technologies used in KM were known beforehand and since (ii) typologies of basic knowledge are neglected in the KM literature, emphasis will here be put on the content of KM systems, i.e. the types of knowledge. References will be given to the relevant philosophers.

Francis Bacon, forerunner of enlightenment: The British philosopher Francis Bacon (1561-1626) taught: "Knowledge itself is power." His intention was the emancipation of the mind from the predominance by the church. His doctrine was accompanied by technological development, according to Durant (1926, p. 105) "Paper now came cheaply from Egypt, replacing the costly parchment that had made learning the monopoly of priests; printing, which had long awaited an inexpensive medium, broke out like a liberated explosive, and spread its destructive and clarifying influence everywhere."

Bacon, in his publication, *"The Praise of Knowledge"* (1592), even defined the individual by his/her knowledge: "My praise shall be dedicate to the mind itself. The mind is the man, and knowledge mind; a man is but what he knoweth" (Durant, 1926; p. 111). Today, one might not fully agree with this statement because everybody is also determined by his/her character, his/her morals and other attributes, not only by his/her knowledge.

Such ideas as those by Bacon are the forerunners of the epoch of enlightenment, i.e. the philosophy of the 17th and 18th century with Descartes in

France (1596-1650), John Locke in England (1732-1704), Kant in Germany (1724-1804) and many others who set the foundation of modern science.

Did Francis Bacon ring in the knowledge age and/or the knowledge society, perhaps even KM? Possibly, at least in a very rudimentary state. But he did not mean printed material as an end; instead, he meant individual human knowledge – only supported by printed material as a means to the end.

Bacon argues with passion: "Is not that knowledge alone that doth clear the mind of all perturbations?" (Durant, 1926; p. 111).

Russell (1979, p. 527) wrote: "Bacon's most important book, *The Advancement of Learning*, is in many ways remarkably modern. . . . The whole basis of his philosophy was practical: to give mankind mastery over the forces of nature by means of scientific discoveries and inventions."

Bacon did not explicitly consider KM; how could he, 400 years ago? He concentrated, however, on human knowledge, and not its sediment: printed (or electronically stored) information. For him, printed material (and the same is true for electronic devices) are only carriers of information and help to increase human knowledge, but the printed documents, as such, do not own knowledge themselves, because they do not have consciousness.

There are some relations between Francis Bacon and René Descartes who was 35 years younger than Bacon. One of the most important doctrines by Descartes was the sentence: *"Cogito ergo sum,"* ("I think, therefore I am.") (Angeles, 1992; p. 47 f.). To think means creation of knowledge, of understanding, of insight.

Socrates and his pretended ignorance: About 2,000 years prior to Bacon, Socrates postulated: "All I know is that I know nothing," (Angeles, 1992; p. 280). Was it only modesty? Certainly not! Or was it an insincere understatement, because he was considered one of the wisest men in his time, and he probably knew it? Again no! Instead, he was convinced that his own knowledge was almost negligible in comparison to the conglomeration of all the knowledge of mankind and to the not yet discovered secrets of the world.

The skepticism outspoken by Socrates in the quoted sentence, was his certainty. And it is (at least almost) true for everybody. The piece of knowledge that anybody owns is nearly zero compared to the knowledge of the world and the hidden secrets of nature.

In spite of the small amount of knowledge that anybody owns, it is worth to expand his/her knowledge because knowledge helps to master one's own live: live long learning.

Discussion

Knowledge Networks: Here lies a trigger for KM: Since the knowledge of anybody is – in spite of any individual's effort in learning – narrowly restricted, the cooperation between groups of individuals may have the potential to increase the available group knowledge remarkably. This requires leadership, i.e. knowledge management.

This goes together with the development of information processing. The German philosopher, Jürgen Mittelstrass (born 1936), has repeatedly warned that all of us may become information giants and, at the same time, be knowledge dwarfs (Mittelstrass. 1972; p. 8d). This means that each of us may have immediate access to almost any information available through information systems, but, at the same time, understand less and less of the information available. This deficiency can to some extent be overcome by knowledge networks.

Knowledge a priori versus knowledge a posteriori: Knowledge has alternatively two different origins (Müller-Merbach, 2007a): deduction (emphasized by Descartes) and induction (emphasized by Locke).

René Descartes founded French rationalism and suggested the deductive method of knowledge creation. Russell (1979; p. 549), interprets Descartes: "Knowledge of external things must be by the mind, not by the senses." Angeles (1992; p. 157) seconds: "All knowledge is derived by a deductive process similar to that in axiomatic geometry from this primitive and absolutely infallible truth."

Example 1. Any triangle has an angular sum of 180°, any quadrangle an angular sum of 360°, any polygon with n nodes an angular sum of (n-2)*180°. This can be derived by deduction; no empirical experience is necessary. "The truth of a priori knowledge (a) is not derived from sense experience, (b) cannot be checked against sense experience, and (c) cannot be refuted by any sense experience," (Angeles 1992; p. 159).

The other origin of knowledge is British empiricism. According to Russell (1979; p. 589), John Locke "may be regarded as the founder of empiricism, which is the doctrine that all our knowledge ... is derived from experience." Other empiricists are George Berkeley (Ireland, 1685-1753) and David Hume (Scotland, 1711-1776). According to Angeles (1992; p. 85), empiricism is defined as "the view that all ideas are abstractions formed by compounding ... what is experienced." He added: "Experience is the sole source of knowledge," and "All that we know is ultimately dependent on sense data."

It was Immanuel Kant (Germany) who came up with a synthesis between the rational, deductive, French, Cartesian doctrine and the empirical, inductive, British process of knowledge creation. He termed them a priori and a posteriori knowledge.

Karl R. (Charles) Popper (1902-1994) stated that scientific discoveries based upon empirical experience can never be proven to be right. Instead, they are subject to the threat of falsification in principle.

Knowledge a priori and knowledge a posteriori may require quite different handling approaches in KM systems.

Type and token: Another pair of knowledge terms are type and token, as suggested by Charles Sanders Peirce (1839-1914), or schema and actualization, or generic acts and individual acts, according to Georg Henrik von Wright (1916-2003). The type level represents the general structure of anything, whereas the token level applies to a single case (Müller-Merbach, 2007c).

Example 2. A general system of linear equations could be written at the type level such as: $\boldsymbol{Ax} = \boldsymbol{b}$ (in matrix notation). At the token level, a case could perhaps read:

$$\begin{aligned} 5x_1 + 7x_2 &= 41 \\ 3x_1 + 2x_2 &= 18 \\ (\text{Solution} : x_1 = 4, x_2 &= 3) \end{aligned}$$

Example 3. A balance sheet and a profit and loss account of an enterprise would at the type level just refer to the formal structure of these documents. At the token level, the concrete numbers of a particular enterprise and a particular year would be presented.

The two levels are mutually interdependent. Familiarity with the type level is required as a frame to understand and to cope with any actual case and would include the general rules. Familiarity with cases is necessary in order to collect experience.

The four causes of Aristotle: Aristotle (384/3-322/1 BC) created a four-part system of describing things of any kind: (i) material cause, (ii) formal cause, (iii) efficient cause, and (iv) final cause. It is surprising how well the four causes are suitable to describe anything. Bertrand Russell (1872-1970) gives an example: "Let us take again the man who is making a statue. The material cause of the statue is the marble, the formal cause is the essence of the statue to be produced, the efficient cause is the contact of the chisel with the marble, and the final cause is the end that the sculptor has in view" (Russell 1979; p. 181).

These four causes can well be used for KM documentation, e.g. product documents: (i) The material cause is represented by the bill-of-material documents. (ii) The formal cause is represented by the construction drawings. (iii) The efficient cause is represented by the production process documents. (iv) The final cause is represented by the user documents.

Aristotle's documentation system is universal. It is only surprising that this four causes schema is not widely used. It is quoted in many philosophical publications, but almost nowhere in connection with KM, product management, database design, or business administration in general.

Information, knowledge, and opinion: Mittelstrass (1972) distinguishes between information, knowledge, and opinion. So does Müller-Merbach (2006b). The terminology in this field is much broader and includes e.g.: data, news, intelligence, prudence, comprehension, ability, judgment, sapience, inspiration, insight, understanding, wisdom, and many more. Any discussion of such terms should (i) make clear what the author means by the single terms, and (ii) help the author to use the terms in a consistent, not in an arbitrarily changing sense. This indicates a difficulty at the present state: The corresponding technical terms of KM are used quite arbitrarily and with changing content.

It does not seem to be necessary that everyone uses a unique terminology. It could perhaps be sufficient if every contributor (author or speaker) provides the reader (or listener) with a clear statement on how the contributor's terms should be

understood; see Eysenck (1979) where he distinguishes between definitions of real objects and concepts. Real objects always have concrete things to be compared with, while concepts do not have concrete things to be compared with. Thus, everyone has a personal understanding of concepts such as live, love, intelligence (Eysenck's example), knowledge, etc. To have a productive discussion about any such concept, there is a need to clarify the individual understandings of the concepts.

The distinction between information, knowledge, and opinion seems to be quite useful:

- Information may be understood as objective properties of something. It can be written down on paper or stored in computer systems;
- Knowledge may be understood as something like information plus understanding or insight. Knowledge may be understood as a property that only human beings can have. A book or an information system may be designed with the input of the knowledge of many human beings. However, the book or the computer itself does not have knowledge in this sense. Human beings can learn and therefore develop knowledge by reading books. These human beings develop knowledge from information;
- However, neither information nor knowledge initiates much action. It is one's opinion why one votes for candidate A, B, or C in political elections. It is one's opinion why one has a preference for car F, G, or H. It is one's opinion to either listen to the music of Debussy or Duke Ellington or Johnny Cash.

This is the reason why the author emphasizes the combination of information management, knowledge management, and opinion management (Müller-Merbach, 2006b).

Only living beings can have knowledge and can have opinions.

Five a posteriori types of knowledge: Knowledge can be quite different, due to its origin. Five types of origin are distinguished here (Fig. 1, the horseshoe of *a* posteriori knowledge):

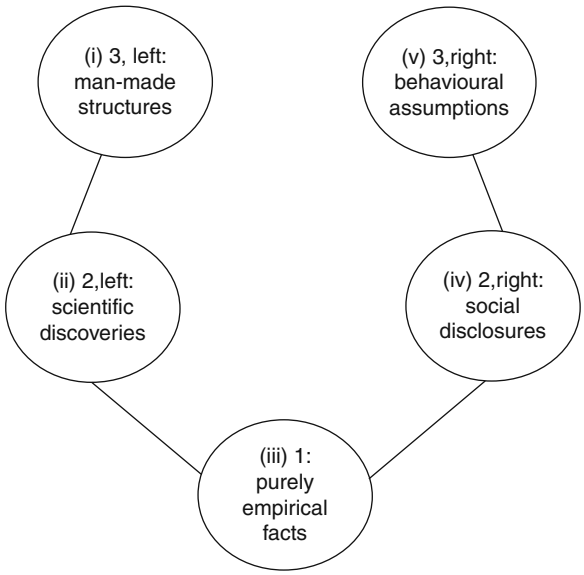
(i) *Man-made structures:* Many structures which are designed by man have to be dealt with. These can be laws, contracts, statutes, machines, (mathematical) models, constructions (and their drawings), bill-of-material-graphs etc. It is a KM task to design formal models, databases for those structures and to implement them into information systems. It is also a KM task to make these structures understandable to human beings. This may require a corresponding course of study, be it quantitative economics or engineering or product design etc.

(ii) *Scientific discoveries:* In other cases, knowledge is based on scientific understanding, e.g., on gravitation, on vibration and oscillation. This may require a scientific background.

(iii) *Purely empirical facts:* In other cases, one may have to deal with purely empirical facts, such as statistical distributions (e.g., of population).

(iv) *Social disclosures:* In other cases, there may be a need of knowledge based on the social sciences, e.g. the influence of prices on demand. Such information is often vague, i.e., much less reliable than the results of scientific discoveries. But, such disclosures may provide empirical evidence to start from.

(v) *Behavioral assumptions:* In other cases, one may depend on assumptions about people



Knowledge Management, Fig. 1 Horseshoe of five types of a posteriori (i.e. empirical) knowledge, organized in three levels (facts only – natural and social sciences – decisions by man) and two branches (*left*: precise, positive; *right*: vague, conditional), (Müller-Merbach (2007b)

and their behavior, their desires, their objectives, their needs, their actions and reactions, their motivation, etc. This kind of knowledge may be related to results of the liberal arts and social sciences.

Quite frequently, an interdisciplinary mix of knowledge is required for the solution of problems. Therefore, KM may require an interdisciplinary understanding.

Utopia of Total Knowledge Management: Any KM in practice would be far away from a collection of all the knowledge of the world. Such a collection could hardly be handled, and it could hardly be designed. However, it could be challenging to think about the structure and the size of such a collection. It would have to be much more than a collection of all available encyclopedia. It would have to be a network in which all the related entries would be connected.

Total KM is utopia today and will remain utopia.

KM in practice should start with tiny islands of KM, and then perhaps spread out.

Large-scale KM systems are extremely rare, in contrast to large-scale information systems. It is recommended to start KM with small projects.

Professional organization of knowledge management: KM is supported by several professional societies. In some countries, KM working groups or KM divisions were founded within computer science societies and OR societies, as well as in other disciplines. In addition, the Knowledge Management Professional Society (KMPro) is an independent organization that was founded in the Washington, D.C. in 2001.

There are at least five independent KM professional journals:

- *Journal of Knowledge Management*, Quarterly, English, U.K., since 1997.
- *Journal of Knowledge Management Practice*, Quarterly, English, Canada, since 1998.
- *Journal of Information & Knowledge Management*, Quarterly, English, Singapore, since 2002.
- *Electronic Journal of Knowledge Management*, English, U.K., since 2003.
- *Knowledge Management Research & Practice*, Bimonthly, English, U.K., since 2003.

An *Encyclopedia of Knowledge Management* was published in 2006 (Schwartz 2006).

Many reviews and surveys of KM have been published, such as a review of the main approaches to KM (Lloria 2008), and survey on concept maps (Martin and Wrice 2009). One of the earliest foundations of KM is the frequently quoted book by Nonaka and Takeuchi, (1995). A broad and practical introduction to KM is Nissen (2006).

Lagrange Multipliers

The multiplicative, linear-combination constants that appear in the Lagrangian of a mathematical programming problem. They are generally dual variables if the dual exists, so-called shadow prices in linear programming, giving the rate of change of the optimal value with constraint changes, under appropriate conditions.

Lagrangian Function

The general mathematical-programming problem of minimizing $f(\boldsymbol{x})$ subject to a set of constraints $\{g_i(\boldsymbol{x}) \leq b_i\}$ has associated with it a Lagrangian function defined as $L(\boldsymbol{x}, \boldsymbol{\lambda}) = f(\boldsymbol{x}) + \sum_i \lambda_i[g_i(\boldsymbol{x}) - b_i]$, where the components λ_i of the nonnegative vector $\boldsymbol{\lambda}$ are called Lagrange multipliers. For a primal linear-programming problem, the Lagrange multipliers can be interpreted as the variables of the corresponding dual problem.

Introduction

Many practical optimization problems include decision variables that are integer or 0-1. These problems, called mixed-integer programming problems or MIP for short, are in general difficult to solve, and there have been traditionally two classes of approaches to solve them: branch-and-bound or enumeration, and heuristic methods, either ad hoc or generic. Broadly speaking, branch-and-bound methods construct a tree, usually

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

binary, that allows the systematic exploration of all integer or 0-1 combinations of the discrete variables. Logical considerations and/or bounds on the optimal value computed as one moves down the tree may allow the pruning of a branch and backtracking to its root because one discovers that it would lead to infeasibilities or inferior solutions. Typically, bounds are obtained by solving a simpler, relaxed, optimization problem, most of the time the continuous relaxation of the MIP problem in which integer or 0-1 variables are allowed to take on fractional values. Heuristics, on the other hand, search for better and better feasible integer solutions, and do not usually compute bounds on the optimum, and therefore, even though they are getting more and more sophisticated and excel at finding optimal or near optimal solutions, cannot guarantee the quality of the solutions found.

Lagrangian relaxation stands somehow at the crossroads of both approaches. More powerful in terms of bound quality than the continuous relaxation, it also produces partially infeasible, but integer, solutions. These can usually serve as excellent starting points for specialized heuristics, referred to as Lagrangian heuristics. Contrary to the general heuristics mentioned above, given that one has found a bound called the Lagrangian bound, one knows whether the best solution found is good enough, or if it requires further investigation.

There is an enormous amount of literature devoted to the theory and applications of Lagrangian relaxation, starting with the seminal papers of Held and Karp (1970, 1971) and of Geoffrion (1974), although one could trace it back to earlier sources, for instance Everett's multipliers work (1963). Some early guides include (Fisher 1981, 1985).

Some of the questions to be addressed: Why use Lagrangian relaxation for integer programming problems? How does one construct a Lagrangian relaxation? What tools are there to analyze the strength of a Lagrangian relaxation? Are there more powerful extensions than standard Lagrangian relaxation, and when should they be used? Why is it that one can sometimes solve a strong Lagrangian relaxation by solving trivial subproblems? How does one compute the Lagrangian relaxation bound? Can one take advantage of Lagrangian problem decomposition? Does the strength of the model used make a difference in terms of bounds? Can one strengthen Lagrangian relaxation bounds by cuts, either kept or dualized? How can one design a Lagrangian heuristic? Can one achieve better results by remodeling the problem prior to doing Lagrangian relaxation?

The problems considered here have some integer variables, linear objective functions and constraints, and everything described below applies to maximization as well as minimization problems via the trivial sign transformations:

$$\text{Max } \{f(x)|x \in V\} = -\text{Min } \{-f(x)|x \in V\}.$$

Notation

If (P) is an optimization problem,

FS(P) denotes	the set of feasible solutions of problem (P)
OS(P)	the set of optimal solutions of problem (P)
v(P)	the optimal value of problem (P)
u^k, s^k, etc.,	the value of u, s, etc., used at iteration k
x^T	the transpose of x
x^k	the k^{th} extreme point of some polyhedron (see context)
$x^{(k)}$	a solution found at iteration k.
$\subset$	denotes strict inclusion.
Co(V)	denotes the convex hull of set V.

Relaxations of Optimization Problems

Geoffrion (1974) formally defines a relaxation of a generic minimization problem as follows.

Definition 1. *Problem* (RP_{min}): Min $\{g(x)|x \in W\}$ *is a relaxation of problem* (P_{min}): Min $\{f(x) \mid x \in V\}$ *if and only if* (i) *the feasible set of* (RP_{min}) *contains that of* (P_{min}), *and* (ii) *over the feasible set V of* (P_{min}), *the objective function of* (RP_{min}) *dominates* (*is better than*) *that of* (P_{min}), *i.e.*, $\forall\, x \in V$, $g(x) \leq f(x)$.

It clearly follows that $v(RP_{min}) \leq v(P_{min})$, in other words ($RP_{min}$) is an optimistic version of (P_{min}): it has more feasible solutions than (P_{min}), and for feasible solutions of (P_{min}), its own objective function is at least as good as (smaller than or equal to) that of (P_{min}), thus it has a smaller minimum.

Lagrangian Relaxation (LR)

In the rest of the note, (P) is assumed to be of the form $\text{Min}_x\{fx|Ax \leq b, Cx \leq d, x \in X\}$, where X contains the integrality restrictions on x, i.e. $X = \mathbb{R}^{n-p} \times \mathbb{Z}^p$, or $X = \mathbb{R}^{n-p} \times \{0,1\}^p$. Let I($X$) be the set of the p indices of x restricted to be integer (or binary). The constraints $Ax \leq b$ are assumed complicating, in the sense that, without them, problem (P) would be much simpler to solve. The constraints $Cx \leq d$ (possibly empty) will be kept, together with X, to form the Lagrangian relaxation of (P) as follows. Let λ be a nonnegative vector of weights, called Lagrangian multipliers.

Definition 2. *The Lagrangian relaxation of* (P) *relative to the complicating constraints* $Ax \leq b$, *with nonnegative Lagrangian multipliers* λ, *is the problem* (LR_λ) $\text{Min}_x\{f\ x + \lambda(Ax - b)|Cx \leq d, x \in X\}$.

Notice that (LR_λ) is still an integer programming problem, so its solutions, unlike those of the continuous relaxation, are integer solutions. However they need not be feasible solutions of (P), as they may violate some, or all, of the complicating constraints $Ax \leq b$, which are not enforced any more. In (LR_λ), the slacks of the complicating constraints $Ax \leq b$ have been added to the objective function with weights λ. One says that the constraints $Ax \leq b$ have been dualized. (LR_λ) is a relaxation of (P), since (i) FS (LR_λ) contains FS(P), and (ii) for any x feasible for (P), and any $\lambda \geq 0$, $fx + \lambda(Ax - b)$ is less than or equal to fx (i.e., not worse, since it is a minimization problem). It follows that $v(\text{LR}_\lambda) \leq v(\text{P})$, for all $\lambda \geq 0$, i.e., the optimal value $v(\text{LR}_\lambda)$, which depends on λ, is a lower bound on the optimal value of (P).

Definition 3. *The problem of finding the tightest Lagrangian lower bound on* v(P) *, i.e.*, (LR) $\text{Max}_{\lambda \geq 0}$ $v(\text{LR}_\lambda)$, *is called the Lagrangian dual of* (P) *relative to the complicating constraints* $Ax \leq b$. v(LR) *is called the Lagrangian relaxation bound, or simply the Lagrangian bound.*

Let (LP) denote the linear programming relaxation of problem (P). By LP duality, any Lagrangian relaxation bound is always at least as good as the LP bound, i.e., v(P), never worse. Notice also that (LR) is a problem in the dual space of the Lagrangian multipliers, whereas (LR_λ) is a problem in x, i.e., in the primal space.

Feasible Lagrangian solution

Let $x(\lambda)$ denote an optimal solution of (LR_λ) for some $\lambda \geq 0$, then $x(\lambda)$ is called a Lagrangian solution. One may be tempted to think that a Lagrangian solution $x(\lambda)$ that is feasible for the integer problem (i.e., that satisfies the dualized constraints) is also optimal for that problem. In fact this is generally not the case. What is true is that the optimal value of (P), v(P), lies in the interval between $fx(\lambda)+\lambda[Ax(\lambda)-b]$ and $fx(\lambda)$, where $fx(\lambda)$ is the value of a feasible solution of (P), thus an upper bound on v(P), and $fx(\lambda)+\lambda[Ax(\lambda)-b]$ is the optimal value of the Lagrangian problem (LR_λ), thus a lower bound on v(P). If, however, complementary slackness holds, i.e., if $\lambda[Ax(\lambda)-b]$ is 0, then $fx(\lambda)+\lambda[Ax(\lambda)-b] = v(\text{P}) = fx(\lambda)$, and $x(\lambda)$ is an optimal solution for (P).

Theorem 1. (1) *If* $x(\lambda)$ *is an optimal solution of* (LR_λ) *for some* $\lambda \geq 0$, *then* $fx(\lambda)+\lambda[Ax(\lambda)-b] \leq v(\text{P})$. *If in addition* $x(\lambda)$ *is feasible for* (P), *then* $fx(\lambda) +\lambda[Ax(\lambda)-b] \leq v(\text{P}) \leq fx(\lambda)$.

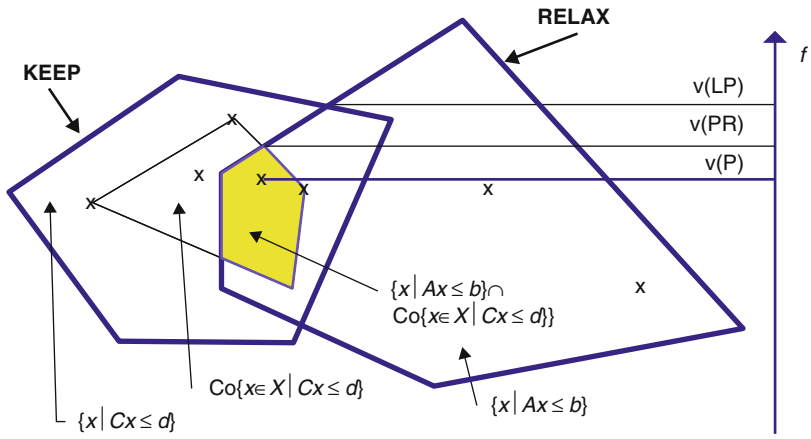
(2) *If in addition* $\lambda[Ax(\lambda)-b] = 0$, *then* $x(\lambda)$ *is an optimal solution of* (P), *and* $v(\text{P}) = fx(\lambda)$.

Remarks. Notice first that (2) is a sufficient condition of optimality, but it is not necessary. I.e., it is possible for a feasible $x(\lambda)$ to be optimal for (P), even though it does not satisfy complementary slackness. If the constraints that are dualized are equality constraints, and if $x(\lambda)$ is feasible for (P), complementary slackness holds automatically, thus $x(\lambda)$ is an optimal solution of (P), with $v(\text{P}) = fx(\lambda)$.

Geometric Interpretation

The following theorem, from (Geoffrion 1974), is probably what sheds most light on Lagrangian relaxation. It gives a geometric interpretation of the Lagrangian dual problem in the x- space, i.e., in the primal space, and this permits an in-depth study of the strength of specific Lagrangian relaxation schemes.

Theorem 2. *The Lagrangian dual* (LR) *is equivalent to the primal relaxation* (PR) $\text{Min}_x\{fx|Ax \leq b, x \in Co\{x \in X|Cx \leq d\}\}$, *in the sense that* v(LR) = v(PR) (Fig. 1).



Lagrangian Relaxation, Fig. 1 Geometric interpretation of Lagrangian relaxation

This result is based on LP duality and properties of optimal solutions of linear programs. Remember though that this result may not be true if the constraint matrices are not rational.

The following important definition and results follow from this geometric interpretation.

Definition 4. *One says that* (LR) *has the Integrality Property* (IP *for short*) *if* $\mathrm{Co}\{x \in X | Cx \leq d\} = \{x \in \mathbb{R}^n | Cx \leq d\}$.

If (LR) has the Integrality Property, then the extreme points of $\{x \in \mathbb{R}^n | Cx \leq d\}$ are in X. The unfortunate consequence of this property, as stated in the following corollaries, is that such an LR scheme cannot produce a bound stronger than the LP bound. Sometimes, however, this is useful anyway because the LP relaxation cannot be computed easily. This may be the case for instance for some problems with an exponential number of constraints that can be relaxed anyway into easy to solve subproblems. The traveling salesman problem is an instance of a problem which contains an exponential number of (subtour elimination) constraints. A judicious choice of dualized constraints leads to Lagrangian subproblems that are 1-tree problems, thus eliminating the need to explicitly write all the subtour elimination constraints (Held and Karp 1970, 1971).

Here are the two corollaries of Theorem 2 that explain the important role played by the Integrality Property.

Corollary 1. *If* $\mathrm{Co}\{x \in X | Cx \leq d\} = \{x \in \mathbb{R}^n | Cx \leq d\}$, *then* $v(\mathrm{LP}) = v(\mathrm{PR}) = v(\mathrm{LR}) \leq v(\mathrm{P})$.

In that case, the Lagrangian relaxation bound is *equal* to (cannot be better than) the LP bound.

Corollary 2. *If* $\mathrm{Co}\{x \in X | Cx \leq d\} \subset \{x \in \mathbb{R}^n | Cx \leq d\}$, *then* $v(\mathrm{LP}) \leq v(\mathrm{PR}) = v(\mathrm{LR}) \leq v(\mathrm{P})$, *and it may happen that the Lagrangian relaxation bound is strictly better than the LP bound.*

Unless (LR) does *not* have the Integrality Property, it will *not* yield a stronger bound than the LP relaxation. It is thus important to know if all vertices of the rational polyhedron $\{x \in \mathbb{R}^n | Cx \leq d\}$ are in X.

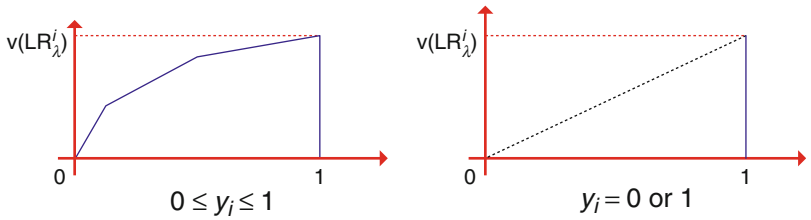
Easy-to-Solve Lagrangian Subproblems

It may happen that Lagrangian subproblems, even though in principle hard to solve because they do not have the Integrality Property, are in fact much easier to solve through some partial decomposition; they can sometimes even be solved in polynomial time, by exploiting their special structure. It is of course important to be able to recognize such favorable situations, especially if one can avoid using Branch-and-Bound to solve them. It should be noted that these favorable cases do not in general occur naturally, but only after some constraint(s) have been dualized, due to a weakening of the original links between continuous and integer variables.

One case is due to what is sometimes called the Integer Linearization Property (or ILP for short) for mixed 0-1 problems.

Integer Linearization Property

Geoffrion (1974) and Geoffrion and McBride (1978) described and used this important property of *some* Lagrangian subproblems. W.l.o.g., assume that all



Lagrangian Relaxation, Fig. 2 Integer linearization property

variables are indexed by $i \in I$, and maybe by some additional indices, and that some of the 0-1 variables are called y_i. If, except for constraints containing only these 0-1 variables y_i, the Lagrangian problem, say, (LR_λ), has the property that the value taken by a given y_i decides alone the fate of all other variables containing the same value of the index i – that usually means that if variable y_i is 0, all variables in its family are 0, and if it is 1, they are solutions of a subproblem – one may be able to reformulate the problem in terms of the variables y_i only. Often, but not always, when this property holds, it is because the Lagrangian problem, after removal of all constraints containing only the y_i's – call it (LRP_λ), for partial problem – decomposes into one problem (LRP^i_λ) for each i, i.e., for each 0-1 variable y_i. The use of this property is based on the following fact. In problem (LRP^i_λ), the integer variable y_i can be viewed as a parameter, however one does know that for the mixed-integer problem (LRP^i_λ), the feasible values of that parameter are only 0 and 1, and one can make use of the fact that there are only two possible values for $v(LRP^i_\lambda)$, the value computed for y_i=1, say v_i $(= v_i.y_i$ for y_i=1), and the value for y_i=0, that is, 0 $(= v_i.y_i$ for y_i=0), which implies that for all possible values of y_i, $v(LRP^i_\lambda) = v_i.y_i$. Hence the name integer linearization, as one replaces a piecewise linear function corresponding to $0 \le y_i \le 1$ by a line through the points (0, 0) and (1, v_i) (Fig. 2).

One may in such cases obtain LR bounds much tighter than the LP bounds, even though the subproblems are trivial to solve.

Constructing a Lagrangian Relaxation

There are often many ways in which a given problem can be relaxed in a Lagrangian fashion. A few standard ones are listed here, mostly to point out that often some reformulation prior to relaxation can help, and that for many complex models, intuition and some understanding of the constraint interactions may suggest ingenious and efficient relaxation schemes.

(1) **One can isolate an interesting subproblem and dualize the other constraints**.

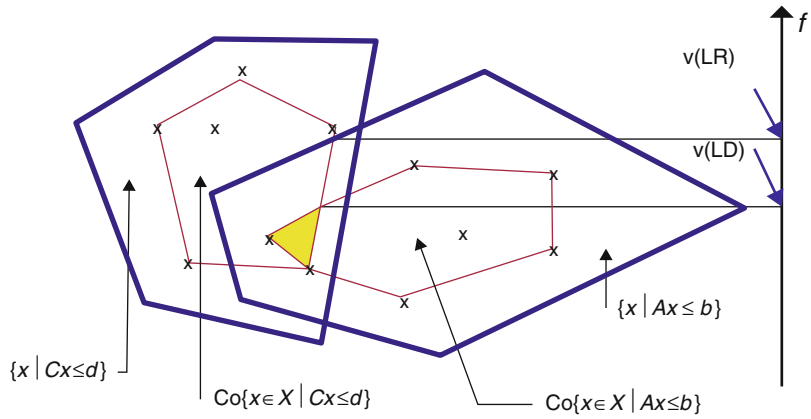
This is the most commonly used approach. It has the advantage that the Lagrangian subproblems are interesting (in the sense usually that they have a special structure that can be exploited) and there may even exist specialized algorithms for solving them efficiently.

(2) **If there are two (or more) interesting subproblems with common variables, one can split these variables first, then dualize the copy constraint.**

This is called Lagrangian decomposition (LD) (Soenen 1977), variable splitting (Näsberg et al. 1985), or variable layering (Glover and Klingman 1988). One must first reformulate the problem using variable splitting, in other words, one must rename the variables in part of the constraints as if they were independent variables. Problem (P): $\mathrm{Min}_x\{f\ x | Ax \le b, Cx \le d, x \in X\}$ is clearly equivalent to problem (P′): $\mathrm{Min}_{x,y}\{f\ x | Ax \le b, x \in X, Cy \le d, y \in X, x = y\}$, in the sense that they have equal optimal values (but notice that they have different variable spaces). In addition if x^* is an optimal solution of (P), then the solution $(x, y) \equiv (x^*, x^*)$ is optimal for (P′), and if (x^*, y^*) is an optimal solution of (P′) with $x^* = y^*$, then x^* is optimal for (P). One dualizes the copy constraint $x = y$ in (P′) with multipliers λ, this separates the problem into an x-problem and a y-problem: (LD_λ) $\mathrm{Min}_{x,y}\{fx + \lambda(y - x) | Ax \le b, x \in X,\ Cy \le d,\ y \in X\} = \mathrm{Min}_x\{(f - \lambda)x \mid Ax \le b,\ x \in X\} + \mathrm{Min}_y\{\lambda y \mid Cy \le d, y \in X\}$.

This process creates a staircase structure, and thus decomposability, in the model. Notice that here λ is not required to be nonnegative.

Remember also that when one dualizes equality constraints, a feasible Lagrangian solution is



Lagrangian Relaxation, Fig. 3 Geometric interpretation of Lagrangean decomposition

automatically optimal for the original integer programming problem. The copy constraint being an equality constraint, if both Lagrangian subproblems have the same optimal solution, that solution is optimal for the IP problem.

Guignard and Kim (1987) showed that the LD bound can strictly dominate the LR bounds obtained by dualizing either set of constraints:

Theorem 3.

$$\begin{aligned} &\textit{If } v(\mathrm{LD}) = \mathrm{Max}_{\lambda}[\mathrm{Min}_{x}\{(f-\lambda)x|\ Ax \le b, x \in X\} \\ &\qquad + \mathrm{Min}\{\lambda y|Cy\ \le\ d, y \in X\}] \textit{ then} \\ &\qquad v(\mathrm{LD}) = \mathrm{Min}\ \{fx \overset{y}{|}\, x \in \mathrm{Co}\{x \in X|Ax \le b\} \\ &\qquad \cap\, \mathrm{Co}\{x \in X|Cx \le d\}. \end{aligned}$$

This new geometric interpretation is demonstrated in Fig. 3.

Corollary 3.

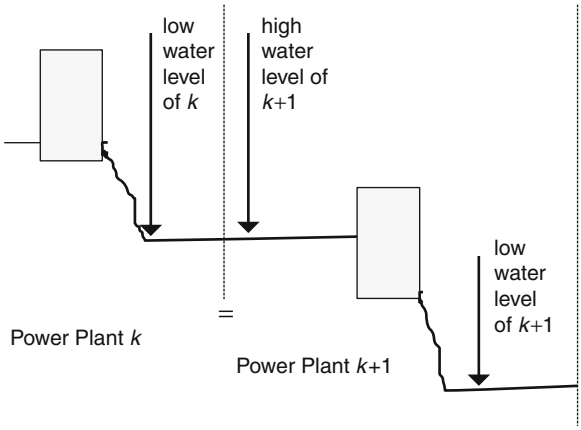
- *If one of the subproblems has the Integrality Property, then v(LD) is equal to the better of the two LR bounds corresponding to dualizing either* $Ax \le b$ *or* $Cx \le d$.
- *If both subproblems have the Integrality Property, then* $v(LD) = v(LP)$.

A very important application of the splitting variable scheme can be found in stochastic optimization, when the uncertainty is represented by 2-stage or multistage scenario trees. The non-anticipativity constraints (or NAC) must be satisfied by the variables attached to the scenario groups or nodes in the tree. Splitting variables in the NAC and dualizing the copy constraints produces a Lagrangean decomposition of the Deterministic Equivalent Model. See Escudero (2009) and Birge and Louveaux (2011), among others.

Occasionally the variable splitting will correspond to a physical split of one of the problem's decision variables. This is illustrated by the following example.

Example 1. Guignard and Yan (1993) described the following problem and scheme for a hydroelectric power management problem.

Electric utility production planning is the selection of power generation and energy efficiency resources to meet customer demands for electricity over a multi-period time horizon. The project described in the paper is a real-world hydropower plant operations management problem of a dispatch type. The system consists of a chain of 10 consecutive hydropower plants separated by reservoirs and falls with 23 identical machines installed to generate electric power. Specifically there are two machines installed in eight power plants (plants 1, 2, 3, 4, 5, 6, 7, and 10), three machines in one power plant (plant 8) and four machines in the last power plant (plant 9). Each machine has two or four work parts for producing electric power, according to different water throughput. Since demand for electric power varies with different time periods, power plant managers must make optimal decisions concerning the number of machines that should be operated in each power plant during each time period. Managing the power generation requires decisions concerning water



Lagrangian Relaxation, Fig. 4 Lagrangian decomposition splits the water level

releases at each plant k in each time period. A period is two hours. The model (which is confidential) was constructed by an independent consulting firm. This results in a large mixed-integer program. The problem is complex, with 2,691 variables, 384 of which are binary, and 12,073 constraints. The firm had tried to solve the problem for the utility company with several of the best MIP software packages available, with help from the software companies themselves. Yet they did not succeed. Guignard and Yan repeated the tests with several solvers running under GAMS, on several RISC systems, also to no avail. The best result after 5 days and six hours on an HP workstation was a bracket [3174.97, 3534.17], i.e., a residual gap of more than 11%.

In order to reduce the complexity of the model, they tried several Lagrangian relaxations and decompositions. One of the decompositions tested consists in "cutting" each reservoir in half (see Fig. 4), i.e. splitting the water level variable in each reservoir, and dualizing the following copy constraint:

$$\text{high water level in } k+1 = \text{low water level in } k.$$

This Lagrangian decomposition produces one power management problem per power plant k. These subproblems do not have a special structure, but are much simpler and smaller than the original problem, are readily solvable by commercial software, and do not have the Integrality Property. They were solved by Branch-and-Bound.

This LD shrinks problem size, and yields Lagrangian bounds much stronger than the LP bounds. In addition the Lagrangian solutions can be modified to provide feasible schedules.

(3) **One can dualize linking constraints**:

After possibly some reformulation, problems may contain independent structures linked by some constraints: $\text{Min}_{x,y}\{f\ x+gy|Ax \le b,\ x \in X,\ Cy \le d,\ y \in Y,\ Ex+Fy \le h\}$. Dualizing the linking constraints $Ex + Fy \le h$ splits the problem into an x-problem and a y-problem. The original problem may only contain x and some reformulation introduces a new variable y, while the relationship between x and y is captured by the new constraints $Ex + Fy \le h$.

Example 2. A production problem over multiple facilities contains constraints related to individual facilities, while the demand constraints link all plant productions. If one dualizes the demand constraints, the Lagrangian problem decomposes into a production problem for each facility, which is typically much easier to solve than the overall problem. If at least one of these subproblems does not have the Integrality Property, this LR may yield a tighter bound than the LP bound. In (Andalaft et al. 2003), a forest company must harvest geographically distinct areas, and dualizing the demand constraints splits the problem into one subproblem per area, which is typically much easier to solve than the overall problem.

(4) **One can sometimes dualize aggregate rather than individual copies of variables.**

Instead of creating a copy y of variable x and introducing y into model (P) by rewriting the constraint $Cx \le d$ as $Cy \le d$, to yield the equivalent model (P′): $\text{Min}_{x,y}\{f\ x|Ax \le b,\ x \in X,\ Cy \le d,\ y \in X,\ x = y\}$, one can also create a problem (P″) equivalent to problem (P) by introducing a new variable y and forcing the constraint $Dy = Cx$. This constraint is in general weaker than the constraint $x = y$. Model (P″) is $\text{Min}_{x,y}\{f\ x|Ax \le b,\ x \in X,\ Dy \le d,\ y \in X,\ Dx = Cy\}$. The LR introduced here dualizes the aggregate copy constraint $Dx = Cy$.

Notice that the copy constraint is an equality constraint, therefore if the Lagrangian subproblems have optimal solutions x and y that satisfy the aggregate copy constraint, i.e., if $Dy = Cx$, then the x- solution is optimal for the IP problem.

Example 3. Consider the bi-knapsack problem

(BKP)$\text{Max}_x\{\sum_i c_i x_i | \sum_i b_i x_i \le m,\ \sum_i d_i x_i \le n, x_i \in \{0,1\}, \forall i\}$.

One can introduce a new variable y, and write $\sum_i b_i x_i = \sum_i b_i y_i$. The equivalent problem is

(BKP')$\text{Max}_{x,y}\{\sum_i c_i x_i | \sum_i b_i y_i \le m,\ \sum_i d_i x_i \le n, \sum_i b_i x_i = \sum_i b_i y_i,\ x_i, y_i \in \{0,1\}, \forall i\}$

and the LR problem is

$$(\text{LR}_\lambda)\text{Max}_{x,y}\left\{\sum_i c_i x_i - \lambda\left(\sum_i b_i x_i - \sum_i b_i y_i\right)\right| \sum_i b_i y_i \le m, \sum_i d_i x_i \le n,\ x_i, y_i \in \{0,1\}, \forall i\}$$
$$= \text{Max}_x\left\{\sum_i (c_i - \lambda b_i) x_i \middle| \sum_i d_i x_i \le n, x_i \in \{0,1\}, \forall i\right\} + \text{Max}_y\left\{\lambda \sum_i b_i y_i) \middle| \sum_i b_i y_i \le m,\ y_i \in \{0,1\}, \forall i\right\}.$$

Here λ is a single real multiplier of arbitrary sign. The Lagrangian bound produced by this scheme is in between that of the LP bound and that of the Lagrangian decomposition bound obtained by dualizing $x_i = y_i\ \forall i$. This is similar in spirit to the copy constraints introduced in Reinoso and Maculan (1992).

It would seem natural that a reduction in the number of multipliers should imply a reduction in the quality of the LR bound obtained. This is not always the case, however, as shown in example 4.

Example 4. Chen and Guignard (1998) considered an aggregate Lagrangian relaxation of the capacitated facility location problem. The model uses continuous variables x_{ij} that represent the percentage of the demand d_j of customer j supplied by facility i, and binary variables y_i, equal to 1 if facility i with capacity a_i is operational. The constraint $\sum_j d_j x_{ij} \le a_i y_i$ imposes a conditional capacity restriction on the total amount that can be shipped from potential facility i.

(CPLP)

$\text{Min}_{x,y}\ \Sigma_i \Sigma_j c_{ij} x_{ij} + \Sigma_i f_i y_i$		
s.t. $\Sigma_i x_{ij} = 1$, all j	(D)	*meet 100% of customer demand*
$x_{ij} \le y_i$, all i, j	(B)	*ship nothing if plant is closed*
$\Sigma_i a_i y_i \ge \Sigma_j d_j$,	(T)	*enough plants to meet total demand*
$\Sigma_j d_j x_{ij} \le a_i y_i$, all i	(C)	*ship no more than plant capacity*
$x_{ij} \ge 0$, $y_i = 0$ or 1, all i, j.		

Constraint (T) is redundant, but may help getting tighter Lagrangian relaxation bounds.

The three best Lagrangian schemes are:

(LR) (Geoffrion and McBride 1978)

One dualizes (D) then uses the integer linearization property. The subproblems to solve are one continuous knapsack problem per plant ((C) with $y_i = 1$) and one 0-1 knapsack problem over all plants (constraint (T)). The Lagrangian relaxation bound is tight, and it is obtained at a small computational cost.

(LD) (Guignard and Kim 1987).

Duplicate (T). Make copies $x_{ij} = x'_{ij}$ and $y_y = y'_i$ and use x'_{ij} and y'_i in (C) and in one of the (T)'s. One obtains the split

{(D), (B), (T)} → APLP

{(B), (T), (C)} → this is like in (LR)

This LD bound is tighter than the (LR) bound, but expensive to compute, in particular because of a large number of multipliers.

(LS) (Chen and Guignard 1998).

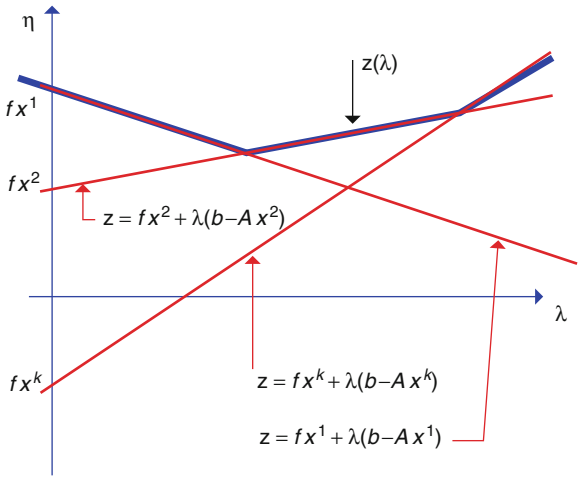
Copy $\sum_j d_j x_{ij} = \sum_j d_j x'_{ij}$ and $y_i = y'_i$ in (C). This yields the same split as (LD), and the same bound. This is very surprising, as it is less expensive to solve (LS) than (LD), in particular because (LS) has far fewer multipliers.

In example 4, creating new copy variables x'_{ij} and y'_i, one can create an LS by dualizing the aggregate (linking) copy constraints $\sum_j d_j x_{ij} = \sum_j d_j x'_{ij}$ and $a_i y_i = a_i y'_i$. Surprisingly, one can prove that the LS bound for this problem is as strong as the LD bound obtained by dualizing individual copies $x_{ij} = x'_{ij}$ and $y_i = y'_i$. This suggests that "aggregating" variables before copying them may be an attractive alternative to Lagrangian decomposition, at least for some problem structures. A more general structure than CPLP is actually described in Chen and Guignard (1998).

Characteristics of the Lagrangian Function

The Lagrangian function $z(\lambda) = v(\text{LR}_\lambda)$ is an implicit function of λ. Suppose that the set $\text{Co}\{x \in X | Cx \le d\}$ is a polytope, i.e., a bounded polyhedron, then there exists a finite family $\{x^1, x^2, \ldots, x^K\}$ of extreme points of $\text{Co}\{x \in X | Cx \le d\}$, i.e., of points of $\{x \in X | Cx \le d\}$, such that $\text{Co}\{x \in X | Cx \le d\} = \text{Co}\ \{x^1, x^2, \ldots, x^K\}$. It then follows that

$$\text{Min}_x\{fx + \lambda(b - Ax) | Cx \le d, x \in X\} = \text{Min}_{k=1,\ldots,K}\{f\ x^k + \lambda(b - Ax^k)\}$$



Lagrangian Relaxation, Fig. 5 The Lagrangean function of a maximization problem

and $z(\lambda)$ is the lower envelope of a family of linear functions of $\lambda, f\ x^k + \lambda\left(b - Ax^k\right)$, k=1,. . .,K, and thus is a concave function of λ, with breakpoints where it is not differentiable, i.e., where the optimal solution of (LR_λ) is not unique. Figure 5 shows a Lagrangian function for the case where (P) is a maximization problem, this (LR) is a minimization problem, and $z(\lambda)$ a convex function of (λ).

A concave function $f(x)$ is continuous over the relative interior of its domain, and it is differentiable almost everywhere, i.e., except over a set of measure 0. At points where it is not differentiable, the function does not have a gradient, but is always has subgradients.

Definition 5. *A vector* $y \in (\mathrm{R}^n)^*$ is *a* subgradient *of a concave function* $f(x)$ *at a point* $x^0 \in \mathrm{R}^n$ *if for all* $x \in \mathrm{R}^n$

$$f(x) - f\left(x^0\right) \leq y \cdot (x - x^0).$$

Definition 6. *The set of all subgradients of a concave function* $f(x)$ *at a point* x^0 *is called the subdifferential of* f *at* x^0 *and it is denoted* $\partial f(x^0)$.

Theorem 4. *The subdifferential* $\partial f(x^0)$ *of a concave function* $f(x)$ *at a point* x^0 *is always nonempty, closed, convex and bounded.*

If the subdifferential of f at x^0 consists of a single element, that element is the gradient of f at x^0, denoted by $\nabla f(x^0)$.

The dual problem (LR) is

$$\begin{aligned}&\mathrm{Max}_{\lambda\ \geq 0} v(\mathrm{LR}_\lambda) = \mathrm{Max}_{\lambda \geq 0} z(\lambda) = \\ (\mathrm{LR})\ &\mathrm{Max}_{\lambda\ \geq 0} \mathrm{Min}_{k=1,\ldots,K}\left\{fx^k + \lambda\left(b - Ax^k\right)\right\} = \\ &\mathrm{Max}_{\lambda\ \geq 0,\eta}\left\{\eta | \eta \leq fx^k + \lambda(b - Ax^k), k = 1, \ldots, K\right\}.\end{aligned}$$

Let λ^* be a minimizer of $z(\lambda)$, $\eta^* = z(\lambda^*)$, λ^k be a current "guess" at λ^*, let $\eta_k = z(\lambda^k)$, and $\mathrm{H}_k = \left\{\lambda | fx^k + \lambda(b - Ax^k) = \eta^k\right\}$ be a level hyperplane passing through λ^k.

- If $z(\lambda)$ is differentiable at λ^k, i.e., if (LR_λ) has a unique optimal solution x^k, it has a **gradient** $\nabla z(\lambda^k)$ at λ^k:

$$\nabla^{\mathrm{T}} z(\lambda^k) = (b - Ax^k) \perp \mathrm{H}_k.$$

- If $z(\lambda)$ is nondifferentiable at λ^k, i.e., if (LR_λ^k) has multiple optimal solutions, the vector $s^k = (b - Ax^k)^{\mathrm{T}}$ is a subgradient of $z(\lambda)$ at λ^k. That vector s^k is orthogonal to H_k.

If one considers the contours $\mathrm{C}\{k\} = \left\{\lambda \in \mathbb{R}_+^m | z(\lambda) \geq a\right\}$, α a scalar, these contours are convex polyhedral sets. See Fig. 6.

Note: A subgradient is not necessarily a direction of increase for the function, even locally, as seen on Fig. 6.

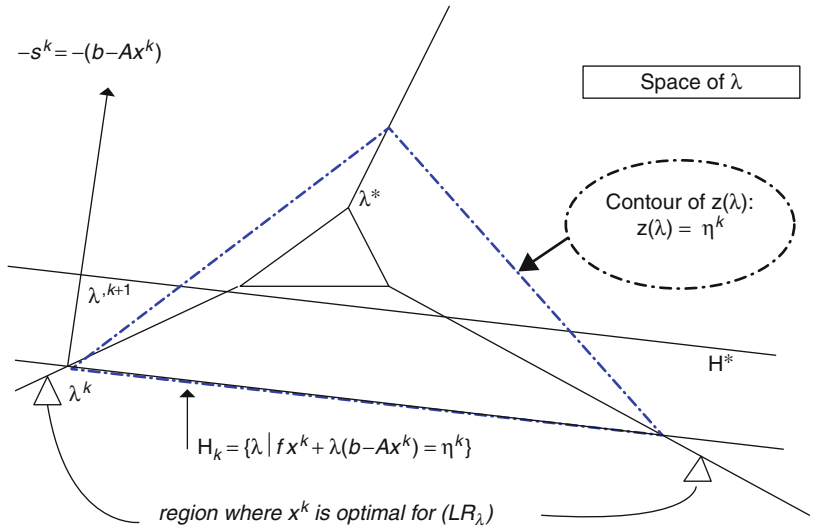
Theorem 5. *The vector* $(b - Ax^k)^{\mathrm{T}}$ is a *subgradient* of $z(\lambda)$ at λ^k.

Primal and Dual Methods to Solve Relaxation Duals

A number of methods have been proposed to solve Lagrangian duals. They are either ad-hoc, like for instance dual ascent methods, or general purpose, usually aiming at solving a generic nonsmooth convex optimization problem. This section reviews the most important approaches.

Subgradient Method

This method was proposed in (Held and Karp 1971). It is an iterative method in which at iteration k, given the current multiplier vector λ^k, a step is taken along a subgradient of $z(\lambda^k)$, then, if necessary, the resulting point is projected onto the nonnegative orthant.



Lagrangian Relaxation, Fig. 6 Contours and subgradient

Let $x^{(k)}$ be an optimal solution of (LR^k_λ). Then $s^k = (b - Ax^{(k)})^T$ is a subgradient of z(λ) at λ^k. If λ^* is an (unknown) optimal solution of (LR), with $\eta^* = z(\lambda^*)$, let λ'^{k+1} be the projection of λ^k on the hyperplane H^* parallel to H_k, defined by

$$H^* = \left\{\lambda | fx^k + \lambda(b - Ax^{(k)}) = \eta^*\right\}.$$

The vector s^k is perpendicular to both H_k and H^*, therefore $\lambda'^{k+1} - \lambda^k$ is a nonnegative multiple of s^k:

$$\lambda'^{k+1} - \lambda^k = \mu s^k, \mu \geq 0.$$

Also, λ'^{k+1} belongs to H^*:

$$f\ x^{(k)} + \lambda'^{k+1}(b - Ax^{(k)}) = \eta^*,$$

therefore $f\ x^k + \mu s^k(b - Ax^{(k)}) = \eta^k + \mu s^k.s^k = \eta^*$
and $\mu = (\eta^* - \eta^k)/||s^k||^2$,
so that $\lambda'^{k+1} = \lambda^k + s^k.\ (\eta^* - \eta^k)\ /||s^k||^2$.

Finally define $\lambda^{k+1} = [\lambda'^{k+1}]^+$, i.e., define the next iterate λ^{k+1} as the projection of λ'^{k+1} onto the nonnegative orthant, as λ must be nonnegative. Given the geometric projections described above, it is clear that λ^{k+1} is closer to λ^* than λ^k, thus the sequence $||\lambda^k - \lambda^*||^2$ is monotone nonincreasing.

Remark. This formula unfortunately uses the unknown optimal value η* of (LR). One can try to use an estimate for that value, but then one may be using either too small or too large a multiple of s^k. If one sees that the objective function values do not improve for too many iterations, one should suspect that η^* has been overestimated (for a maximization problem) and that one is overshooting, thus one should try to reduce the difference η^*-η^k. This can be achieved by introducing from the start a positive factor $\varepsilon_k \in (0,2)$, in the subgradient formula:

$$\lambda^{k+1} = \lambda^k + s^k.\ \varepsilon_k(\eta^* - \eta^k)\ /||s^k||^2,$$

and reducing the scalar ε_k when there is no improvement for too long.

Practical convergence of the subgradient method is unpredictable, sometimes quick and fairly reliable, sometimes erratic. Many authors have studied this problem and have proposed a variety of remedies.

Dual Ascent Methods

In this kind of approach, one takes advantage of the structure of the Lagrangian dual to create a sequence of multipliers that guarantee a monotone increase in Lagrangian function value. This approach had been pioneered by Bilde and Krarup (1967, 1977) for solving approximately the LP relaxation of the uncapacitated facility location problem (UFLP). General principles for developing a successful Lagrangian dual ascent method can be found in (Guignard and Rosenwein 1989).

Constraint Generation Method (Also Called Cutting Plane Method, or CP)

In this method , one uses the fact that $z(\lambda)$ is the lower envelope of a family of linear functions:

$$\begin{aligned}&\mathrm{Max}_{\lambda\geq 0} v(\mathrm{LR}_\lambda) = \mathrm{Max}_{\lambda\geq 0} z(\lambda) =\\ (\mathrm{LR})\ &\mathrm{Max}_{\lambda\geq 0}\mathrm{Min}_{k=1,\ldots,K}\left\{f\,x^k + \lambda\left(b - Ax^k\right)\right\} =\\ &\mathrm{Max}_{\lambda\geq 0,\eta}\left\{\eta | \eta \leq f\,x^k + \lambda\left(b - Ax^k\right), k = 1,\ldots,K\right\}.\end{aligned}$$

At each iteration k, one generates one or more cuts of the form

$$\eta \leq fx^k + \lambda(b - Ax^{(k)}),$$

by solving the Lagrangian subproblem (LR_λ^k) with solution $x^{(k)}$. These cuts are added to those generated in previous iterations to form the current LP master problem:

$$\left(\mathrm{MP}^k\right)\quad \mathrm{Max}_{\lambda\geq 0,\eta}\left\{\eta | \eta \leq fx^{(h)} + \lambda(b - Ax^{(h)}), h = 1,\ldots,k\right\},$$

whose solution is the next iterate λ^{k+1}. The process terminates when $v(\mathrm{MP}^k) = z(\lambda^{k+1})$. This value is the optimal value of (LR).

Column Generation (CG)

(CG) has been used extensively, in particular for solving very large scheduling problems (airline, buses, etc.). It consists in reformulating a problem as an LP (or an IP) whose activities (or columns) correspond to feasible solutions of a subset of the problem constraints, subject to the remaining constraints. The variables are weights attached to these solutions.

There are two aspects to column generation: first, the process is dual to Lagrangian relaxation and to CP. Secondly, it can be viewed as an application of Dantzig and Wolfe's decomposition algorithm (Dantzig and Wolfe 1960, 1961).

Let the $x^k \in \left\{x \in X | Cx^k \leq d\right\}$, $k \in K$, be chosen such that $\mathrm{Co}\left\{x^k\right\} = \mathrm{Co}\{x \in X | Cx \leq d\}$. A possible choice for the x^k's is all the points of $\mathrm{Co}\{x \in X | Cx \leq d\}$ but a cheaper option is all extreme points of $\mathrm{Co}\{x \in X | Cx \leq d\}$.

Problem (P): $\mathrm{Min}_x\{fx | Ax \leq b, Cx \leq d, x \in X\}$ yields the Lagrangian dual (i.e., in the λ-space) problem

$$(\mathrm{LR})\quad \mathrm{Max}_{\lambda\geq 0}\mathrm{Min}_x\{fx + \lambda(Ax - b) | Cx \leq d, x \in X\}$$

which is equivalent to the primal (i.e., in the x-space) problem

$$(\mathrm{PR})\quad \mathrm{Min}_x\{fx | Ax \leq b, x \in \mathbf{Co}\{x \in X | Cx \leq d\}\},$$

which itself can be rewritten as (PR) $\mathrm{Min}_x\left\{f\left(\sum_{k\in K}\mu_k x^k\right)\middle| A\left(\sum_{k\in K}\mu_k x^k\right)x \leq b\right\}$ given $= \mathrm{Min}_x\left\{\sum_{k\in K}\mu_k.(fx^k)\middle|\sum_{k\in K}\mu_k.(Ax^k) \leq b\right\}$, that one can write $x \in \mathrm{Co}\{x \in X | Cx \leq d\}$ as $x = \sum_{k\in K}\mu_k x^k$, with $\sum_{k\in K}\mu_k = 1$ and $\mu_k \geq 0$.

The separation of a problem into a master- and a sub-problem is equivalent to the separation of the constraints into kept and dualized constraints. The columns generated are solutions of integer subproblems that have the same constraints as the Lagrangian subproblems.

The value of the LP relaxation of the master problem is equal to the Lagrangian relaxation bound. The strength of a CG or LR scheme would then seem to be based on the fact that the subproblems do not have the integrality property. It may happen however that such a scheme can be successful at solving problems with the integrality property because it permits the indirect computation of v(LP) when this value could not be computed directly, e.g., because of an exponential number of constraints (Held and Karp 1970, 1971).

One substantial advantage of (CP) or (CG) over subgradient algorithms is the existence of a true termination criterion $v(\mathrm{MP}^k) = z(\lambda^{k+1})$.

Bundle Methods

Lemaréchal (1974) introduced an extension of subgradient methods, called bundle methods, in which past information is collected to provide a better approximation of the Lagrangian function. The standard CP algorithm uses the bundle of the subgradients that were already generated, and constructs a piecewise linear approximation of the Lagrangian function. This method is usually slow and unstable. Three different stabilization approaches have been proposed. At any moment, one has a model representing the Lagrangian function, and a so-called stability center, which should be a reasonable approximation of the true optimal solution.

One generates a next iterate which is a compromise between improving the objective function and keeping close to the stability center. The next iterate becomes the new stability center (a serious step) only if the objective function improvement is "good enough". Otherwise, one has a null step, in which however one improves the function approximation. In addition, this next iterate shouldn't be too far away from the stability center. The three stabilization approaches propose different ways of controlling the amount of move that is allowed. Either the next iterate must remain within a so-called trust region, or one adds a penalty term to the approximation of the function that increases with the distance from the stability center, or one remains within a region where the approximation of the function stays above a certain level (for a maximizaton problem). This proximity measure is the one parameter that may be delicate to adjust in practical implementations. There is a trade-off between the safety net provided by this small move concept, and the possibly small size of the bound improvement.

The Volume Algorithm (VA)

The volume algorithm (Barahona and Anbil 2000), an extension of the subgradient algorithm, can be seen as a fast way to approximate Dantzig-Wolfe decomposition, with a better stopping criterion, and it produces primal as well as dual vectors by estimating the volume below the faces that are active at an optimal dual solution. It has been used successfully to solve large-scale LP's arising in combinatorial optimization, such as set partitioning or location problems.

Subproblem Decomposition

In many cases, the Lagrangian subproblem decomposes into smaller problems, and this means that the feasible region is actually the Cartesian product of several smaller regions. One clear advantage is the reduction in computational complexity for the Lagrangian subproblems: indeed, it is generally much easier to solve 50 problems with 100 binary variables each, say, than a single problem with 5,000 (i.e., 50x100) binary variables.

It also means that in column generation, the columns (i.e., the vectors that are feasible solutions of the kept constraints) decompose into smaller subcolumns, and each subcolumn is a convex combination of extreme points of a small region. By assigning different sets of weights to these convex combinations, one allows mix-and-match solutions, in other words, one may combine a subcolumn for the first subproblem that was generated at iteration 10, say, with a subcolumn for the second subproblem generated at iteration 7, etc. , to form a full size column. If one had not decomposed the problem ahead of time, one may have had to wait a long time for such a complete column to be generated.

By duality, this means that in a cutting plane environment, one can also generate sub-cuts for each subproblem, which amounts to first replacing η by $z - \lambda b$ in

$$\left(\mathrm{MP}^k\right) \mathrm{Max}_{\lambda \geq 0, \eta}\left\{\eta | \eta \leq f\, x^{(h)} + \lambda(b - Ax^{(h)}), h = 1, \ldots, k\right\}$$
$$= \mathrm{Max}_{\lambda \geq 0, z}\left\{z - \lambda b | z \leq (f - \lambda A)x^{(h)}, h = 1, \ldots, k\right\},$$

and then z by a sum of scalars z_l, with $z_l \leq (f^l - \lambda A_l)\, x_l^{(h)}$, where l is the index of the Lagrangian subproblem, f^l, A_l, and $x_l^{(h)}$ are the l^{th} portions of the corresponding submatrices and vectors, and x_l^h is a Lagrangian solution of the l^{th} subproblem found at iteration h, yielding the disaggregated master problem

$$\left(\mathrm{MPD}^k\right) \mathrm{Max}_{\lambda \geq 0, z_l}\left\{\sum\nolimits_l z_l - \lambda b | z_l \leq (f - \lambda A)^l x_l^h, h = 1, \ldots, k\right\}.$$

Example 5. Consider the Generalized Assignment Problem, or GAP (for the minimization case, although it would work in exactly the same way with maximization).

$$\begin{aligned} (\mathrm{GAP})\ \mathrm{Min}\ & \sum\nolimits_i \sum\nolimits_j c_{ij} x_{ij} \\ \text{s.t.}\ & \sum\nolimits_j a_{ij} x_{ij} \leq b_i, \quad \forall i \in I \quad (\mathrm{KP}) \\ & \sum\nolimits_i x_{ij} = 1, \quad \forall j \in J \quad (\mathrm{MC}) \\ & x_{ij} \in \{0, 1\}, \quad \forall i \in I, j \in J. \end{aligned}$$

Its strong Lagrangian relaxation is

$$(\mathrm{LR}_\lambda) \mathrm{Min} \sum\nolimits_{i,j} c_{ij} x_{ij} + \sum\nolimits_j \lambda_j (1 - \sum\nolimits_i x_{ij})$$
$$\text{s.t.} \quad \sum\nolimits_j a_{ij} x_{ij} \leq b_i, \ \forall i \quad (\mathrm{KP})$$
$$= \sum\nolimits_j \lambda_j + \sum\nolimits_i \{\mathrm{Min} \sum\nolimits_j (c_{ij} - \lambda_j) x_{ij} \Big| \sum\nolimits_j a_{ij} x_{ij} \leq b_i, \forall i$$
$$x_{ij} \in \{0, 1\}, \ \forall j\},$$

and (LR) is the maximum with respect to λ of $\mathrm{v}(\mathrm{LR}_\lambda)$.

Let $\mathrm{EP(KP)} = \{x^k | k \in K\}$ be the set of all integer feasible solutions of the constraints (KP), and let $\mathrm{EP(KP_i)} = \{x_i^k | k \in K_i\}$ be the set of all integer feasible solution of the i^{th} knapsack, with $K = \prod_i K_i$. Then a feasible solution of (LR_λ) can be described by $x_{ij} = \sum_{k \in K_i} \mu_k^i x_{ij}^k, \forall i, j$.

The Lagrangian dual is equivalent to the aggregate master problem AMP:

$$\begin{aligned}&(\mathrm{AMP})\ \mathrm{Max}_{\lambda,\zeta}\left\{\zeta | \zeta \le \sum_{i,j} c_{ij} x_{ij}^k + \sum_j \lambda_j (1 - \sum_i x_{ij}^k), \forall k \in K\right\}\\ &= \mathrm{Max}_{\lambda,z}\left\{z + \sum_j \lambda_j | z \le \sum_{ij} (c_{ij} - \lambda_j) x_{ij}^k,\ \forall k \in K\right\}\end{aligned}$$

with the substitution $\zeta = z + \sum_j \lambda_j$.

If one had first written the column generation formulation for the Lagrangian dual, one would naturally have de-coupled the solutions of the independent knapsack subproblems, using the independent sets K_i instead of K, the column generation master problem would have been disaggegated:

$$\begin{aligned}&(\mathrm{DMP})\mathrm{Max}_{\lambda,z} \sum_i z_i + \sum_j \lambda_j\\ &\qquad \text{s.t.} \quad z_i \le \sum_j (c_{ij} - \lambda_j) x_{ij}^k,\ \forall i, \forall k \in K_i\end{aligned}$$

and its dual

$$\begin{aligned}\mathrm{Min}_\mu \sum_{k \in K_i} \sum_{i,j} c_{ij} x_{ij}^k \mu_k^{(i)} \Big| &\sum_{k \in K_i} \sum_i x_{ij}^k \mu_k^{(i)} = 1, \forall j,\\ &\mu_k^i \ge 0, \sum_{k \in K_i} \mu_k^{(i)} = 1, \forall i\},\end{aligned}$$

is clearly the Dantzig-Wolfe decomposition of the primal equivalent

$$(\mathrm{PR}) \quad \mathrm{Min}_x \left\{\sum_{i,j} c_{ij} x_{ij} \Big| \sum_i x_{i,j} = 1,\ x_{ij} \ge 0\right\}$$

of (LR).

Relax-and-Cut

One question that often arises in the context of Lagrangian relaxation is how to strengthen the Lagrangian relaxation bound. One possible answer is the addition of cuts that are currently violated by the Lagrangian solution. It is clear however that adding these to the Lagrangian problem will change its structure and may make it much harder to solve. One possible way out is to dualize these cuts (for a more detailed analysis, see (Guignard 1998)). Remember that dualizing does not mean discarding! The cuts will be added to the set of complicating constraints, and intuitively they will be useful only if the intersection NI (for "new intersection") of the new relaxed polyhedron and of the convex hull of the integer solutions of the kept constraints is "smaller" than the intersection OI (for "old intersection") of the old relaxed polyhedron and of the convex hull of the integer solutions of the kept constraints. This in turn is only possible if the new relaxed polyhedron is smaller than the old one, since the kept constraints are the same in both cases. This has the following implications. Consider a cut that is violated by the current Lagrangian solution:

(1) if the cut is just a convex combination of the current constraints, dualized and/or kept, it cannot possibly reduce the intersection, since every point of the "old" intersection will also satisfy it; so in particular surrogate constraints of the dualized constraints cannot help.
(2) if the cut is a valid inequality for the Lagrangian problem, then every point in the convex hull of the integer points of the kept constraints satisfies it, because every integer feasible solution of the Lagrangian subproblem does;
(3) it is thus necessary for the cut to use "integer" information from both the dualized and the kept constraints, and to remove part of the intersection. (Remember that the Lagrangian solution is an integer point required to satisfy only the kept constraints).

A Relax-and-Cut scheme could proceed as follows:

1. Initialize the Lagrangian multiplier λ.
2. Solve the current Lagrangian problem, let $x(\lambda)$ be the Lagrangian solution. If the Lagrangian dual is not solved yet, update λ. Else end.
3. Identify a cut that is violated by $x(\lambda)$, and dualize it. Go back to 2.

The term Relax-and-Cut was first used by (Escudero et al. 1994). In that paper, a partial description of the constraint set was used, and violated constraints (not cuts) were identified, added to the model and immediately dualized. The idea, if not the name, had actually been used earlier. For instance

in solving TSP problems, subtour elimination constraints were generated on the fly and immediately dualized in Balas and Christofides (1981). The usefulness of constraints is obvious, contrary to that of cuts. A missing constraint can obviously change the problem solution.

Here are examples of cuts that if dualized cannot possibly tighten Lagrangian relaxation bounds.

Non-improving Dualized Cuts: Example for the GAP

Consider again the GAP model.

If one dualizes (MC), the Lagrangian relaxation problem decomposes into one subproblem per *j:*

$$
\begin{aligned}
(\mathrm{LR}_\lambda)\ \mathrm{Min} & \sum_{i,j} c_{ij}x_{ij} + \sum_j \lambda_j\Big(1 - \sum_i x_{ij}\Big) \\
\text{s.t.} \quad & \sum_j a_{ij}x_{ij} \le b_i, \quad \forall i \quad (\mathrm{KP}) \\
= \mathrm{Min}\ & \Big\{\sum_{i,j}(c_{ij} - \lambda_j)x_{ij} + \sum_j \lambda_j \Big| \\
& \sum_j a_{ij}x_{ij} \le b_i, \quad \forall i, \quad x_{ij} \in \{0,\ 1\}, \forall i, j\Big\} \\
= \sum_j \lambda_j + \sum_i & \Big\{\mathrm{Min} \sum_j (c_{ij} - \lambda_j)\ x_{ij} \Big| \\
& \sum_j a_{ij}x_{ij} \le b_i, \quad \forall i\, x_{ij} \in \{0, 1\}, \quad \forall j\Big\}.
\end{aligned}
$$

Thus the i^{th} Lagrangian subproblem is a knapsack problem for the i^{th} machine. After solving all knapsack problems, the solution $x(\lambda)$ may violate some multiple choice constraint, i.e., there may exist some j for which $\sum_i x_{ij} \neq 1$, and as a consequence the condition $\sum_i \sum_j x_{ij} = |J|$ may be violated. Adding this "cut" (it indeed cuts out the current Lagrangian solution!), and immediately dualizing it, does not reduce the intersection, as every point of the old intersection OI already satisfies all multiple choice constraints (MC), i.e., the dualized constraints.

Can kept Cuts Strengthen the Lagrangian Bound?

What happens if one keeps the cuts instead of dualizing them? It is clear that adding these to the Lagrangian problem will change its structure, but it may still be solvable rather easily. The cuts will be added to the set of easy constraints, and intuitively they will be useful only if the intersection NI (for "new intersection") of the relaxed polyhedron and of the new convex hull of the integer solutions of the kept constraints is smaller than the intersection OI (for "old intersection") of the relaxed polyhedron and of the old convex hull of the integer solutions of the kept constraints. This in turn is only possible if the new convex hull polyhedron is smaller than the old one, since the dualized constraints are the same in both cases.

Example 6. Consider again the GAP, and its weak Lagrangian relaxation in which the knapsack constraints (KP) are dualized. One could add to the remaining multiple choice constraints a surrogate constraint of the dualized constraints, for instance the sum of all knapsack constraints, which is obviously weaker than the original knapsack constraints. The Lagrangian problem does not decompose anymore, but its new structure is that of a multiple choice knapsack problem, which is usually easy to solve with specialized software, and much easier than the aggregate knapsack without multiple choice constraints. The above strengthening of the Lagrangian bound is simple, yet potentially powerful.

Lagrangian Heuristics and Branch-and-Price

Lagrangian relaxation provides bounds, but it also generates Lagrangian solutions. If a Lagrangian solution is feasible and satisfies complementary slackness (CS), one knows that it is an optimal solution of the IP problem. If it is feasible but CS does not hold, it is at least a feasible solution of the IP problem and one still has to determine, by BB or otherwise, whether it is optimal. Otherwise, Lagrangian relaxation generates infeasible integer **solutions**. Yet quite often these solutions are nearly feasible, as one got penalized for large constraints violations. There exists a very large body of literature dealing with possible ways of modifying existing infeasible Lagrangian solutions to make them feasible. Lagrangian heuristics are essentially problem dependent. Here are a few hints on how one may want to proceed. One may for instance try to get **feasible** solutions in the following way:

(1) by modifying the solution to correct its infeasibilities while keeping the objective function deterioration small.

Example: in production scheduling, if one relaxes the demand constraints, one may try to change production levels (down or up) so as to meet the demand (de Matta and Guignard 1994).

(2) by fixing (at 1 or 0) some of the meaningful decision variables according to their value in the current Lagrangian solution, and solving optimally

the remaining problem. Chajakis et al. (1996) called this generic approach the lazy Lagrangian heuristic. One guiding principle may be to fix variables that satisfy relaxed constraints.

Part of the success of Lagrangian relaxation comes from clever implementations of methods for solving the Lagrangian dual, with powerful heuristic imbedded at every iteration. In many cases, the remaining duality gap, i.e., the relative percentage gap between the best Lagrangian bound found and the best feasible solution found by heuristics is sufficiently small to forego enumeration. In some instances however an optimal or almost optimal solution is desired, and a Branch-and-Bound scheme adapted to replace LP bounds by LR bounds can be used. If the Lagrangian dual is solved by column generation, the scheme is called Branch-and-Price, as new columns may need to be priced-out as one keeps branching see Desrosiers et al. 1984), (Barnhart et al., 1998). In that case, branching rules need to be carefully designed. The hope is that such schemes will converge faster than LP-based Branch-and-Bound, as bounds will normally be tighter and nodes may be pruned faster. The amount of work done at a node, though, may be substantially more than solving an LP.

Concluding Remarks

- Lagrangian relaxation is a powerful family of tools for solving approximately integer programming problems. It provides
  - stronger bounds than LP relaxation when the problem(s) don't have the Integrality Property.
  - good starting points for heuristic search.
- The availability of powerful interfaces (GAMS, AMPL, etc.) and of flexible IP packages makes it possible for the user to try various schemes and to implement and test them.
- As illustrated by the varied examples described in this paper, Lagrangian relaxation is very flexible. Often some reformulation is necessary for a really good scheme to appear.
- It is not necessary to have special structures embedded in a problem to try to use Lagrangian schemes. If it is possible to decompose the problem structurally into meaningful components and to split them through constraint dualization, possibly after having introduced new variable expressions, it is probably worth trying.
- Finally, solutions to one or more of the Lagrangian subproblems might lend themselves to Lagrangian heuristics, possibly followed by interchange heuristics, to obtain good feasible solutions.

Lagrangian relaxation bounds coupled with Lagrangian heuristics provide the analyst with brackets around the optimal integer value. These are usually much tighter than the brackets coming from LP-based bounds and heuristics

Lanchester Attrition

The concept of an explicit mathematical relationship between opposing military forces and casualty rates. The two classical laws are the linear law, that gives the casualty rate (derivative of force size with respect to time) of one side as a negative constant multiplied by the product of the two sides' force sizes, and the square law, which gives the casualty rate of one side as a negative constant multiplied by the opposing side's force size.

Lanchester's Equations

Joseph H. Engel
Bethesda, MD, USA

Introduction

Lanchester's equations are named for the Englishman, F.W. Lanchester, who formulated and presented them in 1914 in a series of articles contributed to the British journal, *Engineering*, which then were printed in toto in Lanchester (1916). More recent presentation of these results appeared in the 1946 Operations Evaluation Group Report No. 54, *Methods of Operations Research* by Philip M. Morse and George E. Kimball, which was published commercially by John Wiley and Sons (Morse and Kimball 1951). In addition, a reprint of the original 1916 Lanchester work, "Mathematics in Warfare," appeared in *The World of Mathematics*, Vol. 4, prepared by James R. Newman and published by Simon and Schuster in 1956.

The significance of these equations is that they represented possibly the first mathematical analysis of forces in combat, and served as the guiding light (for the U.S. and its allies) behind the development,

during and after World War II, of all two sided combat models, simulations, and other methods of calculating combat losses during a battle.

It appears that M. Osipov developed and published comparable equations in a Tsarist Russian military journal in 1915, perhaps independent of Lanchester's results. A translation of his work into English, prepared by Robert L. Helmbold and Allen S. Rehm, was printed in September 1991 by the U.S. Army Concepts Analysis Agency.

Lanchester's equations present a mathematical discussion of concepts such as the relative strengths of opposing forces in battle, the nature of the weapons, the importance of concentration, and their effects on casualties, and the outcome of the battle. His arguments are paraphrased here, preserving much of his original symbolism. The equations deal with ancient warfare and modern warfare.

Ancient Warfare

Lanchester explained that, because of the limited range of weapons in ancient warfare (like swords), the number of troops on one side of a battle (the Blue force) that are actively engaged in hand-to-hand combat on the combat front at any time during the battle must equal approximately the number of troops responding to them on the other side (the Red force). For this reason, one may assume that the rate at which casualties are produced is constant, because the number of troops actively engaged on each side is constant (until very near the end of the battle), and the rate c (>0), at which Blue combatants become casualties is a product of the fixed number of Red troops engaged and their average individual casualty producing effectiveness (dependent on the average strength of Red's weapons and the effectiveness of the Blue defenses). Similar results apply to k (>0), the Red casualty rate. The two casualty rates need not be the same, as the weapons and defenses of the two sides may differ.

If $b(t)$ is the number of effective Blue troops at time t after the battle has started and $r(t)$ is the number of effective Red troops, the following equations can be assumed to obtain:

$$db/dt = -c, dr/dt = -k. \tag{1}$$

The relationship between the sizes of the two forces may easily be ascertained by observing from (1) that

$$db/dr = c/k, \tag{2}$$

from which it can be deduced that

$$k[b(0) - b(t)] = c[r(0) - r(t)]. \tag{3}$$

In the above equations, $b(0)$ and $r(0)$ are assumed to be the initial (positive) sizes of the forces at time 0, the beginning of the battle, and the equations are valid only as long as $b(t)$ and $r(t)$ remain greater than zero. Assuming the combatants battle until all the troops on one side or the other are useless for combat, having become casualties, the battle ends at the earliest time when $b(t)$ or $r(t)$ becomes equal to zero. Thus, solving for r in (3) when b becomes 0 (or vice versa) yields: when

$$b(t) = 0, r(t) = [c^* r(0) - k^* b(0)]/c$$

and when

$$r(t) = 0, b(t) = [k^* b(0) - c^* r(0)]/k. \tag{4}$$

Thus, if $c^* r(0) > k^* b(0)$, the Red force wins the battle, while if $k^*\ b(0) > c^*\ b(0)$, the Blue force wins the battle. Summarizing these observations by designating the initial effectiveness of the Blue force to be $k^* b(0)$, and that of the Red force $c^* r(0)$, shows that the force with the larger initial effectiveness wins, while equal initial effectiveness ensures a draw.

It is also simple to return to the original differential equations of (1) and to solve them to determine the number of effective troops of either force as a linear function of time. This essentially completes Lanchester's modeling of ancient warfare.

Modern Warfare

Lanchester postulated that the major difference between modern and ancient warfare is the ability of modern weapons (such as rifles and, to a lesser degree bows and arrows, cross bows, etc.) to produce casualties at long range. As a result, the troops on one side of an engagement can, in principle, be fired upon by the entire opposing force. Consequently, assuming

that all of each of the troops on a side have the same (average) ability to produce casualties at a fixed rate, the combined casualty rate against a given side is proportional to the number of effective troops on the other side.

This leads directly to the following differential equations constituting Lanchester's model of modern warfare:

$$db/dt = -c^*r, dr/dt = -k^*b. \quad (5)$$

As in the ancient warfare case, the individual casualty producing rates, c and k, are assumed to be known constants for the duration of the battle.

Now combine these two equations (as was done in the ancient warfare case) and obtain

$$db/dr = (c^*r)/k^*b. \quad (6)$$

Equation (6) is solved to obtain the relationship between the numbers of effective forces on the two sides as the battle progresses. This leads to

$$k\left[b^2(0) - b^2\right] = c\left[r^2(0) - r^2\right]. \quad (7)$$

Since these equations are valid only when $b \geq 0$ and $r \geq 0$, observe, as in the ancient warfare case, that, with the battle ending when the losing side has been reduced through casualties to no effective troops, and the victor has a positive number of effective troops, the force with the larger initial effectiveness, [$k^*b^2(0)$ for Blue and $c^*r^2(0)$ for Red], will win the battle, while equal initial effectiveness produces a draw. Equation (7) and this paragraph constitute Lanchester's Square Law for his model of modern warfare.

Again, as in the ancient warfare case, it is possible to solve the initial differential equations in (5) to obtain the specific functions that describe the behavior of the side of either force as a function of time. These results also appear in Morse and Kimball, (1951), and this essentially completes Lanchester's modeling of modern warfare.

Extensions

In presenting his results, Lanchester used many techniques that are taken for granted in contemporary OR practice. He formulated clear assumptions about the operation of the system he was studying, derived the mathematical consequences of his assumptions, and discussed how variation of assumptions affected results. Consequently he was able to provide specific numerical insights into characteristics of the system that could be translated into useful ways of improving a system that operated in accordance with the specified assumptions.

It was possible for Lanchester to accomplish his mathematical modeling by using what is often referred to as the First Theorem of Operations Research:

> A function of the average equals the average of the function.

The above result applies only in very special circumstances; nevertheless, there are many cases in which use of this theorem allows deterministic results to be derived easily. Such results will usually provide a good approximation of average results occurring in reality. It is through this technique that various chemical formulas or formulas in the physical sciences pertaining to concepts such as temperature, thermodynamics, etc., were derived.

In those formulations, it is assumed that a group of many small objects moving at various speeds with a known average speed will function in the same manner as if all the objects moved at the same (average) speed. Similarly, in his warfare modeling, Lanchester assumed that the casualty producing rate of every one of the troops on one side of a battle was constant and equal to the average (per troop) casualty producing rate of the entire force, and the same is true of the troops on the other side.

The usefulness of Lanchester's work is primarily in its demonstration of the fact that it is possible to draw mathematical and numerical conclusions concerning the occurrence of casualties in certain battles that can be described, a priori, as conforming to certain specified assumptions concerning how the battle is conducted. From such an observation, it is possible to generalize and derive other models that conform to other sets of assumptions, so that a wider range of combat situations can be dealt with. This has led to all sorts of models that can be handled through generalizations of Lanchester's techniques.

The analyst can take into account other factors not specifically covered by Lanchester, such as addition or

withdrawal of troops in the course of an engagement. Movement of forces can be considered. Different weapons and defensive techniques can be studied.

Dispersing and hiding the troops on one side of a battle (as in guerrilla warfare) affects the rate at which they can be hit by the other side, which led Lanchester to present another differential equation for such a force. This leads to analyses in which one or the other or both forces engage in ancient, modern, or guerrilla warfare. There are nine kinds of battles that an analyst can deal with just by adding the consideration of the possibility of guerrilla warfare to his bag of tricks (Deitchman 1962).

Clearly there is a great deal of flexibility in deriving models involving the use of deterministic differential equations that predict specific average results. The probabilistic events that take place during the course of a battle can also be dealt with in comparatively simple cases as demonstrated by B.O. Koopman and described in Morse and Kimball (1951). Regrettably, the mathematics of probabilistic systems is frequently much more difficult than that of deterministic systems, and the need to recognize the existence of all sorts of complications in a battle, frequently leads to rather complicated and abstruse mathematics which can best be handled through the use of computers for the required numerical calculations.

The field of combat simulation is recognized as a direct descendant of the Lanchester approach. Of historic interest in this connection is the fact that Lt. Fiske of the U.S. Navy presented, in 1911, a model of warfare consisting of a salvo by salvo table that computed casualties on two sides of a battle. This material was brought to the attention of contemporary analysts by H.K. Weiss (1962).

Engel (1963) showed that the equations of the Fiske model were difference equations that became, in the limit as the time increment between successive salvos approached zero, identical to the Lanchester differential equations of modern warfare. In a sense, this validated the use of discrete time models that approximated combat models for computer calculations, allowing greater confidence on the part of the analyst that no great surprises would result from a use of such discrete time approximations of combat models.

A cautionary note must be sounded at this point. Before using whatever mathematical model the analyst may have derived in discussing any past or future battles, the analyst must be certain that the assumptions of the model on how the battle will be conducted and terminated pertain to the battle being analyzed. The analyst should be able to derive the appropriate values of any parameters (such as $b(0)$, $r(0)$, c and k) to be used in the Lanchester or other models believed to apply in the case under study. Thought experiments do not suffice. The analyst must examine data to determine whether the assumptions provide a valid description of the way the battle proceeds, and to ascertain from relevant combat and experimental data that the model's numerical values for the parameters are appropriate.

Validation of Equations

Lanchester did not provide any demonstration of the relevance of his models to any specific historic battles, although he did discuss examples from history in which he suggested that the results of certain tactical actions were consistent with results that could be derived from his models. A validation of Lanchester's modern warfare equations was first given by Engel (1954), based on an analysis of the Battle of Iwo Jima during World War II. The analysis showed that the daily casualties inflicted on the U.S. forces over the approximately forty days of the battle were consistent with Lanchester's model for modern warfare. Since that time, additional analyses of combat results and experiments have demonstrated that the values of various parameters can be estimated for use in specified combat situations, and that appropriate combat models can be used in conjunction with those parameter values to obtain results of interest to military planners and decision makers.

The modeling methodology pioneered by Lanchester in the field of combat casualty analysis has served as a most important guide for analysts of military problems. He showed how application of these techniques can be used in developing mathematical models of combat that can be applied in forecasting the results of hypothetical battles. This enables operations research analysts to predict outcomes of these battles, plan tactics and strategy, develop weapons requirements, determine force requirements, and otherwise assist planners and decision makers concerned with the effective use of military forces.

Laplace Transform

For any function $g(t)$ defined on $t \geq 0$ (e.g., a probability density), its Laplace transform is defined as $\int_0^\infty e^{-st} g(t)dt$, $\mathrm{Re}(s) > 0$.

Laplace-Stieltjes Transform

For any function $G(t)$ defined on $t \geq 0$ (e.g., a cumulative probability distribution function), its Laplace-Stieltjes transform (LST) is defined as $\int_0^\infty e^{-st} dG(t), \mathrm{Re}(s) > 0$. When the function $G(t)$ is differentiable, it follows that the LST is equivalent to the regular Laplace transform of the derivative, say $g(t) = dG(t)/dt$.

Large Deviations

In probability theory, the study of asymptotic tail behavior of sequences of probability distributions. For example, the probability that a sample mean exceeds a certain threshold decays exponentially to zero according to some rate function. Large deviations theory is used in stochastic simulation for more effectively estimating rarely occurring events.

Large-Scale Systems

James K. Ho
University of Illinois at Chicago, Chicago, IL, USA

Introduction

In OR/MS, large-scale systems refer to the methodology for the modeling and optimization of problems that, due to their size and information content, challenge the capability of existing solution technology (Lasdon 1970). There is no absolute measure to classify such problems. In any given computing environment, the cost-effectiveness of problem solving generally depends on the dimensions and the volume of data involved. As problems get larger, the cost tends to go up, lowering effectiveness. Even before the physical limits of the hardware or the numerical resolution of the software are exceeded, the effectiveness of the solution environment may have become unacceptable. Efforts to improve on any of the relative performance measures such as solution time, numerical accuracy, memory and other resource requirements, are subjects in the topic of large-scale systems. Since solving larger problems more effectively is also an obvious goal in all specializations of operations research, there are natural linkages and necessary overlaps with most other areas in the field (Nemhauser 1994).

All known methodology for large-scale systems can be viewed as the design of computational techniques to take advantage of various structural properties exhibited by both the problems and known solution algorithms (Koussoulas and Groumpos 1999). Broadly speaking, such special properties can be regarded as either micro-structures or macro-structures. Micro-structures are properties that are independent of permutations in the ordering of the variables and constraints in the problem. An example is sparsity in the constraint coefficients. Macro-structures are those that depend on such orderings. An example is the block structure of loosely coupled or dynamic systems.

Using Micro-Structures of Problems

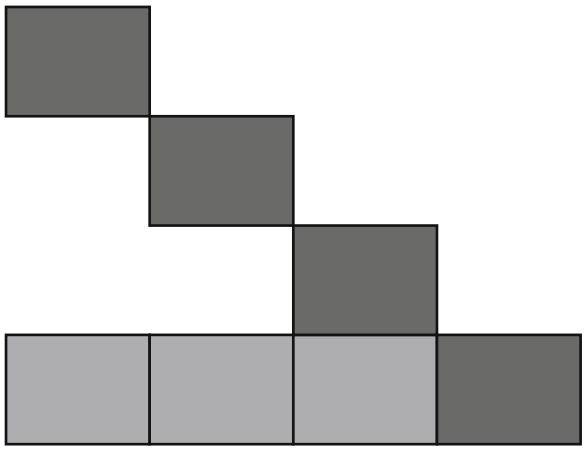
In the modeling of real systems, the larger the problem, the less likely it is for a variable to interact with all the others. If each variable is coupled only to a small subset of the total, the resulting constraints will be sparse. Techniques that eliminate the representation of the nonexistent interactions can reduce storage requirement significantly. For example, a linear program with 10,000 variables and 10,000 constraints has potentially 10^8 coefficients. If on the average, each variable appears in 10 constraints, there will be only 10^5 nonzero coefficients, implying a density of 0.1%. Sparse matrix methods from numerical analysis have been used with great success here. Furthermore, the nonzero coefficients may come from an even smaller pool of unique values. This feature is known as supersparsity and allows additional economy in data storage. Large, complex models are usually generated systematically by applying the logic of the problem iteratively over myriad parameter sets. This may lead to formulations with redundant variables and constraints. Examples include flow balance equations that produce a redundant constraint when total input equals total output; lower and upper bounds that are equal imply the variable can be fixed. Methods to simplify the problem by identifying and removing such redundancies are incorporated into the procedure of preprocessing. It is not unusual to observe reductions of problem dimensions by 10 to 50% with this approach.

Using Micro-Structures of Algorithms

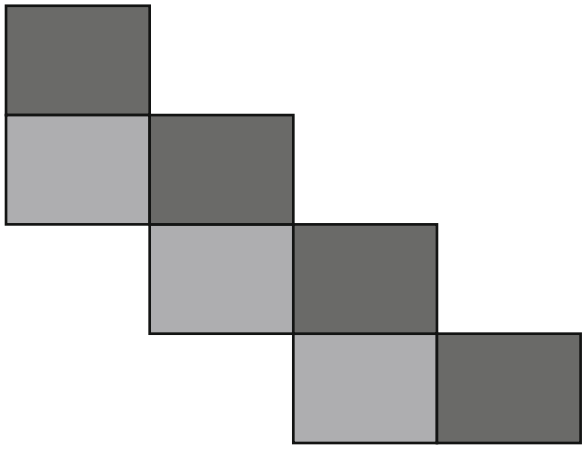
Algorithms may have steps that are adaptable to advanced computing architecture at the micro-processing level. An example is the vectorization of inner-product calculations in the simplex method. A completely different exploit is the relatively low number of iterations required by interior-point methods. As the number of iterations seems to grow rather slowly with problem size, it is a micro-structure of such algorithms that automatically sheds light on the optimization of large-scale systems. Yet another promising approach that falls under this heading is the use of sampling techniques in stochastic optimization.

Using Macro-Structures of Problems

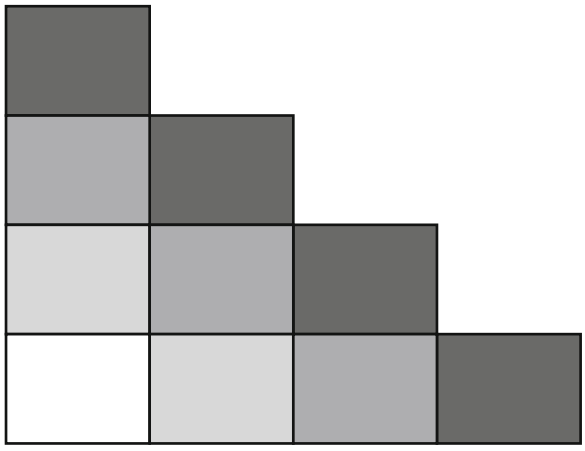
Most large-scale systems are comprised of interacting subsystems. Examples are multidivisional firms with a headquarters coordinating the activities of the semi-autonomous divisions; time-phased models of dynamic systems with linkages only among adjacent time periods; capital investment or financial planning models with each period linked to all subsequent periods. Linear programming modeling of the above examples gives rise to problems with the block-angular, staircase and block-triangular structures, respectively (Figs. 1, 2, and 3). Other variations and combinations are also possible. Two major approaches to take advantage of such structures are decomposition and factorization. Decomposition relies on algorithms that transform the problem into a sequence of smaller subproblems that can be solved independently. Various schemes are devised to coordinate the subproblems and steer them towards the overall solution. Many algorithms are derived from the Dantzig-Wolfe decomposition principle which provides a rigorous framework for this approach. Factorization is the adaptation of existing algorithms to take advantage of the problem structure. In the case of the simplex method, the representation of the basis matrix required at each step can be partitioned into blocks and updated separately. It has been shown that all of the simplex-based techniques proposed over the years under somewhat confusing guises



Large-Scale Systems, Fig. 1 Block-angular structure



Large-Scale Systems, Fig. 2 Staircase structure



Large-Scale Systems, Fig. 3 Block-triangular structure

of partitioning and decomposition are indeed special cases of the factorization approach (Dantzig et al. 1981).

Using Macro-Structures of Algorithms

Both decomposition and factorization algorithms are natural candidates for parallel and distributed computation since they involve the solution of independent subproblems. The latter can be solved concurrently on multiprocessor computers of various architectures. Particularly suitable is the class of Multiple-Instruction-Multiple-Data (MIND) machines that are essentially networks of processors that can execute independent instructions. They represent a cost-effective way to harness tremendous computing power from relatively modest and economical components. One processor can be programmed as the coordinator of the algorithmic procedures. Each of the other processors can be assigned a subproblem and programmed to communicate with the coordinating process. As the gain in overall efficiency is bounded by the number of processors used, the intent of this approach is to realize the full potential of certain algorithms rather than fundamentally enhancing their performance. It is, however, becoming an essential aspect of large-scale systems, as multi-processor computers are expected to be prevalent (Eckstein 1993). Early results have been obtained for decomposition (Ho and Sundarraj 1997), factorization (Ho and Sundarraj 1994), and barrier methods (Lustig and Rothberg 1996).

Concluding Remarks

Linear and mixed integer programming remain the primary focus in the optimization of large-scale systems. New computer architectures with ever-increasing processing power and memory capacities have facilitated the empirical approach to algorithmic development. Experimentation with large-scale problems becomes a viable strategy to identify, test, and fine tune ideas for improvement. This has been especially successful in commercial implementations of both the simplex and interior-point methods exploiting mainly the micro-structures of problems and algorithms. Problems with hundreds of

thousands of constraints and millions of variables are solvable on workstation-grade computers (Fourer 2009). Earlier experiences with macro-techniques in decomposition and factorization did not have the benefits of the more modern technological advances. The results are either inconclusive or less than promising (Ho 1987). Future work, especially in hybrid schemes using advanced hardware, may lead to significant contributions to large-scale non-linear, integer and stochastic optimization.

Learning

James R. Buck
The University of Iowa, Iowa City, IA, USA

Introduction

Learning is a human phenomenon where performance improves with experience. There are a number of reasons for task improvement. As tasks are repeated, elements of the task are: better remembered, cues are more clearly detected, skills are sharpened, eye-hand coordinations are more tightly coupled, transitions between successive tasks are smoothed, and relationships between task elements are discovered. Barnes and Amrine (1942), Knowles and Bell (1950), Hancock and Foulke (1966), Snoddy (1926), *and* Wickens (1992) have described these and other sources of human performance change. All these causes of individual person improvement manifest themselves in faster performance times, fewer errors, less effort, and there is often a better disposition of the person as a result.

Learning is implied by performance changes due primarily to experience. Changes in the methods of performing a task, replacing human activities with machines, imparting information about the job, training, acquiring performance changes with incentive systems, and many other things can cause performance changes other than learning. Thus, detection involves the identification of an improvement trend as a function of more experience. It also involves the elimination of other explanations for this improvement. Analogous to a theory, learning can never be proved; it can only be disproved.

After detecting learning, measurement and prediction follows. These activities involve fitting mathematical models, called learning curves, to performance data. First, there is the selection of an appropriate model. Following the selection of a model, there is the matter of fitting the selected model to performance data. In some cases alternative models are fit to available data and the quality of fit is a basis in the choice of a model.

Some of those sources which contribute to an individual person's improvement in performance with experience are similar to the causes of improvement by crews, teams, departments, companies, or even industries with experience. As a result, similar terms and descriptions of performance change are often fit to organizational performance changes. However, the term progress curves (Konz 1990) is more often applied to cases involving: assembly lines, crews, teams, departments, and other smaller groups of people, whereas the term experience curves is sometimes applied to larger organizational groups such as companies and industries (Hax and Majluf 1982). A principal distinction between these different types of improvement curves is that between-person activities (e.g., coordination) occur as well as within-person learning. In the case of progress curves, there are improvement effects due to numerous engineering changes. Experience curves also embody scientific and technological improvements, as well progressive engineering changes and individual-person learning. Regardless of the person, persons, or thing which improves or the causes of improvement, the same learning curve models are frequently applied. Progress and experience curves are really forms of personification.

Learning occurs in a number of important applications. One of these applications is the prediction of direct labor changes in production. Not only is this application important to cost estimation, it is also important in production planning and manning decisions. Another application is the selection of an operational method. If there are alternative methods of performing particular operations which are needed, then one significant criterion in the selection of an appropriate method is learning because the average cost can favor one method over another that has lower initial performance costs. In other cases, one operation can cause bottlenecks in others unless the improvements with experience are sufficient over time. Also, production errors can be shown to decrease with experience as another form of learning and so learning is important in quality engineering and control.

Performance Criteria and Experience Units

Performance time is the most common criterion used for learning curves in industry. Production cycles are also the most commonly used variable for denoting experience. If t_i is the performance time on the ith cycle, then a learning curve should predict t_i as a function of n cycles. Since learning implies improvement with experience, then one would expect $t_i \leq t_{i-1}$ for the typical case, $i = 1, 2, \ldots, n$ cycles.

An associated time criterion on the ith cycle is the cumulative average performance time on the ith cycle or A_i. Cumulative average times consists of the sum of all performance times up to and including the nth cycle divided by n. In the first cycle, $A_1 = t_1$. With learning, t_i tends to decrease with i and so does A_i. However, A_i decreases at a slower rate than t_i. This effect can be shown by the first-forward difference of A_i, which is

$$\Delta A_n = A_{n+1} - A_n = \frac{\sum_{i=1}^{n+1} t_i}{n+1} - \frac{\sum_{i=1}^{n} t_i}{n} = \frac{t_{n+1} - A_n}{n+1}. \quad (1)$$

So long as t_{n+1} is less than A_n, then ΔA_n is negative and the cumulative average time continues to decrease. It is also noted in (1) that with sequential values of A_i for $i = 1, 2, \ldots, n$, the values of t_i can be found. On the other hand, A_i can be predicted directly rather than t_i.

Another criterion of interest is accuracy. However, it is usually easier to measure errors in production as the complement of accuracy. Thus, the sequence of production errors are $e_1, e_2, \ldots, e_i, \ldots, e_n$ over n serial cycles where e_i is the number of errors found in a product unit as in typing errors per page (Hutchings and Towill 1975). If the person is doing a single operation on a product unit, then either an error is observed with a unit of production or it is not and observations over a production sequence is a series of zeros and ones. A more understandable practice is to define e_i as the fraction of the possible errors, where the observed number of errors is divided by the m possible

errors at an operation (Fitts 1966; Pew 1969). In this way, e_i is 0, some proper fraction, or 1. It also follows that a learning curve could be fit to the series of e_i values over the n observations sequential units of production or to the cumulative average errors. If learning is present, then one would expect to see a general decrease in e_i with increases in $i = 1, 2, \ldots, n$ and also the cumulative average errors would similarly decrease, but with a rate lag compared to the serial errors.

Pew (1969) invented the speed-accuracy-operating-characteristic graph which provides simultaneous analyses of correlated criteria. This operating characteristic consists of a bivariate graph where one axis denotes performance time per unit (complement is the speed) and the other axis denotes the number of errors per unit (complement is the accuracy). Simultaneous plots of speeds and accuracies with experience would be expected to show increases in both criteria with more experience. The slope of these plots with increases of experience describes bias between these criteria. It should be noted that when the power-form model is used for a prediction of learning performance, then logarithmic axes' measurements will linearize the plots.

Other Learning Metrics

Most applications of learning description, usually known as learning curves, use the production units as experience units, either as single units or lots. The time required to produce that product unit is the corresponding performance units. An alternative approach to predicting learning effects is to describe cumulative time as the experience unit (i.e., hours or days) and the number of production units produced during that experience unit. Thus, for cumulative production time $t = 1, 2, 3, \ldots, k, \ldots, m$ and corresponding production of $n_1, n_2, n_3, \ldots, n_k, \ldots, n_m$. Most learning curve models merely relate n_k to k. An alternative model of learning, which is not often shown, is the discrete exponential model which relates pairs of n_k values as

$$n_k = an_1 + b \tag{2}$$

where a and b are parameters. This model was originally proposed by Pegels (1969) for startup cost prediction. Later, Buck, Tanchoco, and Sweet (1976) showed that this model was really a first-order for-ward-difference equation (Goldberg 1961). It follows in this model that

$$n_k = a^k[n_1 - n^*] + n^* \tag{3}$$

where $n^* = b/(1 - a) > n_1$ and $0 < a < 1$. Since the parameter a is a fraction, the first term of (3) approaches zero with increasing k and so n^* is the asymptote. Accordingly, n_k approaches n^* exponentially with each discrete unit of time. Bevis et al. (1970) provided a similar model as

$$n_k = n^* + [n_1 - n^*]e^{-ck} \tag{4}$$

where k is a continuous measure to time and c is a parameter. Buck and Cheng (1993) used the discrete form in traditional format, but they showed that this model can be more difficult to fit to data than the more common power-form model. It can, however, give a more accurate description of human learning.

Learning Curves

Andrew G. Loerch
Center for Army Analysis, Fort Belvoir, VA, USA

Introduction

With experience and training, individuals and organizations learn to perform tasks more efficiently, reducing the time required to produce a unit of output. This simple and intuitive concept is expressed mathematically through the use of the learning curve.

The learning curve was introduced in the literature by Wright (1936) who observed the learning phenomenon through his study of the construction of aircraft prior to World War II. Since then, these models have been used in the areas of work measurement, job design, capacity planning, and cost estimation in many industries. Yelle (1979) summarized 90 articles dealing with learning curves. Dutton et al. (1984) traced the history of progress functions by examining 300 articles. They note that the terms learning curve, progress function, and experience curve are often used interchangeably. However, many authors differentiate between them in the following way. Learning curves are used to describe only direct-labor learning, while progress functions also incorporate learning by managerial and technical personnel, as well as improvements due to technological change. The term experience curve is used to describe learning or progress at the industry level. Experience curves often use price as a surrogate measure for progress or learning. In the discussion below, no distinctions are made between these terms.

Dutton et al. (1984) also noted that learning curves are frequently confused with economies of scale. Although they are observed together in many cases, the two are separate effects with different causes. Progress and learning can occur in the absence of changes in size or scale of operations.

Basic learning-curve theory is described below, with emphasis given to the so-called power model. Other models are then introduced. Finally, issues regarding the estimation of learning-curve parameters are presented.

The Power Model

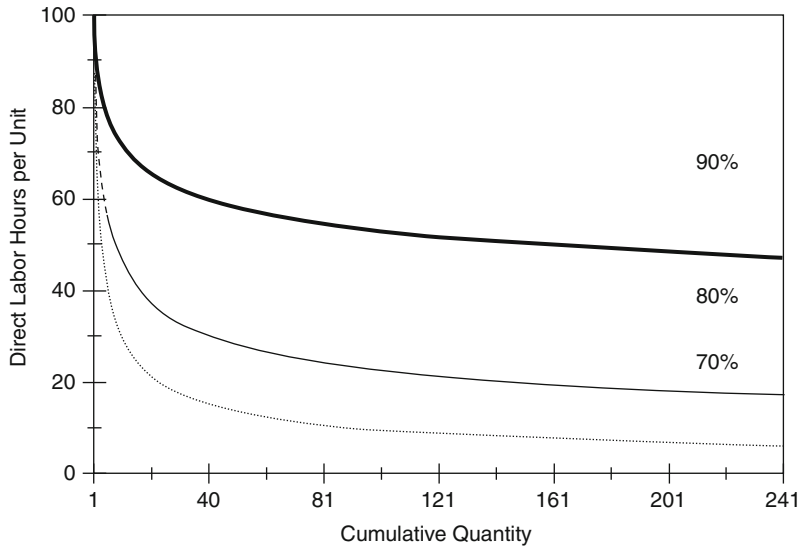
Also known as the log-linear model, the power model is the most frequently encountered implementation of the various learning-curve models. Wright observed that as the quantity of units manufactured doubles, the number of direct labor hours it takes to produce an individual unit decreases at a uniform rate. So, after one doubling of the cumulative production, direct-labor hours may have declined to, say 80% of its previous value. After an additional doubling there is another decline to 80% of that value, or 64% of the original. The learning rate, which is the actual decline per doubling, 80% in the above example, is assumed to be a characteristic of each particular type of manufacturing process.

In this model, learning curves have the following mathematical form:

$$L(y) = Ay^b,$$

where $L(y)$ = the number of hours needed to produce the yth unit, A = the number of hours needed to produce the first unit, y = the cumulative unit number, and b = the learning index, the learning-curve parameter, or the learning-curve slope parameter. To account for the effect of doubling, the learning-curve index is computed as follows:

$$b = (\log r)/(\log 2),$$



Learning Curves, Fig. 1 Learning curves with different rates

where r is the learning rate. Figure 1 shows graphs of three such curves with different learning rates.

Note that this model is also applicable to cost in addition to direct-labor hours. In a cost application, the parameter A would represent the cost of the first unit produced. The use of learning-curve costing is complicated by the problem of accounting for inflation and the change in hourly wages over time. In any event, labor hours can be easily converted into cost.

In the above model, the number of direct-labor hours required to produce the yth unit, or the cost of producing the yth unit is computed. Thus, the model is referred to as the Unit Formulation, and it is attributed to James Crawford who introduced its use to the Lockheed Corporation in 1944 (Smith 1989). A related model based on the original work of Wright is the so-called Cumulative Formulation, where, in the above notation, $L(y)$ would represent the average labor hours or cost of all the units produced through the yth unit. Note that the cumulative formulation tends to smooth the effects of unusually high or low labor hours or costs for individual or groups of units, and it has been found to be more useful for application to batch-type production processes. Although much of the work on learning curves has been directed at specifying the functional relation between unit costs or direct-labor hours and cumulative output, the range of output measures has been expanded to include, for example, industrial accidents per unit output, defects and complaints to quality control per unit output, and service requirements during warranty periods.

Variations of the Power Model

While the log-linear model has been, and is the most widely used model, several other geometries have been found to provide a better fits in particular sets of circumstances. Some of the more well-known models are:

1. Plateau model,
2. Stanford-B model, and
3. S-model.

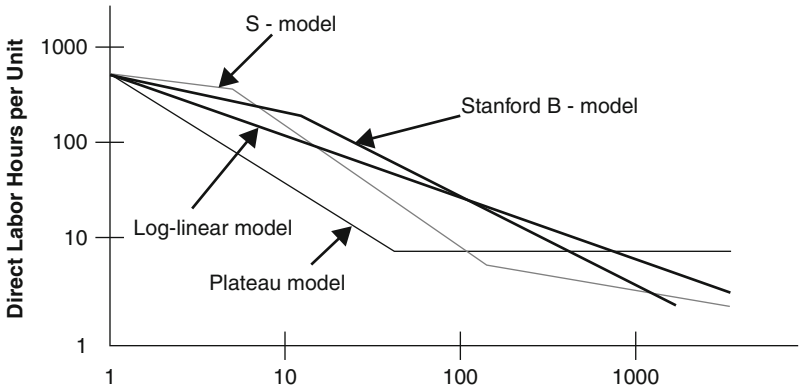
Figure 2 depicts these models on a logarithmic scale.

The plateau model was first described by Conway and Schultz (1959). It is used to represent the phenomenon that the learning phase of a process is finite and is followed by a steady state phase. This model is often associated with machine-intensive manufacturing.

The Stanford-B model, expressed symbolically as

$$L(y) = A(B + y)^b,$$

represents a process that experiences accelerated learning after B units are produced (other notation as



Learning Curves, Fig. 2 Log-log plot of learning curve geometrics

previously defined). This model was developed at the Stanford Research Institute and is useful for processes with design changes (Garg and Milliman 1961).

The *S*-model, described by Cochran (1960), combines reduced learning at the outset of production, with another slackening of learning later in the production process. This model is usually approximated as a three-segment straight line on a log-log graph and is sometimes used for heavy labor-intensive industries.

The choice of the appropriate model is usually based on empirical studies of the process in question and historical experience with similar processes. The utilization of these more complex representations involves increased difficulty in parameter estimation, coupled with limited improvement in accuracy. As such, the basic log-linear model continues to find favor among practitioners.

Other Factors Affecting Learning

Frequently, other factors affect production that, if ignored, could bias the estimation of the rate of learning. As mentioned, the presence of economies of scale would result in the situation where a more than proportional increase in output would be obtained due to an increase in inputs. If the effects of this variable are not controlled for in the estimation of learning rates, and the scale of the operation is gradually increased over time, the amount of learning would be overestimated. Other such factors that are independent of direct labor learning include increased capital investment, multiple shifts, time lapses between performance of operations, and production rate. Argote and Epple (1990) provided a review of the literature regarding the incorporation of factors that affect learning.

Estimation of Learning-Curve Parameters

Most estimation schemes rely on the logarithmic representation of the learning curve, written as follows:

$$\log L = \log A + \log y.$$

The learning-curve parameters, A and b, are estimated either by plotting historical values on a log-log graph and visually fitting a line, or by computing the least squares regression line through the log-log data. Several computer programs are commercially available to estimate the learning-curve parameters.

Frequently, organizations collect historical data for batches or lots, as opposed to discrete units. To estimate the parameters in this case, the batch's average labor or cost and the unit whose labor or cost corresponds to that average, the lot midpoint, must be known. The logarithm of this value is then used as the independent variable in the regression with the log of the average unit cost of the lot as the dependent variable. Note that the unit expressed by the batch size divided by two is not the lot midpoint since the learning curve is nonlinear. The actual lot midpoint, Q, is represented as the following:

$$Q = \left[\frac{(y_l - y_f + 1)(1+b)}{(y_l + .5)^{1+b} - (y_f - .5)^{1+b}}\right]^{-1/b},$$

where $y_f =$ the first unit of the batch, and $y_l =$ the last unit of the batch. Observe that this value cannot be computed without first knowing the learning-curve index, b. As such, the approximate algebraic lot midpoint is used. This value is computed by:

$$Q = \frac{y_f + y_l + 2\sqrt{y_f y_l}}{4}$$

The learning-curve parameters are estimated first using the approximate value of Q for each lot. The value of b is then used to calculate the actual lot midpoint, and the parameters are estimated again, and then iterated until the desired accuracy is obtained.

Concluding Remarks

Research in the area of learning curves has been extensive and many models have been hypothesized to describe the learning process. Learning-curve models have proven to be useful tools in many business and government applications. These include cost estimation, bid preparation and evaluation, labor requirement estimation, establishment of work standards, and financial planning.

Level Crossing Methods

Percy H. Brill
University of Windsor, Windsor, Ontario, Canada

Introduction

Level crossing methods for obtaining probability distributions in stochastic models such as queues and inventories were originated by Brill (1975, 1976, 1979) and elucidated further in Brill and Posner (1974, 1975, 1977, 1981), and Cohen (1976, 1977). These methods began as an essential part of system point theory and are also known as system point analysis, sample path analysis, or level crossing technique, approach, theory, or analysis in the literature (Brill 1975, 2008). Level crossing methods are very useful rate conservation techniques for stochastic models (Miyazawa 1994).

Model and Stationary Distribution

Consider a stochastic process $\{W(t), t \geq 0\}$ where both the parameter set and state space are continuous. The random variable $W(t)$ at time point t may denote the content of a dam with general efflux, the stock on hand in an (s,S) or (r,nQ) inventory system with stock decay, or the virtual wait or workload in a queue. Assume that upward jumps of $\{W(t)\}$ occur at Poisson rate λ_u and downward jumps at Poisson rate λ_d. Let upward and downward jump magnitudes have cumulative distribution function (CDF) B_u and B_d, respectively. Assume that the model parameters are such that the stationary distribution of $W(t)$ exists as $t \to \infty$. Let G and g denote the stationary CDF and probability density function (PDF), respectively. The aim here is to obtain expressions for g and G in terms of the model parameters by using a level crossing approach.

Sample Paths

A sample path of the $\{W(t)\}$ process is a right-continuous, real-valued function on the nonnegative reals whose value at time-point t is the realized value of random variable $W(t)$. Denote an arbitrary sample path by the function $X(t)$, $t \geq 0$. The function X has either jump or removable discontinuities on a sequence of strictly increasing time points $\{\tau_n, n = 0, 1, \ldots\}$, where $\tau_0 = 0$ without loss of generality. Typically, the time points $\{\tau_n\}$ represent input or output epochs in dams, arrival epochs in queues, or demand or replenishment epochs in inventories. Assume that when a sample path is positive valued, it decreases continuously on time segments between jump points, described by $dX(t)/dt = -rX(t), X(t) > 0, \tau_n \leq t < \tau_{n+1}$, $n = 0, 1, 2, \ldots$ wherever the derivative exists, and where $r(x) > 0$ for $x > 0$. Note that for the virtual wait process in queues, $r(x) = 1(x > 0)$ and $r(0) = 0$. In an (s,S) continuous review inventory system, where the stock on hand decays at constant rate k, then $r(x) = k$ for all x between the reorder level s and order-up-to-level S.

Level Crossing by Sample Paths

Let x denote a fixed state space level and t_0 an arbitrary positive time point. Let t_0 be one of the jump time points $\{\tau_n\}$, $n = 1, 2, \ldots$ and let d_0 and u_0 denote the corresponding downward and upward jump magnitudes, respectively, where at least one of u_0, d_0, is strictly positive. The sample path may down cross level x at $t_0 > 0$ if t_0 is any positive epoch, but it can up cross level x at t_0 only if t_0 is one of the $\{\tau_n\}$.

If a sample path down crosses level x at t_0 which is not one of the $\{\tau_n\}$, then the down crossing is a continuous down crossing, since the sample path is continuous at t_0. If a sample path down crosses level x at t_0 which is one of the $\{\tau_n\}$, then the downward jump of magnitude d_0 brings it from above x to a level below x. If a sample path up crosses level x at t_0, then, necessarily, t_0 is one of the epochs $\{\tau_n\}$, and the upward jump of magnitude u_0 brings it from below x to a level above x.

If both u_0 and d_0 are strictly positive at t_0 which is one of the $\{\tau_n\}$, the model mechanism would determine whether the downward or upward jump is considered to precede the other. In inventories without lead time, for example, stock depletions due to demands (downward jumps) precede stock replenishments (upward jumps). The jumps are not part of the sample path per se, but serve only to construct the path. One may also define level crossings at some time point t_0 by considering the net jump which has magnitude $|u_0 - d_0|$ and upward (downward) direction if $u_0 > d_0 (u_0 < d_0)$.

Level Crossings and the Stationary Distribution

Down crossings — Let $D^u_{ct}(x)$ denote the number of continuous down crossings of level x and $D^j_t(x)$, the number of jump down crossings of level x during $(0, t)$, $t > 0$. Then, for $r(x) = 1, x > 0$ and $r(0) = 0$, it follows with probability 1 that

$$\lim_{t\to\infty} \frac{D^c_t(x)}{t} = r(x)g(x) \quad (\text{for all } x), \tag{1}$$

(Brill 1975). The following also holds with probability 1:

$$\lim_{t\to\infty} \frac{D^j_t(x)}{t} = \lambda_d \int_{y=x}^{\infty} \bar{B}_d(y-x) g_d(y) dy \quad (\text{for all } x), \tag{2}$$

where g_{od} is the limiting PDF at embedded downward jump points as $t \to \infty$ and $\bar{B} \equiv 1 - B$.

Both Eqs. 1 and 2 also hold upon replacing $D^u_{ct}(x)$ and $D^u_{ty}(x)$ by their expectations, denoted by $E[D^c_t(x)]$ and $E[D^u_{ty}(x)]$, respectively, and deleting with probability 1. For exponentially distributed interarrivals between downward jumps (Poisson downward jumps), then $g_d \equiv g$, which is the *PASTA* principle.

Up crossings —Let $U^j_t(x)$ denote the number of jump up crossings of level x during $(0, t)$. Then, with probability 1,

$$\lim_{t\to\infty} \frac{U^j_t(x)}{t} = \lambda_u \int_{-\infty}^{x} \bar{B}_u(x-y) g_u(y) dy \qquad (\text{for all x}), \tag{3}$$

where g_u is the limiting PDF at embedded upward-jump time points as $t \to \infty$ (Brill 1975).

Formula (3) gives an expression for the long-run up crossing rate of level x by any typical sample path at upward jump points, in terms of an integral of the density g_u. For Poisson upward jumps, $g_u \equiv g$ by the PASTA principle.

A Conservation Law for Level Crossings

For each state space level, the following conservation law holds:

long run total down crossing rate = long run total up crossing rate.

This conservation law, together with Eqs. 1, 2 and 3, enables one to write an integral equation for the PDF g in which every term has a precise interpretation as a sample-path down or up crossing rate, namely,

$$r(x)g(x) + \lambda_d \int_{y=x}^{\infty} \bar{B}_d(y-x) g(y) dy = \lambda_u \int_{y=-\infty}^{x} \bar{B}_u(x-y) g(y) dy \qquad (\text{for all } x). \tag{4}$$

In (4), the left-hand side depicts the total sample path long-run down crossing rate of level x, while the right-hand side depicts the long-run up crossing rate of the level x. Equation (4) is then solved for g by using standard applied mathematics techniques.

Applicability

The level crossing technique is applicable to dams with limited capacity, blocked-input rules, various control level policies, etc.; to complex variants of M/G/1, M/M/c, G/M/1 queues with reneging, bounded virtual wait, server vacations, various state dependencies, cyclic-service queues; and to a wide class of inventory, production/inventory, counter, risk reserve, and related models.

The same level crossing ideas as in Eqs. 1, 2 and 3 have been applied to cycles in regenerative processes by Cohen (1976, 1977). Upon combining the regenerative-processes level crossing approach and the embedded level crossing technique of Brill (1976, 1979) with the previously widely known bubble diagram method (rate into a state = rate out of that state) for discrete state continuous time Markov chains, level crossing methods can be applied to obtain probability distributions and other characteristics in a broad class of stochastic models.

Level Crossing Estimation

The principle established in formula (1) motivates the idea of using $D^c_t(x)/[tr(x)]$ as an estimate for $g(x)$ when t is large. Level crossing estimation (also known as system point estimation) consists of three main steps: (I) simulating a single sample path over a large simulated time t; (ii) enumerating the continuous down crossings of all state space levels over $(0, t)$; and (iii) computing both point and interval estimates of g, G and the moments (Brill 1991).

► Isoquant

Lexicographic Ordering

An ordering of a set of vectors based on the lexicopositive (negative) properties of the vectors. For example, the sequence of vectors $\{\boldsymbol{x}_1,\ldots,\boldsymbol{x}_q\}$ is ordered in a lexicographic sense if $\boldsymbol{x}_i - \boldsymbol{x}_j$ is lexico-positive for $i > j$. Such orderings are similar to dictionary ordering of words and are used to prove finiteness of the simplex algorithm.

See

► Cycling
► Lexico-Positive (Negative) Vector

Lexico-Positive (Negative) Vector

A vector $\boldsymbol{x} = (x_1,\ldots, x_n)$ is called lexico-positive (negative) if $\boldsymbol{x} \neq 0$ and the first nonzero term is positive (negative). The vector $\boldsymbol{x}$ is lexico-negative if $-\boldsymbol{x}$ is lexico-positive. A vector $\boldsymbol{x}$ is greater than a vector $\boldsymbol{y}$ in a lexico-positive sense if $\boldsymbol{x} - \boldsymbol{y}$ is lexico-positive.

Libraries

Arnold Reisman[1] and Xiaomei Xu[2]
[1]Reisman and Associates, Shaker Heights, OH, USA
[2]Cleveland, OH, USA

The American Heritage Dictionary of the English Language (1976, p. 753) defines a library is

"a repository for literary and artistic materials such as books, periodicals, newspapers, pamphlets, and prints kept for reading or reference." This rather classical notion of a library does not recognize the fact that libraries are now a subset of the broader field known as Information Systems (IS). Nevertheless, the scope of this article will be delimited to institutions which can be defined as above, albeit with some leeway.

The history of the application of operations research/management science to libraries is not very distinguished. Contributions in the library field were constrained up to and through the decade of the 1970s by the fact that few operations researchers chose libraries as a field of interest. Moreover, librarians have not sought out operations researchers to help in their problem solving, nor did they offer a particularly fertile environment for doing OR studies (Chen 1974). On the other hand, since the 1970s, computer science has made significant inroads into the library field by merging with library science to create local and extended area computer networks linking users with comprehensive databases.

The first known application of OR to libraries in the United States can be credited to Bacon and Machol (1958). The 1960s recorded a more widespread interest (Cox 1964; Morse 1968; Cook 1968). A comprehensive review on library operations research was done by Kantor (1979). In that review, Kantor summarized all of the previous review articles. Most noteworthy of these from the OR point of view are the bibliographies by Slamecka (1972) and Kraft and McDonald (1977), and surveys and/or assessments by Bommer (1975), Kraft and McDonald (1976), Leimkuhler (1970, 1972, 1977a, 1977b), Churchman (1972) and Morse (1972).

Literature on utilization of OR in libraries has classified the field in several different ways. Kantor (1979) classified papers and projects into the following groups according to the purpose of the research: system description; modeling the system; parameter identification; optimization or multi-valuation; and application. Rowley and Rowley (1981) classified the work by the nature of the research (recurrent problems, on/off decisions, etc.). For the purposes of this article, a three-dimensional classification is used with one of the dimensions adopting Rowley's (1981) classification, with slight modifications. Based on the type of problems being analyzed, the application areas are operational or recurrent problems, such as book storage problems; strategies or on/off decisions, such as library location problems; and control/design problems, such as loan policy problems (Rowley and Rowley 1981).

The second dimension on the application of OR in libraries is a classification according to the type of OR techniques used:

1. *Queueing models* – Given the average book circulation time ($1/\mu$) and the mean number of persons who borrow the book (λ), the expected circulation rate of that particular book is derived using queueing theory (Morse 1968).
2. *Simulation* – With the number of staff, the volumes of various jobs (users' requests, new issues, overdue fees, etc.) and the job processing times specified, simulation is used to estimate the delays, processing times and utilization of each member of staff and the whole facility (Thomas and Robertson 1975).
3. *Facility location algorithms* – The library facilities and relocation problems are discussed by Min (1988).
4. *Mathematical programming* – If there are two types of information services, both of which share the same set of resources (staff time in scanning, indexing, abstracting, etc.), and each of them has a different unit profit, a linear programming problem is used to find out how many services of each type to produce to maximize the total profit (Rowley and Rowley 1981, *58–64*).
5. *Network flow models* – Given the heights and thicknesses of a given collection of books and the cost of different shelf heights, a network model is developed to determine the optimal number of shelf heights for minimizing shelving costs through finding the shortest path in a directed network (Gupta and Ravindram 1974).
6. *Decision theory* – A decision regarding whether or not to install a library security system is addressed given the installation cost and the probabilities of success and failure (Rowley and Rowley 1981, 91–92).
7. *Search theory* – Patterns of browsing in libraries are addressed in Morse (1970).
8. *Transportation models* – A routing problem is explored for a vehicle delivering materials to branches (Heinritz and Hsiao 1969; McClure 1977).

9. *Inventory control theory* – An EOQ model is used to determine the optimal order quantity for the stock of a certain library supply (Rowley and Rowley 1981, 111–116).
10. *Probability and statistics* – Library book circulation and individual book popularities are considered as probabilistic processes by Gelman and Sichel (1987) who demonstrated the superiority of beta over the negative binomial distribution.
11. *Benefit cost analysis* – Library planning is addressed by Leimkuhler and Cooper (1971).

Each of these categories could be, in turn, further characterized by whether or not the research work was grounded, e.g., based on real world library systems involving real data and/or bona fide librarians in the study as opposed to models which were basically what might be called logico/deductive. A more thorough discussion is given in Reisman and Xu (1994), where Table I, page 37, provides a taxonomic review of the vast bulk of the literature in the field.

As can be seen from the above delineation and the referenced table, the utilization of OR in libraries is far from achieving its full potential. Except for simulation and probability and statistics based applications, the bulk of the literature is not well grounded in real life settings. The literature reflects the gap between the complex mathematical models in OR and the usually not very quantitatively educated library workers (Stueart and Moran 1987). To enhance the application of OR in libraries, Bommer (1975) suggested a closer working relationship between operations researchers and library managers.

LIFO

The Last-In, First-Out queue discipline in which customers are selected for service in reverse order of their arrival (meant to be equivalent to the last-come, first-served scheme).

See

- LCFS
- Queueing Theory

Light-Tailed Distribution

A probability distribution that has an exponentially decaying complementary CDF, e.g., the normal (Gaussian) and exponential distributions.

See

- Heavy-Tailed Distribution

Likelihood Ratio Method

A method for gradient estimation in simulation used for sensitivity analysis and optimization; also known as the score function method.

See

- Perturbation Analysis
- Score Functions
- Simulation Optimization

Limiting Distribution

Let $p_{ij}(t)$ be the probability that a stochastic process takes on value j at time t (discrete or continuous), given that it began at time 0 from state i. If for each j, $p_{ij}(t)$ approaches a limit p_j as $t \to \infty$ independent of i, the set $\{p_j\}$ is called the limiting or steady-state distribution of the process. For Markov chains in discrete time, the existence of a limiting distribution implies that there is a stationary (or invariant) distribution found from $\boldsymbol{\pi} = \boldsymbol{\pi P}$, where $\boldsymbol{P}$ is the single-step transition matrix, such that $\boldsymbol{\pi} = \boldsymbol{p}$. Similarly, for continuous-time chains, the steady-state distribution is the probability vector satisfying the global balance equations $\boldsymbol{\pi Q} = \boldsymbol{0}$, where $\boldsymbol{Q}$ is the transition rate matrix.

See

- Markov Chains
- Markov Processes
- Stationary Distribution
- Statistical Equilibrium

Lindley's Equation

An integral equation for the steady-state waiting-time distribution in the first-come, first-served, single-server G/G/1 queue. If $W_q(x)$, $x \geq 0$, is the

steady-state distribution function of the delay or waiting time in the queue, then, for $x \geq 0$,

$$W_q(x) = \int_{-\infty}^{x} W_q(x-y)dU(y)$$

with $W_q(x) = 0$ for $x < 0$, where the function $U(y)$ is the distribution function of the random variable defined as the service time minus the interarrival time.

Lindley's equation can also be used to refer to the finite-time transient recursive equation relating delays in the first-come, first-served, single-server G/G/1 queue as follows:

$$D_{n+1} = \max(0, D_n + S_n - A_n),$$

where D_n is the delay of the nth arriving customer, S_n is the service time of the nth arriving customer, and A_n is the interarrival time between the nth and $(n + 1)$st arriving customer.

- ▶ Queueing Theory

Line

A line is the set of points $\{x|x = (1-\lambda)x_1 + \lambda x_2\}$, where x_1 and x_2 are points in n-dimensional space and λ is a real number. The line passes through the points x_1 and x_2, $x_1 \neq x_2$.

Line Segment

The straight line joining any two points in n-dimensional real space is a line segment. More specifically, if x_1 and x_2 are the two points, then the set of points $\{x|x = (1-\lambda)x_1 + \lambda x_2, 0 \leq \lambda \leq 1\}$ is the line segment joining x_1 and x_2.

See

- ▶ Line

Linear Combination

For a set of vectors $(\boldsymbol{x}_1, \ldots, \boldsymbol{x}_n)$, a linear combination is another vector $\boldsymbol{y} = \sum_j \alpha_j \boldsymbol{x}_j$, where the scalar coefficients α_j can take on any values.

Linear Equation

The mathematical form $a_1x_1 + a_2x_2 + \ldots + a_nx_n = b$ is a linear equation, where the a_j and b can take on any values.

See

- ▶ Hyperplane

Linear Functional

A linear functional $f(\boldsymbol{x})$ is a real-valued function defined on an n-dimensional vector space such that, for every vector $\boldsymbol{x} = \alpha\boldsymbol{u} + \beta\boldsymbol{v}$, $f(\boldsymbol{x}) = f(\alpha\boldsymbol{u} + \beta\boldsymbol{v}) = \alpha f(\boldsymbol{u}) + \beta f(\boldsymbol{v})$ for all n-dimensional vectors $\boldsymbol{u}$ and $\boldsymbol{v}$ and all scalars α and β.

Linear Inequality

The mathematical form $a_1x_1 + a_2x_2 + \ldots + a_nx_n \leq b$ or $a_1x_1 + a_2x_2 + \ldots + a_nx_n \geq b$ is a linear inequality, where the numbers a_j and b can take on any values. The set of vectors $\boldsymbol{x} = (x_1, \ldots, x_n)$ that satisfy the inequality form a solution half space.

Linear Programming

Frederick S. Hillier
Stanford University, Stanford, CA, USA

Introduction

Linear programming is one of the most widely used techniques of operations research and management science. Its name means that planning (programming) is being done with a mathematical model (called a linear-programming model) where all the functions in the model are linear functions.

Linear Programming Models

Linear programming models come in a variety of forms. To illustrate one common form, consider the problem of determining the most profitable mix of products for a manufacturer. Let n be the number of possible products. For each product j ($j = 1, 2, \ldots, n$), a decision variable x_j is introduced to represent the decision on its production rate. Let c_j be the profit per unit of product j produced, and let Z be the total rate of profit resulting from the choice of product mix. This choice is constrained by the limited capacities of the production facilities available for these products. Let m be the number of different types of facilities needed. For each type i ($i = 1, 2, \ldots, m$), let b_i be the amount of capacity available per unit time and let a_{ij} be the amount of capacity used by each unit produced of product j ($j = 1, 2, \ldots, n$). The resulting linear programming model then is to choose $x_1, x_2, \ldots, x_n$ so as to

$$\begin{aligned} \text{Maximize } Z &= c_1x_1 + c_2x_2 + \cdots + c_nx_n \\ \text{subject to : } & a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n \le b_1 \\ & a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n \le b_2 \\ & \vdots \qquad\qquad \vdots \\ & a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n \le b_m \end{aligned}$$

and

$$x_1 \ge 0, x_2 \ge 0, \ldots, x_n \ge 0.$$

The linear function being maximized in this model is called the objective function. The m inequalities with a linear function on the left-hand side are referred to as functional constraints (or structural constraints), and the inequalities in the bottom row are nonnegativity constraints. The constants (c_j, b_i, and a_{ij}) are the parameters of the model. Any choice of values of ($x_1, x_2, \ldots, x_n$) is called a solution, whereas a solution satisfying all the constraints is a feasible solution, and a feasible solution that maximizes the objective function is an optimal solution.

Many other applications of linear programming having nothing to do with product mix also fit this same form for the model. In these cases, activities of some other kind replace the production of products, and resources of some other kind replace production facilities. For each activity j ($j = 1,2, \ldots, m$), the decision variable x_j represents the decision on the level of that activity. The problem then is to allocate these limited resources to these interrelated activities so as to obtain the best mix of activities (i.e., an optimal solution) according to the overall measure of performance adopted for the objective function.

Another common form for a linear programming model is to minimize the objective function, subject to functional constraints with $\ge$ signs and nonnegativity constraints. A typical interpretation then is that the objective function represents the total cost for the chosen mix of activities and the functional constraints involve different kinds of benefits. In particular, the function on the left-hand side of each functional constraint gives the level of a particular kind of benefit that is obtained from the mix of activities, and the constant on the right-hand represents the minimum acceptable level for that benefit. The problem then is to determine the mix of activities that gives the best tradeoff between cost and benefits according to the model.

Still other linear-programming models have an equality instead of inequality sign in some or all of the functional constraints. Such constraints represent fixed requirements for the value of the function on the left-hand side.

It is fairly common for large linear-programming models to include a mixture of functional constraints — some with $\le$ signs, some with $\ge$ signs, and some with $=$ signs. Nonnegativity constraints always have a $\ge$ sign, but it occasionally is appropriate to delete this kind of constraint for some or all of the decision variables.

Successful applications of linear programming sometimes use very large models. As described in a later section, exceptionally efficient algorithms are available for solving these models. When using state-of-the-art implementations of these algorithms and a powerful desktop computer or workstation, a model with several thousand functional constraints and decision variables is considered to be of moderate size. Having a few tens of thousands of functional constraints and even more decision variables is not considered particularly large. Far bigger problems with millions of functional constraints and decision variables sometimes are solved, depending largely on whether they have a special structure that can be exploited.

With large models, it is inevitable that mistakes and faulty decisions will be made initially in formulating the model and inputting it into the computer. Therefore, a thorough process of testing and refining the model, i.e., model validation, is needed. The usual end-product is not a single static model, but rather a long series of variations on a basic model to examine different scenarios as part of post-optimality analysis (discussed later). A sophisticated modeling language usually is needed to efficiently formulate the model and then to expedite a number of model management tasks, including accessing data, transforming data into model parameters, modifying the model whenever desired, and analyzing solutions from the model.

Some Applications of Linear Programming

The applications of linear programming have been remarkably diverse. They all involve determining the best mix of activities, where the decision variables represent the levels of the respective activities, but these activities arise in a wide variety of contexts. In the context of financial planning, the activities might be investing in individual stocks and bonds (portfolio selection), or undertaking capital projects (capital budgeting), or drawing on sources for generating working capital (financial-mix strategy). In the context of marketing analysis, the activities might be using individual types of advertising media, or performing marketing research in segments of the market. In the context of production planning, applications range widely from the product-mix problem (discussed earlier) to the blending problem (determining the best mix of ingredients for various individual final products), and from production scheduling to personnel scheduling.

In addition to manufacturing, these kinds of production planning applications also arise in agricultural planning, health-care management, the planning of military operations, policy development for the use of natural resources, etc.

Linear programming has had a great impact on improving the efficiency and profitability of numerous organizations around the world. A considerable number of these applications have won a prestigious prize in the annual international competition for the Franz Edelman Award for Achievement in Operations Research and the Management Sciences. To mention a few typical award-winning applications: Bixby et al. (2006) describe how Swift & Company saved $12 million in 1 year by optimizing its product mix while dynamically scheduling its beef-fabrication operations at five plants in real time as it receives orders; Lee and Zaider (2008) discuss how a breakthrough in optimizing the application of brachytherapy to prostrate cancer is having a profound impact on both health care costs (potentially saving $500 million annually) and quality of life for treated patients; Holloran and Bryne (1986) were early pioneers in applying linear programming at United Airlines to design the work schedules for all the employees at the various reservation offices and airports, thereby saving the company more than $6 million annually; Leachman, Kang, and Lin (2002) describe how Samsung Electronics Corp. captured an additional $200 million in annual sales revenue by using a linear- programming model with tens of thousands of decision variables and functional constraints to increase the efficiency of its processes for manufacturing random access memory devices. Hillier and Lieberman (2010, Chap. 3) also reference other award-winning applications of linear programming.

Another important kind of application of linear programming arises from its close relationship to several other important areas of operations research and management science, including integer programming, nonlinear programming, and game theory. Linear programming often is useful to help solve problems in these other areas as well.

Some Special Types of Linear Programming Models

One particularly important special type of linear programming problem is the transportation problem. A typical application of the transportation problem is to determine how a corporation should distribute a product from its various factories to various distributors. In particular, given the amount of the product produced at each factory and the amount needed by each distributor, one can determine how much to ship from each factory to each distributor in order to minimize total shipping cost. Other applications extend to areas such as production scheduling.

Camm et al. (1997) describe an award-winning application of the transportation problem at Procter & Gamble that saved over $200 million annually by redesigning the company's production and distribution system for its North American operations. A major part of the study revolved around formulating and solving transportation problems for individual product categories.

The assignment problem is a special type of linear-programming problem where assignees are being assigned to perform tasks. For example, the assignees might be employees who need to be given work assignments. Assigning people to jobs is a common application of the assignment problem. However, the assignees need not be people. They also could be machines, or vehicles, or plants, or even time slots to be assigned tasks. It can be shown that the mathematical structure of the model for the assignment problem is a special case of that for the transportation problem.

Both the transportation problem and the assignment problem are a special case of another key type of linear-programming problem, called the minimum-cost network-flow problem, that involves determining how to distribute goods through a distribution network at a minimum total cost. In particular, the nodes of this network include at least one supply node and at least one demand node, and then the rest of the nodes are transshipment nodes. Given the capacity of each arc for transmitting flow, the objective is to minimize the total cost of sending the supply from the supply nodes through the network to satisfy the given demand at the demand nodes.

Klingman et al. (1987) describe a classic award-winning application of this type at the Citgo Petroleum Corporation. This minimum-cost network-flow problem involved the distribution of petroleum products through a distribution network consisting of pipelines, tankers, barges, and hundreds of terminals. This application is credited with saving the company well over $15 million annually. (Another application of linear programming involving Citgo's refinery operations was implemented at about the same time and achieved additional savings of about $50 million per year).

Another special case of the minimum-cost network-flow problem is the maximum-flow problem. Given a connected network with capacity constraints on the maximum flow through each arc, the objective now is to maximize the flow through the network from the source node to the sink node. Some typical applications include maximizing the flow through a distribution network, or through a supply network, or through a system of pipelines, or through a system of aqueducts, or through a transportation network.

The shortest-path problem (also called the shortest-route problem) is still another important special type of linear-programming problem that is also a special case of the minimum-cost network-flow problem. The objective now is to find the path through a network from an origin to a destination that minimizes the total distance traveled. Arc distances also can represent costs or times so the objective becomes to minimize the total cost or total time of a sequence of activities.

Ireland et al. (2004) describe how the Canadian Pacific Railway saves roughly $100 million annually by using network optimization techniques to route its freight each day over a massive rail network that encompasses much of North America. Numerous shortest-path problems are solved each day as part of the overall approach for this award-winning application.

There have been many other award-winning applications of the special types of linear-programming problems that are described above. Hillier and Lieberman (2010, Chap. 9) reference some of these applications.

Solving Linear Programming Models

Two crucial events have been primarily responsible for the great impact of linear programming since its

emergence in the middle of the twentieth century. One was the invention in 1947 by George Dantzig of a remarkably efficient algorithm, called the simplex method, for finding an optimal solution for a linear-programming model. The second crucial event was the computer revolution that makes it possible for the simplex method to solve huge problems.

The simplex method exploits some basic properties of optimal solutions for linear programming models. Because all the functions in the model are linear functions, the set of feasible solutions (called the feasible region) is a convex polyhedral set. The vertices (extreme points) of the feasible region play a special role in finding an optimal solution. A model will have an optimal solution if it has any feasible solutions (all the constraints can be satisfied simultaneously) and the constraints prevent improving the value of the objective function indefinitely. Any such model must have either exactly one optimal solution or an infinite number of them. In the former case, the one optimal solution must be a vertex of the feasible region. In the latter case, at least two vertices must be optimal solutions, and then all convex-linear combinations of these vertices also are optimal. It is sufficient, therefore, to find the vertices with the most favorable value of the objective function in order to identify all optimal solutions.

Based on these facts, the simplex method is an iterative algorithm that only examines vertices of the feasible region. At each iteration, it uses algebraic procedures to move along an outside edge of the feasible region from the current vertex to an adjacent vertex that is better. The algorithm terminates (except perhaps for checking ties) when a vertex is reached that has no better adjacent vertices, because the convexity of the feasible region then implies that this vertex is optimal.

The simplex method is an exponential-time algorithm (in the worst case). However, it consistently has proven to be very efficient in practice. Running time tends to grow approximately with the cube of the number of functional constraints, and less than linearly with the number of variables. Problems with many thousands of functional constraints and a larger number of decision variables are routinely solved. One key to its efficiency on such large problems is that the path followed generally passes through only a tiny fraction of all vertices before reaching an optimal solution. The number of iterations (vertices traversed) generally is of the same order of magnitude as the number of functional constraints.

The running time of the simplex method also is greatly affected by the degree of sparsity of the matrix of constraint coefficients, where the measure of sparsity is the proportion of the coefficients that are not zero. Having a very sparse coefficient matrix (say, less than 1%) can greatly accelerate the simplex method.

There also exist useful variants of the simplex method, including especially the dual simplex method, that sometimes are used to solve linear-programming problems. (Using the terminology introduced at the beginning of the next section, the dual simplex method operates on the primal problem as if the simplex method is being applied simultaneously to the dual problem).

In addition, specialized versions of the simplex method also are available for exploiting the special structure in some of the special types of linear-programming problems described in the preceding section. In particular, the network-simplex method does this for the minimum-cost network-flow problem and the transportation-simplex method does it for the transportation problem. A variety of special algorithms also are available for the assignment problem, the maximum-flow problem, and the shortest-path problem. Therefore, even though the general simplex method can solve huge instances of these problems, these special purpose algorithms can solve even vastly larger instances.

Any of the various textbooks on linear programming cited in the references will provide additional details about the simplex method and these related algorithms.

Some 37 years after the invention of the simplex method, N. Karmarkar (1984) created great excitement in the operations research/management science community by announcing a new polynomial-time algorithm for linear programming, along with claims of being many times faster than the simplex method. Actually, the first polynomial-time algorithm for linear programming had been announced earlier by L. G. Khachiyan (1979), but his ellipsoid method proved to be not nearly competitive with the simplex method in practice. Karmarkar's algorithm moves through the interior of the feasible region until it converges to an optimal solution, and so is referred to as an

interior-point method. The announcement did not include details needed for computer implementation.

Following Karmarkar's announcement, there was a long flurry of research activity to fully develop and refine similar interior-point methods, along with sophisticated computer implementations. The application of these methods to linear programming now has reached a high level of sophistication. These methods commonly are called barrier methods or barrier algorithms because they are based on introducing a logarithmic barrier function. A specific barrier algorithm then may be given a specific name to identify its main features. For example, the primal-dual predictor-corrector algorithm developed by Mehrotra (1992) established a structure that has commonly been adopted by subsequent algorithms. Ye (1997), Vanderbei (2008), and Luenberger and Ye (2008) provide further details about the interior-point approach.

A key feature of the interior-point approach is that both the number of iterations (trial solutions) and total running time tend to grow very slowly (even more slowly than for the simplex method) as the problem size is increased. Therefore, the best implementations of this approach tend to become faster than the simplex method (or the dual simplex method) for relatively large problems. This is not always true, because the efficiency of each approach depends greatly in different ways on the special structure in each individual problem. Indeed, one of the by-products of the emergence of the interior-point approach has been a major renewal of efforts to improve the efficiency of computer implementations of the simplex method and its variants. Impressive progress has been made. Consequently, when tests have been conducted to determine when a leading barrier algorithm, the simplex method, or the dual simplex method will solve various huge problems more quickly, the dual simplex method or simplex method occasionally wins. As time goes on, improving computer technology (such as massive parallel processing) will substantially increase the size of problems that any of the algorithms can solve.

A considerable number of excellent software packages for linear programming and its extensions now are available to fill a variety of needs. Leading packages include CPLEX, Express-MP, Gurobi, and LINDO. Frontline Systems also has excellent solvers, including its Risk Solver Platform, for use with Excel spreadsheets.

As mentioned earlier, when dealing with large linear-programming problems, modeling languages also are needed to efficiently input, formulate, and manage the model. The available modeling languages include AMPL, MPL, OPL, GAMS, and LINGO. These languages are designed to be integrated with the kinds of solvers mentioned in the preceding paragraph.

Duality Theory and Postoptimality Analysis

Associated with any linear-programming problem is another linear-programming problem called the dual. Furthermore, the relationship between the original problem (called the primal) and its dual is a symmetric one, so that the dual of the dual is the primal. For example, consider the two related linear-programming models shown below in matrix notation (where $\boldsymbol{A}$ is a matrix, $\boldsymbol{c}$ and $\boldsymbol{y}$ are row vectors, $\boldsymbol{b}$, $\boldsymbol{x}$, and the null vector $\boldsymbol{0}$ are column vectors, all with compatible dimensions, and $\boldsymbol{x}$ and $\boldsymbol{y}$ are the decision vectors):

Maximize $\boldsymbol{cx}$	Minimize $\boldsymbol{yb}$
subject to: $\boldsymbol{Ax} \leq \boldsymbol{b}$	subject to: $\boldsymbol{yA} \geq \boldsymbol{c}$
and $\boldsymbol{x} \geq \boldsymbol{0}$.	and $\boldsymbol{y} \geq \boldsymbol{0}$.

For each of these problems, its dual is the other problem.

There are many useful relationships between the primal and dual problems, so the dual provides considerable information for analyzing the primal. This is especially helpful when conducting postoptimality analysis, i.e., analysis done after finding an optimal solution for the initial validated version of the model. A key part of most linear-programming studies, this analysis addresses a variety of what-if questions of interest to the decision makers. The purpose is to explore various scenarios about future conditions that may deviate from the initial model. The dual simplex method frequently is helpful for quickly re-optimizing these revised models.

Although the parameters of the given linear-programming model are treated as constants, they frequently represent just best estimates of a quantity whose true value may turn out to be quite

different. A key part of postoptimality analysis is sensitivity analysis, an investigation of the parameters to determine which ones are sensitive parameters, i.e., those that change the optimal solution if a small change is made in the given parameter value, and exploring the implications. For certain parameters, the decision makers may have some control over its value (e.g., the amount of a resource to be made available), in which case sensitivity analysis guides the decision on which value to choose. An extension of sensitivity analysis called parametric programming enables systematic investigation of simultaneous changes in various parameters over ranges of values.

Fletcher et al. (1999) present an interesting case study of how an OR team at the Pacific Lumber Company made extensive use of detailed sensitivity analysis to develop a sustained yield plan for the company's entire landholding. This plan is credited with increasing the company's present net worth by over $398 million while also generating a better mix of wildlife habitat acres.

Extensions of the simplex method are well suited for performing these kinds of postoptimality analysis. However, this is less true for interior-point methods. Therefore, even when an interior-point method is used to find an optimal solution, a switch may be made to the simplex method for subsequent analysis.

When there is substantial uncertainty about what the true values of the parameters will turn out to be, it may be necessary to use a different analysis approach, called linear programming under uncertainty, in which some or all the parameters are treated as random variables. This is especially pertinent when planning must be done for multiple time periods into an uncertain future. For example, Infanger (1993) discusses solving large-scale multi-stage stochastic linear programs.

Further Reading

Dantzig (1982) describes some of the early history of linear programming. Gass (1990) gives an entertaining introduction to the field. Hillier and Lieberman (2010) expand on all the topics mentioned here at an elementary level, and F.S. Hillier and M.S Hillier (2011) emphasize the application of linear programming from a managerial viewpoint. Dantzig (1963) provides the classic textbook on the theory of linear programming. Other excellent textbooks on linear programming and its extensions include Bertsimas and Tsitsiklis (1997), Dantzig and Thapa (1997, 2003), Vanderbei (2008), Luenberger and Ye (2008), Murty (2010), and Bazaraa, Jarvis and Sherali (2010), Marsten, Subramanian, Saltzman, Lustig, and Shanno (1990) discuss the basic concepts underlying interior-point methods.

Linear-Fractional Programming Problem

The linear-fractional programming problem is one in which the objective to be maximized is of the form $f(\boldsymbol{x}) = (\boldsymbol{cx} + \alpha)/(\boldsymbol{dx} + \beta)$ subject to $\boldsymbol{Ax} \leq \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$, where α and β are scalars, $\boldsymbol{c}$ and $\boldsymbol{d}$ are row vectors of given numbers, and $\boldsymbol{b}$ is the right-hand-side vector. The problem can be converted to an equivalent linear programming problem by the translation $\boldsymbol{y} = \boldsymbol{x}/(\boldsymbol{dx} + \beta)$, provided that $\boldsymbol{dx} + \beta$ does not change sign in the feasible region.

See

► Fractional Programming

Lipschitz Continuous

A function $f(x)$ is said to be Lipschitz continuous if there exists a real constant $K > 0$ (called the Lipschitz constant) such that for every pair of points $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, $||f(\boldsymbol{x}_1) - f(\boldsymbol{x}_2)|| \leq K||\boldsymbol{x}_1 - \boldsymbol{x}_2||$. If $K < 1$, then the function is called a contraction.

Little's Law

Susan Albin
Rutgers, The State University of New Jersey, Piscataway, NJ, USA

Little's Law, among the most fundamental and useful formulas in queueing theory, relates the number of customers in a queueing system to the waiting time of customers for a system in steady state as

$$L = \lambda W$$

- $L =$ The average number of customers in the system including customers in service
- $\lambda =$ The average arrival rate of customers to the system; and
- $W =$ The average time a customer spends in the system including the time in service

An alternate form of Little's Law addresses only the customers in the waiting line, or queue, i.e.,

$$L_q = \lambda W_q$$

- L_q = The average number of customers in the queueing (excluding customers in service);
- λ = The average arrival rate of customers to the queueing system; and
- W_q = The average time that a customer spends in the queueing (excluding the time in service).

Little's Law, formally proven in Little (1961) and simplified in Stidham (1974), is remarkably general, requiring only that the queueing is ergodic and that no service needs are artificially created or destroyed (i.e., the system is work conserving). The result holds for any arrival process, service-time distribution, and number of servers. It applies for all queueing disciplines, with the customers not necessarily served in order of arrival, and for a specific class of customers that are distinguished from others by priority or some other characteristic. Little's formula holds for every infinite sample path realization of the queueing system, and it is approximately valid in finite intervals, with the accuracy increasing as the interval increases.

In the study of queueing, whether by mathematical analysis, simulation or direct data collection, it is often simpler to find either the average number in system or the average waiting time. Once the simpler one has been found, Little's Law gives the other. For example, in an operating manufacturing system, if average time in the system (lead time) is simpler to estimate from data, Little's Law can be used to estimate the average number of parts in the system (in process inventory).

An outline of a proof of Little's Law is based on depicting a sample path of the number in the system over an interval of time T for a steady-state queueing system with arrival rate λ (Fig. 1). The number of customer-minutes spent in the system equals A, the area under the curve. The average number of customers that arrive in the interval is λT (approximately); thus the average number of minutes in the system per customer is $W = A/(\lambda T)$. The average number of customers in the system $L = A/T$. Manipulating the two equations, taking limits, and accounting for end effects yields Little's Law.

An outline of a proof of Little's Law is based on depicting a sample path of the number in the system over an interval of time T for a steady-state queueing system with arrival rate λ (see Fig. 1). The number of customer-minutes spent in the system equals A, the area under the curve. The average number of customers that arrive in the interval is λT (approximately); thus the average number of minutes in the system per customer is $W = A/(\lambda T)$. The average number of customers in the system $L = A/T$. Manipulating the two equations, taking limits, and accounting for end effects yields Little's Law.

Little's Law in Distributional Form

L. D. Servi
The MITRE Corporation, Bedford, MA, USA

Since Little's Law first appeared in 1961, its simplicity and importance have established it as a basic tool of queueing theory. Little's Law relates the average number of customers in a system, N, with the average

time in the system, T, under very broad conditions. For example, Keilson and Servi (1988) have demonstrated that for many systems, the relationship between the queueing length and the time in the system can be characterized beyond just their average value.

This is possible, however, if a class of customers arrives according to a Poisson process, is served first-in, first-out (FIFO) within the class, and is processed as either

1. An ordinary single-server queueing,
2. A single-server queueing with one or more classes of priority which processes each class according to a preemptive-resume, preemptive-repeat, or nonpreemptive discipline,
3. A vacation model system, where the server takes one or more vacations when the queueing is depleted,
4. A polling system, where a single server moves cyclically between (real or virtual) queueing, either serving the customers at the queueing to exhaustion, employing a Bernoulli schedule, or serving at most K customers at a queueing before moving on, or
5. An $M/G/G/\ldots G/1$ tandem queueing system, where the output of one queueing is the input of another and the service times at successive queueing are i.i.d. service times for successive arrivals.

More precisely, Keilson and Servi (1988) demonstrated that, if for a given class of customers,

(C-1) The arrival process is Poisson with rate λ,

(C-2) All arriving customers enter the system and remain in the system until served,

(C-3) The customers leave the system one at a time in order of arrival, and

(C-4) For any time t, the arrival process after time t, and the time in the system of any customer arriving before time t, are statistically independent,

then the relationship between the probability distribution of the number in the system and the time in the system follows the simple formula

$$\pi_N(u) = \alpha_T(\lambda - \lambda u) \tag{1}$$

where $\pi_N(u) = E[u^N]$ is the probability generating function of N and $\alpha_T(s) = E[e^{sT}]$ is the Laplace transform of the density of T.

Since $d^n\pi_N(u)/du^n = E[N(N-1)\ldots(N-n+1)]$ for $u = 1$ and $d^n\alpha_T(s)/ds^n = (-1)^n E[T^n]$ for $s = 0$, one can relate the moments of queueing lengths to the moments of the time in the system by computing successive derivatives of (1) with respect to u and then evaluating at $u = 1$. For example,

$$\begin{aligned}
E[N] &= E[\lambda T] \\
E\left[N^2\right] &= E\left[(\lambda T)^2\right] + E[\lambda T] \\
E\left[N^3\right] &= E[\lambda T] + 3E\left[(\lambda T)^2\right] + E\left[(\lambda T)^3\right] \\
E\left[N^4\right] &= E[\lambda T] + 7E\left[(\lambda T)^2\right] + 6E\left[(\lambda T)^3\right] + E\left[(\lambda T)^4\right] \\
E\left[N^5\right] &= E[\lambda T] + 15E\left[(\lambda T)^2\right] + 25E\left[(\lambda T)^3\right] + 10E\left[(\lambda T)^4\right]
\end{aligned} \tag{2}$$

The first of these equations is the familiar Little's Law. As is the case of the Pascal Triangle, there is a simple relation between the coefficients. Specifically, one can show that

$$E[N^n] = \sum_{m=1}^{n} S(n,m) E[\lambda T]^m \tag{3}$$

where $S(u, m)$ is a Stirling number of the second kind defined by the recursion $S(n+1,m) = mS(n,m) + S(n,m-1)$ for $n+1 \geq m \geq 1$, $S(n,0) = S(n,n+1) = 0$ for $n \geq 1$ and $S(1,1) = 1$ (Abramowitz and Stegun 1972).

Similarly,

$$E[(\lambda T)^n] = \sum_{m=1}^{n} \bar{S}(n,m) E[N^m]$$

where $\bar{S}(n,m)$ are Stirling numbers of the first kind which satisfy $\bar{S}(n,m-1) = \bar{S}(n,m-1) - n\bar{S}(n,m)$ for $n+1 \geq m \geq 1$, $\bar{S}(n,0) = \bar{S}(n,n+1) = 0$ for $n \geq 1$ and $\bar{S}(1,1) = 1$.

The first two equations of (2) imply the simple but non-intuitive formula

$$\frac{Var[N]}{E[N]} = \frac{Var[\lambda T]}{E[\lambda T]} + 1.$$

The system could refer to the queueing and the pool of customers in service or exclusively to the queueing. In the latter case, additional systems satisfy conditions (C-1)–(C-4). For example, for a multi-server system,

the customers do not leave the system consisting of the queueing and the pool of customers in service on a first-in, first-out basis [and hence violate condition (C-3)]. However, if the system refers exclusively to the queueing, then condition (C-3) is satisfied.

These results have been generalized, for example, to systems with non-Poisson arrivals (Bertsimas and Mourtzinou 1997), to systems operating under heavy traffic (Szczotka 1992), to systems having batch arrivals (Takahashi and Miyazawa 1994), and has been used as the basis to derive explicit formulae for the distribution of the number in the system (or queueing) as well as the time in the system (or queueing) for a number of more classical systems (Keilson and Servi 1990).

Local Improvement Heuristic

A heuristic rule which examines all the solutions that are closely related to a given initial solution and is guaranteed to reach at least a local optimum.

See

- ▶ Heuristic Procedure
- ▶ Local Optimum

Local Maximum

A function $f(x)$ defined over a set of points S is said to have a local maximum at a point $\boldsymbol{x}_0$ in S if $f(\boldsymbol{x}_0) \geq f(\boldsymbol{x})$ for all $\boldsymbol{x}$ in a neighborhood of $\boldsymbol{x}_0$ in S. The point $\boldsymbol{x}_0$ is referred to as a local optimum (maximum).

See

- ▶ Quadratic Programming

Local Minimum

A function $f(\boldsymbol{x})$ defined over a set of points S is said to have a local minimum at a point $\boldsymbol{x}_0$ in S if $f(\boldsymbol{x}_0) \leq f(\boldsymbol{x})$ for all $\boldsymbol{x}$ in a neighborhood of $\boldsymbol{x}_0$ in S. The point $\boldsymbol{x}_0$ is referred to as a local optimum (minimum).

Local Solution

A best solution in a feasible neighborhood.

Location Analysis

Charles ReVelle[1] and Vladimir Marianov[2]
[1]The Johns Hopkins University, Baltimore, MD, USA
[2]Pontificia Universidad Católica de Chile, Santiago, Chile

Introduction

The term location analysis refers to the development of formulations and algorithms/methodologies to site facilities of diverse kinds in a spatial or geographic environment. The facilities may be sited with relation to demand points, supply points, or with respect to one another. Although facility layout falls within this definition, this topic is not generally considered under the rubric of location analysis. Common descriptive terms for location analysis are deployment, positioning, and siting, although these terms are actually the outcome that follows the execution of a formulation or algorithm.

Location settings may be classified into two broad categories: planar problems and network problems. Planar problems typically assume that the distances between facilities and demand points, supply points or other facilities are given by a metric, a formula that calculates distance between points based on their coordinates in space. Network problems, in contrast, assume that travel can only occur on an underlying network and that distances are the lengths (or cost) of the shortest paths between the particular points on the network. A further distinction between these categories is provided by the assumption in most planar problems of an infinite solution space, that is, that facilities can be sited anywhere on the plane, perhaps subject to exclusion areas or regions. These planar problems are most often non-linear optimization problems and more abstract in their application than network-based problems. In contrast to the infinite solution space assumed by most planar problems, all but a few network problems restrict facilities to sites that have been specified in advance as eligible to house those facilities. The network problems tend to be linear zero-one optimization problems and so pose challenges in their resolution to integers. First, planar problems and approaches to them will be discussed; followed by a discussion about network location formulations and their solution.

Planar Location Problems

The most famous of the planar problems and the first location problem to be posed historically is the minimum Euclidean single facility location problem first stated by Fermat as a mathematical problem: "Given three points in the plane, find a fourth such that the sum of its distances to the three given points is a minimum" (Kuhn 1967). It is often referred to as the Weber problem, after the German economist who first discussed it in economic terms (Weber 1909). The minimum problem considers points dispersed on the plane that send items to or receive finished product from some central factory or facility. The problem seeks the central point that minimizes the sum of weights (quantities) times the distances to all dispersed points. The problem assumes that the Euclidean distances separate the dispersed points and the central point, that the central point can be anywhere on the plane, and that a weight or loading is associated with each of the dispersed points. An iterative solution method that can be shown to converge to an optimal solution was offered in the 1930s, lost to view, and rediscovered in the early 1960s by several independent investigators. In the minisum multiple facility problem (the multi-Weber problem), a number of central facilities are to be sited, each one associated with a cluster or partition of the dispersed points.

An allocation problem arises, i.e., the problem of deciding which facility serves each dispersed point.

The history of the minisum problem is reviewed in Wesolowsky (1993). Only in the early 1990s has this problem yielded to exact methods, followed by heuristics and metaheuristics (Brimberg et al. 2008).

While the Weber problem in its single and multi-facility forms utilizes the Euclidean metric for distances, the minisum rectilinear problem utilizes the Manhattan or rectilinear metric for distances and minimizes the sum of weights times these distances to the central point. The rectilinear distance between two points is the sum of the horizontal and vertical separation of the points. Because the problem can be reduced to the choice among a set of eligible points, the multi-facility rectilinear minisum problem yields either to heuristics or to the linear integer-programming formulation used for the *p*-median problem, a problem that will be discussed under network location models. When the classic metrics are set aside, solution of the minisum problem generally becomes more difficult, except in the case of minimizing the weighted sum of squared distances, in which case the single facility minisum solution is simply the centroid.

A second important objective setting in planar problems is the siting of a single facility under the objective of minimizing the maximum distance that separates any demand/supply point from the central facility. The problem may utilize either of the two classic metrics, Euclidean or rectilinear. No matter the number of dispersed points, the minimax single facility location problem with rectilinear distances yields to either a geometric solution or to a four-constraint linear program. The minimax single facility location problem with Euclidean distances is a nonlinear-programming problem, but can also be solved by a geometric argument. Multi-facility versions of the planar minimax location problems may yield to heuristics resembling those applied to the *p*-median problem. A good general reference dealing in part with planar location problems is the text of Love et al. (1988), Plastria (1995) provides a comprehensive review for the researcher in planar location.

It is worth mentioning that researchers in continuous location, seeking a greater realism in their problems, have sought to project the most likely real distances on a road network between a pair of points given the spatial coordinates of these points. This literature is reviewed in Brimberg and Love (1995).

Network Location Problems

In contrast to the use of formula-based metrics for the siting of facilities on a plane, network location problems always measure distances across the links of the network. Interestingly, the assumption of an infinite solution space can be made in network-based location problems as well. That is, the infinite solution space would consist of all the points on every arc of the network. For some problems, including the *p*-median, the solution space can be reduced without loss of optimality from all the points on all the arcs to a limited number of eligible points when the triangle inequality holds throughout the network. Many network problems simply assume a prespecified set of eligible facility sites based on needed characteristics of such points, such as transportation infrastructure, availability of lots or warehouse space, etc.

Within network location research two distinct foci are found. The first is cost minimizing/profit maximizing siting that is goods-oriented, an activity especially of the manufacturing and distribution industries. The second is people or service-oriented siting, an activity mostly of government at a number of levels from local to national, but also of private companies. The divisions are not perfect, as it will be seen, but are, at the least, useful for discussion purposes. These two settings will be taken up in that order followed by presentations of some variations and adaptations of these classes.

Goods-Oriented Siting

By far, the problem setting considered most extensively in the goods oriented location category is the simple plant location problem (SPLP). The problem assumes that an unknown number of plants are to be sited to manufacture product for distribution to a number of spatially dispersed demand points. The plants have no limit as to the amount manufactured, and each point must be fully supplied with its demand. The objective is the

minimization of the total of manufacturing cost and distribution cost. Manufacturing includes a fixed opening cost and an expansion cost that can be linear or nonlinear. The problem may be stated mathematically as:

$$\text{minimize} \quad z = \sum_{i=1}^{m}\sum_{i=1}^{n} c_{ij}x_{ij} + \sum_{i=1}^{m} f_i y_i$$

subject to :

$$\sum_{i=1}^{m} x_{ij} = 1, \qquad j = 1, \ldots, n,$$

$$y_i - x_{ij} \geq 0, \qquad i = 1, \ldots, m; j = 1, \ldots, n,$$

$$x_{ij}, y_i \in \{0, 1\}, \quad i = 1, \ldots, m; j = 1, \ldots, n.$$

i = the index of eligible plant sites of which there are m;
j = index of demand points of which there are n;
f_i = opening cost for a plant at i;
c_{ij} = cost to deliver j's full demand from i, including the production cost at i;
$y_i \in \{0, 1\}$, it is 1 if a plant opens at i and 0 otherwise; and
$x_{ij} \in \{0, 1\}$, it is 1 if i delivers j's full demand and 0 otherwise.

The above problem formulation is due to Balinski (1965), and is one of several formulations possible for the SPLP. It is presented here because it is the basis for a number of solution methods.

The SPLP has attracted attention since the 1950s when heuristics were first suggested. In the 1960s, Balinski offered his formulation of the problem but dismissed it as unreliable. In addition, several branch and bound algorithms were created to solve the SPLP, but these algorithms proved impractical for large problems. In the mid-1970s, Bilde and Krarup (1977) and Erlenkotter (1978) both proposed dual ascent algorithms for the SPLP; the basic algorithm proposed by these two sets of investigators has proved to be capable of handling relatively large problems. Morris (1978) investigated 500 randomly generated plant location problems and found that if the formulation above were solved as a linear program (without integer requirements on any of the variables) that 96% of the problems so solved presented with all zero-one variables. Morris' experience thus suggested that linear programming alone was a powerful technique for the SPLP formulation that Balinski had abandoned. The problem has since been successfully pursued by Lagrangian relaxation by Galvão (1989) and Korkel (1989), who modified the dual ascent algorithm referred to above to solve remarkably large problems.

While the SPLP has attracted considerable attention, a related form, the capacitated plant location problem (CPLP), languished until the late 1980s. The CPLP sets limits on the amount that could be manufactured at any site, but in all other respects is the same as the SPLP. First attacked by Davis and Ray (1969), the problem later received attention from Pirkul (1987), who provided both references to prior work and a solution algorithm based on Lagrangian relaxation. The CPLP also describes a problem in solid waste management in which waste is generated at population nodes and must be disposed of at sanitary landfills with limited capacities. Landfills are to be sited in this problem statement.

Many other plant location style problems can be stated. A maximum profit version of the SPLP is one such statement. The time dimension has been incorporated in a number of models, Melo et al. (2005). Multiple products can be treated as well. Another line of research focuses on the representation of the cost, since in many cases there are economies of scale or costs that are piecewise linear. Inventory, as well as other logistics costs can be also integrated in these models, see Snyder et al. (2007). Finally, demands, prices, and costs can be viewed as random, leading to stochastic versions of the plant location problem. The SPLP has been not only used for goods-oriented siting, but also for the design of telecommunications networks; in particular, for solving a problem called the Concentrator Location Problem, whose mathematical structure is identical to that of the warehouse or plant location problem. Shen (2007) surveys integrated supply chain design models.

Public Service-Oriented Siting

Nearly all of the plant location problems – excluding the concentrator location problem – emphasize the flow/movement of goods. In contrast, service oriented siting problems focus on the accessibility of people to services or services to people. Flow/movement is part of the equation in some of the models, but simple geographic coverage can suffice in others.

The same two objectives treated under planar problems, minisum and minimax, have also been considered for network location problems of service

siting. The minisum network location problem is known as the *p*-median problem; the minimax network location problem is known as the *p*-center problem. Both were posed together in seminal papers by Hakimi (1964, 1965). He also proved that there is always an optimal solution considering location only at nodes of the network.

The *p*-median problem, which seeks the minimum cost assignment of each population node to one of *p* facilities, resembles the SPLP in all but one modeling aspect. Indeed, so strong is the resemblance of *p*-median to the simple plant location model that the same algorithms may be used for solution of both with minor adaptation, Galvão (1989). The single difference between the two models is easy to explain once a mathematical-programming formulation of the *p*-median is offered. The *p*-median problem seeks to site *p* facilities in such a way that the least total of people times distance traveled to the assigned facility is achieved. Division of this objective by the total of population reveals that minimization of the total population-miles objective also minimizes the average distance that people travel to service. Travel/assignment is always assumed to the closest among the *p* facilities.

The *p*-median problem may be formulated as:

$$\text{minimize} \quad Z = \sum_{i=1}^{n} \sum_{j=1}^{n} a_i d_{ij} x_{ij}$$

subject to :

$$\sum_{j=N_i}^{n} x_{ij} = 1, \quad i = 1, 2, \ldots, n,$$

$$x_{jj} - x_{ij} \geq 0, \quad i, j = 1, 2, \ldots, n; i \neq j,$$

$$\sum_{j=1}^{n} x_{jj} = p$$

$$x_{ij} \in \{0, 1\}, \quad i, j = 1, 2, \ldots, n,$$

a_i = relevant population at demand node i;
d_{ij} = shortest distance from node i to node j;
N = number of nodes;
P = number of facilities; and
$x_{ij} \in \{0, 1\}$; it is 1 if node i assigns to a facility at j and 0 otherwise.

It can be seen from a comparison of the *p*-median formulation and that of the SPLP that the objectives differ only in the presence or absence of fixed opening costs and their opening variables, and that the constraints differ only in the presence or absence of a constraint on the number of facilities. In all other respects, the formulations look virtually identical. If the constraint on the number of facilities in the *p*-median formulation is brought to the objective with a multiplier λ, the objective becomes

$$\sum_{i=1}^{n} \sum_{j=1}^{n} a_i d_{ij} x_{ij} + \sum_{j=1}^{n} \lambda x_{jj}.$$

The subscripts reflect flow between central facilities and demand points. The *p*-median is now fully equivalent to an SPLP with equal opening costs, thus making all the techniques for solution of the SPLP available for solution of the *p*-median. Ranging the multiplier λ in the *p*-median is equivalent to trading off people miles against the number of facilities by use of the weighting method of multi-objective programming. Among the methods available for the SPLP that can be used for the *p*-median are relaxed linear programming (ReVelle and Swain 1970), the dual ascent methodology (Bilde and Krarup 1977; Erlenkotter 1978) and Lagrangian relaxation (Galvão 1989). A number of other researchers have used heuristics for the *p*-median problem; a listing of many of the early methods for the *p*-median problem appeared in ReVelle et al. (1977). Newer and more effective heuristic and metaheuristic methods are reviewed in Mladenovic et al. (2007) and Reese (2006). As the SPLP, the *p*-median also has a capacitated version in which each facility can serve up to a certain number of people.

While the *p*-median problem attracted considerable attention, researchers found its focus on the average condition of population accessibility to be limiting. Concern for those worst off relative to their distance to the nearest facility, that is, for the maximum distance or time separating population centers from service, gave rise to another concept, that of coverage. A population node is considered to be covered, i.e., adequately served, if it has a facility sited within some maximum distance or time; that is, sited within a time standard. Coverage can either be required for all demand points within the standard, or maximization of demand covered can be sought, giving rise to a host of new problems, the earliest of which is the location set covering problem (LSCP).

The LSCP seeks to position the least number of facilities so that every point of demand has at least

one facility sited within the time or distance standard. The problem can be stated as a linear zero-one programming problem as follows:

$$\text{minimize} \quad z = \sum_{j \in J} x_j$$

$$\text{subject to :} \sum_{j \in N_i} x_j \geq 1 \quad \forall i \in I,$$

$$x_j \in \{0, 1\} \quad \forall j,$$

i, I = index and set of demands;
j, J = index and set of eligible sites for facilities;
$x_j \in \{1, 0\}$, 1 if a facility placed at j and 0 otherwise;
d_{ji} = the shortest distance (or time) from site j to demand point i;
S = the maximum distance (or time) that a demand point can be from its nearest facility; and
$N_i = \{j | d_{ji} \leq S\}$ = the set of facility sites eligible to serve demand point i, by virtue of being within S of i.

While general set covering problems may require integer-programming algorithms to solve them, the LSCP appears to possess special properties. In particular, solution of the linear-programming formulation on data from a geographic problem without any zero-one requirements produces all zero-one answers with remarkable regularity (over 95% of the time). If a set of eligible facility sites is specified in advance, the LSCP can be used to derive solutions to the p-center problem as well. The p-center problem seeks to position p facilities in such a way that the maximum distance that separates any population node from its nearest facility is as small as possible. Solutions to this problem can be found by solving a sequence of LSCP problems, with decreasing distance standards. As the distance decreases, the number of facilities required to cover all demands increases. The minimum distance standard that makes total coverage feasible with p facilities is the solution of the p-center problem (Minieka 1970). If, however, any point on any link of the network is eligible to house a facility (the infinite solution space case), the solution of the p-center problem remains open and challenging.

The LSCP, however, has several shortcomings as a meaningful problem statement. First, population is absent from the problem statement; proximity and population are not linked even though they should be. Second, all population nodes require coverage within the standard, a requirement that could and often proves very costly in terms of the number of facilities/servers required.

Recognizing these shortcomings of the LSCP, several researchers have created new models for siting that utilized the coverage concept not as a requirement but as a goal. The most widely known of these models is referred to as the maximal covering location problem (MCLP) or the partial covering problem, depending on the specific formulation. The MCLP seeks the positions for p facilities among a prespecified set of eligible points that maximize the population that has a facility sited within a distance or time standard S, that is, that maximizes the population covered. The MCLP can be stated as:

$$\text{maximize} \quad z = \sum_{i \in I} a_i y_i$$

$$\text{subject to :} \quad y_i \leq \sum_{j \in N_i} x_j \, \forall i \in I,$$

$$\sum_{j \in J} x_j = p,$$

$$x_j, y_i \in \{0, 1\}, \forall i, j,$$

where additional notation is
a_i = the population at demand node i;
$y_i \in \{1, 0\}$, it is 1 if demand i is covered by a facility within N_i and 0 otherwise; and
p = the number of facilities that can be sited.

Basically, while the LSCP is attempting to find the least resources to cover all demand nodes within the distance goal, the MCLP is attempting to distribute lesser and limited resources to achieve as much population coverage as possible (Church and ReVelle 1974).

Related Research and Extensions

The basic models described above have caught the interest of a number of researchers. The literature on the subject keeps growing.

Drezner (1987) addressed the unreliable p-median in which facilities can become inactive. Marianov and

Serra (1998) proposed models that include the effect of queuing at the facilities, while Marianov (2003) maximized the amount of people willing to get service from a facility when there is demand elasticity to travel distance and queueing. The user point of view has been embedded in the p-median by Drezner and Drezner (2007), who investigated the effect on location of considering customers' behavior, represented through gravity models.

Uncertainty has also been considered in covering models. In probabilistic covering models, the presence or availability of a vehicle or server within a time standard is not guaranteed. The probabilistic models suggest a chance constraint on vehicle availability, that is, a requirement that a vehicle be available within the time standard with a specified level of reliability, see ReVelle and Marianov (1991). The chance constraint may be a strict requirement or may be treated as a goal for each population demand node. Many of the probabilistic, as well as redundant/backup coverage models, and multiple vehicle type models were reviewed by Marianov and ReVelle (1995). A review of the applications of probabilistic coverage models to emergency systems is provided by Goldberg (2004).

A number of other lines of research within the network location setting have been pursued. Among these are hierarchical location models, models in which a hierarchy of interacting/interrelated facility types are sited. One example is the health care hierarchy in developing nations, that consists of hospitals, clinics, and remote doctors. Another is a banking system consisting of central banks, branch banks, and teller machines. Morphological relations in hierarchical systems is reviewed by Narula (1986), with a brief treatment of the topic given in Daskin (1995). Serra and ReVelle (1994) provide algorithms for the median version of these hierarchical problems where coherence of assignments is enforced. Church and Eaton (1987) present an interesting set of hierarchical models with referral between levels.

The concept of coverage has been challenged, since in some situations it does not seem reasonable to consider a demand as covered if it is within, say, 500 m from a facility, but not covered if it is at 500.1 m. Models using a gradual coverage have been reviewed by Eiselt and Marianov (2009a). In these models, the coverage function, originally a step function, can take different shapes, representing quality of coverage as a function of the distance.

Another significant line of siting research is embodied in the competitive location models in which facilities are sited in a competitive market environment with goals of capturing market share from other retailers or manufacturers, or maximizing profit in the presence of competitors. Two problems are usually solved: the follower's problem, which is to locate facilities in such a way that the market capture from existing competitors is maximized; and the leader's problem, which is to locate first in a virgin market, anticipating possible followers that will try to cannibalize the leader's market share. A review of competitive location models in continuous and discrete space is provided by Dasci (2011).

Another line of location research involves the siting of noxious facilities. Such facilities may be undesirable in of themselves and should be distant from population centers or may be required to be distant from one another. However, they usually cannot be too far, since operation costs can be prohibitive, as in garbage processing plants or jails. Several approaches have been proposed for these facilities: maximizing their distance to population; maximizing the minimum facility-population distance; compensating the population that is affected by such a facility; and expropriation. A review of obnoxious facility location problems can be found in Melanchrinoudis (2011). Another line of research addresses both location of obnoxious facilities and routing of hazardous waste (Nagy and Salhi 2007).

A problem of increasing interest is the location of hubs. As airlines and courier companies focus on logistic improvements, the location of these traffic concentration points becomes more relevant. This line of research was started by (O'Kelly 1986) and has grown towards several fronts. Hub problems can be classified into the same categories as the original location problems: hub-median, hub-location, hub-covering and hub-center problems. They can be solved on the plane (O'Kelly 1986), or on networks. Campbell et al. (2002) provide a taxonomy of hub problems. Competition and queuing effects have also been considered when locating hubs (Marianov and Serra 2003; Eiselt and Marianov 2009b).

Finally, the tools developed for location in a geographical setting can be also used in very

different spaces: to locate employees and tasks in a skill space, finding the best measurement points in the eye for glaucoma detection, and locating candidates and voters in an issue space.

Concluding Remarks

The wide variety of important applications and modeling challenges are reported in many OR/MS journals, including *Computers & Operations Research* (including *Location Science*); *European Journal of Operational Research*, *Journal of the Operational Research Society*; *IIE Transactions* and *Papers in Regional Science*. In addition, the proceedings of the triennial International Symposium on Locational Decisions (ISOLDe) have appeared in separate volumes of *Annals of Operations Research*, beginning with 1984 Boston/Martha's Vineyard conference.

Logic Programming

Logic programming deals with the use of symbolic logic for problem representation and inferential reasoning. A popular logic programming language is Prolog (PROgrammation en LOGique), developed in the early 1970s by the French computer scientists, Alain Colmerauer and Philippe Roussel. Prolog has been used to develop a man-machine communication system in natural language.

Logistics and Supply Chain Management

Marius M. Solomon
Northeastern University, Boston, MA, USA

Introduction

For quite some time, logistics has accounted for a significant percentage of the U.S. gross domestic product (GDP). The Council of Supply Chain Management Professionals estimated that in 2008 the country's logistics costs were about $1.3 trillion, or 9.4% of the $13.8 trillion GDP. Year-to-year carrying costs decreased by 13.2% due to smaller inventories and lower interest rates while transportation costs rose by 2% as a result of higher fuel prices. These figures and a number of other key economic developments highlight logistics and supply chains as areas where large productivity improvements have and continue to be attained. Given the intrinsic complexity of logistics problems in today's global supply chains, such improvements could not have been achieved without the use of analytical tools, including operations research/management science (OR/MS) methodologies.

The mathematical difficulty of strategic, tactical, and operational logistics decisions and the magnitude of the potential cost savings to be achieved by utilizing OR/MS models and algorithms have attracted researchers since the early days of the field. Witness to this are the pioneering efforts of researchers in 1950s, 1960s, and 1970s. Most of the methods developed made extensive use of network models and algorithms coupled with different types of inventory techniques.

Over the last twenty five years, fueled by major developments in modeling and algorithmic methodology, constant breakthroughs in computer technology, and web-based applications, operations researchers have found logistics to be a very fertile design and implementation area. They addressed an ever increasing variety of problems with escalating complexity and size. The body of supply chain applications of OR/MS techniques also expanded at a progressively swifter pace. In what follows, the focus will be on some of the more important areas in logistics and supply chain management and, where possible, on OR/MS applications in large-scale logistics systems.

Networking and Routing

Network design and freight routing have been addressed by Braklow et al. (1992) in the context of less-than-truckload (LTL) transportation. The authors formulate the problem as a nonlinear, multicommodity network design problem. Its solution is based on a hierarchical decomposition of the overall problems into a series of optimization subproblems. The network design problem is solved using interactive optimization, where the user guides the search performed by a local improvement heuristic which adds (drops) links to (from) the load planning network. The subproblems involve the routing of the LTL shipments, of truckload shipments and of empty trailers. The former two problems are solved using shortest path algorithms, while the latter problem involves the solution of a classical linear transhipment problem. They must be reoptimized every time a change is made in the load planning network. This is performed sufficiently fast to make interactive optimization possible. The model has been used as a tactical decision tool for load planning by one of the largest LTL motor carriers. It has also been used at the strategic level to determine the location and size of new terminals.

The research of Simão et al. (2010) is illustrative of the evolution of the OR/MS methodology which had to match the increasing complexity of real-world problems due to their size and dynamism. The authors address the problem faced by a major transportation company that wanted the ability to significantly improve how it managed the dynamics of its fleet of over 6,000 long haul drivers. The issues under consideration were how to handle hiring, changes in work rules, and examine scenarios permitting the drivers to spend more time at home. Simão et al. used approximate dynamic programming (ADP) to solve this problem. ADP is a simulation-based algorithm that optimizes complex stochastic problems through iterative learning. This approach was capable to deal with both complex dynamics and multiple forms of uncertainty regarding drivers and loads and to anticipate the future impact of decisions. The model allowed the company to avoid costs and achieve savings in the millions of dollars and, at the same time, substantially improve its customer service.

While logistics encompasses a broad set of activities, two key elements are transportation

and storage. Generally, very intricate trade-offs occur between these two areas. The first focus will be on transportation issues and then address inventory matters. Transportation is in fact the most costly component of many logistics systems and supply chains. A very important segment of transportation management is the routing and scheduling of vehicles. This facet is of significant importance across land, air, and water transportation. Similar problems are also encountered in a variety of manufacturing, warehousing and service sector environments.

This area has been reviewed in several insightful surveys, including that written by Laporte (2009). The author highlights the major developments in the OR/MS methodology for the vehicle routing problem (VRP) over the last fifty years. He reviews successful exact algorithms and heuristics introduced in the literature ranging from extremely sophisticated optimal decomposition algorithms to powerful metaheuristics. His work is complemented by the books edited by Toth and Vigo (2002) and Golden et al. (2008) who put together articles spanning a multitude of VRP variants. All these sources also provide a wealth of references to research conducted over the years in the ever increasing universe of VRP problems.

While Laporte highlights the outstanding progress made by optimal algorithms, he also notes that such methods have their limitations with respect to increasing larger problems. Certainly, they can be transformed into optimization-based heuristics which can solve larger problems. However, when it comes to huge instances, heuristics are still the answer. Laporte also observed that over time the research community has designed metaheuristics that have become more and more over-engineered at the expense of computation time. He suggests researchers should consider producing simpler and more flexible algorithms capable of faster handling of a broader variety of constraints, even if they cause a slight decrease algorithmic effectiveness.

The application of OR/MS methods in this area has lead to significant achievements in practice. Kant et al. (2008) report on a very successful implementation undertaken by Coca-Cola Enterprises (CCE), the world's largest bottler and distributor of Coca-Cola products. The CCE fleet in the U.S. is only surpassed in size by that of the U.S. Postal Service. The software developed is very flexible and handles a variety of practical constraints in determining the truck routes from each distribution center to the retail outlets. Hundreds of dispatchers use this software daily to plan the routes for tens of thousands of trucks. The deployment of the software has resulted in annual cost savings of tens of millions of dollars. In addition, CCE has experienced fewer missed deliveries and gained the ability to deal with tighter time windows, thereby substantially enhancing its customer service. Given the success of the software, Coca-Cola decided to roll it out in other parts of its business.

A variety of routing settings also involve the temporal aspect in the form of customer imposed time windows. A unified framework for all time constrained vehicle routing and crew scheduling problems was developed by Desaulniers et al. (1998). This paper presents a more general model than previously considered which integrates all the different time constrained vehicle routing and crew scheduling problem types examined up that point in the literature. The model extends well-known generic formulations to allow the modeling of all real-world circumstances encountered to date in this environment. This enables the reader to understand the common structure of these problems. It also allows one to perceive the relations between the various problems, the different forms of the model used previously in the literature, and assorted applications across a unified formulation. This also permits the reader to note the diversity of specialized algorithms that have been designed to solve them, and to comprehend the difficulties inherent in certain modeling aspects.

The common structure of these problems is a multi-commodity network flow model with additional resource constraints. Time is one example of a resource. Resource variables help manage complex nonlinear cost functions and difficult local constraints (e.g., time windows, vehicle capacity, and union rules). To solve the nonlinear multi-commodity problems in this class, the paper presents a branch-and-bound framework. It shows that a variety of strategies and algorithms can be utilized for the computation of lower bounds and for devising branching schemes. The lower bounds are derived by using a decomposition approach. In their paper, Desaulniers et al. focus on an extension of the Dantzig-Wolfe decomposition principle and establish that this is valid even for nonlinear objective functions and constraints.

They also illustrate that it embeds the column generation-based methods using set partitioning formulations previously suggested in the literature as special cases. The branching module used to obtain integer solutions compatible with column generation is more general, but yet simpler than other prior strategies. Branching decisions and cuts appear either in the master problem or in the subproblem structures. Finally, the authors examine the constrained shortest path problems that appear at the subproblem level of the decomposition. The paper displays the variety of specialized dynamic programming algorithms that have been developed to solve these and more general single commodity problems and the aspects which have not yet received attention.

Optimal algorithms stemming from the above framework have emerged as the most preferred solution methodologies. These branch, price, and cut algorithms have been widely applied not only in a variety of routing and scheduling transportation contexts, but also in crew scheduling, network design, production, and telecommunications, as well as other areas. These algorithms have become even more powerful due to different classes of strong cutting planes that have been proposed to tighten the lower bounds. Significant improvements in the quality of the lower bounds computed in the search tree have also resulted from utilizing the elementary shortest path problem with resource constraints at the subproblem level.

Crew Scheduling

Two notable application areas of the above framework are the urban transit crew scheduling problem and the airline crew scheduling problem. Blais et al. (1990) describe a software package to handle the former problem. It consists of several modules. The first uses standard network flow methodology to solve the bus scheduling problem. Next, crew scheduling is handled in two steps. In the first, several approximations are used to permit the fast derivation of a linear- programming solution. Using this solution, specific driver assignments are then obtained in step two by means of solving a quadratic-integer program heuristically and using an optimal matching algorithm. Finally, a shortest path algorithm utilizing the marginal costs from the matching problem is used to improve the solution. The software has been successfully implemented in a number of cities worldwide.

With respect to exact algorithms, very large multiple-depot vehicle scheduling problems can be solved to optimality in reasonable times. The same holds true for practical crew scheduling problems encountered in urban mass transit and in air transportation. However, the joint consideration of these two problems proved to be much more challenging. Haase et al. (2001) address this simultaneous vehicle and crew scheduling problem in urban mass transit systems. They propose an optimization algorithm based on the above Dantzig-Wolfe column-generation framework for the problem variant involving a single depot case and a homogeneous vehicle fleet. The authors take a crew-first, vehicle-second approach where decision variables are defined only for the scheduling of drivers. The bus routes are handled within constraints. These constraints ensure that optimal bus itineraries can be obtained in polynomial time once the crews have been scheduled. The authors provide computational results that indicate that this technique was capable to optimally solve larger problems than previously reported in the literature. An easily achieved optimization-based heuristic version of the method is was able to solve even larger instances.

The evolution in airline crew scheduling from the manual methods of the early 1970s to the powerful OR/MS based software now in use mirrors the developments that have occurred in many other logistics areas. In addition, research in crew scheduling is part of the stream of research spearheading the development of optimization methods capable of handling practical size problems. This new generation of optimal algorithms discussed above blends the effectiveness of advanced optimization methods, designed to take advantage of special problem structures, with the efficiency of sophisticated computer science techniques, and the computing power of workstations.

Air transport carriers use a five-phase tactical planning and scheduling process. The schedule planning phase first determines all flight segments, or legs, to be flown during a given period, according to the forecasted demand, the time slots that the company owns at different airports, and the competition. The next phase is fleeting, where each equipment type or

fleet is assigned to individual legs. The fleeting solution provides a decomposition for the problems to be considered in the next three phases. For each fleet, the flight legs with their corresponding scheduled departure and arrival times become inputs to the aircraft routing phase. At this stage, for each type of aircraft, routes are build that must encompass all legs to be flown and satisfy maintenance requirements. The fourth phase builds valid crew pairings, also known as crew rotations, to minimize crew cost. A pairing is a detailed schedule of activities, such as flight legs, deadhead legs (crew members fly as passengers), briefings and debriefings, breaks and nighttime rests that start and end at the same crew base. In the fifth phase, employees are assigned to monthly blocks where each block describes the activities of a crew member during the month. When this process accounts for employee preferences it is called rostering. When blocks are built without regard to crew members' desires, the process is called bidding, in which case, crew members choose blocks according to seniority.

Butchers et al. (2001) provide a historical account and discuss the OR/MS techniques developed for crew scheduling and rostering at a major airline over a fifteen year period. It highlights the fact that the use of such methodologies created major savings for the company, while at the same time providing rosters that benefited the crew members. The account is also illustrative of the advantages to be derived from close collaborations between industry and academia. Nevertheless, the airline planning process phases considered had to be treated sequentially due to the size of the problems involved. The fact that in this planning process the output of an earlier phase provides the input to the next later phase generally leads to suboptimal policies.

Researchers have started to solve selected subsets of planning problems such as fleeting and aircraft routing and aircraft routing and crew pairing simultaneously. Representative of this line of work is that of Sandhu and Klabjan (2007) that addresses the fleeting, aircraft routing, and crew pairing phases in an integrated fashion. The maintenance requirements that must be satisfied in the aircraft routing phase are, however, not considered. The authors propose two optimal algorithms, one using a Benders decomposition approach and the other involving a combination of Lagrangian relaxation and column generation. Based on computational experiments conducted using data from a major carrier, they conclude that if improvements are sought in a short amount of time, the former method should be used. However, if sufficient computing time is available, the usual case in this planning environment, then the latter technique should be utilized. In addition, the authors found the Lagrangian relaxation/column generation approach more robust and practical.

Real-Time Logistics

While the size of problems solved by optimization algorithms increases constantly, heuristics remain a viable tool for very large-scale and/or very complex problems. Dispatching, an intricate activity given the need for a solution in real-time to large-scale problems, lends itself naturally to heuristic solutions. The use of fast route construction/route improvement heuristics to deal with the practical complexities of the problem typifies the kind of research conducted in the 1980s. The highly dynamic character of dispatching is also apparent in truckload transportation. In this environment characterized by high demand uncertainty, a motor carrier must continuously manage the assignment of drivers to loads across the country. Stochastic network optimization models exemplify the type of methodology developed to solve this dynamic vehicle allocation problem. Powell et al. (1995) provide an extensive survey of this problem area.

When shipments could not be forecasted with accuracy, Moore et al. (1991) report having built mixed-integer programming (MIP) and simulation models. The use of these techniques for operational purposes has stemmed from the successful solution of a strategic decision through similar methods. This decision involved the significant reduction in the number of carriers used and the creation of partnerships with them. To solve the carrier selection problem for a global, integrated aluminum company, the authors developed an MIP and further analyzed its results using simulation. This problem represented an important part of a redesign effort aimed at centralizing previously decentralized transportation and purchasing decisions. In particular, by creating a central dispatch center and supporting decisions with OR/MS methodologies, the company improved on time delivery and reduced annual freight costs by

millions of dollars. Overall, this implementation was a reflection of the lean manufacturing philosophy extended to logistics. Furthermore, as logistics has evolved into an information technology centric environment, partnerships with carriers now involve electronic data interchange and web based information sharing.

Supply chains have become a competitive weapon in the global economy. The remarkable advances in telecommunications and information technology have enabled companies to focus on velocity and timeliness throughout the supply chain. To achieve these competitive advantages, they must be able to make effective use of the vast amount of real-time information now available to them. The Dynamic Vehicle Routing Problem (DVRP) is a prime example of a distribution context where intelligent use of real-time information can differentiate one company from another by means of superior on-time service. The DVRP is the dynamic counterpart of the VRP. In the latter problem, the objective is generally to minimize the travel cost for several vehicles that must visit and service a number of customers. Constraints specifying capacity restrictions, time windows within which to start service at customers, and additional requirements on the drivers and vehicles restrict the optimization space. In the VRP all routing and demand information is known with certainty prior to the day of operations, so routes can be planned ahead. In contrast, in the DVRP part or all of the necessary information becomes available only during the day of operation. In other words, not all information relevant to the planning of the routes is known by the planner when the routing process begins and information can change after the initial routes have been constructed.

The practical significance of the DVRP is highlighted by the variety of environments it can model. An important application is the pickup and delivery of overnight mail. Other scenarios include the distribution of heating oil or liquid gas to private households, residential utility repair services, such as cable and telephone, and appliance repair. Additional settings are the transportation of the elderly and physically disabled, taxi cab services, and emergency services, such as police, fire, and ambulance dispatching.

Gendreau and Potvin (2004) have edited a special issue of *Transportation Science* dealing with many issues in real-time fleet management. These were created by the consideration of transportation and fleet management activities as an integral part of the supply chain, their coordination with other aspects of the supply chain, and the explosive growth of web-based logistics services. The paper by Larsen et al. (2004) is illustrative of this type of research. The authors examine the traveling salesman problem with time windows for various degrees of dynamism. The objective is to minimize lateness and examine the impact of this criterion choice on the distance traveled. The focus on lateness is motivated by the problem faced by overnight mail service providers. A real-time solution method is proposed that requires the vehicle, when idle, to wait at the current customer location until it can service another customer without being early. In addition, the authors develop several enhanced versions of this method that may reposition the vehicle at a location different from that of the current customer based on a priori information on future requests. The results obtained on both randomly generated data and on a real-world case study indicate that all policies proved capable of significantly reducing lateness. The results also show that this can be accomplished with only small distance increases.

Another important setting for the application of OR/MS methodologies to support real-time decisions is in the airline industry. Airlines must build aircraft routes and crew rotations to provide scheduled service while maximizing profits. This objective must be achieved in an environment that is difficult to predict. Hence, planning decisions– made in advance– may have to be altered by real-time decisions when perturbations occur in order to minimize customer inconvenience and costs to the airline. Changes made on the day of operations result from bad weather conditions, headwinds on route, technical difficulties with aircraft, crew and passenger delays, and peak-hour congestion at airports. This challenging problem is very important in practice since perturbations are costly in terms of rescheduling issues and especially in terms of loss of traveler goodwill. This is because they can lead to delaying or canceling flights, swapping aircraft among flights or using spare aircraft (if any exist), which in turn affect future deployment of aircraft and crews. Dispatchers usually adjust the planed schedules as soon as a perturbation occurs. They have little time to analyze cost-effective scheduling alternatives. Therefore, it is important to find a good balance between the optimality of a proposed solution and the speed with which it is obtained.

Historically, the day of operations solutions have relied mainly on management information systems and graphical user interfaces, and on simple heuristics to support the decision process. Exact algorithms also have been deployed in practice to provide optimal or near-optimal solutions. Yu et al. (2003) present an optimization based decision support system developed for a large air carrier that provides crew-recovery solutions. The software proved capable of handling major disruptions and in turn it allowed the airline to recover quickly and derive benefits in the millions of dollars.

Inventory in the Supply Chain

The fundamental and often complex trade-offs between transportation and inventory costs are a central issue in supply chain management. Blumenfeld et al. (1987) present an ingenious analysis of the production network of a manufacturer of vehicle components. Their bottom-up approach begins with the analysis of the trade-offs on a single link. These are obtained using a standard economic order quantity (EOQ) model. Using several realistic approximations, the authors are then able to extend their analysis to much more complex networks. In particular, one approximation allows the decomposition of a large network into a number of small independent subnetworks, where shipment sizes can be computed using the single link model. This work involving simple, easy to understand models, supplemented by insightful graphical information, is representative of a line of research complementary to combinatorial optimization.

In light of intense global competitive pressures, many companies have tried to decrease their inventory investment while maintaining or improving customer service in their vital business processes. Yet, the implementation of lean manufacturing has lead to significant increases in product variety. In turn, this has augmented the complexity of the after-sales service logistics networks. Cohen et al. (1990) describe the design of a spare parts inventory control system capable of supporting multiple service levels. The building block of their approach is a periodic review, stochastic model for the one-part, one-location case. This model is then extended to a multi-product, one-location case, called the service allocation problem. This is solved using a greedy heuristic. A decomposition approach is utilized for the overall multi-product, multi-echelon problem. It involves a bottom-up procedure which begins by solving the service allocation problems at the lowest echelon. The solutions are then used to deal with the next higher echelon. The algorithm proceeds in this fashion, level-by-level up to the highest echelon. The model has been implemented by a global computer manufacturer. It has found applicability both as a strategic network redesign tool and as a weekly operational device.

Inventory investment becomes progressively more substantive with increases in the size of companies holding it. While enterprise resource planning software has provided much needed inventory visibility in the supply chain, these systems do not optimize inventory levels. OR/MS methods do, but as they have become increasingly sophisticated over time, the scale and complexity of supply chains has also augmented. The paper by Farasyn et al. (2011) is representative of these issues. It discusses the implementation of various inventory management solutions at Procter and Gamble (P&G). Given the company has 500 different supply chains, it chose a two pronged approach to realize improvements in inventory levels. P&G first focused on the wide-ranging use of spreadsheet-based inventory models throughout its supply chains. This part of the implementation involved four methods that can locally optimize different parts of the supply chains. The next step dealt with the deployment of integrated multi-echelon inventory software in the company's more complex supply chains. The use of OR/MS technologies led to savings of $1.5 billion in 2009, while service levels were maintained or increased. The authors also highlight the fact that this successful implementation did not rely on tools alone. A buy-in from the various entities involved was of equal importance and so was the fit between the necessities of a business unit and the inventory techniques it will use.

Supply Chain Management

Corporations have evolved from the vertical management of separate individual functions to the horizontal management across all functions. Many of

the old conflicts among business units, including transportation versus inventory have given way to the concept of the total logistics cost. Supply chain management is the natural progression of applying these concepts throughout distribution channels by means of pipeline inventory management and information sharing by all involved parties.

The implementation of a comprehensive set of OR/MS tools in a variety of business areas of a large oil company is discussed in Klingman et al. (1987). It is not surprising to see that this industry was at the leading edge of computer integrated horizontal management across functional areas. OR/MS techniques such as linear programming have been utilized in the oil industry since the 1950s. The work of the above authors included such tools as mathematical programming, statistics, forecasting, expert systems, artificial intelligence, organizational theory, cognitive psychology and information systems. A core element was the optimization-based integrated system for supply, distribution, and marketing. This strategic tool is used to make a number of decisions including how much product to buy or trade, how much to hold in inventory, and how much to ship by each mode of transportation. The system is based on the minimum-cost flow network model.

Since then, supply-chain management has become a key application area for OR/MS methodologies, with an explosive growth in the development of models and algorithms and their implementation. Some researchers took an economics perspective, including game theory and information management approaches, while others examined inventory models. Supply chain configuration has also been at the forefront of research in this area. Researchers have examined the integration and coordination between production and distribution, location and routing, routing and inventory, and routing and crew scheduling. They have proposed a vast assortment of heuristic and optimal methods for these aspects of supply chains and a variety of single and multi-objective decision support systems for the overall system design, (Simchi-Levi et al. 2004).

Sophisticated OR/MS models and algorithms are only part of successful implementations. Ulstein et al. (2006) drive home the idea of the collaboration between business and academia, and business and the community as additional necessary ingredients. Their work was conducted for Elkem's silicon division which is the largest supplier of silicon metal and ferrosilicon in the world. With the slowdown in the global economy that started in 2000, the corporation realized the need to improve the efficiency of its supply chain network and evaluate its product portfolio. To help the division to manage this process, the authors developed a strategic planning model. This mathematical-programming model addresses decisions pertaining to future plant structure, including possible closures, new plant acquisitions, and investments in production equipment. The silicon division has used the model and its scenario analysis capabilities extensively to obtain important benefits. The company agreed to a restructuring process, that included reopening a closed furnace and investing $17 million in equipment conversion. Overall, as a result of the restructuring plan, Elkem has achieved significant and sustained improvements in yearly revenue for the silicon division. Many companies face supply-chain design problems with a similar level of complexity. They can benefit from following the close collaborative process described in this paper and from using optimization tools to solve their decision problems.

Sustainability issues are becoming a requisite part of a supply chain studies. For example, Nagurney and Nagurney (2010) consider a company's multicriteria decision problem that attempts to minimize the total costs associated with its supply chain activities, along with the emissions generated by its manufacturing, storage and distribution facets. The business incurs both capital and operational costs. The authors propose a network optimization framework and illustrate an algorithm applied to a number of sustainable supply chain examples. Carter and Easton (2011) trace the evolution of the field from the original research on social and environmental areas, to issues of corporate social responsibility, and the eventual realization that sustainability is part of the bottom line. They provide a comprehensive review of the sustainable supply-chain management literature. One of the salient features of the paper is the relationship between supply chain risk management and contingency planning and sustainable supply chains.

Longest-Route Problem

In a directed network, the finding of the longest route between two nodes is the longest-route problem. In an acyclic network, one that represents the precedence

relationships between activities in a project, the longest route in the network represents the critical path, with the value of the longest route equal to the value of the earliest completion time of the project.

Lottery

In utility theory and decision analysis, a lottery consists of a finite number of alternatives of prizes $A_1 \ldots A_n$ and a chance mechanism such that prize A_i will be an outcome of the random experiment with probability $p_i \geq 0, \Sigma_i p_i = 1$.

See

- ▶ Utility Theory

Lower-Bounded Variables

The condition $l_j \leq x_j$, $l_j \neq 0$, defines x_j as a lower-bounded variable. Such conditions are often part of the constraint set of an optimization problem. For linear programming, these conditions can be removed explicitly by appropriate transformations, given that the problem is feasible when $x_j = l_j$ for each j.

M

Machine Learning

A term used in the artificial intelligence community to indicate automated improvement based on experience or empirical data in accomplishing a given task such as optimizing an objective function.

See

► Artificial Intelligence

MAD

Mean absolute deviation.

Maintenance

Maintenance is the support of successful system operation during long periods of usage by means of: (1) regular or sample check-ups; (2) planned or preventive replacement of the system's units; (3) failure diagnosis; and/or (4) spare units supply. Operations research models for a system maintenance analysis are represented mainly by optimization models for the improvement of system and equipment reliability.

For (1) and (2), one usually uses methods of controlled stochastic processes. For (3), one uses special methods based on mathematical logic, while (4) is considered in the scope of optimal redundancy and inventory control.

Manpower Planning

David J. Bartholomew
The London School of Economics and Political Science, London, UK

Introduction

Manpower (or, human resource) planning is concerned with the quantitative aspects of the supply of and demand for people in employment. At one extreme this might include the whole working population of a country, but it has been most successful when applied to smaller, more homogeneous systems like individual firms or professions. The term manpower planning appears to date from the 1960s though many of the ideas can be traced back much further. In recent years terms such as Workforce Panning and Personnel Planning have been used in the same sense. A history of the subject up to the 1980s,from a U.K. perspective, will be found in Smith and Bartholomew (1988). The literature of the subject is very scattered reflecting the diverse disciplinary origins of the practitioners, but most of the technical material is to be found in the journals of operations research, probability, and statistics. There was an initial surge of publication in the late 1960s and early 1970s and since then book length treatments include Grinold and Marshall (1977), Vajda (1978), and Bennison and Casson (1984). Bartholomew, Forbes and McClean (1991) gives a thorough coverage of the technical material and contains an extensive bibliography. Since then there has been a period of consolidation. The earlier theoretical work has largely proved adequate for practical needs, though there have been developments in closely related areas. See, for example, Kalamatianou and McLean (2003).

The essence of manpower planning is summed up in the aphorism that its aim is to have the right numbers of people of the right kinds in the right places at the right time. The basic approach is first to classify the members of a system in relevant ways. These will often be on the basis of such things as grade, salary level, sex, qualifications, and job title. The state of the system at any point in time can then be described by the numbers in these categories, often referred to as the stocks. Over time, changes occur as individuals join, leave the system or move within it. The numbers making these transitions are called the flows. The factors giving rise to change may be predictable or unpredictable but will include such things as individual decisions to leave, changes in demand for goods, management decisions on promotion or organizational structure and so on. The operations researcher's role is to describe and model the system as a basis for optimizing its performance.

Stochastic Models

The presence of uncertainty in so many aspects of the functioning of a manpower system means that any adequate model has to be stochastic. Two probability processes, in particular, have proved to be both flexible and realistic. These are the absorbing Markov chain and the renewal process. The former is appropriate in systems where the stocks are free to vary over time under the impact of constant flow rates, or probabilities. The art of successful application is to define the classification of individuals that all those within a category have approximately the same probability of moving to any other category. Loss from the system corresponds to absorption, and the theory of Markov chains can then be used to predict future stock numbers for various sets of transition probabilities. Later work has extended these methods by allowing the intervals between transitions to be random variables in which case a semi-Markov process or a Markov renewal process results.

When the numbers in the categories are fixed, as they often are when the categories are grades or based on job function, a different approach must be used. Transitions cannot then be regarded as generated by fixed probabilities, but arise in response to the occurrence of vacancies. The result is a replacement, or renewal process, where movement is driven by wastage (or the creation of new places). It was shown in Bartholomew, Forbes and McClean (1991) that the flows of vacancies could be modelled by a Markov chain in a manner very similar to that used for the modeling of the flows of people.

If a system is relatively small or if the rules governing its operation are complex, the only realistic way to model it may be to use a computer-based simulation model. The term simulation is commonly

used in two distinct senses in this context. Primarily it means that each individual movement is generated in the model by a random mechanism. Secondly, it is sometimes used of any algorithm for computing the aggregate properties of a system treated deterministically.

Forecasting and Control

Broadly speaking all models may be used in two modes for forecasting or control. In the early stages of a study one usually wishes to forecast the future state of the system if current trends continue. Next, it will usually be desirable to carry out a sensitivity analysis to explore the consequences of variations from present conditions. This leads on to questions of control where the question is how those parameters under management control should be chosen to achieve some desired goal. The distinction between forecasting and control can be illustrated using a simple form of the Markov model. According to this model successive vectors of expected stocks are related by an equation of the form

$$\boldsymbol{n}(T+1) = \boldsymbol{n}(T)\boldsymbol{P} + \boldsymbol{R}$$

where T represents time, $\boldsymbol{P}$ is a matrix of transition probabilities, and $\boldsymbol{R}$ is a vector of recruitment numbers. In forecasting mode, estimated or guessed values of $\boldsymbol{P}$ and $\boldsymbol{R}$ could be used to predict future values of $\boldsymbol{n}(T)$. In principle, $\boldsymbol{P}$ and $\boldsymbol{R}$ could both depend on T. In control mode, one would be asking how some or all of the elements of $\boldsymbol{P}$ and $\boldsymbol{R}$ should be chosen to attain a given $\boldsymbol{n}$ within a specified time. This gives rise to questions of attainability (whether the problem is solvable) and maintainability (whether an $\boldsymbol{n}$ can be maintained once it is reached). These matters have led to an interesting set of theoretical questions about the solvability of such problems in deterministic or stochastic environments. At a more practical level it has led to the formulation of optimization problems expressed in goal programming and/or network analysis terms (Gass 1991; Klingman and Phillips 1984).

The wastage flow (also known as attrition or turnover) is an important element in a manpower system both because it is highly variable and, largely, beyond the control of management. It has been intensively studied mainly through the survivor function or, equivalently, the frequency distribution of completed length of service. In practice the analysis is complicated by the fact that the data are usually censored and sometimes truncated also. This work has three main objectives: measurement, prediction, and gaining insight into the factors determining wastage.

The demand side of the manpower equation has proved to be less tractable. Demand for people is equivalent to the supply of jobs and this depends on technological, political, social, and economic factors many of which may be specific to particular organizations or industries. To take only one example, the demand for qualified medical manpower will depend on such varied things as demographic changes, the willingness of government or users of the service to pay, and the appearance and spread of new diseases like AIDS. The methods used have been, and have to be, as diverse as the fields of application. Because of the considerable uncertainties involved it is important to monitor constantly the changing environment and to adjust plans accordingly. A once-and-for-all plan has no place in manpower planning.

Marginal Value

The marginal value is the extra cost of producing one extra unit of output. Similarly, marginal revenue is the extra revenue resulting from selling an extra unit of goods. From the economics of a firm, when marginal revenue equals marginal costs, the firm is in an equilibrium optimal condition in terms of maximizing profits. Depending on the application, the dual variables of a linear-programming problem can be interpreted as marginal values. The economic interpretation of the dual variables is complicated by alternate optimum solutions (corresponding to different bases) that may yield different values of the dual variables. Thus, there may be two or more marginal values for the same constraint. Such multiple values must be interpreted with care.

Introduction

Marketing offers a rich and unique domain for applications of operations research (OR) methods, models, and approaches. Not only does the marketing area offer opportunities to develop and apply OR models and methods to increasingly important decisions affecting ALL companies, nonprofits, governments, societies, and individuals, but also unique opportunities to further the much needed collaboration between academics and practitioners, and for bridging the silos between marketing and the other management disciplines and functions.

Since customers (individuals or groups) are at the heart of the marketing system, OR modeling approaches help characterize, understand, and predict their behaviors. For consumers and organizational buyers, that behavior involves the search for solutions to a want or desire, the screening or evaluation of alternatives, the selection of a best alternative, the act of purchase, the post-purchase feedback to the firm as well as to other customers and learning that affects future purchasing behavior. In fact, such applications of OR to marketing problems have become even more prevalent, with website morphing (Hauser et al. 2009), Netzer's work on optimal email campaigns, and optimal in-store movement using the traveling salesman paradigm (Hui et al. 2009).

Firms and other non profit organizations (such as museums, politicians, government organizations) capitalize on that knowledge or model of individual behavior by focusing on such decisions as product/service design, pricing, distribution, promotion, advertising, personal selling, and the likely customer responses to them. In addition, at a higher level, these

decisions must be integrated and coordinated with the activities of other management functions (finance, manufacturing, R&D, etc.) and linked to other product and market decisions of the organization, including the critical resource allocation decisions among products, markets, distribution options, and businesses. Such critical decisions are evaluated based on their return on investment (ROI) under alternative scenarios reflecting different views of the future.

The external scenarios range from pessimistic views of recurring financial crisis, catastrophic natural disasters, continued terrorist activities and political unrest around the world, through continuation of the status quo, to optimistic scenarios of growth and prosperity driven by the fast growing economies of Asia and a recovery of the West. For marketers, these scenarios lead to consideration of strategic alternatives derived from a narrow view of modeling, e.g., the impact of a specific marketing activity (such as advertising expenditures) through an integrated view of all marketing touch points and product/service/solutions/customer experience, to the design of full strategy integration across the various management functions, incorporating multiple short and long-term performance measures.

Background

The American Marketing Association defines marketing as: "... the process of planning and executing the conception, pricing, promotion, and distribution of ideas, goods, and services to create exchanges that satisfy individual and organizational objectives."

As a management function, marketing includes such activities as advertising, sales and marketing research. Or, more simply put, marketing's organizational role is the interface between a firm and its customers. It is also a critical participant in cross-functional processes aimed at developing and launching new products and services that create customer value, i.e., products and services that customers want.

As a philosophy, marketing views the need to understand, anticipate and meet customer needs as the key to organizational success. As such, the customer is the final arbitrator of the value of any product or service offering. Marketing philosophy also extends the concept of customer orientation to internal customers and other stakeholders.

Thus, marketing is concerned with anticipating and understanding human needs and wants and translating those needs and wants into the demand (as economists use the term) for products and services. Those needs and wants are satisfied with products and services that are increasingly being developed in collaboration with empowered consumers. Businesses that exemplify this view include Build-a-Bear, Dell, and others offering opportunities for customization of the products and services, as well as firms that now scrape blogs, discussion forums, and other user-generated content to bring the digital voice of the customer into the firm, and help determine the appropriate responses (Ghose and Han 2011).

Products and services have functional as well as image characteristics. They are made available to the customer through a variety of channels ranging from physical retail stores to online websites, to mail order to social network platforms (e.g., Facebook). In order to effect an exchange, individuals have to be aware of, emotionally engaged, and understand the product (through advertising or other communication media), find the product worth their money (by comparing the product's total cost — its purchase price adjusted by any promotional offerings plus the cost of maintaining, using and disposing of the product — with the benefits promised in terms of performance and image), and participate in the exchange process.

While historically marketing models of behavior saw a product's value as consisting of the sum of the utilities of the features and benefits of which it is comprised (Green et al. 1973), and that is still a significant part of marketing modeling, newer conceptual models also take into account the perceived value of others, the recommendation of others, and the ability to share those experiences with others via one's social network (Stephen and Toubia 2010), or via the network externalities generated by other adopters.

Exchanges have typically been aggregated to the context of a market segment, which consists of the customers sharing a particular and similar need and who are willing to engage in exchange to satisfy that need. However, it is no longer uncommon to see exchange activities take place between the firm and individual consumers rather than at the level of a market segment (which represents higher level of aggregation). In essence, technology has allowed marketing in the 21st century to be infinitely tailored

because of the wealth of individual-level data that is now tractable due to the advances in the interactive media, and consumers' motivation and ability to customize the offerings.

OR Marketing Model Types

OR in marketing helps decision makers by harnessing measurement models and theoretical models and embedding them within a decision model (or more generally, within a decision-support system). The corresponding models are called **measurement models**, **stylized theoretical models**, and **decision-making models**, respectively (although it may be equally helpful to interpret these categories as classification dimensions for interpreting the multiple purposes of models).

Measurement Models — The purpose of measurement models is to describe and predict a current or anticipated either an individual consumer or the market reaction to a product or service as a function of various independent variables. The phrase "market reaction" here should be interpreted broadly. It is not necessarily units demanded but could be some other related variables. For example, in Guadagni and Little's (1983) model, the dependent (reaction) variable is the probability that the individual will purchase a given brand on a given purchase occasion. Choice models often have several independent variables including whether the brand was on sale (deal) at a given purchase occasion, regular price of the brand, deal price (if any), brand loyalty of the individual, etc. In addition, sometimes the focus of such models may be on certain variables preceding the steady-state demand (e.g., awareness, first-trial, repeat purchase). These examples suggest that measurement models can deal with individual (disaggregate) demand or aggregate (segment or market-level) demand as well as transitory or steady-state demand. Note that advances in measurement models can be due to better data (e.g., scanner data) or better estimation methods and procedures (maximum-likelihood methods for generalized logit models, for example). In traditional marketing problems such as customer satisfaction and customer-defined quality, OR measurement models have greatly enhanced the relatively simplistic survey-based approaches to the measurement of these constructs. Relying on advances in structural equation modeling. as well as the new area of empirical industrial organization, allows researchers to address more realistic and rich problems, such as competitive pricing behavior in markets with a large number of products (e.g., Sudhir 2001).

Stylized Theoretical Models — The purpose of stylized theoretical models is to explain and provide insights into marketing phenomena: a stylized theoretical model typically begins with a set of assumptions that describes a particular marketing environment. Some of these assumptions may be purely mathematical, but are also intuitively logical with the objective of making the analysis tractable. Others are substantive assumptions with real empirical grounding. Two well-known theoretical modeling efforts are Bell, Keeney and Little (1975), who show what functional forms of market share models are consistent with a certain set of reasonable criteria, and Basu et al. (1985), who show what form of sales force compensation plan is optimal under a set of assumptions about firm and salesperson objectives and behavior.

Such stylized theoretical models have helped improve the ability to design optimal product lines, issues related to specialization versus vertical integration (McGuire and Staelin 1983), aligning the incentives between manufacturers and retailers (Jeuland and Shugan 1983), designing pricing strategies for traditional goods, and also information goods. Stylized models have helped improve how companies offer short-term price discounts (Raju et al. 1990), how such short-term price discounts pass through to the consumer, and how retailers might improve their private label offerings. As marketing systems evolved, especially with the advent of new technologies, such stylized models have significantly improved understanding of new platforms and mechanisms for interactions between buyers and sellers. Stylized theoretical models have also helped in the understanding of the role brands play in a competitive market, including the symbolic role that brands play in social interactions, and how firms may improve their advertising and communications strategies (Chen et al. 2009).

While the emphasis in this work is on developing stylized theoretical models, most work in this area also rigorously tests the ability of these models to predict firm and market behavior. Recent empirical work in

Marketing, Table 1 The frontiers of decision models (DM)

	DM frontiers today	DM frontiers tomorrow
Time Scale	Days and weeks, if not months	Moving toward real time in data entry, data access, data analysis, implementation, and feedback
Focus of DM	Support strategic decisions	Support both strategic and operational decisions
Mode of Operation	Individual and PC-centric	Organization and Network centric – support multiple employees in multiple locations on multiple devices
Decision Domain	Marketing	Marketing and other functions, such as Supply Chain and Finance
Company Interface	Loosely coupled to company's IT systems	Woven into IT-supported company's operations and decision processes
Intervention Opportunities	Discrete, Problem-driven	Continuous, Process-driven
DM Goal	Support analysis and optimization	Support robust and adaptive organizational decision processes
DM System Design	As a tool to understand information and enhance decisions	As tool to enhance productivity and success of business models
DM System Operation	Interactive (User interacts with model)	Interactive as well as autonomous (embedded)
DM Outputs	Recommended actions; What if analyses	Visualization of markets and their behavior (e.g., Dashboard), Extended reality (e.g., Business model simulation), Explanation (Why?), Automated implementation (e.g., create alerts, automate actions)
DM Implementation Sequence	Intervention Opportunity → Implementation of decisions → Integration with IT Systems	Integration with IT → Intervention Opportunity → Implementation of decisions

the structural economics also contains stylized theoretical models where observed outcomes are assumed to arise from equilibrium actions taken by agents, modulo stochastic error (Dube et al. 2010). In this manner, joint theory and empirical work has begun to play a larger role. Distinguishing features of stylized theoretical models, especially the ones that use economic modeling and game-theory as tools, are that they explicitly recognize that companies must make decisions in a competitive environment and recognize that they compete with other firms who also are capable of making sound decisions. It is through this explicit recognition that these models are able to provide companies with a theoretically sound and empirically grounded means of improving strategic marketing decisions.

Decision-Making Models — These models are designed to directly help marketing managers make better decisions. They incorporate measurement models as building blocks, but go beyond measurement models in recommending specific actions (e.g., optimal marketing-mix decisions) for the manager. The techniques used to derive the optimal policies vary across applications, and include calculus, dynamic programming, optimal control, and calculus of variations techniques, as well as linear and integer programming. These models have been developed for each marketing variable and for the entire marketing mix program (i.e., a product and service offering including pricing, distribution, etc.). Little's BRANDAID is a classical example of such a model. Lilien et al. (2011) elaborate on the impact such models have had.

Since 2000, many enhanced decision-making models have been developed that are embedded inside enterprise information systems. Examples include revenue management systems used by airlines and hotels and recommender systems used by web sites such as Amazon.com and netflix.com. Table 1, adapted from Lilien and Rangaswamy (2006), summarizes the many ways that decision models are evolving to provide enterprises with real-time and automated decision making capabilities.

The Emergence of Marketing Science

By most accounts, OR in marketing began its growth in the 1960s and 1970s. The literature used a variety of OR methods to address marketing problems: those

problems included product design/development decisions, distribution system decisions, sales force management decisions, advertising and mass communication decisions, and promotion decisions (Kotler 1971). The OR tools that were most prevalent in the 1960s and earlier included mathematical programming, simulation, stochastic processes applied to models of consumer choice behavior, response function analysis, and various forms of dynamic modeling (difference and differential equations, usually of the first order). Some uses of game theory were reported, but most models that included competition used decision analysis, risk analysis, or market simulation games.

Nearly three times the number of marketing articles appeared in the OR literature in the 1970s as appeared in the period from 1952 though 1969. In addition to the increase in the number of articles, reviews by Lilien and Kotler (1983) showed that a number of new areas had begun to emerge. These included descriptive models of marketing decisions, the impact of and interaction of marketing on organizational design, subjective decision models, strategic planning models, models for public and non-profit organizations, organizational buying models, and the emergence of the concept of the Marketing Decision Support System (MDSS). In addition, while the number of published articles rose dramatically, the impact on organizational performance did not appear to be equally significant, raising questions about effective implementation. Much of the literature of the 1970s pointed to the need to expand the domain of application. The "limitations" sections of some of the papers in the 1970s pointed out that many important phenomena that were being overlooked (such as competition, dynamics, and interactions amongst marketing decision variables) were both important and inherently more complex to model. Hence, the level of model complexity and the insightfulness of the analyses in marketing seemed destined to escalate in the 1980s and beyond.

The 1980s saw another more-than doubling of the number of published OR articles in marketing compared to the earlier decade. Two of the areas that produced much of this growth were stylized theoretical models and process-oriented models. The shortening of product life cycles and the impact of competitive reactions in the market place preclude most markets from approaching steady state or equilibrium. Areas of special research focus in that decade included extensive focus on consumer choice models (focusing on the dynamics and heterogeneity of the choice process and the implications for decision making) and the new product area (where the moves and countermoves of competitors keep the marketplace in a constant state of flux).

The 1990s saw new trends in marketing science (and in marketing in general), with the electronic marketplace changing the locus and the nature of the transaction. The concept of the physical marketplace is being replaced by that of market space, and marketing science has found new territories to develop theories and applications. Most of this, of course, is due to the applied nature of the marketing discipline in which solutions to problems emanate from the data and the problem at hand. As the physical marketplace is being replaced by the physical in conjunction with digital marketplace, OR methods that allow for cross-channel optimization are being developed.

The first decade of the 21st century has seen the marketspace/customer centricity trend continue, as customers have gained increased influence and power in all areas of marketing. User-generated content and customers as co-producers and co-marketers are increasingly accepted. Understanding and monitoring these new market structures are central to the new view of marketing. Markets are now made up of customer-networks, and models for understanding and managing such networks are being developed. And the study of the role of the marketing manager and the related decision support systems has evolved from Little's (1979) perspective to a domain of mainstream interest both to academics and practitioners (see Wierenga 2011).

Another important trend is the emergence of two-sided and multi-sided platforms, wherein a business builds a platform that enables many distinct audiences to engage with the business as well as interact with each other, to create economic value, often in the presence of network externalities (Eisenmann et al. 2006). Typically, value appropriation occurs through cross-subsidies, wherein the costs of acquiring one group (e.g., consumers) are subsidized by another group (e.g., advertisers), and the platform itself retains part of the value created. eBay (buyers and sellers), Amazon.com (consumers and affiliates), HMO (patients and doctors), and credit-card payment systems (merchants and consumers) are

often given as examples of platforms. Even many traditional businesses are transforming into platforms that connect players in a complex eco-system (e.g., iPhone as a device connecting application developers with consumers). Cross-subsidies between audiences creates complex transaction flows that offer opportunities for OR modelers to help in carefully managing prices, revenues, and subsidies to optimize business performance.

Trends of OR Use in Marketing

The OR literature in marketing is vast, as reviewed in Lilien and Rangaswamy (2008). Models have been used to explore most facets of marketing and the marketplace, and increasingly marketing research is integrated with appropriate modeling. Some key trends include the following:

1. **OR in marketing is having important impact both on academic development in marketing and in marketing practice**. During the 1980s two new and important journals were started that emphasize the OR approach: *Marketing Science* and the *International Journal of Research in Marketing* (IJRM). Both are healthy, popular, and extremely influential, especially among academics. Another journal, *Quantitative Marketing and Economics* was started in 2003. Together, they reflect the developments of marketing models.
2. **Digital marketing represents vast area of opportunity for OR**. By transforming the market place into marketspace, the revolution in the marketplace brings a host of modeling opportunities and challenges, such as: How are new products and ideas generated, diffused, and discussed in a digital environment? How can a firm manage the natural conflict in physical and electronic distribution channels? How can firms offer different prices to different groups of customers in an electronically linked world? How and when word-of-mouth among consumers evolves? When marketing, manufacturing and the customer are interlinked in the digital environment, what opportunities emerge in the marketing-manufacturing interface? Digital marketing has other major implications, such as the development of new markets (on-line auctions, electronic bargaining) and the possibility of involving customers directly in the development of information products (Dell stores, IBM Jam, and others). More recently, it has become feasible to model large-scale social networks consisting of millions of nodes and billions of links, such as for example to link in near real-time a TV event (e.g., Super Bowl ad) with the Twitter and Facebook feeds triggered by the ad, to potential impact on market outcomes. These provide opportunities to apply OR modeling for analyzing flows of information and influence in such networks to link those to consequences for the firm (e.g., profit) or adverse spread of word of mouth in the marketplace.
3. **New data sources are having a major impact on marketing modeling**. One of the most influential developments of the 1980s and 1990s has been the impact of scanner data on the marketing models field. Scanner data and the closely related single source data (of communication and consumption data) have enabled marketing scientists to develop and test models with much more precision than ever before. Indeed, the very volume of new data has helped spawn tools to help manage the flow of new information inherent in such data. Data mining methods applied to some of the new, massive direct-response data bases has resulted in much more precise customer targeting and promotion-selection procedures. Two new data sources are providing opportunities for OR modelers in marketing: (1) Large integrated data warehouses created by companies to feed enterprise systems, such as CRM, are creating opportunities for developing more fine-grained models that integrate traditional demand side modeling undertaken by marketing modelers with supply side modeling issues such as inventory management, multi-channel logistics, and the like. (2) User-generated data (e.g., online product reviews posted by consumers, social media activities such as twitter feeds) that provide information in real-time about market sentiments offer opportunities for modelers to develop new tools for supporting marketing decision makers. New models for text analysis and synthesis (e.g., to convert reviews into numeric scores representing valence and volume

of sentiments) developed by computer scientists represent a start, but many new opportunities exist in this nascent area to translate huge volumes of raw data into insights for action. Traditional quantitative data sources have been employed by marketing modelers extensively, but more and more attention is now being given to analyzing qualitative and textual data through data and text mining as well as sentiment analysis software packages developed in computer sciences. While the 1990s presented the land of promise for these methods, the 2000s saw it materialize. Thus, the number of people in the information systems area working on traditional marketing problems has increased dramatically, blurring the lines between these related disciplines.

4. **Stylized theoretical modeling is still a mainstream research tradition in marketing**. Stylized models allow researchers to state explicitly as set of assumptions or axioms and then derive theoretical propositions with respect to the phenomena being considered. Such propositions provide valuable managerial insights.
5. **Competition and interaction are major thrusts of marketing models today**. The saturation of markets and the economic fights for survival has changed the focus of interest in marketing models, probably forever. A key-word search of past volumes of *Marketing Science*, *Journal of Marketing Research*, and *Management Science* (marketing articles only) reveals multiple entries for "competition," "competitive strategy," "non-cooperative games," "competitive entry," "late entry," and "market structure." These terms are largely missing in a comparable search in the 1960s and early 1970s.
6. **Marketing research and modeling are facing new challenges**. Both marketing research and modeling, especially as applied to new product development, have to be reformed to address such issues as global scope, electronically interconnected product development sites, the potential for mass customization and rapid prototyping/testing. These issues drive the development of models that incorporate nontraditional customer information, including trade show-participant feedback, user co-development, lead user methods, data and text mining, and Internet panels. Similarly, advertising and marketing mix modeling face comparable challenges, which have led to numerous efforts to develop single source data, related modeling, experiments, and dashboards. Another challenge is to develop models, beyond those developed for the consumer package good industry, that capture adequately various idiosyncratic characteristics of industries such as financial services, entertainment, life sciences, and B2B industries.
7. **Beyond Marketing Analytics—Marketing Engineering**. Marketing analytics, a term that refers to any systematic analysis of marketplace behavior and transactions is giving way to advance marketing analytics or marketing engineering, a term Lilien and Rangaswamy (2006) have popularized to refer to the use of decision models for making marketing decisions. Many of these decisions are now being automated, with decision models making routine pricing and promotion decisions in low-risk stable environments. But the confluence of new data sources, theories, hardware and software, and computer networks has now put these decision models on the desktop of marketing executives everywhere. The use of OR in marketing through marketing engineering is accelerating because of at least six trends (Lilien and Rangaswamy 2008):
   - Investments in infrastructure firms need to maintain extensive, integrated corporate information warehouses (also called data warehouses).
   - The use of On-Line Analytic Processing (OLAP — or just-in-time OR!) to integrate modeling capabilities with data bases.
   - Deploying intelligent systems to automate many modeling tasks.
   - Developing computer simulations for decision training and for exploring multiple options.
   - Installing groupware systems to support group decision making.
   - Enhancing user interfaces to make the use of even complex modeling systems accessible to a wide range of users.
8. **Marketing Management Support Systems and Artificial Intelligence**. A marketing management support systems (MMSS) is defined as any device, combining information technology, analytical

capabilities, marketing data, and marketing knowledge, made available to marketing decision makers with the objective to improve the quality of marketing management (Wierenga and Van Bruggen 2000). Marketing models, with their origin in OR constitute the analytical part of MMSS. However, in marketing there are also many weakly-structured problem areas, where qualitative considerations and judgment are more important. Here, the knowledge and the expertise of the marketer are key resources. Therefore, marketing management support systems not only include the primarily quantitative, data-driven decision-support systems, but also support technologies that are aimed at supporting marketing decision making in weakly structured areas.

9. **Expert Systems**. Marketing expert systems have been developed for many domains of marketing, e.g., (i) to find the most suitable type of sales promotion; (ii) to recommend the execution of advertisements (positioning, message, presenter) (Burke et al. 1990); (iii) to screen new product ideas, and (iv) to automate the interpretation of scanner data, including writing reports. For an overview, see Wierenga and Van Bruggen (2000, Chapter 5). An example of a system especially developed for supporting a particular marketing function is BRANDFRAME. This system supports the decision making of a product or brand manager, which is a typical marketing job. More recently, expert systems in marketing are less often stand-alone systems, but are woven into the company's overall IT systems (Lilien and Rangaswamy 2008).
10. **Neural Networks and Predictive Modeling**. As mentioned earlier, in marketing companies can work more and more with data about individual customers. As a consequence of this development, customer relationship management systems (CRM) became important. An essential element of CRM is the customer database that contains information about each individual customer. This information may refer to socio-economic characteristics (age, gender, education, income), earlier interactions with the customer (e.g., offers made and responses to these offers, complaints, service), and information about the purchase history of the customer (i.e., how much purchased and when). This data can be used to predict the response of customers to a new offer or to predict customer retention/churn. Such predictions are very useful, for example, for selecting the most promising prospects for a mailing or for selecting customers in need of special attention because they have a high likelihood of leaving the company (campaign optimization). A large set of techniques is available for this kind of predictive modeling. Prominent examples are neural networks and classification and regression trees. Both techniques are rooted in artificial intelligence. CRM is a quickly growing area of marketing. Companies want to achieve maximum return on their often large investments in customer databases. (Van Bruggen and Wierenga 2010).
11. **Analogical Reasoning and Case-Based Reasoning (CBR)**. Analogical reasoning plays an important role in human perception and decision making. When confronted with a new problem, people seek similarities with earlier situations and use previous solutions as the starting point for dealing with the problem at hand. Analogical reasoning is also the principle behind the field of case-based reasoning (CBR) in Artificial Intelligence. A CBR system comprises a set of previous cases from the domain under study and a set of search criteria for retrieving cases for situations that are similar (or analogous) to the target problem. Applications of CBR can be found in weakly-structured domains such as architecture, engineering, law, and medicine. By their nature, many marketing problems have a good fit with CBR. A recent application uses CBR as a decision-support technology for designing creative sales promotion campaigns (Van Bruggen and Wierenga 2010).
12. **Adaptive Experimentation**. While OR applications in marketing have been focused on models, given the increased uncertainty, complexity and speed of change of the business environment, it is unlikely that one can model optimal strategies. The alternative to the search for a silver bullet is the adoption of an adaptive experimentation philosophy (Wind 2007) that allows experimentation with a number of innovative strategies, facilitates learning, helps create an innovative organizational culture that reduces the pressures for risk averse decisions, encourages relevant measurement and provides

a competitive advantage. As sophisticated firms such as Google and most direct response companies Increasingly engage in adaptive experimentation, a new role for many of the OR marketing models (including marketing mix models) is in suggesting hypotheses that guide the experimental variables and design. Adaptive experimentation is consistent with the philosophy of OR and should be considered in any portfolio of approaches to aid decision makers in making better decisions.

13. **Documentation of the Impact of OR Marketing Models on the Organization is Now Mainstream**. The emergence of the INFORMS Society for Marketing Science Practice Prize and work by Lilien (2011) and Wierenga (2011) have underscored the need to study how marketing integrated with the concepts of OR can become a mainstream research domain for marketing academics while having a greater impact on the operations of firms. According to a *Business Week* article in 2010, the Fortune 1,000 companies spend over $1 trillion in marketing annually. Yet, according to a McKinsey report (2009), most of these companies do not use marketing models to improve their marketing investment related decision making, even though the small percentage of companies that do (17% of B2C and 7% of B2B) seem to realize considerable benefits from their use. In a controlled experimental study, Lilien shows that the managers using decision models realize measurable improvements in decision performance when compared to managers who have access to the same data, but without a decision-support model to optimally interpret the data. Research is ongoing on what factors influence companies to deploy marketing models, under what conditions their impact is maximized, and how decision tools should be designed to enhance their usability and impact.

Concluding Remarks

OR/marketing models and approaches have had significant impact on academic research and practice. Marketing science has also been used to address important societal problems, e.g., Bradlow (2009) discusses the use of marketing science to aid in creatively solving problems related to the financial crisis. Developments in constructing, testing and applying new marketing science models will continue to benefit management and society.

Markov Chain Equations

William J. Stewart
North Carolina State University, Raleigh, NC, USA

Introduction

For a continuous-time Markov chain, the probability distribution at any time t, $\boldsymbol{\pi}(t)$, is calculated from the Chapman-Kolmogorov differential equation,

$$\frac{d\boldsymbol{\pi}(t)}{dt} = \boldsymbol{\pi}(t)\boldsymbol{Q}. \tag{1}$$

where the vector $\boldsymbol{\pi}(t)$ is of length n, the number of possible states in the Markov chain, and its ith component, $\pi_i(t)$, expresses the probability that the Markov chain is in state i at time t, and $\boldsymbol{Q}$ is the infinitesimal generator or transition rate matrix, a square matrix of order n whose elements satisfy

$$q_{ij} \geq 0, \quad i \neq j;$$
$$q_{ii} = \sum_{j=1,\, j\neq i}^{n} q_{ij}, \quad \text{for all } i = 1,\ 2,\ \ldots,\ n.$$

When the number of states in the Markov chain is relatively small (e.g., less than a thousand), computing numerical solutions of the chain equations is generally easy, and (1) can be solved readily by software such as MATLAB. But two difficulties arise when the number of states is large: The first is the sheer size of the matrices involved; the second is how well-conditioned or how ill-conditioned the equations are. These difficulties exist even in the simpler setting considered here when all that is required is the stationary solution of the Markov chain obtained by setting the left-hand side of (1) to zero and solving the linear system of equations that results.

It is not unusual for the number of states in a Markov chain model to exceed the millions. Such size impacts both the storage of the matrix and the number of vectors needed to compute the solution. Very large matrices cannot be stored in the usual two-dimensional array format; there is simply not enough storage space available. In addition, this would be very wasteful, since most of the matrix elements are zero. In general, each state communicates directly with only a small number of states and so the number of nonzero elements in the matrix is usually equal to a small multiple of the number of states. If the states can be ordered sequentially so that each communicates only with its closest neighbors, then the nonzero elements of Q lie close to the diagonal and a banded storage technique can be used. Otherwise, it is usual to store only the nonzero elements in a double-precision one-dimensional array and use two integer one-dimensional arrays to indicate the position of each nonzero element in the matrix. In addition to storing the transition matrix, a certain

number of double-precision vectors, of size equal to the number of states, is also needed. In the simplest numerical methods, two such vectors suffice. In other more sophisticated methods, many more (possibly in excess of 50) may be needed.

A second difficulty in solving Markov chains numerically is that of the degree of ill-conditioning of Q. In certain models, the difference in the rates at which events can occur may be many orders of magnitude, as is the case when a model allows for both human interaction and electronic transactions. These differences in magnitude may lead to ill-conditioned systems, that is to say, a small change in one of the parameters can result in a large change in the solution. It is appropriate to distinguish between numerical conditioning and numerical stability; the first has already been described and is a function of the problem itself; the second describes the behavior of an algorithm in attempting to compute solutions. A stable algorithm will not allow the error to grow out of proportion to the degree of ill-conditioning of the problem. In other words, a stable algorithm will give as good a solution as can be expected for the particular problem to be solved. A further effect of large differences in transitions rates is that they can create convergence problems for iterative solution methods.

Numerical Methods for Computing Stationary Distributions

The goal is to solve the matrix equation

$$\boldsymbol{\pi Q} = 0. \tag{2}$$

By setting $\boldsymbol{P} = \boldsymbol{Q}\Delta t + \boldsymbol{I}$, where $\Delta t \leq (\max_i |q_{ii}|)^{-1}$, this equation may be written as

$$\boldsymbol{\pi P} = \boldsymbol{\pi}. \tag{3}$$

In carrying out this operation, the continuous-time system represented by the transition rate matrix, $\boldsymbol{Q}$, is essentially converted to a discrete-time system represented by the stochastic transition probability matrix, $\boldsymbol{P}$. In the discrete-time system, transitions take place at intervals of time Δt, this parameter being chosen so that the probability of two transitions taking place in time Δt is negligible. The stationary distribution π may be computed from either of these equations.

Direct Methods — Since Eq. (2) is a homogeneous system of linear equations, one may use standard linear solution methods based on Gaussian elimination. Assume that the Markov chain is ergodic. In this case, the fact that the system of equations is homogeneous does not create any problems, because any of the n equations can be replaced by the n normalizing equation, $\sum_{j=1}^{n} \pi_j = 1$, and thereby convert it into a nonhomogeneous system with nonsingular coefficient matrix and nonzero right hand side. The solution in this case is well defined. It turns out that replacing an equation with the normalizing equation is not really necessary.

The usual approach taken is to construct an $\boldsymbol{LU}$ decomposition of $\boldsymbol{Q}$ and replace the final zero diagonal element of $\boldsymbol{U}$ with an arbitrary value. The solution computed by back substitution on $\boldsymbol{U}$ must then be normalized. Furthermore, since the diagonal elements are equal to the negated sum of the off-diagonal elements ($\boldsymbol{Q}$ is, in a restricted sense, diagonally dominant), it is not necessary to perform pivoting while computing the $\boldsymbol{LU}$ decomposition. This simplifies the algorithm considerably.

The problems of the size and nonzero structure (the placement of the nonzero elements within the matrix) still remain. Obviously this method works well when the number of states is small. It will also work well when the nonzero structure of $\boldsymbol{Q}$ fits into a narrow band along the diagonal. In these cases, a very stable variant, referred to as the GTH (Grassmann, Taskar, and Heyman) algorithm, may be used. In this variant, all subtraction is avoided by computing diagonal elements as the sum of off-diagonal elements. This is possible since the zero-row-sum property of an infinitesimal generator is invariant under the basic operation of Gaussian elimination, namely adding a multiple of one row into another. For an efficient implementation, the GTH variant requires convenient access to both the rows and the columns of the matrix. This is the case when a banded structure is used to store $\boldsymbol{Q}$, but is generally not the case with other compact storage procedures. When the number of states becomes large and the structure in not banded, the direct approach loses its appeal and one must resort to other methods.

Iterative Methods — For iterative methods, the first approach is to solve Eq. (3) in which $\boldsymbol{P}$ is a matrix of transitions probabilities. Let the initial probability distribution vector be given by $\boldsymbol{\pi}^{(0)}$. After the first transition, the probability vector is given by $\boldsymbol{\pi}^{(1)} = \boldsymbol{\pi}^{(0)}\boldsymbol{P}$; after k transitions it is given by $\boldsymbol{\pi}^{(k)} = \boldsymbol{\pi}^{(k-1)}\boldsymbol{P} = \boldsymbol{\pi}^{(0)}\boldsymbol{P}^{\boldsymbol{k}}$. If the Markov chain is ergodic, then $\lim_{k\to\infty}\boldsymbol{\pi}^{(k)} = \boldsymbol{\pi}$. This method of determining the stationary probability vector, by successively multiplying some initial probability distribution vector by the matrix of transition probabilities, is called the Power method. Observe that all that is required is a vector–matrix multiplication operation. This may be conveniently performed on sparse matrices that are stored in compact form. Because of its simplicity, this method is widely used, even though it often takes a very long time to converge. Its rate of convergence is a function of how close the subdominant eigenvalue of P is to its dominant unit eigenvalue. In models in which there are large differences in the magnitudes of transition rates, the subdominant eigenvalue can be pathologically close to one, so that for all intensive purposes the Power method fails to converge.

It is also possible to apply iterative equation solving techniques to the system of equations given by (2). The well-known Jacobi method is closely related to the Power method, and it also frequently takes very long to converge. A better iterative method is Gauss-Seidel. Unlike the previous two methods, in which the equations are only updated after each completed iteration, the Gauss-Seidel method uses the most recently computed values of the variables as soon as they become available and, as a result, almost always converges faster than Jacobi or the Power method. All three methods can be written so that the only numerical operation is that of forming the product of a sparse matrix and a probability vector, so all are equal from a computation per iteration point of view.

Block Methods — In Markov chain models, it is frequently the case that the state space can be meaningfully partitioned into subsets. Perhaps the states of a subset interact only infrequently with the states of other subsets, or perhaps the states possess some property that merits special consideration. In these cases, it is possible to partition the transition rate matrix accordingly and to develop iterative methods based on this partition. In general, such block iterative methods require more computation per iteration, but this is offset by a faster rate of convergence.

If the state space of the Markov chain is partitioned into N subsets of size $n_1, n_2, \ldots, n_N$ with $\sum_{i=1}^{N} n_i = n$, then block iterative methods essentially involve the solution of N systems of equations of size n_i, $i = 1,2,\ldots, N$, within a global iterative structure, such as Gauss-Seidel, for instance: thus the Block Gauss-Seidel method. Furthermore, these n systems of equations are nonhomogeneous and have nonsingular coefficient matrices and either direct or iterative methods may be used to solve them. It is not required that the same method be used to solve all the diagonal blocks, so that it is possible to tailor methods to the particular block structures.

If a direct method is used, then a decomposition of the diagonal block may be formed once and for all before initializing the global iteration process. In each subsequent global iteration, solving for that block then reduces to a forward and backward substitution operation. The nonzero structure of the blocks may be such that this is a particularly attractive approach. For example, if the diagonal blocks are themselves diagonal matrices, or if they are upper or lower triangular matrices or even tridiagonal matrices, then it is very easy to obtain their LU decomposition, and a block iterative method becomes very attractive.

If the diagonal blocks do not possess such a structure, and when they are of large dimension, it may be appropriate to use an iterative method to solve each of the block systems. In this case, there are many inner iterative methods (one per block) within an outer (or global) iteration. A number of tricks may be used to speed up this process. First, the solution computed for any block at global iteration k should be used as the initial approximation to the solution of this same block at iteration $k + 1$. Second, it is hardly worthwhile computing a highly accurate solution in early (outer) iterations. Only a small number of digits of accuracy should be required until the global process begins to converge. One convenient way to achieve this is to carry out only a fixed small number of iterations for each inner solution.

Iterative Aggregation/Disaggregation Methods — Related to block iterative methods, these methods are particularly powerful when the Markov chain is nearly completely decomposable, as the partitions are chosen based on how strongly the states of the Markov chain interact with one another.

Projection Methods — An idea that is basic to sparse-linear systems and eigenvalue problems is that of projection processes. Whereas iterative methods begin with an approximate solution vector that is modified at each iteration and which (supposedly) converges to a solution, projection methods create vector subspaces and search for the best possible approximation to the solution that can be obtained from that subspace. With a given subspace, for example, it is possible to extract a vector $\hat{\pi}$ that is a linear combination of a set of basis vector for that space and which minimizes $|\hat{\boldsymbol{\pi}}\boldsymbol{Q}|$ in some vector norm. This vector $\hat{\pi}$ may then be taken as an approximation to the solution of $\boldsymbol{\pi Q} = 0$. This is the basis for the Generalized Minimal Residual (GMRES) algorithm. Another popular projection method is the method of Arnoldi. The subspace most often used is the Krylov subspace, $K_m = \text{span}\{\boldsymbol{v}_1, \boldsymbol{v}_1\boldsymbol{Q}, \ldots, \boldsymbol{v}_1\boldsymbol{Q}^{m-1}\}$, constructed from a starting vector v_1 and successive iterates of the power method. The computed vectors are then orthogonalized with respect to one another. It is also possible to construct iterative variants of these methods. When the subspace reaches some maximum size, the best approximation is chosen from this subspace and a new subspace generated using this approximation as the initial starting point.

Preconditioning techniques are frequently used to improve the convergence rate of iterative Arnoldi and GMRES. This typically amounts to replacing the original system $\boldsymbol{\pi Q} = 0$ by $\boldsymbol{\pi Q M}^{-1} = 0$, where $\boldsymbol{M}$ is a matrix whose inverse is easy to compute. The objective of preconditioning is to modify the system of equations to obtain a coefficient matrix with a fast rate of convergence. It is worthwhile pointing out that preconditioning may also be used with the basic power method to improve its rate of convergence. The inverse of the matrix $\boldsymbol{M}$ is generally computed from an incomplete *LU* factorization of the matrix $\boldsymbol{Q}$.

Stochastic Automata Networks

Stochastic Automata Networks (SANs) provide a means of performing Markov chain modeling without the problem of having to store huge transition matrices. A SAN consists of a number of individual stochastic automata that operate more or less independently of each other. Each individual automaton is represented by a number of states and rules that govern the manner in which it moves from one state to the next. The state of an automaton at any time t is just the state it occupies at time t, and the state of the SAN at time t is given by the state of each of its constituent automata. An automaton may be thought of as a component in a Markov chain state descriptor.

The use of SANs is important in the performance modeling of parallel and distributed systems, since such systems are often viewed as collections of components that operate more or less independently, requiring only infrequent interaction such as synchronizing their actions or operating at different rates depending on the state of parts of the overall system. This is exactly the viewpoint adopted by SANs. Furthermore, the state space explosion problem associated with Markov chain models is mitigated by the fact that the state transition matrix is not stored, nor even generated. Instead, it is represented by a number of much smaller matrices, one for each of the stochastic automata that constitute the system, and from these all relevant information may be determined without explicitly forming the global matrix. A considerable saving in memory is realized by storing the matrix in this fashion.

The compact form in which the transition matrix that characterizes the model is kept (called the SAN Descriptor) is written as

$$\sum_{j=1}^{N+2E} \otimes_{i=1}^{N} \boldsymbol{Q}_j^{(i)},$$

where N is the number of automata in the SAN, E is the number of synchronizing events and $\boldsymbol{Q}_j^{(i)}$ is a square matrix of low dimension. In order to benefit from this compact form, the descriptor is never expanded into a single large matrix. Consequently, all subsequent operations must necessarily work with the model in its descriptor form, and hence, numerical operations on the underlying Markov chain infinitesimal generator become more costly. Research efforts directed at reducing these costs include the development of a generalized tensor algebra to permit functional transitions to be handled at the same low costs as constant transitions, design of algorithms to reduce the amount of computation involved in forming the product of a vector and a SAN descriptor, and finding suitable preconditioners with which to speed up iterative methods.

Introduction

Markov chain Monte Carlo (MCMC) methods numerically approximate the integral or expectation, $E[g(Y)] = \int g(y) f(y|\Theta) dy$, where Y is a random variable with distribution $f(y|\Theta)$, which is parameterized by Θ, and $g(Y)$ is an integrable function of Y, where the integral is with respect to either Lebesgue measure for continuous random variables or counting measure for discrete ones. A simple way to compute $E[g(Y)]$ is through Monte Carlo (MC) simulation, which approximates the integral as an average of $g(Y)$ across a random sample from $f(y|\Theta)$: $\overline{g(Y)} = \frac{1}{n} \sum_{i=1}^{n} g(y_i)$. The estimation variance is proportional to n^{-1}, regardless of the dimension of Y, and the estimator can be made arbitrarily accurate by letting the size of the sample $n \to \infty$ by the strong law of large numbers. MCMC addresses settings where random variates for $f(y|\Theta)$ cannot be generated easily, e.g., through the inverse transform method, the acceptance-rejection method (also called rejection sampling), or importance sampling. These methods generally rely on independent and identically distributed (i.i.d.) random draws to approximate the integral.

MCMC methods relax this independence assumption to construct a Markov chain of draws $\{y_i, i = 1, \ldots, n\}$, with a stationary distribution equal to. $f(y|\Theta)$. MCMC uses recursive simulation where the random number generator for Y_i depends on the previous draw y_{i-1}, hence the name Markov chain Monte Carlo. MCMC's range of applications is astonishing, and continues to expand. A large part of these applications have been in Bayesian statistics, but MCMC originated in image processing and physics and continues to be used in these fields, as well as in biology, engineering, demography, finance and marketing. MCMC was started by the work of Metropolis et al. (1953) and Hastings (1970). Gibbs sampling as a special case developed through the work of Besag (1974), Geman and Geman (1984), and Gelfand and Smith (1990). Important extensions were developed by Albert and Chib (1993), Green (1995), Richardson and Green (1997) and Neal (2003). Texts include Gill (2008), Press (2003), Gelman et al. (2003), and Zellner (1971). Essential MCMC methods are reviewed here, while details can be found in the references above.

Discussion

Metropolis-Hastings Sampler: The Metropolis-Hastings (MH) sampler is very general and sparked the MCMC revolution. For $i = 1, \ldots, n$, it generates a candidate sample y_i from a proposal distribution $h(y|y_{i-1}, \Phi)$ and transforms it to make it behave as if it came from $f(y|\Theta)$ (The support of h is a subset of that of f). If the proposal distribution h depends on the previous value y_{i-1}, the algorithm is called Random Walk Metropolis-Hastings (rMH), while if it does not depend on previous values, it is called Independence Metropolis-Hastings (iMH). The algorithm works as follows, for $i = 1, 2, \ldots, n$

1. Initialize the chain at y_0 that is in the support of f.
2. Given that a prior value y_{i-1} has been obtained, sample a candidate value $y^* \sim h(y|y_{i-1};\Phi)$ and sample $u_i \sim U(0,1)$.
3. Calculate $\alpha(y_{i-1}, y^*) = \frac{f(y^*|\Theta)}{f(y_{i-1}|\Theta)} \cdot \frac{h(y_{i-1}|y^*,\Phi)}{h(y^*|y_{i-1},\Phi)}$.
4. Accept the candidate $y_i = y^*$, if $\alpha(y_{i-1}, y^*) > u_i$, otherwise set $y_i = y_{i-1}$.

The normalizing constants for f and h cancel in Step 3, so that they only need to be known up to such constants. The MH algorithm creates a Markov chain with transition function $q(y_{i-1}, y_i) = h(y_i|y_{i-1},\Phi)\tau(y_{i-1}, y_i)$ where $\tau(y_{i-1}, y^*) = \min[\alpha(y_{i-1}, y^*), 1]$ is the acceptance probability from Step 4. The chain is reversible because $f(y_{i-1}|\Theta)q(y_{i-1}, y_i) = f(y_i|\Theta)q(y_i, y_{i-1})$, and is therefore ergodic with stationary distribution f. This has the crucial implication that regardless of the initial value in Step 1, the draws from the Markov chain will eventually be from f. Monte Carlo is a special case if the candidate distribution h is equal to f: then $\alpha(y_{i-1}, y^*) = 1$. If $h(y|y_{i-1},\Phi)$ is symmetric in $(y - y_{i-1})$, e.g. a normal distribution with mean y_{i-1}, then the ratio in h cancels in Step 3.

The performance of MH depends on the proposal distribution. In rMH if the proposal distribution is too tight around the last value of the chain, then the candidate is highly likely to be accepted, and the Markov chain will tour the support of f very slowly, so n will have to be quite large to obtain reliable MCMC estimates. Conversely, if the variance of the proposals is too large, the MCMC algorithm will reject most of the candidate values, and the chain will hardly budge. For the estimator to be valid, the chain needs to visit areas of the support of f with non-negligible probabilities.

Convergence: Starting from an arbitrary y_0, the chain passes through a transitory period, say $i = 1, \ldots, l$ for $l < n$, where the draws are not from f. These initial draws are not used in the MCMC approximation of $E[g(Y)]$: $\overline{g(Y)} = \frac{1}{n-l} \sum_{i=l+1}^{n} g(y_i)$. In theory, under very general conditions the rate of convergence is geometric in the second eigen value of the transition function. Problems can occur if the target distribution is multimodal, and f is zero between modes, so that subsets of the support do not communicate with each other. Then the chain can become stuck in isolated regions of the support unless the proposal distribution h is sufficiently broad to bridge the gaps. In practice, it may be difficult to conclusively determine l. One procedure for monitoring convergence is to run multiple chains from different initial values and to compute multiple estimates. If the between-chain variance of the estimators is small relative to the within-chain variance, then the chain has likely converged. A host of other diagnostic measures are available, that may help identify likely convergence of the chain.

Blocked MH Sampler: Depending on the structure of f, it may be convenient to block Y into sub-vectors Y_s for $s = 1, 2, \ldots, S$. The distribution of each sub-vector is conditioned on all others to obtain the full conditional distributions: $f(y_s|y_{-s};\Theta)$, with y_{-s} denoting y with y_s omitted $h_s(y_s|y_{-s};\Phi)$ is the proposal distribution for Y_s. This leads to the following algorithm for $i = 1, 2, \ldots, n$ and $s = 1, 2, \ldots, S$:

1. Initialize y_0 in the support of f.
2. Sample a candidate value $y_s^* \sim h_s\left(y_s|y_{-s,i-1};\Phi\right)$ and $u_i \sim U(0,1)$.
3. Calculate $\alpha_{s,i} = \frac{f(y^*|\Theta)}{f(y_{i-1}|\Theta)} \cdot \frac{h_s(y_{s,i-1}|y^*;\Phi)}{h_s(y_s^*|y_{s,i-1};\Phi)}$, where y^* is identical to y_{i-1}, except for sub-vector s, which equals y_s^*.
4. Accept the candidate $y_{s,i} = y_s^*$, if $\alpha_{s,i} > u_i$, otherwise keep $y_{s,i-1}$.

This algorithm cycles through the s sub-vectors (in arbitrary order, systematically or randomly) and updates them separately though MH-steps. Not every sub-vector needs to be updated at every iteration i.

Gibbs Sampler: In many applications, some or even all of the full conditional target distributions $f(y_s|y_{-s};\Theta)$ can be sampled directly, which greatly simplifies the Blocked MH algorithm. This can be seen by substituting the full conditional distributions for the proposal distributions in Step 3 of the Blocked MH: $\alpha_{s,i} = \frac{f(y^*|\Theta)}{f(y_{i-1}|\Theta)} \cdot \frac{f(y_{s,i-1}|y^*;\Theta)}{f(y_s^*|y_{s,i-1};\Theta)}$. Because $f(y|\Theta) = f(y_s, y_{-s}|\Theta)$, and $y_{-s}^* = y_{-s,i-1}$, it holds that $\alpha_{s,i} = \frac{f\left(y_{-s,i-1}|\Theta\right)}{f\left(y_{-s,i-1}|\Theta\right)} = 1$. The algorithm for the Gibbs sampler modifies the Blocked MH by replacing Step 2 with directly drawing $y_{s,i} \sim f\left(y_{s,i}|y_{-s,i};\Theta\right)$ and skipping Steps 3 and 4 for these blocks.

Modifications of the Gibbs sampler have been proposed to speed up convergence and provide the chains with better properties. For three sub-vectors y_1, y_2, y_3, for example, the Collapsed Gibbs Sampler

draws from the unconditional joint distribution $y_{1:2,i} \sim f(y_1, y_2|\Phi)$, and the full conditional distribution $y_{3,i} \sim f(y_3|y_{1,i}, y_{2,i}; \Phi)$. The Grouped Gibbs Sampler on the other hand, groups two sub-vectors and draws from the full conditionals $y_{1:2,i} \sim f\left(y_1, y_2|y_{3,i-1}; \Phi\right)$ and $y_{3,i} \sim f(y_3|y_{1,i}, y_{2,i}; \Phi)$. The relative simplicity of the Gibbs sampling algorithms has contributed to their popularity, and many extensions, three important ones being the Auxiliary Variable, Slice and Reversible Jump Samplers.

Auxiliary Variable Sampler: Introducing an auxiliary random variable Z can simplify MCMC if there is a joint distribution $h(y, z|\theta, \Psi)$ such that $f(y|\Theta) = \int h(y, z|\theta, \Psi)dz$, and both $h(y|z, \Theta, \Psi)$ and $h(z|y, \Theta, \Psi)$ are easy to sample. Using these two full conditional distributions, it is then straightforward to sample from $h(y, z|\theta, \Psi)$, using Gibbs sampling. The Auxiliary Variable Gibbs Sampler is then, for $i = 1, 2, \ldots, n$:

1. Sample $y_i \sim h(y|z_{i-1}, \Theta, \Psi)$.
2. Sample $z_i \sim h(z|y_i, \Theta, \Psi)$.

An additional advantage is that the introduction of the augmented variable helps mixing.

Slice Sampler: A special case of the Auxiliary Variable Sampler arises if $f(y|\Theta)$ an be factored as $f(y|\Theta) \propto k(y|\Theta) \cdot h(y|\Theta)$. The auxiliary variable Z in this case is chosen such that the joint density $f(y, z) \propto I[0 < z < k(y|\Theta)] \cdot h(y|\Theta)$. The resulting sampler is called the Slice Sampler and iterates between the following full conditional distributions, for $i = 1, 2, \ldots, n$:

1. Sample $z_i \sim U(0, k(y_{i-1}|\Theta))$, from a uniform distribution on 0 and $k(y_{i-1}|\Theta)$.
2. Sample $y_i \sim h(y|\Theta)I[0 < z_i < k(y|\Theta)]$, from the distribution $h(y|\Theta)$ truncated on the set $\{y : z_i < k(y|\Theta)\}$.

Slice sampling is applicable in cases where $k^{-1}(y|\Theta)$ can be analytically obtained, and the truncated distribution $h(y|\Theta)I[0 < z_i < k(y|\Theta)]$ can be sampled from, often by using the inverse transform method. The extension to distributions that factor as $f(y|\Theta) \propto h(y|\Theta) \cdot \prod_t k_t(y|\Theta)$ is straightforward if all $k_t^{-1}(y|\Theta)$ an be obtained, now by sampling multiple $z_{i,t} \sim U(0, k_t(y_{i-1}|\Theta))$.

Reversible Jump Sampler: The above algorithms assume that the dimension of Y is constant. The Reversible Jump (RJ) sampler is an extension of MH that constructs a Markov chain that transverses spaces of different dimensions. The spaces are labeled m, and $Y^{(m)}$ is the random variable Y restricted to space m. The dimension of $Y^{(m)}$ or $\dim\left(Y^{(m)}\right)$ depends on m (In Bayesian statistics – details below – RJ is used to transverse different models where m indicates the model, and then simulate $Y^{(m)}$ given model m). The state space for the Markov chain is $\left(M, Y^{(M)}\right)$ with joint distribution $f\left(m, y^{(m)}|\Theta\right) = f\left(y^{(m)}|m, \Theta_y\right)f(m|\Theta_m)$ where $P(M = m) = f(m|\Theta_m)$ is a discrete distribution, and $f\left(y^{(m)}|m, \Theta_y\right)$ is the distribution of Y restricted to space m. RJ is a strategy to simulate $\left(M, Y^{(M)}\right)$ when a convenient random number generator for $f\left(m, y^{(m)}|\Theta\right)$ does not exist.

As with MH, the goal is to construct a reversible Markov chain with stationary distribution $f\left(m, y^{(m)}|\Theta\right)$. Reversible moves between any $\left(m, y^{(m)}\right)$ and $\left(m', y^{(m')}\right)$ require a bijective mapping, which does not exist when the spaces have different dimensions. The trick is to augment $y^{(m)}$ with a random variable $u^{(m)}$ so that $\dim\left(y^{(m)}\right) + \dim\left(u^{(m)}\right)$ is constant across all m: $\dim\left(y^{(m)}\right) + \dim\left(u^{(m)}\right) = \dim\left(y^{(m')}\right) + \dim\left(u^{(m')}\right)$. RJ requires a bijective, differentiable function $\left(y^{(m')}, u^{(m')}\right) = T_{m,m'}\left(y^{(m)}, u^{(m)}\right)$ that uniquely maps $\left(y^{(m)}, u^{(m)}\right)$ to $\left(y^{(m')}, u^{(m')}\right)$ with reverse mapping $T_{m',m} = T_{m,m'}^{-1}$. Given the current state $\left(m, y^{(m)}\right)$ of the Markov chain, candidate values are generated by: (1) selecting a new value m' according to the proposal distribution $q\left(m'|m, \Psi\right)$; (2) generating $u^{(m)}$ from $h_{m,m'}\left(u^{(m)}|y^{(m)}, \Phi\right)$; and (3) computing the candidate $\left(y^{(m')}, u^{(m')}\right) = T_{m,m'}\left(y^{(m)}, u^{(m)}\right)$. For the Markov chain to be reversible, the implied distribution of $u^{(m')}$, $h_{m',m}\left(u^{(m')}|y^{(m')}, \Phi\right)$, is required to move from $\left(y^{(m')}, u^{(m')}\right)$ to $\left(y^{(m)}, u^{(m)}\right)$ using the reverse mapping $T_{m',m}$. Implementation details of the RJ are as much art as science, because the construction of $\left\{T_{m,m'}\right\}$ for all m and m' and the selection of proposal distributions are tailored specifically for each application. The RJ algorithm for $i = 1, 2, \ldots, n$ is:

1. Initialize the chain at $\left(m_0, y_0^{m_0}\right)$ in the support of f.
2. Given m_{i-1} and $y_{i-1}^{(m_{i-1})}$ are obtained, set $m = m_{i-1}$ and $y = y_{i-1}^{(m_{i-1})}$ and
   a. Sample $m' \sim q(m'|m, \Psi)$;
   b. Sample $u \equiv u^{(m)} \sim h_{m,m'}\left(u^{(m)}|y, \Phi\right)$;
   c. Compute proposal $y' \equiv y^{(m')}$ from $(y', u') = T_{m,m'}(y, u)$.

3. Calculate
$$\alpha(y,y') = \frac{f\left(m',y'|\Theta\right)}{f(m,y|\Theta)} \cdot \frac{h_{m',m}\left(u'|y',\Phi\right)}{h_{m,m'}(u|y,\Phi)} \cdot \frac{q(m|m',\Psi)}{q(m'|m,\Psi)} \cdot \left|\frac{\partial T_{m,m'}(y,u)}{\partial y \partial u}\right|.$$
4. Sample $v_i \sim U(0,1)$ and accept the candidate $\left(m_i, y_i^{(m_i)}\right) = (m', y')$ if $\alpha(y,y') > v_i$, otherwise set $\left(m_i, y_i^{(m_i)}\right) = \left(m_{i-1}, y_{i-1}^{(m_{i-1})}\right)$.

In step 3, $\left|\frac{\partial T_{m,m'}(y,u)}{\partial y \partial u}\right|$ is the Jacobian of the transformation $T_{m,m'}$, which is needed because it is a deterministic function for the change in variables from $\left(y^{(m)}, u^{(m)}\right)$ to $\left(y^{(m')}, u^{(m')}\right)$. As in the MH algorithm, the distributions $f\left(m, y^{(m)}|\Theta\right)$, $q\left(m'|m,\Psi\right)$, and $h_{m,m'}\left(u^{(m)}|y,\Phi\right)$ only need to be known up to normalizing constants which cancel in step 3. It should be noted that while $\alpha(y,y')$ in its general form provided in step 3 is somewhat complex, in a wide range of practical applications it simplifies considerably, for example when the proposal distributions are symmetric (see above), when $\dim\left(y^{(m')}\right) > \dim\left(y^{(m)}\right)$, in which case the mapping reduces to $\left(y^{(m')}\right) = T\left(y^{(m)}, u^{(m)}\right)$, and when moves are limited to $m' \in \{(m_{i-1}-1), m_{i-1}, (m_{i-1}+1)\}$.

***Example*:** In Bayesian statistics the parameters of a model are considered random variables, reflecting a priori uncertainty on the part of the researcher that is reduced a posteriori after the data are observed. Inference focuses on their posterior distribution, which summarizes all information about the parameters. According to Bayes Theorem, the posterior distribution is proportional to the prior distribution of the parameters times the distribution of the data given the parameters. Bayesian estimation and inference has gained great popularity in business, in particular in marketing and finance, because even without strictly accepting the (attractive) fundamental properties of Bayesian inference, pragmatic Bayesians have found great value in MCMC algorithms to estimate complex models, especially as uninformative prior distributions can be used. Simpler illustrative examples follow.

***Example 1*:** The Weibull distribution is used in duration analysis applications to bankruptcy in finance, and in customer relationship management (CRM) in marketing. The observations $\{x_j\}$ for $j = 1,\ldots,J$ are a random sample of durations from a Weibull distribution: $f(x|\theta,\delta) = \theta\delta x^{\delta-1}\exp(-\theta x^{\delta})$ for $x > 0$. The prior distributions of the parameters are Gamma distributions: $p(\theta) = \frac{s_0^{r_0}}{\Gamma(r_0)}\theta^{r_0-1}\exp(-s_0\theta)$ and $p(\delta) = \frac{a_0^{b_0}}{\Gamma(b_0)}\delta^{a_0-1}\exp(-b_0\delta)$. The joint posterior distribution of the parameters is: $\pi\left(\theta,\delta|\{x_j\}\right) \propto p(\theta)p(\delta)\prod_{j=1}^{J} f\left(x_j|\theta,\delta\right)$, which does not have a convenient random number generator and can be sampled with MH within Gibbs. The full conditional distribution of θ given the data and δ_{i-1} is also a Gamma distribution: $\pi\left(\theta|\delta_{i-1},\{x_j\}\right) \propto \theta^{r_0+n-1}\exp\left(-\theta\left[s_0 + \sum_{j=1}^{J} x_j^{\delta_{i-1}}\right]\right)$. The full conditional distribution of δ given the data and θ_i does not have a known distributional form: $\pi\left(\delta|\theta_i,\{x_j\}\right) \propto \delta^{a_0+n-1}\left[\prod_{j=1}^{J} x_j^{\delta-1}\right]\exp\left(-b_0\delta - \theta_i\sum_{j=1}^{J} x_j^{\delta}\right)$. Thus, rMN can be used to generate the candidate δ^*. The MCMC algorithm to approximate the posterior distribution of the parameters is, for $i = 1,2,\ldots,n$:

1. Initialize the chain at (θ_0,δ_0).
2. Draw θ_i from a Gamma distribution $\theta_i = G\left(r_0 + n, s_0 + \sum_{j=1}^{J} x_j^{\delta_{i-1}}\right)$.
3. Sample $u_i \sim U(0,1)$, and generate a candidate δ^* from a log-normal distribution: $g(\delta^*|\delta_{i-1},\sigma) \propto \frac{1}{\delta^*}\exp\left[-\frac{1}{2\sigma^2}\left(\ln(\delta^*) - \ln(\delta_{i-1})\right)^2\right]$.
4. Compute $\alpha(\delta_{i-1},\delta^*) = \frac{\pi\left(\delta^*|\theta_i,\{x_j\}\right)\delta_{i-1}}{\pi\left(\delta_i|\theta_i,\{x_j\}\right)\delta^*}$.
5. Accept $\delta_i = \delta^*$ if $\alpha(\delta_{i-1},\delta^*) > u_i$, otherwise set $\delta_{i-1} = \delta_{i-1}$.

Extensions involve the parameterization of θ in terms of predictor variables $\theta_j = w_j\beta$, and the case where the durations are censored by the observation time; the estimations of the models in question involve extensions of the algorithms above.

***Example 2*:** Change-point regression models are popular in finance to describe financial time series data with a structural change, and used in marketing in models of stochastic preference and market shares. Here, the data $\{x_t\}$ are observed for time points $t = 1,\ldots,T$, and assumed to follow a binomial distribution: $f(x_t|\pi_t) = \pi_t^{x_t}(1-\pi_t)^{1-x_t}$; for $x_t \in \{0,1\}$. Two regression functions are

separated in time by an unknown switch-point $\tau : \pi_t = \Phi\left(w_t^{'}\beta_k\right)$, with $\beta_k = \beta_1$ for $t \leq \tau$, and $\beta_k = \beta_2$ for $t > \tau$. Φ is the Normal CDF used as an inverse link function, w_t is a vector of regressors, and $\beta_k \sim N(b_0, B_0)$ the prior distributions of its coefficients. The 'switch-point' has a uniform discrete prior on a subset of the observed timepoints: $\tau \sim U(c, d)$. The MCMC algorithm simplifies through the introduction of an auxiliary variable $z_t \sim N\left(w_t^{'}\beta_k, 1\right)$, with, $x_t = I(z_t > 0)$, and $I(\cdot)$ the indicator function. The MCMC algorithm to approximate the posterior distribution of the parameters is, for $i = 1, 2, \ldots, n$:

1. Sample for: $k = 1, 2:\ \beta_{k,i} \sim N(b_{k,i}, B_{k,i})$, with $b_{k,i} = B_{k,i}\left(B_0^{-1}b_0 + \sum_{t=L_{k,i}}^{t=U_{k,i}} w_t^{'}z_{t,i}\right)$, $B_{k,i} = \left(B_0^{-1} + \sum_{t=L_{k,i}}^{t=U_{k,i}} w_t w_t^{'}\right)$, and $L_{k,i} = 1 + (k-1)\tau_i$, $U_{k,i} = \tau + (k-1)(T - \tau_i)$.
2. Sample, for $L_{k,i} < t < U_{k,i}$: $z_{t,i} \sim N\left(w_t^{'}\beta_{k,i}, 1\right)I(z_{t,i} < 0)$ if $x_t = 0$, and $z_{t,i} \sim N\left(w_t^{'}\beta_{k,i}, 1\right)I(z_{t,i} > 0)$ if $x_t = 1$.
3. Sample τ_i using $Pr(\tau_i = r) = \frac{\prod_{t\leq r} f\left(x_t|w_t^{'}\beta_{1,i}\right)\prod_{t>r} f\left(x_t|w_t^{'}\beta_{2,i}\right)}{\sum_{s=c}^{d}\prod_{t\leq s} f\left(x_t|w_t^{'}\beta_{1,i}\right)\prod_{t>s} f\left(x_t|w_t^{'}\beta_{2,i}\right)}$.

Extensions of this MCMC procedure for multiples witch points are available, and extensions to an unknown number of switch points require RJMCMC.

***Example 3*:** Mixture models are used in finance to describe financial returns during different economic regimes, and are popular in marketing to identify unobserved heterogeneity in response-based market segmentation. The data $\{x_j\}$ are observed for individuals $j = 1, \ldots, J$, and assumed to follow a mixture Normal distribution with K classes and probabilities δ_k for which $0 < \delta_k < 1$ and $\sum_{k=1}^{m} \delta_k = 1$. Thus, $x_j \sim \sum_{k=1}^{m} \delta_k N\left(w_j^{'}\beta_k, \sigma_k^2\right)$. Here, β_k are class-specific regression coefficients associated with the vector of regressors w_t, with prior distributions $\beta_k \sim N(b_0, B_0)$. Further Inverse Gamma and Dirichlet priors are specified for: $\sigma_k^2 \sim IG\left(\frac{a_0}{2}, \frac{A_0}{2}\right)$and $\delta_{1:m} \sim D(c_0, \ldots, c_0)$. The MCMC algorithm simplifies by introducing an auxiliary variable with a multinomial prior distribution: $z_j \sim M(\delta_{1:m})$ that indicates the membership of individual j in class k, that is $z_j = 1, \ldots, m$. The MCMC algorithm is, for $i = 1, 2, \ldots, n$:

1. Sample, for $k = 1, \ldots, m : \beta_{k,i} \sim N(b_{k,i}, B_{k,i})$, with $b_{k,i} = B_{k,i}\left(B_0^{-1}b_0 + \sum_{\{j:z_j=k\}} w_j^{'}x_j\right)$, and $B_{k,i} = \left(B_0^{-1} + \sum_{\{j:z_j=k\}} w_j w_j^{'}\right)$.
2. Sample, for $k = 1, \ldots, m :$ $\sigma_{k,i}^2 \sim IG\left(\frac{a_0+n_k}{2}, \frac{A_0+\sum_{\{j:z_j=k\}}\left(x_j - w_j^{'}\beta_{k,i}\right)^2}{2}\right)$, with $n_k = \sum_{\{j:z_j=k\}} 1$.
3. Sample $\delta_{1:m} \sim D(c_0 + n_1, \ldots, c_0 + n_m)$.
4. Sample z_j using $Pr(z_j = k) = \frac{\delta_k f\left(x_j|w_t^{'}\beta_{k,i}, \sigma_{k,i}^2\right)}{\sum_s \delta_s f\left(x_j|w_t^{'}\beta_{s,i}, \sigma_{s,i}^2\right)}$.

This sampler, like that for many mixture models, suffers from "label switching," a problem in which the class parameters switch across the class labels during the iterations. Several solutions are available, including ordering the mixture probabilities or post-processing of the draws.

Furthermore, the above algorithm can be extended to include the number of classes $m = 1, \ldots, m_{\max}$, using RJMCMC. A step is added to the algorithm in which two randomly chosen classes (k_1 and k_2) are merged (k_*), or one randomly chosen class is split. A splitting decision is usually made with probability $\eta_m = 0.5$, a merging decision with $(1 - \eta_m)$, for, $m = 2, \ldots, (m_{\max} - 1)$, and $\eta_1 = 0$ and $\eta_{m_{\max}} = 1$. The merge move involves matching of moments of the class-distributions, involving the computation of β_{k_*} such that the mean $\mu_{k_*} = w^{'}\beta_{k_*}$ of the new class matches that of k_1 and k_2, as does the variance $\sigma_{k_*}^2$:

M1. Randomly select $k_1 \propto 1/m$ and find k_2 'most similar' to k_1.
M2. Compute $\delta_{k_*} = \delta_{k_1} + \delta_{k_2}$.
M3. Match $\mu_{k_*} = \frac{\delta_{k_1}}{\delta_{k_*}}\mu_{k_1} + \frac{\delta_{k_2}}{\delta_{k_*}}\mu_{k_2}$.
M4. Compute $\sigma_{k_*}^2 = \frac{\delta_{k_1}}{\delta_{k_*}}\left(\mu_{k_1}^2 + \sigma_{k_1}^2\right) + \frac{\delta_{k_2}}{\delta_{k_*}}\left(\mu_{k_2}^2 + \sigma_{k_2}^2\right) - \mu_{k_*}^2$.
M5. Recompute z_j using step 4 above.

The split move operates as follows, and again involves matching of the first two moments of the class-distributions, of the old and new classes:

S1. Randomly select $k_* \propto 1/m$, and draw the auxiliary variables $u_{1:3} \sim Beta(a, b)$.
S2. Compute $\delta_{k_1} = u_1\delta_{k_*}$, and $\delta_{k_2} = (1 - u_1)\delta_{k_*}$.
S3. Match $\mu_{k_1} = \mu_{k_*} - u_2\sigma_{k_*}\sqrt{\frac{\delta_{k_2}}{\delta_{k_1}}}$, and $\mu_{k_2} = \mu_{k_*} + u_2\sigma_{k_*}\sqrt{\frac{\delta_{k_1}}{\delta_{k_2}}}$.

S4. Compute $\sigma_{k_1}^2 = u_3\left(1-u_2^2\right)\sigma_{k_*}^2 \frac{\delta_{k*}}{\delta_{k_1}}$, and $\sigma_{k_2}^2 = (1-u_3)\left(1-u_2^2\right)\sigma_{k_*}^2 \frac{\delta_{k*}}{\delta_{k_2}}$.

S5. Recompute z_j using step 4 above.

The split/merge proposal is accepted with probability $\min(\alpha(y,y'),1)$, computed as outlined in the RJ algorithm above (and the split is rejected if k_2 is not 'most similar' to k_1 to ensure reversibility). Here $h_m\left(u^{(m)}|y,\Phi\right) = Beta\,(a,b)$, and $q\left(m'|m,\Psi\right) = P\left(m'|m_{i-1}\right) = 0.5$ in the RJ algorithm described above. The split/merge moves are reversible, as $T_{m,m'}$ is defined in S2-S4, and $T_{m,m'}^{-1}$ in M2-M3. The split/merge moves may be combined with "birth/death" moves, randomly chosen with probabilities 0.5/0.5. In a birth move the parameters of a new class are drawn at random from proposal distributions on the appropriate support (e.g., $\delta_{k_*} \sim Beta, \beta_k \sim MVN, \sigma_k^{-2} \sim Gamma$), and the weights are rescaled so that they sum to one. In a death move an empty class is deleted, and the remaining weights are rescaled (Richardson and Green 1997).

Markov Chains

Carl M. Harris
George Mason University, Fairfax, VA, USA

Introduction

A Markov chain is a Markov process $\{X(t), t \in T\}$ whose state space S is discrete, while its time domain T may be either continuous or discrete. Only considered here is the countable state-space problem. Classic texts treating Markov chains include Breiman (1986), Çinlar (1975), Chung (1967), Feller (1968), Heyman and Sobel (2004), Isaacson and Madsen (1976), Iosifescu (1980), Karlin and Taylor (1975), Kemeny and Snell (1976), Kemeny, Snell and Knapp (1976), and Meyn and Tweedie (2009).

As a stochastic process of the Markov type, chains possess the Markov or lack-of-memory (memoryless) property, which means that the probabilities of future events are completely determined by the present state of the process and the probabilities of its behavior from the present point on. In other words, the past behavior of the process provides no additional information in

determining the probabilities of future events if the current state of the process is known. Thus, the discrete process $\{X(t), t \in T\}$ is a Markov chain if, for any $n > 0$, any $t_1 < t_2 < \ldots < t_n < t_{n+1}$ in the time domain T, any states $i_1, i_2, \ldots, i_n$ and any state j in the state space S,

$$\Pr\{X(t_{n+1}) = j | X(t_1) = i_1, \ldots, X(t_n) = i_n\} = \Pr\{X(t_{n+1}) = j | X(t_n) = i_n\}.$$

The conditional transition probabilities on the right-hand side of this equation can be simplified by mapping the n time points directly into the nonnegative integers and renaming state i_n as i. Then the probabilities are only a function of the pair (i, j) and the transition number n. Oftentimes, it is assumed that the transition probabilities are stationary, i.e., time invariant, resulting in a square (possibly infinite) matrix $\boldsymbol{P} = [p_{ij}]$ (viz., the single-step transition matrix), which gives all conditional probabilities of moving to state j in a transition, given that the chain is currently in state i. (Any matrix with the property that its rows are nonnegative numbers summing to one is called a stochastic matrix, whether or not it is associated with a particular Markov chain).

Examples of Markov Chains

1. *Random Walk*. In its simplest form, an object moves to the left one space at each transition time with probability p or to the right with probability $1 - p$. The problem can be kept finite by requiring reflecting barriers at fixed left-and right-hand points, say M and N, such that the transition probabilities send the chain back to states $M + 1$ and $N - 1$, respectively, whenever it reaches M or N. One important variation on this problem allows the object to stay put with non-zero probability.
2. *Gambler's Ruin*. A gambler makes repeated independent bets and wins \$1 on each bet with probability p or loses \$1 with probability $1 - p$. The gambler starts with an initial stake and will play repeatedly until all money is lost or until the fortune increases to \$$M$. Let X_n equal the gambler's wealth after n plays. The stochastic process $\{X_n, n = 0, 1, 2, \ldots\}$ is a Markov chain with state space $\{0, 1, 2, \ldots, M\}$. The Markov property follows from the assumption that outcomes of successive bets are independent events. The Markov model can be used to derive performance measures of interest for this situation, such as the probability of losing all the money, the probability of reaching the goal of \$$M$, and the expected number of bets before the game terminates. All these performance measures are functions of the gambler's initial state x_0, probability p and goal \$$M$. (The gambler's fortune is thus a random walk with absorbing boundaries 0 and M). The gambler's ruin problem is a simplification of more complex systems that experience random rewards, risk, and possible ruin, such as insurance companies.
3. *Coin Toss Sequence*. Consider a series of independent tosses of a fair coin. One Markov chain is obtained by associating state 1, 2, 3 or 4 at time n depending on whether the outcomes of tosses $n - 1$ and n are (H,H), (H,T), (T,H) or (T,T), respectively.

Define the n-step transition probability $p_{ij}^{(n)}$ as the probability that the chain moves from state i to state j in n steps, and write

$$P_{ij}^{(n)} = \Pr\{X_{m+n} = j | X_m = i\} \quad \text{for all } m \geq 0 \;\; n > 0.$$

Then it follows that the n-step transition probabilities can be computed using the Chapman-Kolmogorov equations

$$P_{ij}^{(n+m)} = \sum_{k=0}^{\infty} p_{ik}^{(n)} \, p_{kj}^{(m)} \text{ for all } n, m, i, \; j \geq 0.$$

In particular, for $m = 0$,

$$P_{ij}^{(n)} = \sum_{k=0}^{\infty} p_{ik}^{(n-1)} p_{kj} = \sum_{k=0}^{\infty} p_{ik} p_{kj}^{(n-1)}, \qquad n = 2, 3, \ldots; i, j \geq 0.$$

Denoting the matrix of n-step probabilities by $\boldsymbol{P}^{(n)}$, it follows that $\boldsymbol{P}^{(n)} = \boldsymbol{P}^{(n-k)} \boldsymbol{P}^{(k)} = \boldsymbol{P}^{(n-1)} \boldsymbol{P}$ and that $\boldsymbol{P}^{(n)}$ can be calculated as the nth power of the original single-step transition matrix $\boldsymbol{P}$.

To calculate the unconditional distribution of the state at time n requires specifying the initial probability distribution of the state, namely, $\Pr\{X_0 = i\} = p_i, i \geq 0$. Then the unconditional distribution of X_n is given by

$$\Pr\{X_n = j\} = \sum_{i=0}^{\infty} \Pr\{X_n = j | X_0 = i\} \Pr\{X_0 = i\}$$
$$= \sum_{i=0}^{\infty} p_i p_{ij}^{(n)}$$

which is equivalent to multiplying the row vector $\boldsymbol{p}$ by the jth column of $\boldsymbol{P}$.

Properties of a Chain

The ultimate long-run behavior of a chain is fully determined by the location and relative size of the entries in the single-step transition matrix. These probabilities determine which states can be reached from which other ones and how long it takes on average to make those transitions. More formally, state j is said to be reachable from state i, written $i \to j$, if it is possible for the chain to proceed from i to j in a finite number of transitions, i.e., if $p^{(n)} > 0$ for some $n \geq 0$. If, in addition, $j \to i$, then the two states are said to communicate with each other, written as $i \leftrightarrow j$. If every state is reachable from every other state in the chain, the chain is said to be irreducible, i.e., the chain is not reducible into subclasses of states that do not communicate with each other.

Furthermore, the period of state i is defined as the greatest common divisor, $d(i)$, of the set of positive integers n such that $p_{ii}^{(n)} > 0$ (with $d(i) \equiv 0$ when $p_{ii}^{(n)} = 0$ for all $n \geq 1$). If $d(i) = 1$, then i is said to be aperiodic; otherwise, it is periodic with period $d(i)$. Clearly, any state with $p_{ii}^{(n)} \geq 0$ is an aperiodic state. All states in a single communicating class must have the same period, and the full Markov chain is said to be aperiodic if all of its states have period 1.

For each pair of states (i, j) of a Markov chain, define $f_{ij}^{(n)}$ as the probability that a first return from i to j occurs in n transitions and f_{ij} as the probability of ever returning to j from i. If $f_{ij} = 1$, the expectation m_{ij} of this distribution is called the mean first passage time from i to j. When $j = i$, write the respective probabilities as $f_i^{(n)}$ and f_i, and the expectation as m_i, which is called the mean recurrence time of i. If $f_i = 1$ and $m_i < \infty$, state i is said to be positive recurrent or nonnull recurrent; if $f_i = 1$ and $m_i = \infty$, state i is said to be null recurrent; if $f_i < 1$, state i is said to be transient.

A major result that follows from the above is that if $i \leftrightarrow j$ and i is recurrent, then so is j. Furthermore, if the chain is finite, then all states cannot be transient and at least one must be recurrent; if all the states in the finite chain are recurrent, then they are all positive recurrent. More generally, all the states of an irreducible chain are either positive recurrent, null recurrent, or transient.

Example: Reflecting Random Walk

Consider such a chain with movement between its four states governed by the single-step transition matrix

$$\boldsymbol{P} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 1/3 & 1/3 & 1/3 & 0 \\ 0 & 2/3 & 0 & 1/3 \\ 0 & 0 & 1 & 0 \end{bmatrix}. \quad (1)$$

All the states communicate since there exists a path with non-zero probability from state 1 back to state 1 hitting all the other states in the interim. All the states are recurrent and aperiodic, as well.

If the random walk were infinite instead and without reflecting barriers (on either side), then the chain would be recurrent if and only if it is equally probable to go from right to left from each state; for otherwise the system would drift to $+\infty$ or $-\infty$ without returning to any finite starting point.

Limiting Behavior

The major characterizations of the stochastic behavior of a chain are typically stated in terms of its long-run or limiting behavior. Define the probability that the chain is in state j at the nth transition as $\pi_j^{(n)}$, with the initial distribution written as $\pi_j^{(0)}$. A discrete Markov chain is said to have a stationary distribution $\boldsymbol{\pi} = (\boldsymbol{\pi_0}, \boldsymbol{\pi_1}, \ldots)$ if these (legitimate) probabilities satisfy the vector–matrix equation $\boldsymbol{\pi} = \boldsymbol{\pi P}$. When written out in simultaneous equation form, the problem is equivalent to solving

$$\pi_j = \sum_i \pi_i p_{ij}, \quad j = 0, 1, 2, \ldots, \text{ with}$$
$$\sum_i \pi_i = 1.$$

The chain is said to have a long-run, limiting, equilibrium, or steady-state probability distribution $\boldsymbol{\pi} = (\boldsymbol{\pi_0}, \boldsymbol{\pi_1}, \ldots)$ if

$$\lim_{n\to\infty} \pi_j^{(n)} = \lim_{n\to\infty} \Pr\{X_n = j\} = \pi_j, \;\; j = 0, 1, 2, \ldots$$

A Markov chain that is irreducible, aperiodic and positive recurrent is said to be ergodic, and the following theorem relates these properties to the existence of stationary and/or limiting distributions.

Theorem: If $\{X_n\}$ is an irreducible, aperiodic, time-homogeneous Markov chain, then limiting probabilities

$$\pi_j = \lim_{n\to\infty} \Pr\{X_n = j\}, \;\; j = 0, 1, 2, \ldots$$

always exist and are independent of the initial state probability distribution. If all the states are either null recurrent or transient, then $\pi_j = 0$ for all j and no stationary distribution exits; if all the states are instead positive recurrent (thus the chain is ergodic), then $\pi_j > 0$ for all j the set $\{\pi_j\}$ also forms a stationary distribution, with $\pi_j = 1/m_j$.

It is important to observe that the existence of a stationary distribution does not imply that a limiting distribution exists. An example is the simple Markov chain

$$\boldsymbol{P} = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}.$$

For this chain, it is easy to show that the vector $\boldsymbol{\pi} = (1/2, 1/2)$ solves the stationary equation. However, since the chain is oscillating between states 1 and 2, there will be no limiting distribution. The chain clearly has period 2, which violates the sufficient conditions for the above ergodic theorem. Combined with the earlier discussion, this implies that an irreducible finite-state chain needs to be aperiodic to be ergodic. Note that the stationary distribution (1/2, 1/2) still has meaning because it gives the fraction of time the chain spends in each state in the limit, even though there is periodic oscillation.

More on the Reflecting Random Walk

The example Markov chain with single-step transition matrix given by (1) is ergodic, so its steady-state probabilities are found by solving $\boldsymbol{\pi} = \boldsymbol{\pi P}$, written out as the simultaneous system

$$\begin{aligned}
\pi_1 &= \frac{1}{3}\pi_2 \\
\pi_2 &= \pi_1 + \frac{1}{3}\pi_2 + \frac{1}{3}\pi_3 \\
\pi_3 &= \frac{1}{3}\pi_2 + \pi_4 \\
\pi_4 &= \frac{2}{3}\pi_3.
\end{aligned}$$

When these equations are solved and normalized (to sum to 1), a unique solution is found $\boldsymbol{\pi} = (1/9, 3/9, 3/9, 2/9)$. Furthermore, the limiting n-step matrix, $\lim_{n\to\infty} \boldsymbol{P}^n$, would have identical rows all equal to the vector $\boldsymbol{\pi}$.

More on the Gambler's Ruin Problem

For the Gambler's Ruin, there are three classes of states, $\{0\}$, $\{1, 2, \ldots, M-1\}$, and $\{M\}$. After a finite time, the gambler will either reach the goal of M units or lose all the money. Of particular interest is the probability that the gambler's fortune will grow to M before all the resources are lost, denoted here by p_i, $i = 0, 1, \ldots, M$. It is not too difficult to show that

$$p_i = \begin{cases} \dfrac{1 - [(1-p)/p]^i}{1 - [(1-p)/p]^M} & \text{if } p \neq \dfrac{1}{2} \\ \dfrac{i}{M} & \text{if } p = \dfrac{1}{2}. \end{cases}$$

More on the Coin Toss Sequence Problem

For the coin toss sequence example, the single-step transition matrix is given by

$$\boldsymbol{P} = \begin{bmatrix} 1/2 & 1/2 & 0 & 0 \\ 0 & 0 & 1/2 & 1/2 \\ 1/2 & 1/2 & 0 & 0 \\ 0 & 0 & 1/2 & 1/2 \end{bmatrix}.$$

This particular matrix is very special since its columns also add up to 1; such a matrix is said to be doubly stochastic. It can be shown that any doubly stochastic transition matrix coming from a recurrent and aperiodic finite chain has the discrete uniform stationary probabilities $\pi_j = 1/M$.

Concluding Remarks

For continuous-time Markov chains, the analog for the single-step transition matrix is the transition rate matrix (infinitesimal generator), where the matrix entries of probabilities are replaced by rates of exponentially distributed random variables. The holding time in a state in a continuous-time Markov chain is exponentially distributed, the analog to the geometric holding time in a state of a discrete-time Markov chain. Well-known examples of continuous-time Markov chains include birth-death processes (analog to random walk), the Poisson process, and many queueing systems with exponentially distributed interarrival and service times, e.g., Jackson queueing networks.

Markov Decision Processes

Chelsea C. White III
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

The finite-state, finite-action Markov decision process (MDP) is a model of sequential decision making under uncertainty. MDPs have been applied in such diverse fields as health care, highway maintenance, inventory, machine maintenance, cash-flow management, and regulation of water reservoir capacity (Derman 1970; Hernandez-Lermer 1989; Ross 1995; White 1969). After defining an MDP and providing a simple illustrative example, various solution procedures for several different types of MDPs are presented, all of which are based on dynamic programming (Bertsekas 2007; Howard 1971; Puterman 2005; Sennott 1999).

Problem Formulation

Let $k \in \{0,\ 1,\ \ldots,\ K-1\}$ represent the kth stage or decision epoch, i.e., when the kth decision must be selected; $K < \infty$ represents the planning horizon of the Markov decision process. Let s_k be the state of the system to be controlled at stage k. This state must be a member of a finite set S, called the state space, where $s_k \in S$, $k = 0, 1, \ldots, K$. The state process $\{s_k, k = 0, 1, \ldots, K\}$ makes transitions according to the conditional probabilities

$$p_{ij}(a) = \Pr\{s_{k+1} = j | s_k = i,\ a_k = a\},$$

where a_k is the action selected at stage k. The action selected must be a member of the finite action space A, which is allowed to depend on the current state value, i.e., $a_k \in A(i)$ when $s_k = i$, thus allowing a_k to be selected on the basis of the current state s_k for all k. Let δ_k be a mapping from the state space into the action space satisfying $\delta_k(s_k) \in A(s_k)$. Then δ_k is called a policy and a sequence of policies $\pi = \{\delta_0, \ldots, \delta_{K-1}\}$ is known as a strategy.

Let $r(i, a)$ be the one-stage reward accrued at stage $k = 0, 1, \ldots, K-1$, if $s_k = i$ and $a_k = a$. Assume $\bar{r}(i)$ is the terminal reward accrued at stage K (assuming $K < \infty$) if

$s_k = i$. The total discounted reward over the planning horizon accrued by strategy $\pi = \{\delta_0, \ldots, \delta_{K-1}\}$ is then given by

$$\sum_{k=0}^{K-1} \beta^k r(s_k, a_k) + \beta^K \bar{r}(s_k)$$

where $a_k = \delta_k(s_k)$, $k = 0, 1, \ldots, K-1$, where β is the nonnegative real-valued discount factor. The problem objective is to select a strategy that maximizes the expected value of the total discounted reward, with respect to the set of all strategies. Any such strategy is called an optimal strategy.

Example — An inspector must decide at each stage, on the basis of a machine's current state of deterioration, whether to replace the machine, repair it, or do nothing. Assume that the machine can be in one of M states, i.e., the state space is $S = \{1, \ldots, M\}$, where 1 represents the perfect machine state, M represents the failed machine state, and $1 < m < M$ represents an imperfect but functioning state of the machine. Each week the machine inspector can choose to let the machine produce (the do-nothing decision $a = 1$), completely replace the machine (the replace decision $a = R$), or perform some sort of maintenance on the machine, $1 < a < R$. Thus, the action space is $A = \{1, \ldots, R\}$. Generally, these problems are expressed in terms of costs rather than rewards, which can be formulated as $r(i, a) = -c(i, a)$, where $c(i, a)$ be the cost accrued over the following week if at the beginning of the week the machine is in state i and the machine inspector selects action a. Let β be the current value of a dollar to be received next week. Assume the transition probabilities $p_{ij}(a)$ are known for all $i, j \in S$, $a \in A$, where generally $p_{i1}(\mathrm{R}) = 1$ and $p_{ij}(1) = 0$ if $j < i$.

Dynamic Programming Formulation (Finite Stage Case)

To formulate the MDP as a dynamic program for the finite planning horizon case, let $f_k(i)$ be the optimal expected total discounted reward accrued from stage k through the terminal stage K, assuming $s_k = i$. Note that $f_k(i)$ should differ from $f_{k+1}(s_{k+1})$ only by the reward accrued at stage k. In fact, it is easily shown that f_k and f_{k+1} are related by the dynamic programming optimality equation

$$f_k(i) = \max_{a \in A(i)} \left\{ r(i, a) + \beta \sum_{j \in S} p_{ij}(a) f_{k+1}(j) \right\},$$

which has boundary condition $f_K(i) = \bar{r}(i)$. Note also that an optimal strategy $\pi^* = \{\delta_0^*, \ldots, \delta_{K-1}^*\}$ necessarily and sufficiently satisfies

$$f_k(i) = r[i, \delta_k^*(i)] + \beta \sum_j p_{ij}[\delta_k^*(i)] f_{k+1}(j)$$

for all $k = 0, 1, \ldots, K-1$. Thus, the action that should be taken at stage k, given $s_k = i$, is any action that achieves the maximum in

$$\max_{a \in A(i)} \left\{ r(i, a) + \beta \sum_j p_{ij}(a) f_{k+1}(j) \right\}.$$

The Infinite Horizon Discounted Reward Case

For the infinite horizon setting where $K = \infty$, there may exist strategies that could generate an infinite reward. However, if the discount factor β is strictly less than 1, no such strategy exists, which can be verified by noting that

$$\sum_{k=0}^{\infty} \beta^k r(s_k, a_k) \le \sum_{k=0}^{\infty} \beta^k \max_{(i,a)} |r(i, a)| = \frac{\max_{(i,a)} |r(i, a)|}{1 - \beta}.$$

Not surprisingly, the dynamic program for the infinite horizon case can be related to the dynamic program for the finite horizon case. Defining m as the number of stages to go until the terminal stage of the finite horizon case, the dynamic program for the finite horizon problem can then be rewritten as

$$g_{m+1}(i) = \max_{a \in A(i)} \left\{ r(i, a) + \beta \sum_j p_{ij}(a) g_m(j) \right\}$$

where $f_k(i) = g_{K-k}(i)$. Now the optimal expected total discounted reward should be $g(i) = \lim_{m \to \infty} g(i)$ for initial state i, which should satisfy

$$g(i) = \max_{a \in A(i)} \left\{ r(i,a) + \beta \sum_j p_{ij}(a) g(i) \right\} \quad (1)$$

if the limit and maximization operators can be interchanged. It so happens that this interchange is possible under the conditions considered here, and hence the optimal expected total discounted reward uniquely satisfies (1). It can also be shown that an optimal strategy exists that is stage invariant and that this strategy, or equivalently, policy, satisfies

$$g(i) = r[i, \delta^*(i)] + \beta \sum_j p_{ij}[\delta^*] g(j) \quad (1a)$$

for all $i \in S$.

Solution Procedures

Three different computational approaches for determining g and δ^* in (1) are presented.

Linear Programming — The following linear program can solve the infinite-horizon discounted MDP:

$$\text{minimize} \sum_{i \in S} g(i)$$
$$\text{subject to} \quad g(i) - \beta \sum_j p_{ij}(a) g(j) \geq r(i,a)$$

where the constraint inequality must be satisfied for all $i \in S$ and $a \in A(i)$, $i \in S$.

Successive Approximations — This procedure, in its simplest form, involves determining $g_m(i)$ for large m, using the iteration equation

$$g_m(i) = \max_{a \in A(i)} \left\{ r(i,a) + \beta \sum_j p_{ij}(a) g_{m-1}(j) \right\},$$

where $g_0(i)$ can be arbitrarily selected; however, it is generally beneficial to select g_0 as close to g as possible if there is some way of estimating g *a priori*.

Policy Iteration — This computational procedure involves the following iterative approach:

Step 0: Select δ

Step 1: Determine g_δ where g_δ, satisfy

$$g_\delta(i) = r[i, \delta(i)] + \beta \sum_j p_{ij}[\delta(i)] g_\delta(j).$$

Note that

$$g_\delta = (I - \beta P_\delta)^{-1} r_\delta$$

where $P_\delta = \{p_{ij}[\delta(i)]\}$, $g_\delta = \{g_\delta(i)\}$, $r_\delta = \{r[i, \delta(i)]\}$, I is the identity matrix, and the inverse is guaranteed to exist since $\beta < 1$.

Step 2: Determine δ' that satisfies

$$r[i, \delta'(i)] + \beta \sum_j p_{ij}[\delta'(i)] g_\delta(j) = \max_{a \in A(i)} \left\{ r(i,a) + \beta \sum_j p_{ij}(a) g_\delta(j) \right\}.$$

Step 3: Set $\delta = \delta'$ and return to Step 1 until g_δ and $g_{\delta'}$ are sufficiently close.

Note that each of the above solution procedures is far more efficient than exhaustive enumeration. Combining policy iteration and successive approximations can lead to efficient computational procedures for large-scale infinite-horizon discounted MDPs.

Markov Decision Processes without Discounting (The Average Reward Case)

Assume that the criterion is

$$\lim_{K \to \infty} \left(\frac{1}{K+1} \right) E \left\{ \sum_{k=0}^{K} r(S_k, a_k) \right\}$$

which is the expected average reward criterion. When the system operates under stationary policy δ, it can be shown that there exist values $v_\delta(i)$, $i \in S$, and a state independent gain γ_δ, which satisfy

$$\gamma_\delta + v_\delta(i) = r[i, \delta(i)] + \sum_j p_{ij}[\delta(i)] v_\delta(i) \quad (2)$$

if P_δ is ergodic. Let γ^*, δ^* and v be such that

$$\gamma^* + v(i) = \max_{a \in A(i)} \left\{ r(i,a) + \beta \sum_j p_{ij} v(j) \right\} = r[i, \delta^*(i)] + \sum_j p_{ij}[\delta^*(i)] v(j)$$

where P_δ is assumed ergodic for all δ. Then, γ^* is the value of the criterion generated by an optimal strategy and δ^* is an optimal strategy. The following is a policy iteration procedure for determining γ^*, δ^* and v, where it is necessary only to know v up to a positive constant due to the sum-to-one characteristic of the probabilities.

Algorithm. Step 0: Choose δ.

Step 1: Solve equation (2) for v_δ and γ_δ, where for some i, $v_\delta(i) = 0$.

Step 2: Determine a policy δ' that achieves the maximum in

$$\max_{a \in A(i)} \left\{ r(i,a) + \sum_j p_{ij} v_\delta(i) \right\}.$$

Step 3: Set $\delta = \delta'$ and go to Step 1 until γ_δ and $\gamma_{\delta'}$ are sufficiently close.

Concluding Remarks

The discussion has focused on the MDP setting where the state and action spaces are finite; the reward is separable with respect to stage; all rewards, the discount factor, and all transition probabilities are known precisely and the current state can be accurately made available to the decision maker before selection of the current alternative. The references treat more general settings. Much research effort is devoted to improving the computational tractability of large-scale MDPs so as to improve both the validity and tractability of this modeling tool. One such approach is approximate dynamic programming, which is treated in detail in Volume II of Bertsekas (2007).

Markov Processes

Douglas R. Miller
George Mason University, Fairfax, VA, USA

Introduction

A Markov process is a stochastic process $\{X(t), t \in T\}$ with state space S and time domain T that satisfies the Markov property, which is also known as lack of memory. In general, probabilities of behavior of a stochastic process at future times usually depend on the behavior of the process at times in the past. The Markov property means that probabilities of future events are completely determined by the present state of the process: if the current state of the process is known, then the past behavior of the process provides no additional information in determining the probabilities of future events. Mathematically, the process $\{X(t), t \in T\}$ is Markov if, for any $n > 0$, any $t_1 < t_2 < \ldots, < t_n < t_{n+1}$ in the time domain T, and any states $x_1, x_2, \ldots, x_n$ and any set A in the state space S,

$$\Pr\{X(t_{n+1}) \in A | X(t_1) = x_1, \ldots, X(t_n) = x_n\} = \Pr\{X(t_{n+1}) \in A | X(t_n) = x_n\}.$$

The conditional probabilities on the right-hand side of this equation are the transition probabilities of the Markov process; they play a key role in the study of Markov processes. The transition probabilities of the process are presented as a transition function $p(s, x; t, A) = \Pr\{X(t) \in A \,|\, X(s) = x\}$, $s < t$, for $s, t \in T$, $x \in S$, and $A \subset S$. The initial distribution of the

process is $q(A) = \Pr\{X(0) \in A\}$, for $A \subset S$. The distribution of a Markov process is uniquely determined by an initial distribution $q(\cdot)$ and a transition function $p(\cdot,\ldots,\cdot)$: for $0 = t_0 < t_1 < \ldots < t_n$ in the time domain, and subsets A_1, A_2,..., A_n of the state space S,

$$\Pr\{X(t_1) \in A_1, \ldots, X(t_n) \in A_n\}$$
$$= \int_{x_0 \in S} q(dx_0) \int_{x_1 \in A_1} p(t_0, x_0; t_1, dx_1) \cdots$$
$$\int_{x_{n-1} \in A_{n-1}} p(t_{n-2}, x_{n-2}; t_{n-1}, dx_{n-1}) p(t_{n-1}, x_{n-1}; t_n, A_n).$$

An equivalent interpretation of the Markov property is that the past behavior and the future behavior of the process are conditionally independent given the present state of the process: for any $m > 0$, any $n > 0$, any $t_{-m} < \ldots, < t_{-1} < t_0 < t_1 < \ldots, < t_n$ in the time domain, and any state x_0 and any sets $A_1, A_2, \ldots, A_m$ and $B_1, B_2, \ldots, B_n$ in the state space S,

$$\Pr\{X(t_{-m}) \in A_m, \ldots, X(t_{-1}) \in A_1, X(t_1) \in B_1, \ldots, X(t_n) \in B_n | X(t_0) = x_0\}$$
$$= \Pr\{X(t_{-m}) \in A_m, \ldots, X(t_{-1}) \in A_1 | X(t_0) = x_0\} \cdot \Pr\{X(t_1) \in B_1, \ldots, X(t_n) \in B_n | X(t_0) = x_0\}.$$

A Markov process has stationary transition probabilities if the transition probabilities are time invariant, i.e., for s, $t > 0$, $\Pr\{X(s + t) \in A \mid X(s) = x\} = \Pr\{X(t) \in A | X(0) = x\}$. In this case the transition function takes the simplified form $p_t(x, A) = \Pr\{X(t) \in A \mid X(0) = x\}$. Most Markov process models assume stationary transition probabilities.

Classification of Markov Processes

There is a natural classification of Markov processes according to whether the time domain T and the state space S are denumerable or non-denumerable. This yields four general classes. Denumerable time domains are usually modeled as the integers or non-negative integers. Non-denumerable time domains are usually modeled as the continuum ($\mathcal{R}$ or $[0, \infty]$). Denumerable state spaces can be modeled as the integers, but it is often useful to retain other descriptions of the states rather than simply enumerating them. Non-denumerable state spaces are usually modeled as a one or higher dimensional continuum. Roughly speaking, discrete is equivalent to denumerable and continuous is equivalent to non-denumerable. In 1907, Markov considered a discrete time domain and a finite state space; he used the word "chain" to denote the dependence over time, hence the term Markov chain for Markov processes with discrete time and denumerable states. See Maistrov (1974) for some historical discussion and see Appendix B of Howard (1971) for a reprint of one of Markov's 1907 papers. There is no universal convention for the scope of definition of Markov chain. Chung (1967) and most elementary operations research/management science textbooks (e.g., Hillier and Lieberman 2009) define Markov processes with denumerable state spaces to be Markov chains. Iosifescu (1980) and the Romanian school use the convention that Markov chain applies to discrete time and any state space, while Markov process applies to continuous time and any state space. The terminology varies in popular texts: Karlin and Taylor (1975, 1981) and Ross (1995) agree with Chung; Breiman (1968) and Çinlar (1975) agree with the Romanians. The terms discrete-time Markov chain (DTMC) and continuous-time Markov chain (CTMC) are sometimes used to clarify the situation.

Here are four examples of Markov processes representing the four classes with respect to discrete or continuous time and denumerable or continuous state space.

(a) *Gambler's Ruin* (*discrete time/denumerable states*). A gambler makes repeated bets. On each bet he wins \$1 with probability p or loses \$1 with probability $1 - p$. Outcomes of successive bets are independent events. He starts with a certain initial stake and will play repeatedly until he loses all his money or until he increases his fortune to \$$M$. Let X_n equal the gambler's wealth after n plays. The stochastic process $\{X_n, n = 0, 1, 2, \ldots\}$ is a discrete time Markov chain (DTMC) with state space $\{0, 1, 2, \ldots, M\}$. The Markov property follows from the assumption that outcomes of successive bets are independent events. The Markov model can be used to derive performance measures of interest for this situation: for example, the probability he loses all his money, the probability he reaches his goal of \$$M$, and the expected number of times he makes a bet. All these performance measures are

functions of his initial stake x_0, probability p and goal M. (The gambler's fortune is a random walk with absorbing boundaries 0 and M.) The gambler's ruin is a simplification of more complex systems that experience random rewards, risk, and possible ruin; for example, insurance companies.

(b) *A Maintenance System* (*continuous time/denumerable states*). A system consists of two machines and one repairman. Each machine operates until it breaks down. The machine is then repaired and put back into operation. If the repairman is busy with the other machine, the just broken machine waits its turn for repair. So, each machine cycles through the states: operating (O), waiting (W), and repairing (R). Labeling the machines as "1" and "2" and using the corresponding subscripts, the states of the system are (O_1,O_2), (O_1,R_2), (R_1,O_2), (W_1,R_2) and (R_1,W_2). Assume that all breakdown instances and repairs are independent of each other and that the operating times until breakdown and the repair times are random with exponential distributions. The mean operating times for the machines are $1/\alpha_1$ and $1/\alpha_2$, respectively (so the machines break down at rates α_1 and α_2). The mean repair times for the machines are $1/\beta_1$ and $1/\beta_2$, respectively (so the machines are repaired at rates β_1 and β_2). Letting $X_i(t)$ equal the state of machine i at time t, the stochastic process $\{(X_1(t), X_2(t)), 0 \leq t\}$ is a continuous time Markov chain (CTMC) on a state space consisting of five states. The Markov property follows from the assumption about independent exponential operating times and repair times. (The exponential distribution is the only continuous distribution with lack-of-memory.) For this type of system there are several performance measures of interest: for example, the long-run proportion of time both machines are broken or the long-run average number of working machines. This maintained system is a simplified example of more complex maintained systems.

(c) *Quality Control System (discrete time/continuous states)*. A manufacturing system produces a physical part that has a particularly critical length along one dimension. The specified value for the length is α. However, the manufacturing equipment is imprecise. Successive parts produced by this equipment vary randomly from the desired value, α. Let X_n equal the size of the nth part produced. The noise added to the system at each step is modeled as $D_n \sim \text{Normal}(0, \delta^2)$. The system can be controlled by attempting to correct the size of the $(n+1)$st part by adding $c_n = -\beta\,(x_n - \alpha)$ to the current manufacturing setting after observing the size x_n of the nth part; however, there is also noise in the control so that, in fact, $C_n \sim \text{Normal}\,(c_n,(\gamma c_n)^2)$ is added to the current setting. This gives $X_{n+1} = X_n + C_n + D_n$. The process $\{X_n,\ n = 0, 1, 2,\ldots\}$ is a discrete-time Markov process on a continuous state space. The Markov property will follow if all the noise random variables $\{D_n\}$ are independent and the control random variables $\{C_n\}$ depend only on the current setting (X_n) of the system. Performance measures of interest for this system include the long-run distribution of lengths produced (if the system is stable over the long-run). There is also a question of determining the values of β for which the system is stable and then finding the optimal value of β.

(d) *Brownian Motion* (*continuous time/continuous states*). In 1828, English botanist Robert Brown observed random movement of pollen grains on the surface of water. The motion is caused by collisions with water molecules. The displacement of a pollen grain as a function of time is a two-dimensional Brownian motion. A one-dimensional Brownian motion can be obtained by scaling a random walk: Consider a sequence of independent, identically-distributed random variables, Z_i, with $\Pr\{Z_i = +1\} = \Pr\{Z_i = -1\} = 1/2$, $i = 1, 2,\ldots$. Let $S_n = \sum_{i=1}^{n} Z_i$, $n = 0, 1, 2,\ldots$. Then, let $X_n(t) = n^{-1/2} S_{[nt]}, 0 \leq t \leq 1$, $n = 1, 2,\ldots$, where $[nt]$ is the greatest integer $\leq nt$. As $n \to \infty$, the sequence of processes $\{X_n(t), 0 \leq t \leq 1\}$ converges to $\{W(t), 0 \leq t \leq 1\}$, standard Brownian motion or the Wiener process; see Billingsley (1968). The Wiener process is a continuous-time, continuous-state Markov process. The sample paths of the Wiener process are continuous. Diffusions are the general class of continuous-time, continuous-state Markov processes with continuous sample paths. Diffusion models are useful approximations to discrete processes analogous to how the Wiener process is an approximation to the above random

walk process $\{S_n,\ n = 0,\ 1,\ 2,\ldots\}$; see Glynn (1990). Geometric Brownian motion $\{Y(t), 0 \le t\}$ is defined as $Y(t) = \exp(\sigma W(t))$, $0 \le t$; it is a diffusion. Geometric Brownian motion has been suggested as a model for stock price fluctuations; see Karlin and Taylor (1975). A performance measure of interest is the distribution of the maximum value of the process over a finite time interval.

There are various performance measures that can be derived for Markov process models. Some specific performance measures were mentioned for the above examples. Some general behavioral properties and performance measures are now described. The descriptions are for a discrete-time Markov chain $\{X_n,\ n = 0,\ 1,\ 2,\ldots\}$ but similar concepts apply to other classes of Markov processes. A Markov chain is strongly ergodic if X_n converges in distribution as $n \to \infty$, independent of the initial state x_0. A Markov chain is weakly ergodic if $n^{-1}\sum_{i=1}^{n} X_i$ converges to a constant as $n \to \infty$, independent of the initial state x_0. Also as $n \to \infty$, under certain conditions and for real-valued functions f: $S \to \mathbb{R}$, $f(X_n)$ converges in distribution, $n^{-1}\sum_{i=1}^{n} f(X_i)$ converges to a constant, and $n^{-1/2}\sum_{i=1}^{n}[f(X_i) - Ef(X_i)]$ is asymptotically normal. Markov process theory identifies conditions for ergodicity, conditions for the existence of limits, and provides methods for evaluation of limits when they exist. For example, in the above maintained system example, $f(\cdot)$ might be a cost function and the performance measure of interest is long-run average cost. The above performance is long-run (or infinite-horizon, or steady-state, or asymptotic) behavior. Short-run (or finite-horizon, or transient) behavior and performance is also of interest. For a subset A of the state space S, the first passage time T_A is the time of the first visit of the process to A: $T_A = \min\{n\colon X_n \in A\}$. The hitting probability $\Pr\{T_A < \infty\}$, the distribution of T_A, and $E(T_A)$ are of interest. In the gambler's ruin example, the gambler wants to know the hitting probabilities for sets $\{0\}$ and $\{M\}$. Transient analysis of Markov processes investigates these and other transient performance measures. The analysis of performance measures takes on different forms for the four different classes of Markov processes.

Evaluation of performance measures for Markov process models of complex systems may be difficult. Standard numerical analysis algorithms are sometimes useful, and specialized algorithms have been developed for Markov models; for example, see Grassmann (1990). Workers in the field of computational probability have developed and evaluated numerical solution techniques for Markov models by exploiting special structure and probabilistic behavior of the system or by using insights gained from theoretical probability analysis. In this spirit, Neuts (1981) has developed algorithms for a general class of Markov chains. A structural property of Markov chains called reversibility leads to efficient numerical methods of performance evaluation; see Keilson (1979), Kelly (1979), and Whittle (1986). There is a relationship between discrete-time and continuous-time Markov chains called uniformization or randomization that can be used to calculate performance measures of continuous-time Markov chains; see Keilson (1979) and Gross and Miller (1984). For Markov chains with huge state spaces, Monte Carlo simulation can be used as an efficient numerical method for performance evaluation; see, for example, Hordijk, Iglehart and Schassberger (1976) and Fox (1990).

There are classes of stochastic processes related to Markov processes. There are stochastic processes that exhibit some lack of memory but are not Markovian. Regenerative processes have lack of memory at special points (regeneration points) but at other times the process has a memory; see Çinlar (1975). A semi-Markov process is a discrete-state continuous-time process that makes transitions according to a DTMC but may have general distributions of holding times between transitions; see Çinlar (1975). It is sometimes possible to convert a non-Markovian stochastic process into a Markov process by expanding the state description with supplementary variables; that is, $\{X(t), 0 \le t\}$ may be non-Markovian but $\{(X(t), Y(t)),\ 0 \le t\}$ is Markovian. Supplementary variables are often elapsed times for phenomena with memory; in this way very general discrete state stochastic systems can be modeled as Markov processes with huge state spaces. The general model for discrete-event dynamic systems is the generalized semi-Markov process (GSMP); see Whitt (1980) and Cassandras and Lafortune (2008).

The index set T of a stochastic process $\{X(t), t \in T\}$ may represent "time" or "space" or both, leading to temporal processes, spatial processes, or spatial-temporal processes when the index set is time, space, or space-time, respectively. Stochastic processes with multi-dimensional index sets are called random

fields. The Markov property can be generalized to the context of multi-dimensional index sets resulting in Markov random fields; see Kelly (1979), Kindermann and Snell (1980) and Whittle (1986). Markov random fields have many applications. They are models for statistical mechanical systems (interacting particle systems). They are useful in texture analysis and image analysis; see Chellappa and Jain (1993).

Markov Property

When the behavior of a stochastic process $\{X(t), t \in T\}$ at times in the future depends only on the present state of the process (past behavior of the process affects the future behavior only through the present state of the process); viz., for any $n > 0$, any set of time points $t_1 < t_2 < \ldots < t_n < t_{n+1}$ in the time domain T, and any

states $x_1, x_2, \ldots, x_n$ and any set A in the same space, $\Pr\{X(t_{n+1}) \in A | X(t_1) = x_1, \ldots, X(t_n) = x_n\} = \Pr\{X(t_{n+1}) \in A | X(t_n) = x_n\}$.

- ▶ Markov Processes

Markov Random Field

A random field that satisfies a generalization of the Markov property.

See

- ▶ Markov Processes
- ▶ Random Field

Markov Renewal Process

When the times between successive transitions of a Markov chain are independent random variables indexed on the to and from states of the chain.

See

- ▶ Markov Chains
- ▶ Markov Processes
- ▶ Networks of Queues
- ▶ Renewal Process

Markov Routing

The process of assigning customers to nodes in a queueing network according to a Markov chain over the set of nodes, where $p(j, k)$ is the probability that a customer exiting node j proceeds next to node k, with $1 - \sum p(j, k)$ being the probability a customer leaves the network from node j (the sum is over all nodes of the network, including leaving the network altogether).

Markovian Arrival Process (MAP)

- ▶ Matrix-Analytic Stochastic Models

Marriage Problem

Given a group of m men and m women, the marriage problem is to couple the men and women such that the total happiness of the group is maximized when the assigned couples marry. The women and the men determine an $m \times m$ table of happiness coefficients, where the coefficient a_{ij} represents the happiness rating for the couple formed by woman i and man j if they marry. The larger the a_{ij}, the higher the happiness. The problem can be formulated as an assignment problem whose solution matches each woman to one man. This result, which is due to the fact that the assignment problem has a solution in which the variables can take on only the values of 0 or 1, is sometimes used to prove that monogomy is the best form of marriage.

See

- ▶ Assignment Problem

Martingale

A stochastic process (with finite expectation) for which the conditional expectation of future values is equal to the present value. For example, for a discrete-time process $\{X_0, X_1, X_2, \ldots\}$,

$$E[X_{n+1} | X_0, X_1, \ldots X_n] = X_n.$$

Master Problem

The transformed extreme-point problem that results when applying the Dantzig-Wolfe decomposition algorithm.

► Dantzig-Wolfe Decomposition Algorithm

Matching

Richard W. Eglese
Lancaster University, Lancaster, UK

Introduction

Matching problems form an important branch of graph theory. They are of particular interest because of their application to problems found in Operations Research. Matching problems also form a class of integer-linear programming problems which can be solved in polynomial time. A good description of the historical development of matching problems and their solutions is contained in the preface of Lovasz and Plummer (2009).

Given a simple non-directed graph $G = [V, E]$ (where V is a set of vertices and E is a set of edges), then a matching is defined as a subset of edges M such that no two edges of M are adjacent. A matching is said to *span* a set of vertices X in G if every vertex in X is incident with an edge of the matching. A perfect matching is a matching which spans V. A maximum matching is a matching of maximum cardinality, i.e. a matching with the maximum number of members in the set.

A graph is called a bipartite graph if the set of vertices V is the disjoint union of sets V_1 and V_2 and every edge in E has the form (v_1, v_2) where v_1 is a member of V_1 and v_2 is a member of V_2.

Matching on Bipartite Graphs

The first type of matching problems consists of those which can be formulated as matching problems on a bipartite graph. For example, suppose V_1 represents a set of workers and V_2 represents a set of tasks to be performed. If each worker is able to perform a subset of the tasks and each task may be performed by some subset of the workers, the situation may be modeled by constructing a bipartite graph G, where there is an edge between v_1 in V_1 and v_2 in V_2 if and only if worker v_1 can perform task v_2. If it is assumed that each worker may only be assigned one task and each task may only be assigned to be carried out by one worker, the problem is an assignment problem. To find the maximum number of tasks which can be performed, the maximum matching on G must be found. If a measure of effectiveness can be associated with assigning a worker to a task, then the question may be asked as to how the workers should be assigned to tasks to maximize the total effectiveness. This is a maximum weighted matching problem. If costs are given in place of measures of effectiveness, the minimum cost assignment problem can be solved as a maximum weighted matching problem after replacing each cost by the difference between it and the maximum individual cost. This assumes all workers or all tasks must be assigned.

Both forms of assignment problem can be solved by a variety of algorithms. For example, a maximum matching on a bipartite graph can be found by modeling the problem as a network flow problem and finding a maximum flow on the model network. A more efficient algorithm is due to Hopcraft and Karp (1973). A well-known algorithm for solving the maximum weighted matching problem (for which the maximum matching problem can be considered a special case) on a bipartite graph is often referred to as the Hungarian method and was introduced by Kuhn (1955, 1956). Kuhn casts the procedure in terms of a primal-dual linear program. The algorithm can be implemented so as to produce an optimal matching in $O(m^2 n)$ steps, where n is the number of vertices and m is the number of edges in the graph. The details are given in Lawler (1976). Although this is an efficient algorithm, it may be necessary to find faster implementations for problems of large size or when the algorithm is used repeatedly as part of a more complex procedure. Various methods have been proposed including those due to Jonker and Volgenant (1986) and Wright (1990).

Job Scheduling

Another example of a problem which can be modeled as a matching problem arises from job scheduling (Coffman and Graham 1972). Suppose n jobs are to be processed and there are two machines available. All jobs require an equal amount of time to complete and can be processed on either machine. However there are precedence constraints which mean that some jobs must be completed before others are started. What is the shortest time required to process all n jobs?

This example can be modeled by constructing a graph G with n vertices representing the n jobs and where an edge joins two vertices if and only if they can be run simultaneously. An optimum schedule corresponds to one where the two machines are used simultaneously as often as possible. Therefore the problem becomes one of finding the maximum matching on G, from which the shortest time can be derived. In this case though, the graph G is no longer bipartite and so an algorithm for solving the maximum matching problem on a general graph is required.

The first efficient algorithm to find a maximum matching in a graph was developed by Edmonds (1965a). Most successful algorithms to find a maximum matching have been based on Edmonds' ideas. Gabow (1976) and Lawler (1976) show how to implement the algorithm in a time of $O(n^3)$. It is possible to modify the algorithm for more efficient performance on large problems. For example, Even and Kariv (1975) present an algorithm running in a time of $O(n^{5/2})$ and Micali and Vazirani (1980) describe an algorithm with running time of $O(mn^{1/2})$.

Arc Routing

There is a close connection between arc routing problems and matching. Suppose a person must deliver mail along all streets of a town. What route will traverse each street and return to the starting point in minimum total distance? This problem is known as the Chinese Postman Problem as it was first raised by the Chinese mathematician Meigu Guan (1962). It may be formulated as finding the minimum length tour on a non-directed graph G whose edges represent the streets in the town and whose vertices represent the junctions, where each edge must be included at least once. Edmonds and Johnson (1973) showed that this problem is equivalent to finding a minimum weighted matching on a graph whose vertices represent the set of odd nodes in G and whose edges represent the shortest distances in G between the odd nodes. Odd nodes are vertices where an odd number of edges meet. This minimum weighted matching problem can be solved efficiently by the algorithm introduced by Edmonds (1965b) for maximum weighted matching problems where the weights on each edge are the distances multiplied by minus one. The Chinese Postman Problem is therefore easier to solve than the Traveling Salesman Problem where a polynomially bounded algorithm has not yet been established.

For large problems, faster versions of the weighted matching algorithm have been developed by Galil, Micali and Gabow (1982) and Ball and Derigs (1983) which require $O(mn \log n)$ steps. A starting procedure which significantly reduces the computing time for the maximum matching problem is described by Derigs and Metz (1986) and involves solving the assignment problem in a related bipartite graph.

b-Matchings

Given an integer b_i for each vertex v_i of V, a b-matching of G is defined as a subset M of edges, such that at each vertex v_i, the number of edges of M incident on v_i is less than or equal to b_i. A matching is therefore a special case of a b-matching where $b_i = 1$ for all i. Efficient algorithms for b-matching problems are described in Gerards (1995), which also provides a good survey of matching in general.

Lower bounds for Vehicle Routing problems can be obtained by relaxing the subtour elimination and vehicle capacity constraints to give a perfect b-matching problem. Miller (1995) shows that this approach can be used in a branch-and-bound frame-work for this application.

Material Handling

Meir J. Rosenblatt
Washington University in St. Louis, St. Louis, MO, USA
Technion – Israel Institute of Technology, Haifa, Israel

Introduction

Material handling is concerned with moving raw materials, work-in-process, and finished goods into the plant, within the plant, and out of the plant to warehouses, distribution networks, or directly to the customers. The basic objective is to move the right combination of tools and materials (raw materials, parts and finished products) at the right time, to the right place, in the right form, and in the right orientation. And to do it with the minimum total cost.

It is estimated that 20% to 50% of the total operating expenses within manufacturing are attributed to material handling (Tompkins et al. 1996). Material handling activities may account for 80% to 95% of total overall time spent between receiving a customer order and shipping the requested items (Rosaler and Rice 1994). This indicates that improved efficiencies in material handling activities can lead to substantial reductions in product cost and production lead-time; better space and equipment utilization, improved working conditions and safety, improvements in customer service; and, eventually to higher profits and larger market share. Material handling adds to the product cost but contributes nothing to the value added of the products.

Design of material handling systems play a critical role in just-in-time (JIT) manufacturing. Under JIT, production is done in small lots so that production lead-times are reduced and inventory holding costs are minimized, requiring the frequent conveyance of material. Thus, successful implementation of JIT needs a fast and reliable material handling system as a prerequisite. A major, related development with great impact on the material handling process has been the extensive implementation of Total Quality Management (TQM) plans.

Production lot-sizing decisions have a direct impact on the assignment of storage space to different items (products) and consequently on the material handling costs. Therefore, lot sizing decisions must take into account not only setup and inventory carrying costs but also warehouse and material handling costs. In other words, production lot sizing, warehouse storage assignment, and material handling equipment decisions must be made simultaneously.

Also, in a flexible manufacturing environment, where batches of products may have several possible alternative routes, the choice of routing-mix can have a significant effect on shop throughput and work-in-process inventory. However, for such a system to be efficient, an appropriate material handling system needs to be designed. This design issue is especially important when expensive machines are being used. Major waste can be caused by a material handling system that is inappropriate and becomes a bottleneck.

Finally, it should be recognized that (computer-aided) facility layout determines the overall pattern of material flow within the plant and, therefore, has a significant impact on the material handling activities and costs. It is estimated that effective facilities planning and layout can reduce material handling costs by at least 10% to 30% (Tompkins et al. 1996). However, an effective layout requires an effective material handling system. Therefore, it is critical that these decisions are made simultaneously.

Material Handling Equipment

There are several ways of classifying material handling equipment: (1) type of control (operator controlled vs. automated); (2) where the equipment works (on the floor vs. suspended overhead); (3) travel path (fixed vs. flexible). The fixed vs. flexible travel path classification is used here as in Barger (1987). Flexible path equipment can be moved along any route and in general is operator-controlled. Trucks are a common mode of operations. There are several types of trucks depending on the type of handling that is needed, and the following are the most common:

Counterbalanced fork trucks — used both for storage at heights of 20 feet or more, as well as for fast transportation);

Narrow-aisle trucks — mainly used for storage applications;

Walkie Pallet trucks — mainly used for transportation over short hauls; and

Manual trucks — mainly used for short hauls and auxiliary services.

There are three important types of fixed-path equipment:

Conveyors — Conveyors are one of the largest families of material handling equipment. They can be classified based on the load-carrying surface involved: roller, belt, wheel, slat, carrier chain; or on the position of the conveyor: on-floor or overhead;

Automatic Guided Vehicles (**AGVs**) — these are electric vehicles with on-board sensors that enable them to automatically track along a guide path which can be an electrified guide wire or a strip of (reflective) paint or tape on the floor. The AGVs follow their designated path using their sensors to detect the electromagnetic field generated by the electric wire or to optically detect the path marked on the floor. AGVs can transport materials between any two points connected by a guide path — without human intervention. Most of today's AGVs are capable of loading and unloading materials automatically. Most applications of AGVs are for load transportation, however, they could also be used in flexible assembly operations to carry the product being assembled through the various stages of assembly. While AGVs have traditionally been fixed path vehicles, advances in technology permit them to make short deviations from their guide path. Such flexibility may considerably increase their usefulness; and

Hoists, Monorails, and Cranes — Hoists are a basic type of overhead lifting equipment and can be suspended from a rail, track, crane bridge or beam.

A hoist consists of a hook, a rope or chain used for lifting, and a container for the rope/chain. Monorails consist of individual wheeled trolleys that can move along an overhead track. The trolleys may be either powered or non-powered. Cranes have traditionally found wide application in overhead handling of materials, especially where the loads are heavy. Besides the overhead type, there are types of cranes that are wall or floor mounted, portable ones and so on. Types such as stacker cranes are useful in warehouse operations.

Interaction with Automated Storage and Retrieval Systems (AS/RS)

AS/RS consist of high-density storage spaces, computer-controlled handling and storage equipment (operated with minimal human assistance) and may be connected to the rest of the material handling system via some conveying devices such as conveyors and AGVs. Several types of AS/RS are available including: Unit Load, Miniload, Man-On-Board, Deep Lane and Carousels. The AS/RS systems help achieve very efficient placement and retrieval of materials, better inventory control, improved floor space utilization, and production scheduling efficiency. They also provide greater inventory accountability and reduce supervision requirements. Normally, stacker cranes that can move both horizontally and vertically at the same time are used for material handling. Typically, a crane operates in a single aisle, but can be moved between aisles (Rosenblatt et al. 1993). Items to be stored or retrieved are brought to/picked from the AS/RS by a conveyor or an AGV. Such integration can be used to automate material handling throughout the plant and warehouse. A great deal of research has been done on scheduling jobs and assigning storage space in the AS/RS (Hausman et al. 1976).

Issues in Material Handling System Design

Unit load concept — Traditional wisdom is that materials should be handled in the most efficient, maximum size using mechanical means to reduce the number of moves needed for a given amount of material. While reducing the number of trips required is a good objective, the drawback of this approach is that it tends to encourage the acceptance of large production lots, large material handling equipment, and large space requirements. Small unit loads allow for more responsive, less expensive, and less consuming material handling systems. Also, the trend toward continuous manufacturing flow processes and the strong drive for automation necessitate the use of smaller unit loads (Apple and Rickles 1987).

Container size and standardization — This is an issue related to the unit load concept. Container size has an obvious correlation with the size of unit load. Hence, not surprisingly, the current trend is to employ smaller containers. The benefits of smaller containers include compact and more efficient workstations, improved scheduling flexibility due to smaller transfer batch size, smaller staging areas, and lighter duty handling systems. Another consideration that strongly influences the optimal container size is the range of items served by one container. In warehouse operations, unless items vary widely in their physical characteristics, the cost of employing two or more container sizes is almost always higher than in the one-size case (Roll et al. 1989). Use of standard containers eliminates the need for container exchanges between operation sites.

Capacity of the system or number of pieces of equipment — The margins in the design of material handling system require a careful examination of the relative costs of acquiring and maintaining of work centers and handling equipment. In the design of the material handling system for an expensive job shop, enough excess capacity should be provided so that the handling system never becomes the bottleneck.

OR Models in Material Handling

Operations Research (OR) tools have been applied to model and study a variety of problems in the area of material handling. One example, dealing with the initial design phase of material handling, used a graph-theoretic modeling framework (Kouvelis and Lee 1990). Other examples include conveyor systems problems using queueing theory, and transfer lines where dynamic programming techniques were applied. Most of the theoretical work has focused on AGVs and AS/RS. The design and control of AGVs are

extremely complex tasks. The design decisions include determining the optimal number of AGVs (Maxwell and Muckstadt 1982), as well as determining the optimal flow paths (Kim and Tanchoco 1993). Factors to be considered in the design decisions include hardware considerations, impacts on facilities layout, material procurement policy, and production policy. Resulting problems tend to be intractable for any realistic scenario, and hence, heuristics and simulation are the most used techniques in addressing design issues. Control problems including dispatching and routing tasks require real time decisions, making it difficult to obtain optimal solutions. Researchers have attempted to solve simplified problems, for example, by examining static versions instead of dynamic systems (Han and McGinnis 1989), and using simple single-loop layouts (Egbelu 1993).

In the study of warehousing in general, and AS/RS in particular, many different measures of effectiveness of warehouse designs have been considered. The most common ones are throughput as measured by the number of orders handled per day, average travel time of a crane per single/dual command, and average waiting time per customer/order (Hausman et al. 1976). Researchers have considered either simulation or optimization models, usually of the nonlinear integer form, to solve these problems. Yet others have combined optimization and simulation techniques to obtain solutions that are both cost effective and operationally feasible (reasonable service time) (Rosenblatt et al. 1993).

Since factories are increasingly automated, numerical control of machine tools and flexible manufacturing systems is common. Material handling systems frequently involve the use of robots. In the absence of an effective material handling system, an automated factory would be reduced to a set of islands of automation. In the integrated and fiercely competitive global economy, material handling systems play a crucial role in the battle to cut costs and improve productivity and service levels.

Material Requirements Planning

A material requirements planning (MRP) system is a collection of logical procedures for managing, at the most detailed level, inventories of component assemblies, subassemblies, parts and raw materials in a manufacturing environment. It is an information system and simulation tool that generates proposals for production schedules that managers can evaluate in terms of their feasibility and cost effectiveness.

See

- ▶ Hierarchical Production Planning
- ▶ Production Management

Mathematical Model

A mathematical description of (usually) a real-world problem. In operations research/management science, mathematical models take on varied forms (e.g., linear programming, queueing, Markovian systems), many of which can be applied across application areas. The basic OR/MS mathematical model can be described as the decision problem of finding the maximum (or minimum) of a measure of effectiveness (objective function) $E = F(X, Y)$, where X represents the set of possible solutions (alternative decisions) and Y the given conditions of the problem. Although a rather simple model in its concept, especially since it involves the optimization of a single objective, this mathematical decision model underlies most of the problems that have been successfully formulated and solved by OR/MS methodologies.

Mathematical Optimization Society

The Mathematical Optimization Society (MOS) is an international organization dedicated to the support and development of the application, computational methods, and theory of mathematical optimization. The society sponsors the triennial International Symposium on Mathematical Optimization and other meetings throughout the world. Until 2010, its name was the Mathematical Programming Society (MPS), which was founded in 1973.

Mathematical Programming

Mathematical programming is a major discipline in operations research/management science and, in general, is the study of how one optimizes the use and allocation of limited resources. Here the programming refers to the development of a plan or procedure for dealing with the problem. It is considered a branch of applied mathematics as it deals with the theoretical and computational aspects of finding the maximum (minimum) of a function $f(\boldsymbol{x})$ subject to a set of constraints of the form $g_i(\boldsymbol{x}) \leq b_i$. The linear-programming model is the prime example of such a problem.

Mathematical-Programming Problem

A constrained optimization problem usually stated as Minimize (Maximize) $f(\boldsymbol{x})$ subject to $g_i(\boldsymbol{x}) \leq 0$, $i = 1,\ldots, m$. Depending on the form of the objective function $f(\boldsymbol{x})$ and the constraints $g_i(\boldsymbol{x})$ the problem will have special properties and associated algorithms.

Mathematical-Programming System (MPS)

An integrated set of computer programs that are designed to solve a range of mathematical-programming problems is often referred to as a mathematical-programming system (MPS). Such systems solve linear programs, usually by some form of the simplex method, and often

have the capability to handle integer-variable problems and other nonlinear problems such as quadratic-programming problems. To be effective, an MPS must have procedures for input data handling, matrix generation of the constraints, reliable optimization, user and automated control of the computation, sensitivity analysis of the solution, solution restart, and output reports.

Matrices and Matrix Algebra

Alan Tucker
The State University of New York at Stony Brook, Stony Brook, NY, USA

Introduction

A matrix is an $m \times n$ array of numbers, typically displayed as

$$\boldsymbol{A} = \begin{bmatrix} 4 & 3 & 8 \\ 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix},$$

where the entry in row i and column j is denoted as a_{ij}. Symbolically, $\boldsymbol{A} = (a_{ij})$, for $i = 1,\ldots, m$ and $j = 1,\ldots, n$. A vector is a one-dimensional array, either a row or a column. A column vector is an $m \times 1$ matrix, while a row vector is a $1 \times n$ matrix. For a matrix $\boldsymbol{A}$, its ith row vector is usually denoted by $\boldsymbol{a}_i'$ and its jth column by $\boldsymbol{a}_j$. Thus an $m \times n$ matrix can be decomposed into a set of m row n-vectors or a set of n column m-vectors. Matrices are a natural generalization of single numbers, or scalars. They arise directly or indirectly in most problems in operations research and management science.

The word matrix in Latin means womb. The term was introduced by J.J. Sylvester in 1848 to describe an array of numbers that could be used to generate (give birth to) a variety of determinants. A few years later, Cayley introduced matrix multiplication and the basic theory of matrix algebra quickly followed. A more general theory of linear algebra and linear transformations pushed matrices into the background until the 1940s and the advent of digital computers. During the 1940s, Alan Turing, father of computer science, introduced the LU decomposition and John von Neumann, father of the digital computer, working with Herman Goldstine, started the development of numerical matrix algebra and introduced the condition number of a matrix. Curiously, at the same time Cayley and Sylvester were developing matrix algebra, another Englishman, Charles Babbage, was building his analytical engine, the forerunner of digital computers, which are critical to the use of modern matrix models.

Basic Operations and Laws of Matrix Algebra

The language for manipulating matrices is matrix algebra. Matrix algebra is a multivariable extension of single-variable algebra. The basic building block for matrix algebra is the scalar product. The scalar product $\boldsymbol{a} \cdot \boldsymbol{b}$ of $\boldsymbol{a}$ and $\boldsymbol{b}$ is a single number (a scalar) equal to the sum of the products $a_i\ b_i$, i.e., $\boldsymbol{a} \cdot \boldsymbol{b} = \sum_{i=1}^{n} a_i b_i$, where both vectors have the same dimension n. Observe that the scalar product is a linear combination of the entries in vector $\boldsymbol{a}$ and also a linear combination of the entries of vector $\boldsymbol{b}$.

The product of an $m \times n$ matrix $\boldsymbol{A}$ and a column n-vector $\boldsymbol{b}$ is a column vector of scalar products $\boldsymbol{a}_i' \cdot \boldsymbol{b}$, of the rows $\boldsymbol{a}_i'$ of $\boldsymbol{A}$ with $\boldsymbol{b}$. For example, if

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \end{bmatrix}$$

is a 2×3 matrix and

$$\boldsymbol{b} = \begin{bmatrix} b_1 \\ b_2 \\ b_3 \end{bmatrix}$$

is a column 3-vector, then

$$\boldsymbol{Ab} = \begin{bmatrix} \boldsymbol{a_1'} \cdot \boldsymbol{b} \\ \boldsymbol{a_2'} \cdot \boldsymbol{b} \end{bmatrix} = \begin{bmatrix} a_{11}b_1 + a_{12}b_2 + a_{13}b_3 \\ a_{21}b_1 + a_{22}b_2 + a_{23}b_3 \end{bmatrix},$$

so that $\boldsymbol{Ab}$ is a linear combination of $\boldsymbol{A}$. Moreover, for any scalar numbers r, q, any $m \times n$ matrix $\boldsymbol{A}$, and any column n-vectors $\boldsymbol{b}$, $\boldsymbol{c}$:

$$\boldsymbol{A}(r\boldsymbol{b} + q\boldsymbol{c}) = r\boldsymbol{A}\boldsymbol{b} + q\boldsymbol{A}\boldsymbol{c}.$$

The product of a row m-vector $\boldsymbol{c}$ and an $m \times n$ matrix $\boldsymbol{A}$ is a row vector of scalar products $\boldsymbol{c} \cdot \boldsymbol{a}_j$, of $\boldsymbol{c}$ with the columns $\boldsymbol{a}_j$ of $\boldsymbol{A}$. For example, if

$$\boldsymbol{A} = \begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \end{bmatrix},$$

is a 2×3 matrix and $\boldsymbol{c} = [c_1, c_2]$ is a row 2-vector, then

$$\begin{aligned} \mathbf{cA} &= [\mathbf{c} \cdot \mathbf{a_1}, \mathbf{c} \cdot \mathbf{a_2}, \mathbf{c} \cdot \mathbf{a_3}] \\ &= [a_{11}c_1 + a_{21}c_2, a_{12}c_1 + a_{22}c_2, a_{13}c_1 + a_{23}c_2]. \end{aligned}$$

If $\boldsymbol{A}$ is an $m \times r$ matrix and $\boldsymbol{B}$ is an $r \times n$ matrix, then the matrix product $\boldsymbol{AB}$ is an $m \times n$ matrix obtained by forming the scalar product of each row $\boldsymbol{a}_i'$ in $\boldsymbol{A}$ with each column $\boldsymbol{b}_j$ in $\boldsymbol{B}$. That is, the (i, j)th entry in $\boldsymbol{AB}$ is $\boldsymbol{a}_i' \cdot \boldsymbol{b}_j$. Column j of $\boldsymbol{AB}$ is the matrix–vector product $\boldsymbol{A}b_j$ and each column of $\boldsymbol{AB}$ is a linear combination of the columns of $\boldsymbol{A}$. Row i of $\boldsymbol{AB}$ is vector–matrix product $\boldsymbol{a}_i'\boldsymbol{B}$ and each row of $\boldsymbol{AB}$ is a linear combination of the rows of $\boldsymbol{B}$. The matrix–vector product $\boldsymbol{Ab}$ is a special case of the matrix-matrix product in which the second matrix has just one column; the analogous statement holds for the vector–matrix product $\boldsymbol{bA}$.

Matrix multiplication is not normally commutative. Otherwise it obeys all the standard laws of scalar multiplication.

Associative Law. *Matrix addition and multiplication are associative*:$(\boldsymbol{A} + \boldsymbol{B}) + \boldsymbol{C} = \boldsymbol{A} + (\boldsymbol{B} + \boldsymbol{C})$ *and* $(\boldsymbol{AB})\boldsymbol{C} = \boldsymbol{A}(\boldsymbol{BC})$.

Commutative Law. *Matrix addition is commutative:* $\boldsymbol{A} + \boldsymbol{B} = \boldsymbol{B} + \boldsymbol{A}$. *Matrix multiplication is not commutative* (except in special cases): $\boldsymbol{AB} \neq \boldsymbol{BA}$.

Distributive Law. $\boldsymbol{A}(\boldsymbol{B} + \boldsymbol{C}) = \boldsymbol{AB} + \boldsymbol{AC}$ *and* $(\boldsymbol{B} + \boldsymbol{C})\boldsymbol{A} = \boldsymbol{BA} + \boldsymbol{CA}$.

Law of Scalar Factoring. $r(\boldsymbol{AB}) = (r\boldsymbol{A})\boldsymbol{B} = \boldsymbol{A}(r\boldsymbol{B})$.

For $n \times n$ matrices $\boldsymbol{A}$, there is an identity matrix $\boldsymbol{I}$ with ones on the main diagonal and zeros elsewhere, with the property that $\boldsymbol{AI} = \boldsymbol{IA} = \boldsymbol{A}$. Furthermore, the transpose of an $m \times n$ matrix $\boldsymbol{A}$, denoted by $\boldsymbol{A}^T$, is an $n \times m$ matrix such that the rows of $\boldsymbol{A}$ are the columns of $\boldsymbol{A}^T$.

If matrices are partitioned into submatrices in a regular fashion, say, a 4×4 matrix $\boldsymbol{A}$ is partitioned into four 2×2 submatrices,

$$\boldsymbol{A} = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

and a 4×4 matrix $\boldsymbol{B}$ is similarly partitioned, then the matrix product $\boldsymbol{AB}$ can be computed in terms of the partitioned submatrices:

$$\mathbf{AB} = \begin{bmatrix} \mathbf{A_{11}B_{11}} + \mathbf{A_{12}B_{21}} & \mathbf{A_{11}B_{12}} + \mathbf{A_{12}B_{22}} \\ \mathbf{A_{21}B_{11}} + \mathbf{A_{22}B_{21}} & \mathbf{A_{21}B_{12}} + \mathbf{A_{22}B_{22}} \end{bmatrix}.$$

Solving Systems of Linear Equations

Matrices are intimately tied to linear systems of equations. For example, the system of linear equations

$$\begin{aligned} 4x_1 + 2x_2 + 2x_3 &= 100 \\ 2x_1 + 5x_2 + 2x_3 &= 200 \\ 1x_1 + 3x_2 + 5x_3 &= 300 \end{aligned} \tag{1}$$

can be written as

$$\boldsymbol{Ax} = \boldsymbol{b}, \text{ where } \boldsymbol{A} = \begin{bmatrix} 4 & 2 & 2 \\ 2 & 5 & 2 \\ 1 & 3 & 5 \end{bmatrix}, \boldsymbol{x} = \begin{bmatrix} x_1 \\ x_2 \\ x_3 \end{bmatrix}, \boldsymbol{b} = \begin{bmatrix} 100 \\ 200 \\ 300 \end{bmatrix}. \tag{2}$$

Essentially, the only way to solve an algebraic system with more than one variable is by solving a system of linear equations. For example, nonlinear systems must be recast as linear systems to be numerically solved. Since operations research and management science is concerned with complex problems involving large numbers of variables, matrix systems are pervasive in OR/MS.

Observe that the system of equations given by (1) can be approached from the row point of view as a set of simultaneous linear equations and solved by row operations using Gaussian elimination or Gauss-Jordan elimination. The result of elimination will be either no solution, a unique solution or an infinite number of solutions. In linear programming, one typically wants to find a vector $\boldsymbol{x}$ maximizing or

minimizing a linear objective function $\boldsymbol{c} \cdot \boldsymbol{x}$ subject to a system $\boldsymbol{Ax} = \boldsymbol{b}$ of linear constraints. The simplex method finds an optimal solution by a sequence of pivots on the augmented matrix $[\boldsymbol{Ab}]$. A pivot on non-zero entry (i, j) consists of a collection of row operations (multiplying a row by a scalar or subtracting a multiple of one row from another row) producing a transformed augmented matrix $[\boldsymbol{A}' \ \boldsymbol{b}']$ in which entry (i, j) equals 1 and all other entries in the jth column are 0. The pivot step can be accomplished by premultiplying $\boldsymbol{A}$ by a pivot matrix $\boldsymbol{P}$, which is an identity matrix with a modified ith column.

The system of equations given by (1) can also be approached from the column point of view as the following vector equation:

$$x_1 \begin{bmatrix} 4 \\ 2 \\ 1 \end{bmatrix} + x_2 \begin{bmatrix} 2 \\ 5 \\ 3 \end{bmatrix} + x_3 \begin{bmatrix} 2 \\ 2 \\ 5 \end{bmatrix} = \begin{bmatrix} 100 \\ 200 \\ 300 \end{bmatrix}. \qquad (3)$$

Writing the system as (3) raises questions such as which right-hand side vectors $\boldsymbol{b}$ are expressible as linear combinations of the columns of $\boldsymbol{A}$? The set of such $\boldsymbol{b}$ vectors is called the range of the matrix $\boldsymbol{A}$. For a square matrix, the system $\boldsymbol{Ax} = \boldsymbol{b}$ will have a unique solution if and only if no column vector of $\boldsymbol{A}$ can be written as a linear combination of other columns of $\boldsymbol{A}$, or equivalently, if and only if $\boldsymbol{x} = \boldsymbol{0}$ is the only solution to $\boldsymbol{Ax} = \boldsymbol{0}$, where $\boldsymbol{0}$ denotes a vector of all zeroes. When this condition holds, the columns are said to be linearly independent. When $\boldsymbol{Ax} = \boldsymbol{0}$ has non-zero solutions (whether $\boldsymbol{A}$ is square or not), the set of such nonzero solutions is called the kernel of $\boldsymbol{A}$. Kernels, ranges and linear independence are the building blocks of the theory of linear algebra. This theory plays an important role in the uses of matrices in OR/MS. For example, if $\boldsymbol{x}^*$ is a solution to $\boldsymbol{Ax} = \boldsymbol{b}$ and $\boldsymbol{x}^{\mathrm{o}}$ is in the kernel of $\boldsymbol{A}$ (i.e., $\boldsymbol{Ax}^{\mathrm{o}} = \boldsymbol{0}$), then $\boldsymbol{x}^* + \boldsymbol{x}^{\mathrm{o}}$ is also a solution of $\boldsymbol{Ax} + \boldsymbol{b}$, since $\boldsymbol{A}(\boldsymbol{x}^* + \boldsymbol{x}^{\mathrm{o}}) = \boldsymbol{Ax}^* + \boldsymbol{Ax}^{\mathrm{o}} = \boldsymbol{b} + \boldsymbol{0} = \boldsymbol{b}$, and one can show that all solutions to $\boldsymbol{Ax} = \boldsymbol{b}$ can be written in the form of a particular solution $\boldsymbol{x}^*$ plus some kernel vector $\boldsymbol{x}^{\mathrm{o}}$. In a linear program to maximize or minimize $\boldsymbol{c} \cdot \boldsymbol{x}$ subject to $\boldsymbol{Ax} = \boldsymbol{b}$, once one finds one solution $\boldsymbol{x}^*$ to $\boldsymbol{Ax} = \boldsymbol{b}$, improved solutions will be obtained by adding appropriate kernel vectors to $\boldsymbol{x}^*$.

Matrix Inverse

The inverse $\boldsymbol{A}^{-1}$ of a square matrix $\boldsymbol{A}$ has the property that $\boldsymbol{A}^{-1}\boldsymbol{A} = \boldsymbol{AA}^{-1} = \boldsymbol{I}$. The inverse can be used to solve $\boldsymbol{Ax} = \boldsymbol{b}$ as follows: $\boldsymbol{Ax} = \boldsymbol{b} \Rightarrow \boldsymbol{A}^{-1}(\boldsymbol{Ax}) = \boldsymbol{A}^{-1}\boldsymbol{b}$, but $\boldsymbol{A}^{-1}(\boldsymbol{Ax}) = (\boldsymbol{A}^{-1}\boldsymbol{A})\boldsymbol{x} = (\boldsymbol{I})\boldsymbol{x} = \boldsymbol{x}$. Thus $\boldsymbol{x} = \boldsymbol{A}^{-1}\boldsymbol{b}$.

The square matrix $\boldsymbol{A}$ has an inverse if any of the following equivalent statements hold:

1. For all $\boldsymbol{b}$, $\boldsymbol{Ax} = \boldsymbol{b}$ has a unique solution;
2. The columns of $\boldsymbol{A}$ are linearly independent;
3. The rows of $\boldsymbol{A}$ are linearly independent.

The matrix $\boldsymbol{A}^{-1}$ is found by solving a system of equations as follows. The product $\boldsymbol{AA}^{-1} = \boldsymbol{I}$ implies that if $\boldsymbol{x}_j$ is the jth column of $\boldsymbol{A}^{-1}$ and $\boldsymbol{i}_j$ is the jth column of $\boldsymbol{I}$ ($\boldsymbol{i}_j$ has 1 in the jth entry and zeroes elsewhere), then $\boldsymbol{x}_j$ is the solution to the matrix system $\boldsymbol{Ax}_j = \boldsymbol{i}_j$. An impressive aspect of matrix algebra is that even when a matrix system $\boldsymbol{Ax} = \boldsymbol{b}$ has no solution, i.e., in (3) no linear combination of the columns of $\boldsymbol{A}$ equals $\boldsymbol{b}$, there is still a "solution" $\boldsymbol{y}$ in the sense of a linear combination $\boldsymbol{Ay}$ of the columns of $\boldsymbol{A}$ that is as close as possible to $\boldsymbol{b}$, i.e., the Euclidean distance in n-dimensional space between the vectors $\boldsymbol{Ay}$ and $\boldsymbol{b}$ is minimized. There is even an inverse-like matrix $\boldsymbol{A}^*$, called the pseudoinverse or generalized inverse, such that $\boldsymbol{y} = \boldsymbol{A}^*\boldsymbol{b}$. The matrix $\boldsymbol{A}^*$ is given by the matrix formula $\boldsymbol{A}^* = (\boldsymbol{A}^T\boldsymbol{A})^{-1}\boldsymbol{A}^T$, where $\boldsymbol{A}^T$ is the transpose of $\boldsymbol{A}$, obtained by interchanging rows and columns.

Eigenvalues and Eigenvectors

A standard form of a dynamic linear model is $\boldsymbol{p}' = \boldsymbol{Ap}$, where $\boldsymbol{A}$ is an $n \times n$ matrix and $\boldsymbol{p}$ is a n-column vector of populations or probabilities (in the case of probabilities, it is the convention to use row vectors: $\boldsymbol{p}' = \boldsymbol{pA}$). For some special vectors $\boldsymbol{e}$, called eigenvectors, $\boldsymbol{Ae} = \lambda\boldsymbol{e}$, where λ is a scalar called an eigenvalue. That is, premultiplying $\boldsymbol{e}$ by $\boldsymbol{A}$ has the effect of multiplying $\boldsymbol{e}$ by a scalar. It follows that $\boldsymbol{A}^n\boldsymbol{e} = \lambda^n\boldsymbol{e}$. This special situation is very valuable because it is obviously much easier to compute $\lambda^n\boldsymbol{e}$ than $\boldsymbol{A}^n\boldsymbol{e}$.

Most $n \times n$ matrices have n different (linearly independent) eigenvectors. If the vector $\boldsymbol{p}$ as a linear combination $\boldsymbol{p} = a\,\boldsymbol{e}_1 + b\,\boldsymbol{e}_2$ of, say, two eigenvectors $\boldsymbol{e}_1$ and $\boldsymbol{e}_2$, with associated eigenvalues λ_1, λ_2, then by the linearity of matrix–vector products, $\boldsymbol{Ap}$ and $\boldsymbol{A}^2\boldsymbol{p}$ can be calculated as

$$\boldsymbol{Ap} = \boldsymbol{A}(a\boldsymbol{e}_1 + b\boldsymbol{e}_2) = a\boldsymbol{Ae}_1 + b\boldsymbol{Ae}_2 = a\lambda_1\boldsymbol{e}_1 + b\lambda_2\boldsymbol{e}_2$$

and

$$\begin{aligned}\boldsymbol{A}^2\boldsymbol{p} &= \boldsymbol{A}^2(a\boldsymbol{e}_1 + b\boldsymbol{e}_2) = a\boldsymbol{A}^2\boldsymbol{e}_1 + b\boldsymbol{A}^2\boldsymbol{e}_2 \\ &= a\lambda_1^2\boldsymbol{e}_1 + b\lambda_2^2\boldsymbol{e}_2.\end{aligned}$$

More generally,

$$\begin{aligned}\boldsymbol{A}^k\boldsymbol{p} &= \boldsymbol{A}^k(a\boldsymbol{e}_1 + b\boldsymbol{e}_2) = a\boldsymbol{A}^\kappa\boldsymbol{e}_1 + b\boldsymbol{A}^k\boldsymbol{e}_2 \\ &= a\lambda_1^k\boldsymbol{e}_1 + b\lambda_2^k\boldsymbol{e}_2.\end{aligned}$$

If $|\lambda_1| > |\lambda_i|$, for $i \geq 2$, then for large k, λ^{k_1} will become much larger in absolute value than the other λ^{k_j}, and so $\boldsymbol{A^k p}$ approaches a multiple of the eigenvector associated with the eigenvalue of largest absolute value. For ergodic Markov chains, this largest eigenvalue is 1 and the Markov chain converges to a steady-state probability $\boldsymbol{p}^*$ such that $\boldsymbol{p}^* = \boldsymbol{p}^*\boldsymbol{A}$.

Matrix Norms

The norm $|\boldsymbol{v}|$ of a vector $\boldsymbol{v}$ is a scalar value that is nonnegative, satisfies scalar factoring, i.e., $|r\ \boldsymbol{v}| = r\ |\boldsymbol{v}|$, and the triangle inequality, i.e., $|\boldsymbol{u} + \boldsymbol{v}| \leq |\boldsymbol{u}| + |\boldsymbol{v}|$. There are three common norms used for vectors:

1. The Euclidean, or l_2, norm of $\boldsymbol{v} = [v_1, v_2, \ldots, v_n]$ is defined as $|\boldsymbol{v}|_e = \sqrt{\boldsymbol{v}_1^2 + \boldsymbol{v}_2^2 + \cdots + \boldsymbol{v}_n^2}$.
2. The sum, or l_1, norm of $\boldsymbol{v} = [v_1, v_2, \ldots, v_n]$ is defined $|\boldsymbol{v}|_s = |\boldsymbol{v}_1| + |\boldsymbol{v}_2| + \cdots + |\boldsymbol{v}_n|$.
3. The max, or l_∞, norm of $\boldsymbol{v} = [v_1, v_2, \ldots, v_n]$ is $|\boldsymbol{v}|_m = \max\{|\boldsymbol{v}_1|, |\boldsymbol{v}_2|, \ldots, |\boldsymbol{v}_n|\}$.

The matrix norm $||\boldsymbol{A}||$ is the (smallest) bound such that $|\boldsymbol{Ax}| \leq ||\boldsymbol{A}||\ |\boldsymbol{x}|$, for all $\boldsymbol{x}$. Thus

$$||\boldsymbol{A}|| = \max_{\boldsymbol{x}\neq\boldsymbol{0}} \frac{|\boldsymbol{Ax}|}{|\boldsymbol{x}|}. \tag{4}$$

It follows that $|\boldsymbol{A}^k\boldsymbol{x}| \leq ||\boldsymbol{A}||^k\ |\boldsymbol{x}|$.

The Euclidean, sum, and max norms of the matrix are defined by using the Euclidean, sum, and max vector norms, respectively, in (4). When $\boldsymbol{A}$ is a square, symmetric matrix ($a_{ij} = a_{ji}$), the Euclidean norm $||\boldsymbol{A}||_e$ equals the absolute value of the largest eigenvalue of $\boldsymbol{A}$. When $\boldsymbol{A}$ is not symmetric, $||\boldsymbol{A}||_e$ equals the positive square root of the largest eigenvalue of $\boldsymbol{A}^T\boldsymbol{A}$. The sum and max norms of $\boldsymbol{A}$ are very simple to find and for this reason are often preferred over the Euclidean norm: $||\boldsymbol{A}||_s = \max_j\{|\boldsymbol{A}_j|_s\}$ and $||\boldsymbol{A}||_m = \max_i\{|\boldsymbol{A}_i'|_s\}$, where $\boldsymbol{A}_j$ denotes the jth column of $\boldsymbol{A}$ and $\boldsymbol{A}_i'$ denotes the ith row of $\boldsymbol{A}$. In words, the sum norm of $\boldsymbol{A}$ is the largest column sum (summing absolute values), and the max norm of $\boldsymbol{A}$ is the largest row sum.

Norms have many uses. For example, in a linear growth model $\boldsymbol{p}' = \boldsymbol{Ap}$, the kth iterate $\boldsymbol{p}^{(k)} = \boldsymbol{A}^k\boldsymbol{p}$ is bounded in norm by $|\ \boldsymbol{p}^{(k)}\ | \leq ||\boldsymbol{A}||^k\ |\boldsymbol{p}|$. One can show that if the system of linear equations $\boldsymbol{Ax} = \boldsymbol{b}$ is perturbed by adding a matrix $\boldsymbol{E}$ of errors to $\boldsymbol{A}$, and if $\boldsymbol{x}^*$ is the solution to the original system $\boldsymbol{Ax} = \boldsymbol{b}$ while $\boldsymbol{x}^* + \boldsymbol{e}$ is the solution to $(\boldsymbol{A} + \boldsymbol{E})\boldsymbol{x} = \boldsymbol{b}$, then the relative error $|\boldsymbol{e}|/|\ \boldsymbol{x}^* + \boldsymbol{e}|$ is bounded by a constant $c(\boldsymbol{A})$ times the relative error $||\boldsymbol{E}||/||\boldsymbol{A}||$, i.e., $|\boldsymbol{e}|/|\boldsymbol{x}^* + \boldsymbol{e}| \leq c(\boldsymbol{A})\ ||\boldsymbol{E}||/||\boldsymbol{A}||$. The constant $c(\boldsymbol{A}) = ||\boldsymbol{A}||\ ||\boldsymbol{A}^{-1}||$ and is called the condition number of $\boldsymbol{A}$.

A famous linear input–output model due to Leontief has the form $\boldsymbol{x} = \boldsymbol{Ax} + \boldsymbol{b}$. Here $\boldsymbol{x}$ is a vector of production of various industrial activities, $\boldsymbol{b}$ is a vector of consumer demands for these activities, and $\boldsymbol{A}$ is an inter-industry demand matrix in which entry a_{ij} tells how much of activity i is needed to produce one unit of activity j. Here, $\boldsymbol{Ax}$ is a vector of the input for the different activities needed to produce the output vector $\boldsymbol{x}$. The model $\boldsymbol{x} = \boldsymbol{Ax} + \boldsymbol{b}$ can be shown to have a solution if $||\boldsymbol{A}||_s < 1$, i.e., if the columns sums are all less than one. This condition has the natural economic interpretation that all activities must be profitable, i.e., the value of the inputs to produce a dollar's worth of any activity must be less than one dollar.

Algebraically, $\boldsymbol{x} = \boldsymbol{Ax} + \boldsymbol{b}$ is solved as follows:

$$\begin{aligned}\boldsymbol{x} &= \boldsymbol{Ax} + \boldsymbol{b} \rightarrow \boldsymbol{x} - \boldsymbol{AX} = \boldsymbol{b} \rightarrow (\boldsymbol{I} - \boldsymbol{A})\boldsymbol{x} \\ &= b \rightarrow \boldsymbol{x} = (\boldsymbol{I} - \boldsymbol{A})^{-\boldsymbol{I}}\boldsymbol{b}.\end{aligned}$$

When $||\boldsymbol{A}|| \leq 1$, the geometric series $\boldsymbol{I} + \boldsymbol{A} + \boldsymbol{A}^2 + \boldsymbol{A}^3 + \ldots$, converges to $(\boldsymbol{I} - \boldsymbol{A})^{-1}$, guaranteeing not only the existence of a solution to $\boldsymbol{x} = \boldsymbol{Ax} + \boldsymbol{b}$ but also a solution with nonnegative entries, since when $\boldsymbol{A}$ has nonnegative entries, then all the powers of $\boldsymbol{A}$ will have nonnegative entries implying that $(\boldsymbol{I} - \boldsymbol{A})^{-1}$ has nonnegative entries and hence so does $\boldsymbol{x} = (\boldsymbol{I} - \boldsymbol{A})^{-1}\boldsymbol{b}$.

Matrix-Analytic Stochastic Models

Marcel F. Neuts
The University of Arizona, Tucson, AZ, USA

Introduction

A rich class of models for queues, dams, inventories, and other stochastic processes has arisen out of matrix/vector generalizations of classical approaches. Three specific examples are presented: matrix-analytic solutions for M/G/1-type queueing problems, matrix-geometric solutions to GI/M/1-type queueing problems, and the Markov arrival process (MAP) generalization of the renewal point process.

Matrix-Analytic M/G/1-Type Queues

The unifying structure that underlies these models is an imbedded Markov renewal process whose transition probability matrix is of the form:

$$\tilde{\boldsymbol{Q}}(x) = \begin{bmatrix} \boldsymbol{B}_0(x) & \boldsymbol{B}_1(x) & \boldsymbol{B}_2(x) & \boldsymbol{B}_3(x) & \boldsymbol{B}_4(x) & \cdots \\ \boldsymbol{C}_0(x) & \boldsymbol{A}_1(x) & \boldsymbol{A}_2(x) & \boldsymbol{A}_3(x) & \boldsymbol{A}_4(x) & \cdots \\ \boldsymbol{0} & \boldsymbol{A}_0(x) & \boldsymbol{A}_1(x) & \boldsymbol{A}_2(x) & \boldsymbol{A}_3(x) & \cdots \\ \boldsymbol{0} & \boldsymbol{0} & \boldsymbol{A}_0(x) & \boldsymbol{A}_1(x) & \boldsymbol{A}_2(x) & \cdots \\ . & . & . & . & . & \cdots \end{bmatrix}$$

where the elements are themselves matrices of probability mass functions. If the matrix

$$\boldsymbol{A} = \sum_{k=0}^{\infty} \boldsymbol{A}_k(\infty)$$

is irreducible and has the invariant probability vector $\boldsymbol{\pi}$, then the Markov renewal process is positive recurrent if and only if some natural moment conditions hold for the coefficient matrices and if

$$\rho = \boldsymbol{\pi} \sum_{k=1}^{\infty} k\boldsymbol{A}_k \boldsymbol{e} < 1 \quad \text{for } \boldsymbol{e} = (1, \ldots, 1)^T.$$

The quantity ρ is the generalized form of the traffic intensity for the elementary queueing models.

The state space is partitioned in levels $\boldsymbol{i}$, which are the sets of m states (i, j), $1 \leq j \leq m$. The crucial object in studying the behavior of the Markov renewal process away from the boundary states in the level $\boldsymbol{0}$ is the fundamental period, the first passage time from a state in $\boldsymbol{i}$ + 1 to a state in $\boldsymbol{i}$. The joint transform matrix $\tilde{\boldsymbol{G}}(z; s)$ of that first passage time, measured in the number of transitions to lower levels (completed services in queueing applications) and in real time, satisfies a nonlinear matrix equation of the form

$$\tilde{\boldsymbol{G}}(z;s) = z\sum_{k=0}^{\infty}\tilde{\boldsymbol{A}}(s)\left[\tilde{\boldsymbol{G}}(z;s)\right]^k.$$
