Dedication: In Memoriam

To the memory of my very dear colleague Saul Irving Gass, an OR pioneer, practitioner, and statesman, and a true scholar and friend. Saul passed away on March 17, 2013, as this edition of the Encyclopedia *was going to press.*

Preface

The goal of the *Encyclopedia of Operations Research and Management Science* is to provide decision makers and problem solvers in business, industry, government, and academia a comprehensive overview of the wide range of ideas, methodologies, and synergistic forces that combine to form the preeminent decision-aiding fields of operations research and management science (OR/MS). The impact of OR/MS on people's quality of life and economic well-being is a story that deserves to be told in its full detail and glory. The *Encyclopedia of Operations Research and Management Science* is the prologue to that story.

The editors, working with the *Encyclopedia*'s Editorial Advisory Board, surveyed and divided OR/MS into specific topics that collectively encompass the foundations, applications, and emerging elements of this ever-changing field. We also wanted to establish the close associations that OR/MS has maintained with other scientific endeavors, with special emphasis on its symbiotic relationships with computer science, information systems, and mathematics. Based on our broad view of OR/MS, we enlisted a distinguished international group of academics and practitioners to contribute entries on subjects for which they are renowned. We commissioned over 200 major expository entries and complemented them by numerous descriptions, discussions, definitions, and abbreviations. The connections between topics are highlighted by an entry's final "See" statement, as appropriate. Each entry provides a background or history of the topic, describes relevant applications, overviews present and future trends, and lists seminal and current references. To allow for variety in exposition, the authors were instructed to present their material from their research and applied perspectives. In particular, the authors, each of whom is a leading authority on the particular subject, were allowed to use whatever mathematical notation they felt was standard for their topics.

The *Encyclopedia*'s intended audience is technically diverse and wide; it includes anyone concerned with the science, techniques, and ideas of how one makes decisions. As this audience encompasses many professions, educational background, and skills, we were attentive to the form, format, and scope of the entries. Thus, the entries are designed to serve as initial sources of information for all such readers, with special emphasis on the needs of students.

What are Operations Research and Management Science?

Operations research and management science are often equated to one another. If one defines them by the methodologies they employ, the equation would probably stand

inspection. If, however, one defines them by their historical developments and the classes of problems they encompass, the equation becomes fuzzy. OR grew out of the operational problems of the British and U.S. military efforts in World War II. It was augmented methodologically and computationally by the postwar developments of linear programming, game theory, dynamic programming, discrete-event simulation (among others), and the digital computer. A number of additional ideas and problem types from the pre-war years were incorporated into the field as well, including inventory and queueing theories, Markov modeling, and the basic methods of optimization. Early (1950s) practitioners of OR applied its philosophy and techniques to the solution of industrial and business operational problems with great success. It was soon recognized that whatever OR was as a scientific field, it could be used to study and solve the broader planning and strategic issues of organizational management, financial planning, and public policy. From this observation, MS began and flourished in a similar and somewhat overlapping manner to OR.

More formal definitions of OR and MS are readily available. OR can be defined as: (1) the application of the methods of science to complex problems arising in the direction and management of large systems of men, machine, materials, and money in industry, business, government, and defense; (2) the science of deciding how to best design and operate man-machine systems; (3) a scientific method for providing executive departments with a quantitative basis for decision making. MS can be defined as: (1) the application of scientific methodology or principles to management decisions; (2) the use of quantitative methods for solving management and organizational decision problems. Together, OR and MS may be thought of as the science of operational processes, decision making, and management. However, to our minds, the definition of OR/MS is really given by the coverage of the material in this *Encyclopedia*.

Second Edition

The second edition aimed to capture the advances since the 1996 first edition, especially the relationships between OR/MS and information technology, and to update, expand, and correct the original material. With respect to OR/MS advances, new material ranged from the Analytic Network Process to Data Mining to Electronic Commerce to the Theory of Constraints, among the 28 new entries added at that time. First edition entries were updated or rewritten by the original and/or new authors. Based on suggestions from the readers of the first edition, more material on the history of OR/MS was added, including emphasis of its origins by an article on early British OR.

Third Edition

This third edition of the *Encyclopedia of Operations Research and Management Science* moves us closer to our goal of providing a comprehensive overview of the theoretical and applied subject matter that forms the ever-expanding field of OR/MS. Again, many of the second edition entries have been updated by the original authors,

with a few being totally rewritten by new authors. In addition, the following completely new entries have been added, each of which either describes a new topic or replaces a previous short entry:

- Agent-Based Simulation
- Air Traffic Management
- Approximate Dynamic Programming
- Business Intelligence
- Closed-loop Supply Chains
- Combinatorial Auction Theory
- Community OR
- Complementarity Applications
- Computational Biology
- Conditional Value at Risk
- Convex Optimization
- Critical Systems Thinking
- Data Warehousing
- Decision Analysis Practice
- Deep Uncertainty
- Differential Games
- Digital Music
- Disaster Management
- Disease Prevention, Detection, and Treatment
- Financial Engineering
- Flexible Manufacturing Systems
- Fuzzy Sets, Systems, and Applications
- Global Optimization
- Health Care Management
- Health Care Strategic Decision Making
- Heuristics
- Hit and Run Methods
- Influence Diagrams
- Knowledge Management
- Lagrangian Relaxation
- Markov Chain Monte Carlo
- Metaheuristics
- Open Source Software (and COIN-OR)
- Operational Research Society
- Petroleum Refining
- Quadratic Assignment Problem
- Rare Event Simulation
- Regenerative Simulation
- Response Surface Methodology
- Revenue Management
- Sample Average Approximation
- Sensitivity Analysis
- Service Science
- Simulated Annealing
- Societal Complexity
- Statistical Ranking and Selection
- Stochastic Approximation
- Stochastic Input Model Selection

We want to emphasize that the *Encyclopedia of Operations Research and Management Science* is the responsibility of the editors. We made the final determination of the scope, topics, and material. Any shortcoming (editorial, inclusion, omission, emphasis, factual) that the reader may perceive rests with us. Hence, we sincerely welcome comments and feedback on all aspects of the *Encyclopedia*.

Acknowledgments

We wish to thank all the contributors to the *Encyclopedia of Operations Research and Management Science* for their individual efforts and for their cooperation, support, and patience. We would also like to thank the members of the Editorial Advisory Board, past and present, for their help in the initial formulation of the *Encyclopedia* and their subsequent efforts in reviewing the articles. Last but not least, we are grateful to Springer for their help throughout the process of preparing this third edition, and would specifically like to thank the editorial support provided by Jennifer Carlson, Elizabeth Ferrell, Julia Koerting, and Annalea Manalili.

About the Editors

Saul I. Gass received his B.S. in Education and M.A. in Mathematics from Boston University in 1949, and his Ph.D. in Engineering Science/Operations Research from the University of California, Berkeley, in 1965. At the time of his passing, he was Professor Emeritus at the Robert H. Smith School of Business, University of Maryland, College Park, after serving as the Dean's Lifetime Achievement Professor and having been named a University of Maryland Distinguished Scholar-Teacher. He served over 2 years in the Army during World War II prior to entering college. His first job in 1949 was as a mathematician for the Aberdeen Bombing Mission, U.S. Air Force, but shortly thereafter he transferred to Air Force Headquarters where he began his career in operations research when he joined Project SCOOP at the Pentagon-based Directorate of Management Analysis, the organization in which linear programming was first developed. He left Project SCOOP in 1955 to join IBM, where he served as an Applied Science Representative, Manager of the Project Mercury Man-in-Space Program, and Manager of IBM's Federal Civil Programs. He also served on the Science and Technology Task Force of the President's Commission on Law Enforcement. Other positions included Director of Operations Research for the Corporation for Economic and Industrial Research (CEIR), Senior Vice-President of World Systems Laboratories, and Vice-President of Mathematica. He has served as a consultant to the U.S. General Accounting Office, Congressional Budget Office, the National Institute of Standards and Technology, and other operations research and systems analysis organizations. Included in his many publications are the textbooks *Linear Programming* (the first textbook on the subject, now in its fifth edition) and *Decision Making, Models and Algorithms*, and the books *An Illustrated Guide to Linear Programming*, *An Annotated Timeline of Operations Research: An Informal History*, and *Profiles in Operations Research: Pioneers and Innovators*. He served as President of the Operations Research Society of America (ORSA) and Omega Rho and as Vice-President for international activities of the Institute of Operations Research and the Management Sciences (INFORMS) and the International Federation of Operational Research Societies (IFORS). He is a recipient of the ORSA Kimball Medal for distinguished service to the society and the profession, the INFORMS Expository Writing Award, and the Military Operations Research Society's Jacinto Steinhardt Memorial. He is a Fellow of INFORMS and was a Fulbright Research Scholar at the Computer and Automation Research Institution, Hungarian Academy of Sciences.

Michael C. Fu received his S.B. in Mathematics and S.M/S.B. in Electrical Engineering and Computer Science from MIT in 1985, and his Ph.D. in Applied Mathematics from Harvard University in 1989. Since 1989, he has been at the University of Maryland in the Robert H. Smith School of Business, where he is

currently Ralph J. Tyser Professor of Management Science, with a joint appointment in the Institute for Systems Research, A. James Clark School of Engineering. At the University of Maryland, he was named a Distinguished Scholar-Teacher and received the Institute for System Research's Outstanding Systems Engineering Faculty Award and the Business School's Allen J. Krowe Award for Teaching Excellence. He served as Simulation Area Editor of *Operations Research* from 2000 to 2005 and as the Stochastic Models and Simulation Department Editor of *Management Science* from 2006 to 2008, and on the Editorial Boards of the *INFORMS Journal on Computing*, *Mathematics of Operations Research*, *Production and Operations Management*, and *IIE Transactions*. He was Program Chair of the 2011 Winter Simulation Conference. His coauthored book, *Conditional Monte Carlo: Gradient Estimation and Optimization Applications*, received the INFORMS College on Simulation Outstanding Publication Award. He also coauthored the research monograph *Simulation-based Algorithms for Markov Decision Processes*, and coedited the books *Perspectives in Operations Research* and *Advances in Mathematical Finance*. He is a Fellow of IEEE and INFORMS.

A

A* Algorithm

A heuristic search procedure that selects a node in its search tree for expansion such that the selected node has minimum value of the sum of the cost to reach the node plus a heuristic cost value for that node, where the heuristic cost underestimates the true minimum cost of completion.

See

► Artificial Intelligence

Acceptance Sampling

► Quality Control

Acceptance-Rejection Method

In stochastic or Monte Carlo simulation, a method for sampling from a given difficult target probability distribution by sampling from a distribution that is close to the target distribution and relatively easy to sample but possibly rejecting the generated output. Sometimes just called the rejection method.

Active Constraint

A constraint in an optimization problem that is satisfied exactly by a solution.

See

- ▶ Inactive Constraint
- ▶ Slack Variable
- ▶ Surplus Variable

Active Set Methods

- ▶ Quadratic Programming

Activity

(1) A structural variable whose value (level) is to be computed in a linear programming problem.
(2) Project work items having specific beginning and completion points and durations.

See

- ▶ Network Planning
- ▶ Project Management
- ▶ Structural Variables

Activity Level

The value taken by a structural variable in an intermediate or final solution to a linear programming problem.

See

- ▶ Structural Variables

Activity-Analysis Problem

A linear-programming problem of the form Maximize $\boldsymbol{cx}$, subject to $\boldsymbol{Ax} \leq \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$. The variables x_j of the vector $\boldsymbol{x}$ are quantities of products to be produced. The b_i coefficients of the resource vector $\boldsymbol{b}$ represent the amount of resource i that is available for production, the c_j coefficients represent the value (profit) of one unit of output x_j, and the coefficients a_{ij} of the technological matrix $\boldsymbol{A}$ represent the amount of resource i required to produce one unit of product j. The a_{ij} are termed technological or input-output coefficients. The objective function $\boldsymbol{cx}$ represents some measure of value of the total production.

Acyclic Network

A network that contains no cycles.

See

- ▶ Graph Theory
- ▶ Network Optimization

Adjacent

Nodes of a graph or network are adjacent if they are joined by an edge; edges are adjacent if they share a common node.

See

- ▶ Graph Theory
- ▶ Network Optimization

Adjacent (Neighboring) Extreme Points

Two extreme points of a polyhedron that are connected by an edge of the polyhedron.

Advertising

Gurumurthy Kalyanaram[1], Frank M. Bass[1] and Dominique M. Hanssens[2]
[1]The University of Texas at Dallas, Richardson, TX, USA
[2]University of California, Los Angeles, CA, USA

Introduction

Advertising research has focused on three substantive areas: sales response to advertising, optimal advertising policy (constant spending or pulsing), competitive reactions and over-time effects. The research has employed econometric, time-serioes, optimization and game theoretic analytical techniques to address the issues. The advent of enormous amounts of scanner panel and internet data has led to some fruitful modeling at the individual household level. Contributions in each one of the three areas are discussed. A thorough review of optimal control advertising models is given in Feichtinger, Hartl, and Sethi (1994). Mathematical programming also has been a useful technology. Since some early successful applications of this technology for media planning, the progress has been limited because of measurement problems relating to advertising response function (Little and Lodish 1969). Advances in research, however, provide reasons for optimism in identifying the response function (Little 1979; Eastlack and Rao 1986). Heuristic approaches have been developed to estimate the media characteristics of reach and frequency (Rust and Eechambadi 1989).

Sales-Advertising Relationship

The first generally recognized model of importance was proposed by Vidale and Wolfe (1957). Building on a diffusion modeling framework, the Vidale-Wolfe model proposed that advertising directly persuades potential customers not currently buying from the firm, while those who are buying tend to forget (buy less) over time. Formally, the model is represented as follows:

$$x' = ru(1 - x) - kx,\ x(0) = x_0$$

where x is the market share, u is the level of advertising expenditure at time t, and k is the decay constant. The model suggests an exponential reach and decay phenomena with r and k rate parameters. Bass and Parsons (1969), following Bass (1969), developed a dynamic simultaneous equation model of sales and advertising and estimated this model on data for a frequently purchased consumer product. The empirical results from this analysis suggest that the advertising elasticity for the brand is small and the advertising expenditures are responsive to sales increases of other brands. A very interesting feature of this model is that it has good forecasting properties.

As far as estimation technology is concerned, there are three works that have provided insightful results. Bass and Clarke (1972) showed that statistical models of sales-advertising relationship need not be limited to the Koyck (1954) model. For example, nonmonotonic lag distributions are more appropriate for monthly data. Bass and Leone (1986) further examined the data interval issue. Rao (1986) has suggested that one should recognize the role of unobservable advertising expenditures in estimating the parameters of sales-advertising relationship associated with different data intervals.

With the evolution of a better appreciation of the advertising effects, the focus has shifted to models at the individual level. Blattberg and Jeuland (1981) postulated a micromodel that incorporated two well established advertising mechanisms, reach and decay. They assumed that the exposure of an individual to an advertisement can be characterized as a Bernoulli process, and the decay (forgetting) as an exponential process. These assumptions lead to a saw-tooth description of advertising effectiveness. The micromodel is aggregated to derive a model of advertising effects on the firm's sales. The model, while fairly flexible and general, provides insightful interpretations. The advent and explosion of scanner panel data over the last decade has accelerated efforts

to model at the individual level. The work by Pedrick and Zufryden (1991) was representative of this effort. They proposed a nonstationary, integrative, stochastic model approach that melds brand choice, purchase incidence and exposure behavior components. The integrated model, calibrated on scanner panel data, provided good fit and fairly accurate forecasts. Jedidi, Mela, and Gupta (1999) also used the scanner panel data and study the tradeoff between advertising and sales promotion for long-run profitability employing a heteroscedastic, varying parameter joint probit choice model. They show that advertising has a positive effect on brand equity, while sales promotions have a negative effect.

Optimal Advertising Policy

Researchers have been engaged in the examining what might be the optimal advertising policy given a budget constraint. Some have argued that constant advertising or chattering (vacillate between two levels of spending with infinite frequency) is probably the optimal policy (Sasieni 1971; Sethi 1973). However, others have found pulsing (Hahn and Hyun 1990; Feinberg 1992) to be optimal or better. Sasieni (1971) formulated the problem as follows:

$$\max \int_0^\infty [\pi x(t) - u(t)]e^{-rt}dt, \quad \text{with}$$
$$x' = g(x,u),\ x(0) = x_0$$

where $x(t)$ and $u(t)$ refer to sales and advertising at time t and r is the discount rate. Now, let g_u and g_x be the first partial derivatives and g_{uu} the second partial derivative. Then, employing Bellman's approach to dynamic programming and the classical Poincare-Bendixson theorem for phase space of differential equations, Sasieni showed that the optimal advertising policy is constant spending when it is assumed that for a given sales and advertising (1) the sales response would be the same or more positive if advertising level were higher ($g_u \geq 0$), (2) the sales response would be same or more positive if sales were at a lower level ($g_x \leq 0$), and (3) the sales response exhibits diminishing returns to increases in advertising level that so that the response curve is concave ($g_{uu} \leq 0$). The optimal policy, however, becomes chattering when the assumption of concavity of the response function is violated. Clearly, therefore, the shape of the response curve has become a matter of debate. There are many who find evidence for an S-shaped response curve (Little 1979; Eastlack and Rao 1986). A more definitive conclusion on the shape of the response curve would enhance the ability to model advertising better. This is, of course, a question for empirical examination.

Hahn and Hyun (1990) showed that when transaction costs above the ordinary media costs are included in Mahajan and Muller's model (1986), pulsing is the optimal policy. Feinberg (1992) introduced the concept of a filter and modifies the Sasieni model as follows:

$$x' = g(x,z), z' = G(u-z),$$

where z characterizes the filter. The only way to produce something constant in the Sasieni formulation is to fluctuate very rapidly, that is, to chatter. Since chattering is impossible in principle and constant spending is impossible in practice, they are two unrealizable ends of a frequency spectrum and are, in a sense, perceptually equivalent. The introduction of a filter allows Feinberg to mathematically equate the two. The filter exponentially smooths out the input. If the input is constant or chattering advertising, the filter yields a constant output. The filter output, however, is a pulsing policy for any nonconstant periodic input. Feinberg (1992) showed numerically that pulsing is a better policy than constant spending.

Research continues to demonstrate that pulsing is an optimal strategy. Bronnenberg (1998) has shown that under the assumptions of a discrete and interpretable Markov process and a constrained budget, a pulsing strategy is optimal, and the advertising effects on switching or repeat purchase affect both the length of the pulse and the optimal level of advertising. Adapting the Nerlove and Arrow (1962) model of advertising, where advertising is formulated as a function of awareness, Naik, Mantrala and Sawyer (1998) showed that pulsing strategies can generate greater total awareness than continuous advertising when the effectiveness of advertising varies over time.

Competition

This issue has received considerable attention. Three kinds of competitive models — differential game models, hazard rate models and competitive reaction models — have emerged.

The differential game models have been built on the Vidale-Wolfe or Nerlove and Arrow models, and employ either open-loop (Rao 1984) or closed-loop (Erickson 1991) deterministic games to solve them. Rao (1984) casts the model in the standard format. The value to a firm is the discounted profit which is defined as sales minus the advertising cost. Sales and advertising response functions are assumed to be strictly concave and convex, respectively. Further, sales at any time period are expressed as a geometric decay of last period's sales and this guarantees an upper bound for the value to the firm. The context is oligopolistic competition. In this setting, Rao demonstrates an industry open-loop Nash equilibrium. Most of the open-loop differential games confirm Rao's analysis. There have been efforts to compare the open-loop and closed-loop solutions to differential games. It has been found that closed-loop equilibrium strategies provide a better fit of the data, that is, actual spending levels in the market (Erickson 1991).

The work by Bourguignon and Sethi (1981) is a good representation of the hazard rate models applied to the study of competition in the context of advertising. These models are useful in situations where a firm must advertise to deal with the threat of entry by another firm. Bourguignon and Sethi characterize a special class of hazard rates given by $h(p, u) = (1 - F)^{n-1}$ where p and u represent price and advertising, $F(t)$ is the probability that the entry of the firm has occurred in the time interval $[0, t)$, and n is a parameter depicting the nature of potential entrants. Employing Pontryagin's maximum principle, the researchers show that, for certain conditions, the optimal policy for a firm is to forbid the entry of any competitor by setting p and u aggressively.

Competitive reaction to advertising may be assessed by multivariate time-series models. Steenkamp, Nijs, Dekimpe & Hanssens (2005) examined competitive reactions to advertising and promotion in over 400 consumer product categories, using vector-autoregressive models. They found that the predominant competitive reaction to advertising is no reaction at all, and that, when reaction does occur, it is often ineffective. Thus the ultimate impact of most promotion and advertising campaigns depends primarily on the nature of consumer response, not the vigilance of competitors.

Over-Time Effects

Many authors have argued that the effect of advertising extends beyond the period in which the expense is incurred. This raises questions about the duration length, i.e., how long does advertising have an impact, and the combined effect across the various periods during which advertising has an impact.

Leone (1995) reports the empirical generalization that the average advertising duration interval on sales is short, typically between 6 and 9 months. As a consequence, managers should not expect the tangible impact of an individual advertising campaign to last for years. In this respect, one should be aware of the well-documented data aggregation bias, in that the coarser the level of temporal aggregation in the data, the longer the duration interval one tends to obtain; see Russell (1988) for diagnosing and correcting such data aggregation bias.

Dekimpe and Hanssens (1995a) introduced persistence modeling, and demonstrated empirically that it is possible that advertising has a permanent effect on sales. Central in their conceptualisation is that one should take into account various channels through which advertising may impact (subsequent) sales. They identified six such channels: instantaneous effects, delayed response, purchase reinforcement, performance feedback, decision rules, and competitive reactions; see Hanssens (2011) for several business illustrations of the impact of these channels. As shown in Dekimpe and Hanssens (1995a), persistent marketing (advertising) effects can only occur in evolving environments, i.e., where the performance fluctuations are not just temporary deviations from a pre-determined (i.e., deterministic) level. Subsequent research (Nijs et al. 2001; Steenkamp et al. 2005) across many product categories and brands in the CPG (Consumer Packaged Goods) sector has established that such evolution is rare in both primary and secondary demand, and even more so when looking at market shares (Dekimpe and Hanssens 1995b). Evolution in

sales is most common in the early stages of the product life cycle. In such cases, advertising may (but need not) have persistent effects on the brand's future performance evolution. Pauwels and Hanssens (2007) find that, even in overall stable markets, there are selective and usually brief time windows that offer an opportunity for brands to benefit from long-term advertising effects. Still, most evidence to date supports the notion of business-as-usual scenarios, where the actions of brands only lead to temporary performance changes that eventually return to the mean.

In the absence of evolution and, hence, the absence of permanent effects, the question centers on the combined, or cumulative, effect of advertising. Lodish et al. (1995) report in this respect that if increased TV advertising has a significant impact on sales during the year of its expenditure, the sales impact is approximately doubled in the following 2 years. They also report, however, that if there is no significant effect in the short run, there will not be any significant long-term effect either. This finding is echoed in Hanssens (2011), who concludes that "consistently, it has been found that a short-run impact on consumer purchasing (sales) is a prerequisite for a long-term effect" (p. 3). Given that many advertising campaigns have no significant immediate effect, this is quite worrisome. On the other hand, when short-term effects are positive, they can be amplified up to five-fold by brand actions that involve other aspects of marketing, such as product-line extensions and sales promotions, as shown by Pauwels (2004). Similar results are reported in Srinivasan, Vanhuele and Pauwels (2010).

In sum, even when accounting for the fact that advertising's impact may extend beyond the week (month) in which it is spent, fairly small elasticities are typically found. These do not imply that advertising is wasteful, but instead that a tight relationship exists between sales revenue, advertising spending and profitabilty. Firms are well advised to study the effectiveness of their advertising as they make resource allocation decisions.

Concluding Remarks

The models reviewed suggest several conclusions relating to advertising. First, there are two mechanisms – growth and decay – in the advertising process. Second, the sales-advertising response curve is either concave or S-shaped. Third, pulsing is better (and may even be optimal) advertising policy. Fourth, competition matters and can be modeled in several ways. Fifth, the over-time effects of advertising are important; advertising's long-term effect is typically a multiple of its short-term impact; see Tellis and Ambler (2007) for an in-depth discussion of these issues.

Affiliated Values Bidding Model

A bidding model in which a bidder, upon learning that a competitor's valuation for what is being sold is higher than previously thought, will raise (or at least not lower) the bidder's own valuation. Affiliated values models include common value models and independent private value models as limiting cases.

See

► Bidding Models

Affine Transformation

A shifted linear transformation. An affine transformation on an n-dimensional vector space assigns to any point $\boldsymbol{x}$ the point $\boldsymbol{Ax} + \boldsymbol{c}$, where $\boldsymbol{A}$ is an $n \times n$ matrix and $\boldsymbol{c}$ is an n-dimensional vector.

Affine-Scaling Algorithm

An interior point method for linear programming based on affine transformations. In the primal affine-scaling algorithm, a problem in standard form is transformed so that the current solution estimate is mapped to the point (1, 1,. . ., 1). A movement is then made in the transformed space in the direction of the negative

projected gradient. The inverse affine transformation is applied to the resulting point, to obtain a new solution estimate in the original space. In the dual affine-scaling algorithm, similar ideas are used to solve the dual problem, with the affine transformations applied to the dual slack variables.

Agent

An agent is an autonomous decision-making entity that receives sensor information from an environment and acts based on that information. Agents may be humans or computer software, and may include hardware elements (e.g., robots). In agent-based simulation, agents interact within the environment to generate system behavior; and in artificial intelligence, the behavior of an agent is generally directed towards achieving certain goals.

Agent-Based Simulation

Charles M. Macal[1], Michael J. North[1] and Douglas A. Samuelson[2]
[1]Argonne National Laboratory, Argonne, IL, USA
[2]Infologix, Inc., Annandale, VA, USA

Introduction

Agent-based simulation (ABS) is a computational framework for simulating dynamic processes that involve autonomous agents. An autonomous agent acts on its own without external direction in response to situations the agent encounters during the simulation. Modeling a population of autonomous and heterogeneous agents that extensively interact is a defining feature of an ABS. ABS is a simulation approach made possible by advances in computational modeling and software. The agent perspective is unique among simulation approaches, unlike the process or activity perspectives of discrete-event simulation (DES), or the dynamical systems approach of system dynamics (SD). Agent-based simulation is most commonly used to model individual decision making and social and organizational behavior (Bonabeau 2001). Samuelson (2000) provides a brief overview of the early history of agent-based modeling, especially as applied to studying how organizations work, while Samuelson and Macal (2006) trace subsequent developments.

An agent is a general concept having broad applicability. Agents often represent people, or groups of people. Agent relationships represent processes of social interaction (Gilbert and Troitzsch 1999). For example, an individual's daily activities are explicitly modeled in an ABS of infectious disease transmission to understand infection patterns arising from contact patterns of individuals. In a supply chain ABS, agents are firms with decision-making behaviors about material sourcing and ordering, stocking, and shipping. In an ABS composed of artificial agents, collaborating robots search the landscape and communicate their findings to collectively accomplish a task. ABS models have also been developed that extend the notion of agents. Various types of animals, bacterial cells, cells composing the human immune system, and even molecules have been modeled as

individual, interacting agents. By modeling individual agents and their interactions, emergent system behaviors are often observed that were not explicitly programmed into the models.

The notions of behavior, decision making, and interaction apply to modeling many kinds of system. A common reason for modeling a system as an ABS is to consider agent learning and adaptation. At the individual level, learning and adaptation can be modeled as agent behaviors. At the population level, adaptation can be modeled by allowing agents to enter and leave the population, with the more successful agents increasing their relative numbers in the population over time.

The development of agent-based modeling tools, the availability of micro-data on agent transactions and interactions, and advances in computation have made possible a growing number of ABS applications across a variety of domains and disciplines.

Agent-based simulation has historical ties to complexity theory and the field of complex adaptive systems (CAS). CAS concerns itself with questions about how complex systems observed in nature, which are composed of autonomous agents with limited cognitive and perceptual abilities, can self-organize themselves to be better suited to their environment (Holland 1975). The first agent-based modeling software tool, Swarm, was developed to model complex adaptive systems, specifically to investigate aspects of Artificial Life (ALife) (Langton 1989). Holland and Miller (1991) appear to be the first to use the term agent in models of this type.

Agent-based simulation is also closely related to the field of multi-agent systems (MAS), but MAS has a somewhat different focus and legacy; MAS is a subfield of distributed artificial intelligence. Individual-Based Modeling (IBM) is another field related to ABS. IBM has a history associated with ecological modeling, where it was important to model heterogeneous populations of agents, but agent interaction was less important of a consideration. Agent-based modeling (ABM) is often used synonymously for ABS; sometimes the term ABMS is used (Agent-based Modeling and Simulation) to refer to the entire field.

Many models now thought of as agent-based simulations were originally developed in the form of cellular automata (CA). CA were originated by John von Neumann to investigate the theory of machine self-replication. Cellular automata use a grid divided into cells as the environment. The cells immediately surrounding an agent are its neighborhood for cell interaction. For example, a cell's von Neumann neighborhood consists of the four cells immediately above, below, and on either side of the cell; the Moore neighborhood consists of the eight cells completely surrounding the cell. Sakoda's checkerboard model was essentially a cellular automaton that simulated the dynamic process of social interaction in one of the first recognizable examples of an ABS (Sakoda 1971). Schelling used a checkerboard framework to study housing segregation patterns (Schelling 1971). Schelling's model was not computerized, and agents were represented as coins moving on a checkerboard. A key finding by Schelling was that patterns emerge from agents interacting that are not necessarily implied or even consistent with the objectives of the individual agents. Analytical results are seldom available for such simple, yet complex systems. Computer simulation is necessary to determine system behaviors that result from the micro-level agent interactions. Axelrod and Hamilton (1981) studied the emergence of cooperation and reciprocation strategies among agents in an evolutionary game set on a cellular automaton grid (Axelrod and Hamilton 1981). Epstein and Axtell introduced artificial societies in their SugarScape model that represents an entire society "from the ground up" by modeling its individuals and their interactions (Epstein and Axtell 1996). These initial ABS models have been blueprints for agent-based models for many years, and their influence in form and approach can be seen in ongoing ABS developments.

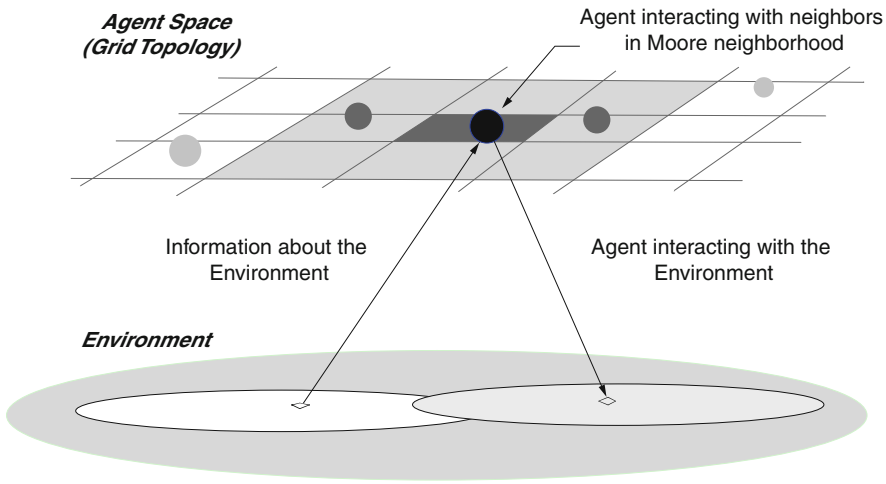
Elements of Agent-Based Simulation

Agent-based simulation does not have an accepted formalism, such as the Discrete Event System Specification (DEVS) formalism for discrete-event simulation (Ziegler et al. 2000). An informal notation for agent-based simulation covers the essential elements of an ABS. Figure 1 shows the elements of a typical ABS.

An agent-based simulation is represented by four elements:

$$\text{ABS} = \{A,\ I,\ E,\ T\} \tag{1}$$

where A = a set of agents, I = agent interaction space, E = an environment independent of the agents, and



Agent-Based Simulation, Fig. 1 Elements of an Agent-based Simulation

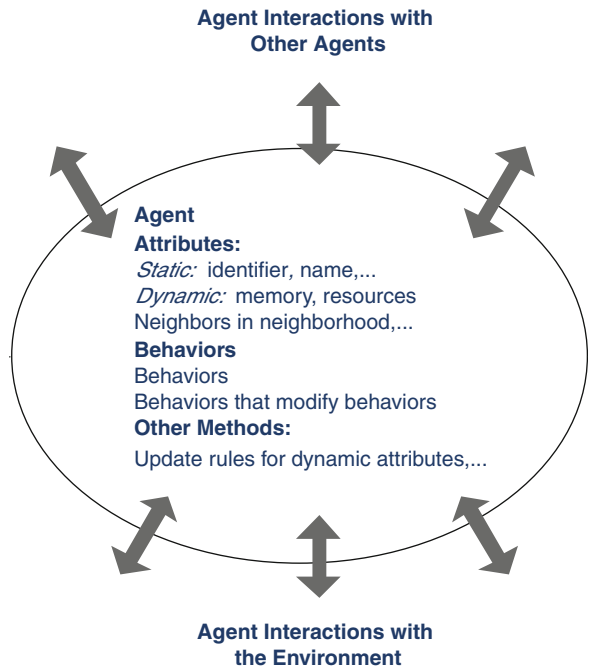
T = a time advance mechanism. An agent interaction space, I, is the social space where agents interact with other agents. The environment, E, is a backdrop against which the agents receive location-specific information, for example, a landscape that agents move over. Agents communicate with the environment, and mobile agents move through it. E encompasses the methods for updating the state of the environment as well as the environment's attributes. The time advance mechanism, T, is the procedure for advancing time in the simulation.

A distinction can be made between ABM and ABS based on (1). The term simulation, as used in the OR/MS community, refers to modeling a dynamic process that unfolds over time (Pritsker 1979). Some optimization algorithms, however, most notably particle swarm optimization (PSO), satisfy all of the requirements of an ABS noted above. Since PSO is a static algorithm without time, the time advance mechanism in (1) is replaced with a more general agent interaction mechanism.

An agent is represented by five elements. Figure 2 shows the elements of a typical agent:

$$a = \{B,\ S,\ D,\ N,\ M\} \qquad a \in A \qquad (2)$$

where B = a set of agent behaviors, S = a set of static attributes for the agent, D = a set of dynamic attributes for the agent, N = the agent's neighborhood, and M = a set of mechanisms for updating the agent's state.



Agent-Based Simulation, Fig. 2 Elements of an Agent

Agent behaviors include rules by which agents transform sensory input information coming from an agent's neighbors and the environment into decisions and actions. Behaviors include deciding, communicating, moving, learning, etc. Each agent has a set of static attributes, S, consisting of, for example, demographic variables such a name, birth date, gender, etc. Dynamic attributes, D, are attributes that are updated during the simulation.

Dynamic attributes include an agent's memory that records relevant agent experiences and interactions. Agents interact with a small subset of agents in a local area termed the agent's neighborhood, N. An agent's neighborhood may be static and fixed in space throughout the entire simulation, or may be dynamic and constantly updated as the agent moves or develops new relationships. The mechanisms for updating the agent's state, M, operate on the agent.

Agents

Based on a study of ABS applications, there does not appear to be general agreement on what constitutes an agent (Macal and North 2010). Some authors consider any model in which a population is represented as a set of individuals to be an ABS. Others require agents to have behaviors that dynamically respond to conditions in the model and to interact extensively with other agents. Still others require an agent to exhibit adaptive behavior to be properly classified as an agent. There are, however, several characteristics that an agent should have to be distinguished from a software object or conventional entity in a simulation model. These are described below.

First, an agent is autonomous and self-directed, able to function independently in its environment and in its interactions with other agents over the limited range of situations it encounters in the model. Thus, agents do not necessarily have any degree of intelligence, but can respond independently to events.

Second, an agent has a well-defined state that varies over time. Just as a system has a state consisting of the collection of its state variables, an agent also has a state that represents the essential attributes associated with its current situation. The state of an agent-based model is the collective states of all the agents in the model, along with the state of the environment. It follows that to implement an agent's behavior requires that the information upon which the agent's behavior is based be included in the set of agent attributes.

Third, an agent is a social entity, having dynamic interactions with other agents that influence its behavior. Agents have protocols for interaction with other agents, such as for communication, movement and contention for space, the capability to respond to the environment, etc.

Agents often have other important characteristics, such as adaptability and purposefulness. An agent may adapt its behaviors, by selecting the most successful behaviors over repeated interactions, and learning new behaviors. An agent may simply execute its behaviors with no apparent purpose or an agent may have goals to achieve, but not necessarily objectives to maximize. Agents in an ABS are often heterogeneous, having diverse characteristics and behaviors across the entire population of agents.

Agents and Behavior

Modeling agent behavior is an important part of developing an ABS. Common approaches are to apply behavioral theories from social and cognitive sciences, develop behavioral representations based on surveys and empirical observations, and hypothesize agent behaviors based on reasonable assumptions amenable to testing in the model.

Rational choice theory provides the most common model of decision-making used in the management and social sciences. Rational choice models are based on the assumption that agents have the ability to compute optimal solutions to arbitrarily complex decision problems based on utility maximization.

Bounded rationality is an alternative to rational choice theory. Bounded rationality assumes that actors are not able to optimize their behaviors because they possess limited computational resources and information on which to base decisions (Simon 1997). Actors instead satisfice: they make suboptimal, yet adequate decisions using simple heuristics or rules of thumb. Learning from experience is important to exploring satisficing behaviors and creating heuristics in which agents have limited information. Agent-based modeling can represent bounded rational agents in which agents learn from repeated experiences and make decisions based on affective factors, i.e., emotion, in addition to rational factors.

Although it is common to describe agent behavior by if-then rules, agent behavior can be modeled in many ways, from simple rules to abstract models. Abstract representations, such as neural networks and genetic programs, relate agent inputs to outputs through adaptive mechanisms and filters. For example, Manson (2006) uses evolutionary programming in agent-based modeling to implement the theory of bounded rationality in a land use ABS.

ABS and Space

In addition to time, most ABS models have a notion of physical space. Some agent-based models are

non-spatial, meaning there is no need for agents to have a locational attribute. In a typical non-spatial ABS, pairs of agents are randomly selected from the pool of agents, the pairs interact, possibly changing the agents' states, and the agents then return to the agent pool for the next iteration. This is equivalent to the assumption of perfect mixing, for example, in an epidemiological model in which agents have random contact and possibly transmit infection. Other examples include molecules randomly reacting as part of a chemical transduction network and economic agents randomly selected to engage in bilateral trades in a market.

Cellular automata grids are an efficient way of representing and updating agent interactions in a dynamic simulation model. By convention, each grid cell in a CA is either unoccupied or occupied by no more than one agent. Many early agent-based models used a CA grid as their environment. But, generally, CA models do not represent how agents interact in the real world. Networks and other structures are now commonly used to represent agent interaction in agent-based simulations.

Networks are general and flexible representations of agent interaction; an agent interacts with the set or a subset of the agents that it is linked to its network. For example, a contact network in an infectious disease ABS indicates the agents contacted by an agent in its daily activities. Networks are static, predefined by the modeler, or dynamic, changing according to the results of agent interactions that occur endogenously in the simulation. For example, an ABS of a social networking site has models that specify why people join and leave the social network. An agent may participate in multiple networks in the same model. For example, an agent in an infectious disease ABS might be connected to an information network of trusted sources of public health information in addition to its contact network.

An agent interaction network can be implemented either implicitly by including a list of an agent's current neighbors as a dynamic agent attribute, or explicitly by creating a network entity which links all agents to their neighbors. This is a model implementation consideration, as the computational performance of the model is sensitive to the approach taken, especially for larger networks.

Other agent interaction topologies are also used in ABS models. These include continuous space in 1-, 2- or 3-dimensions, and geographical information systems (GIS). Keeping track of agent neighbors in continuous space can be computationally challenging, and, often, a spatial bucketing approach is used that leads to some degree of approximation. An example of the use of a GIS topology consists of agents that move over geographically defined patches; for example, neighborhoods or zip-code areas, and is often accomplished by directly linking an ABS with a GIS (Brown et al. 2005).

ABS and Time

Agent-based simulation is sometimes described as a form of discrete-event simulation because of the similarity of the event scheduling mechanisms commonly employed in DES and ABS. An event scheduling mechanism is the logic of how the simulation advances time and how events are generated internally within a model. A scheduling mechanism in a DES moves the simulation forward through time to the next point at which an event is scheduled to occur. In an ABS, events consist of the times at which agent interactions occur. A scheduling mechanism in a continuous simulation moves the simulation forward continuously through time; a continuous simulation is described by a set of differential equations that indicate how the system state changes over time as a function of the current and past states. Virtually all ABS are discrete-event simulations, although the ABS framework does not preclude the development of continuous or combined continuous/discrete simulations.

A special case of discrete-event simulation is time-stepped simulation in which time advances at fixed time increments. Virtually all of the early agent-based simulations were time-stepped simulations in which each agent interacted with its neighbors at each time step. This time advance mechanism is the one used by cellular automata.

A general representation for a time-stepped, discrete-event, agent-based simulation is an iterated map from dynamical systems theory in which a transform function is applied to the system state at each time point to update the state for the next time:

$$x_{t+1} = F(x_{\mathrm{t}})$$

where x_t is the system state at time t and the transform F is a general mapping applied to the system state each time period. The system state, x_t, is composed of the

states of all the agents in the simulation, as well as the state of the environment at t. The transform F is not a function per se, but represents the entirety of the complex logic encoded in the simulation model and can be a deterministic or a stochastic mapping. For example, some ABS models are in the form of a Markov chain model. Agent state transitions are represented by a matrix of probabilities. Slightly more complex ABS models condition agent state transitions on events that have happened to an agent in its past, information stored in an agent's memory, akin to a semi-Markov model.

Conflicts may arise in time-stepped ABS when all agents interact simultaneously at a time step due to agents contending for the same space or resources. A common approach to resolving such conflicts is to randomly reorder the sequence of agent interactions at each time step. This removes any bias in the simulation results due to an arbitrary ordering of agent interactions. The disadvantage is that many replications of the simulation have to be run to generate statistically significant results and understand the full range of model outcomes due to the order of agent updates. If agent interactions are scheduled at discrete real-valued times, as in DES, the problem is avoided because ties at specific times are unlikely.

As the need for realistic, large-scale agent-based simulations has advanced, event-scheduling mechanisms have been generalized in ABS development software tools. The most advanced ABS toolkits provide users the tools to implement time-stepped or discrete-event scheduling. Events can be exogenously specified to occur at particular times, or generated and scheduled endogenously based on the outcomes of agent interactions and agent monitors that detect changes in agent states.

Event calendars offer a major improvement in computational efficiency in DES. At the completion of the computation arising from an event, the system can simply skip to the next time at which an event is scheduled to occur. While calendaring is possible for ABS as well, it is infrequently used. The much higher number of interactions among events in an ABS requires correspondingly more re-computation as the new events affect schedules of other events. In turn, these interactions and re-computations greatly complicate debugging. Finding a computational improvement for ABS along the lines of DES calendaring is a promising area of research.

ABS and Emergence

One of the most oft cited reasons for developing an ABS is the ability to capture emergent processes, i.e., processes whose outcome cannot be understood or anticipated solely from examination of the individual parts of the system (Bedau and Humphreys 2007). Emergence, in the most general sense, refers to the emergence of order, which is a well-defined notion and can be expressed using various entropy measures. It can easily be shown that simple ABS models, which are completely described by deterministic rules, can produce self-organizing, emergent and sustainable patterns that have not been explicitly programmed into the models.

Swarm intelligence is a concept related to emergence (Bonabeau, et al. 1999). Natural systems seemingly exhibit collective intelligence without the existence of, or the direction provided by, a central authority. Typical examples are the workings of ant colonies and beehives, the schooling behavior of fish, and search behavior of collaborating predators. Swarm intelligence has inspired practical optimization techniques such as ant colony optimization and particle swarm optimization that have been used to solve practical scheduling and routing problems. Swarm intelligence algorithms can be implemented in an agent-based simulation framework, as described by (1)-(2) above.

Agent-Based Simulation Applications

Agent-based simulation has been applied in many scientific disciplines—physical, life, medical, social, and management. ABS applications in economics (Tesfatsion and Judd 2006), sociology (Macy and Willer 2002), anthropology (Kohler et al. 2005), cognitive science (Sun 2006), business, marketing (Rand and Rust 2011) and many other areas suggest that ABS is a general technique with wide application. Macal and North (2011) discuss many published applications as diverse as agriculture, air traffic control, anthropology, biomedical research, crime analysis, ecology, energy analysis, epidemiology, evacuation, market analysis, organizational decision making, and social networks.

Agent-based simulation applications range from elegant conceptual models having minimalist detail, to large-scale models having much detail that correspond closely to the real-world system modeled.

Minimalist models are based on a set of idealized assumptions, designed to capture only the most salient features of a real-world system. These models are often used as electronic laboratories to implement and test the implications of qualitative theories for a range of many scenarios.

Large-scale ABS models have been developed that answer real-world policy questions, include real data, and have been shown to pass appropriate validation tests to establish their credibility. Such models have been developed for the operation of physical infrastructures and associated economic markets, including electric power, epidemics, economies, traffic and transportation, pedestrian movement, and evacuation modeling. Agent-based models are useful for modeling very high volumes of entities for cases in which simple sets of agent behaviors are adequate. For example, prior to 2006, discrete-event models of crowd movement could handle no more than a few thousand people in real time. Samuelson et al. (2007, 2010) used custom agent-based software to depict real-time evacuation from a stadium for up to 70,000 people.

Large-scale ABS models have been used to inform policy-making for epidemiological studies (Germann et al. 2006). Here, individual agents are modeled as they go through their daily activities, make contact with other agents, and possibly pass on infection (Carley et al. 2006). The models can incorporate realistic agent behaviors, such as how agents respond to their disease state, public health information, and health care interventions (Epstein 2009). ABS models are used as in silico (computer-based) experimental laboratories to understand how these behaviors might affect the outcome of an epidemic and to understand their possible severity under various assumptions.

Developers of ABS models contend that agent-based modeling offers unique benefits for the problems studied in their disciplines that are beyond conventional modeling approaches. For example, many economic models assume that the real-world system will be driven toward a long-run stable, equilibrium state. The conditions for the equilibrium state are represented by a set of non-linear equations that are to be solved in order to solve the model. An agent-based simulation model, in contrast, makes no assumptions about a long-run equilibrium state, but rather computes the outcome of the process of repeated agent behaviors and interactions (Axtell 2000). Agent-based models are particularly useful for assessing when equilibria are likely to cease to exist, what transient behavior can then be expected, what trigger events are likely to promote stability or instability, and how robust the system is likely to be.

Agent-Based Simulation Development

ABS Design

Methods for developing ABS largely follow established methods for developing any kind of simulation model. Additional tasks include defining agents, modeling agent behaviors and interactions, and validating agent models and results (North and Macal 2007). There is also a close connection between agent-based simulation design and object-oriented modeling through the use of object-oriented design methods, such as design patterns (Grimm et al. 2006).

The complexity of agent interactions can make both model debugging and validation difficult. Because of this, validation and verification of agent-based models is a vital and interesting area of research. A comprehensive review by the National Research Council (2008) proposed a number of principles, primarily a clear definition of the model's intended purpose and a strict adherence to assessing whether the model was useful for that purpose. The effect of stringent adherence to this discipline on the discovery and evaluation of unexpected phenomena appears to be a subject that needs further exploration. An additional, open question is: how complex can a model become without overwhelming the modeler's ability to interpret the output, in particular to distinguish genuine rare emergent phenomena from deficiencies in the programming? One promising approach is to use agents to assist in validation, (Niazi et al. 2009). The rapid development of computational capabilities and new logical approaches in software promise to keep the discussion on ABS validation ongoing and lively.

ABS Toolkits

A number of computing alternatives are available for developing agent-based simulations. These range from laptop computers to computer clusters, and, potentially, to cloud computing.

Desktop computing environments for ABS development include spreadsheets, such as Excel augmented by a macro programming language for

programming agent behaviors and time-advance mechanisms, and general computational mathematics systems such as MATLAB and Mathematica. Desktop computing environments can be used to develop agent models, although the agent-specific functionality must to be written by the developer from scratch, because no agent-based packages exist for these systems. Desktop agent-based models may not scale well for larger applications. Whatever software is chosen, agent-based simulations are often developed in phases using multiple approaches. Projects often begin small, using one of the desktop tools to prototype agent behaviors and to perform limited analyses. They are then scaled up using agent-based toolkits in a later phase of development to capture larger numbers of agents and more complex agent behaviors.

Agent-based models are also developed directly in programming languages such as C++, Java, and Python, especially for large-scale applications. The object-oriented modeling paradigm these languages embody is the basis for most agent-based modeling; an agent can be considered a self-directed object with the capability to autonomously choose actions in response to an agent's situation. The use of object classes as agent templates and object methods to represent agent behaviors is a natural extension to ABS. Most large-scale agent-based modeling toolkits are also object-oriented.

Since the original Swarm toolkit, there has been a steady progression of ABS software toolkits, development environments, and modeling approaches. Open source and/or freely available ABS development environments include NetLogo, Repast Simphony, and MASON (Macal and North 2010). These environments provide special facilities for modeling agents and are designed for new users to get started as quickly as possible in developing ABS. Commercial agent-based modeling software includes AnyLogic, among others.

Concluding Remarks

Agent-based simulation can offer distinct advantages over conventional simulation approaches, depending on the type of problem being modeled. Agent-based simulation is often used when:

- The system being modeled has a natural representation as being composed of interacting agents,
- The past is no predictor of the future, and the behavior of the system must be built from the ground up based on the behaviors and incentives of the individual agents,
- Process structural change needs to be an endogenous result of the simulation, rather than an input to the simulation, and
- Scaling-up to arbitrary levels is important, in terms of the number of agents, agent interactions, and agent states.

Agent-based simulation offers benefits compared to other modeling approaches when agents in the model:

- Have behaviors and make decisions central to the questions to be addressed by the simulation,
- Adapt and change their behaviors in response to actions and events in the model,
- Engage in repeated strategic interactions and can learn from their experiences,
- Have dynamic, changing, or evolving relationships with other agents,
- Self-organize into cohesive groups or organizations and the mechanisms by which this happens are known or hypothesized, and
- Have a spatial component to their behaviors, movements, and interactions.

Agent-based simulation has grown rapidly since the mid-1990s and many new applications continue to be published. Disciplines where simulation has not previously been the modeling technique of choice are experimenting with ABS, and research on the theoretical and methodological foundations of ABS is very active.

Agriculture and the Food Industry

Filmore Bender[1] and Gerald Kahan[2]
[1]University of Maryland, College Park, MD, USA
[2]McCormick and Company, Sparks, MA, USA

It is often difficult to determine where the agricultural sector of an economy ends and the nonagricultural sector begins. For the purpose of this article, the agricultural sector of the economy is defined as production and supply of agricultural inputs, the

production of agricultural goods on farms and ranches, the processing and transportation of those goods, as well as the wholesaling and retailing of finished products. Defined in this way, the agricultural sector of the economy in the United States represents approximately 24% of the gross national product.

As with the nonagricultural sector of the economy, operations research was first used to solve agricultural problems in the 1940s and 1950s. *A Survey of Agricultural Economics Literature, Vol. 2: Quantitative Methods in Agricultural Economics, 1940s to 1970s* traces the development of operations research in addressing problems of importance to agriculture (Judge et al. 1977). This work ranged from quantifying production functions to the development of models, simulation structures and the use of linear programming and nonlinear optimization models to quantify or predict economic consequences, or alternatively, the use of these tools to solve specific problems for specific firms.

Different components of the agricultural economy have embraced the tools of operations research with different levels of enthusiasm. Those sectors of agriculture that can exercise considerable control of inputs and environmental factors (e.g., feeder cattle, broilers, eggs, pork and dairy production) began adopting the tools of operations research during the late 1950s. By 1965, essentially all of the feed formulated for poultry in the United Sates was done using least-cost linear-programming feed formulations. Simultaneously, during the 1960s, the beef industry began to adopt linear programming on a limited basis for least-cost feed formulation and for the development of optimal production and marketing strategies. The use of linear programming for least-cost dairy rations became standard practice during the late 1970s. Forestry, which is a branch of agriculture, uses multi-period linear programming models to determine optimal planting and harvesting schedules.

A number of interesting examples have been reported in the literature which describe how linear programming was used to solve a variety of agriculture problems. Upcraft et al. (1989) reported that the soil water deficit is the main decision variable that British farmers monitor to decide when to irrigate a particular field and how much water to use. The decision is generally based on the soil water deficit in the first strip to be irrigated within each field. A mixed-integer linear program was constructed to model the short-term irrigation scheduling problem for a hose-reel/rain-gun irrigation system. Optimal schedules were produced by quantifying the costs and benefits of irrigation, subject to the constraints of equipment, labor, and availability of water. The model is unique in producing whole farm-irrigation schedules, rather than individual field schedules for hose-reel/rain-gun irrigation systems.

The efficient operation of a beef cattle feedlot is controlled by the price of the animals, purchase and selling weights, and the feeding system. The optimal feeding system involves feeding least-cost rations to animals at each stage in the production process. Glen (1980) reported the development of an optimal method for determining optimal feeding systems that meet the nutrient standards recommended by the US National Research Council. The approach involved using linear programming to determine the least-cost rations to produce specified live weight gains in animals of known live weight. Dynamic programming was used to determine the optimal sequence of rations to feed to produce animals of specified live weight from known live weight at minimum cost, using least-cost rations from the linear programming model. Results from the dynamic programming model can be used to determine the optimal combination of purchase weight, selling weight, and feeding system. The linear programming model must be solved a large number of times to use the dynamic programming model.

In assessing feeding policy in livestock production, it is generally assumed that an optimal feeding policy will involve using least-cost rations throughout the production process. Glen (1980) showed that this assumption may not always be valid, particularly when the supply of some of the feedstuffs used for feeding the livestock is limited. A technique for testing the validity of this assumption was presented using a linear programming model of an integrated crop and intensive beef production enterprise in which some of the crops are used for livestock feeding. An interactive solution procedure was proposed for cases where this assumption was not valid. While the computational burden associated with the procedure for finding an improved solution is large, experience with realistic data suggests that the results from the linear programming model are likely to be optimal.

Intra-year milk supply patterns depend largely on the distribution of cow calving dates which are in turn

influenced by climatic conditions. The most important and least-costly input to milk production is the fresh growth and high digestibility of grass in spring and early summer that often gives rise to a highly seasonal distribution of calving resulting in a seasonal milk supply pattern. However, milk for liquid consumption and production of perishable milk products must be geared to meet a constant consumer demand throughout the year, which necessitates a considerable amount of production outside the least-cost period. Killen and Keane (1978) re-ported on the development of a linear programming model that gives the distribution of calving dates, minimizes production costs, and meets consumer demand for milk and related products. In addition, the dual solution gives a set of seasonal prices which should be paid to producers, equitably compensating them for the costs they incur.

The agricultural sector deals with a biological system. By its very nature, agriculture has elements that foster the use of operations research techniques and other elements that greatly impede the application of these tools. Because many agricultural production units are relatively small in size, they are unable to adopt operations research techniques in a cost effective manner. On the other hand, because agricultural firms are dispersed, those firms that either supply inputs to farms or harvest and process agricultural products can make effective use of truck routing and other spatial optimization techniques.

Because of the savings in costs that can be achieved, as well as the increasing availability of computers and software, it is reasonable to expect increasing use of the tools of operations research in agriculture. In fact, as early as 1973, Beneke and Winterboer published *Linear Programming Applications to Agriculture*, a book devoted exclusively to the use of linear programming in agriculture.

In the food industry, linear programming is becoming increasingly common. Publications have re-ported the use of linear programming in formulating preblended meats (Rust 1976); luncheon or sandwich meat (IBM 1966; Wieske 1981); a protein-enriched luncheon sausage (Nicklin 1979); bologna (IBM 1966); frankfurters (IBM 1966); and a variety of sausage products (MacKenzie 1964; IBM 1966; Skinner et al. 1969). Ice cream is another food product which has been successfully formulated using linear programming (IBM 1964; Dano 1974; Singh et al. 1979).

Cereal-based food blends have been formulated using linear programming to insure adequate levels of good-quality protein. Since these blends are sometimes shipped to developing countries, linear programming has helped to ensure that the prominent grain of the country is present in the blend as a major ingredient. It is desirable to blend cereal grains, since plant proteins are usually deficient in one or more of the essential amino acids. Inglett et al. (1969) used linear programming to bring the essential-amino-acid pattern of a cereal-based food as close as possible to the pattern found in a hen's egg. Cavins et al. (1972) used linear programming to formulate a least-cost cereal-based food. The protein quality was controlled by setting both lower and upper limits on each essential amino acid in terms of its percent of total essential amino acid content. Hsu et al. (1977a, b) studied the blending of a wide range of plant and animal protein sources in formulations for bread, pasta, cookies, and extruded cornmeal snack and sausage. Constraints were used to restrict both the nutritional and functional properties.

Roush et al. (1994) reported on using chance constrained programming to formulate commercial feeds for animals. Nutritional consistency of finished feeds increased by 40 % while costs dropped compared to feeds formulated by linear programming with a margin of safety. With the exception of the probabilistic constraints, the objective function and most other constraints were linear in this model.

A detailed description of the formulation of a low-cholesterol, low-fat beef stew using linear programming was given by Bender et al. (1976). The objective was to minimize cost, while enforcing nutritional and other constraints based on the recommendations for fat-modified and low-cholesterol diets. These constraints were for a 100-g portion of stew and set an upper limit on cholesterol content; a lower limit on protein, vitamin A, thiamin, riboflavin, niacin, vitamin C, and iron; and both an upper and a lower limit on carbohydrate, fat, and calories.

Dano (1974) provided an full description of the application of linear programming to a beer-blending problem, and Wieske (1981) described the formulation of an optimal margarine product. Another application has been the formulation of mayonnaise (Bender et al. 1982).

An interesting problem in the production of champagne was reported by Hruby and Panton (1993). In one of two methods used to produce

champagne in Australia, a base wine called tirage is allowed to ferment and mature in a bottle for as long as 6 months. The tirage is then transferred to a tank for 2 weeks where it is further processed. Finally, fresh bottles are filled with finished product and stored for 6 weeks. Uncertainties in consumer demand and constraints on production stretched a 9 month process into 12 months. In addition, inventories of maturing and finished product were far too high. The problem was solved when a time-staged linear-programming model was used to smooth production and reduce stock levels.

The feasibility of planning menus by computer was generally established in the early 1960s (Balintfy and Blackburn 1964), as was the feasibility of computerized menu analysis (Brisbane 1964). In these models, nutritional requirements were provided at lowest cost. Developing models which meets sensory objectives as well as nutritional requirements has proved to be a much more difficult problem.

Renaud and Yacout (1996) reported on a company that processes lobster primarily for foreign markets. With increasing international competition, stricter standards and decreasing annual volume of lobster catches, the company wanted to know the optimal product mix to maximize profit. Linear programming was used to generate five scenarios that encompassed different possibilities available to management.

[3]Air Force Studies and Analyses, Assessments, and Lessons Learned, Washington, DC, USA

Introduction

Air Force Operations Analysis (OA), as military operations research (OR) was often termed in the Air Force, began in the Army Air Forces in World War II (WWII). After the war, the Air Force became a separate service in 1947, and the service leaders decided to continue operations analysis sections in the headquarters and major commands. The OA office in Air Force Headquarters led procedures for steady state systems of analyst recruitment, training, rotation, etc., through its Air Force Regulation AFR 20-7. This office regulated the OA program until 1971, when it was merged into the Air Force Studies and Analyses office (which has had several titles and organizational settings since its creation in the mid-1960s). In 1993, the Air Force created a Directorate of Modeling, Simulation, and Analysis with the Air Force Studies and Analyses Agency (AFSAA) serving as its field operating agency. The directorate was expanded in 1997 to the Directorate of Command and Control that included an Associate Director for Modeling, Simulation, and Analysis with AFSAA continuing as a Field Operating Agency. In 2001, AFSAA became a direct reporting unit to the Vice Chief of Staff of the Air Force (VCSAF). This agency was converted into an Air Staff function of AF/A9, Studies and Analyses, Assessments, and Lessons Learned, in 2006, reporting as a directorate organization to the Chief of Staff of the Air Force (CSAF). Each of the major commands also established an A9 office overseeing their studies and analyses, assessments, and lessons learned and as a focal point for OR. The Air Force has effectively returned to organizing analysis similar to the way it was during and after WWII.

World War II in the 1940s

Brothers (1951) states, in WWII, 245 analysts (professional personnel, not including clerical and administrative staffs) had been in the OA program at one time or another with the peak strength having been 175. These analysts were distributed over 26 OA sections, one with every combat Numbered Air Force plus several with other overseas Air Force headquarters and several with Air Force training establishments in the continental U.S. Brothers (1951) reports there were many types of studies:

> . . . offensive ones dealing with bombing accuracy, weapons effectiveness, and target damage. . .defensive ones dealing with defensive formations of bombers, battle damage and losses of our aircraft, and air defense of our bases . . . studies of cruise control procedures, maintenance facilities and procedures, accidents, in-flight feeding and comfort of crews, possibility of growing vegetables on South Pacific islands, and a host of others. The first and largest of the OA sections was that at the Eighth Air Force.

McArthur (1990) gives a detailed account of its work and much information about the analysts, with emphasis on the mathematicians. In its foreword, Hugh Miser notes:

> During the two and a half years of existence of the Eighth Air Force section, forty-eight persons with scientific and technical training were involved, representing more than

> a dozen specialties; mathematicians were the largest subgroup, with fifteen persons, thirteen of whom stayed with the section for six months or more. . . . It should be noted that the mathematicians were functioning, not just in a mathematical role, but as scientists, developing theories about actual phenomena and applying them to problems of operations, policy, and plans.

Brothers (1954) gives an account of the well-known improvement in bombing accuracy to which these analysts contributed. The commanding general had asked, "How can I put twice as many bombs on my targets?" In 1942, less than 15% of the bombs dropped fell within 1,000 ft of the aiming point. The rate improved gradually and within two years had reached 60%. Some of the analytical recommendations that played a part in this were the nearly simultaneous release of their bombs by all the bombardiers (instead of the practice of each bombardier aiming and releasing his own bombs), the salvoing of bombs instead of presetting them to release in a string, and the decrease in the number of aircraft per formation from a range of 18–36 to a range of 12–14. The successful work of this first section made other Army Air Forces commands aware of the OA concept and led to the establishment of the other OA sections. Those sections also had their successes, all of which led to the postwar continuation of OA in the Air Force. In the forward of *Operations Analysis in WWII* (United States Army Air Forces 1948), General Carl Spaatz, the Commanding General and later first Chief of Staff of the Air Force, takes credit for requesting and establishing the first OR section while he commanded the Eighth Air Force. With the war's end, most of the analysts returned to universities, laboratories, or other civilian pursuits. Brothers (1951) reports that by January 1946 there were only a dozen left, about half of whom were finishing final reports.

Post-World War II and the Korean War in the 1950s

Brothers (1951) recalls that the United States Air Force (USAF), having decided to establish a peacetime OA program, also decided on the basis of wartime experience that it needed an analysis unit in the headquarters. This unit had two functions: to furnish scientific assistance to the Air Staff, and to serve as a focal point in the Air Force-wide OA organization. AFR 20-7 established the OA Division in Headquarters, USAF, and authorized Air Force commanders to establish OA offices in their commands, getting needed help from the Headquarters OA office.

From the OA low point of January 1946, it had grown by mid-1951 to ten offices in field commands plus the headquarters office. As a stable postwar program was established, the number of analysts grew. By 1951 there were 70 assigned, with 95 authorized. The 95 authorized professional positions were mostly civilian (under Civil Service), as at that time there were few uniformed analysts available. In addition, the RAND Corporation's work emphasized problems of the far future, freeing the OA offices to work primarily on current and near-future problems. However, when analysts were needed in the Korean War, some came from RAND (and a smaller think-tank also), as well as from OA.

Any history of OR, particularly an Air Force one, must highlight Dr. George B. Dantzig's role as "the father of linear programming (LP) and the inventor of the simplex method" and "arguably one of the most influential mathematicians of the twentieth century" (Cottle et al. 2007). WWII interrupted Dantzig's doctoral program studies at the University of California (Berkeley) when he went to support the Army Air Forces' Combat Analysis Branch of Statistical Control, Pentagon. He developed a reporting system with which combat units were able to record the number of sorties flown, aircraft lost and damaged, bombs dropped, and targets attacked; he also became familiar with the Air Force concepts of program planning of interrelated activities, ideas that would later help him structure the basic form of the LP model. The War Department awarded him the Exceptional Civilian Service Medal for his accomplishments. In 1946, Dantzig returned to Berkeley to complete his Ph.D. in mathematics. He then accepted the position as mathematical advisor to the comptroller of the newly established Department of the Air Force. Here he worked on formulating mathematical models of the Air Force's program planning process that led to the first LP models (and the use of the word *programming* in LP). And, most important, while working for the Air Force, Dantzig developed the simplex algorithm for solving

LP problems. Dongarra and Sullivan (2000) include the simplex algorithm as one of the top ten algorithms developed in the twentieth century.

In June of 1947, the Air Force established a major task force to work on the high-speed computation of its planning process, later named Project SCOOP (Scientific Computation of Optimal Programs), under the direction of the economist Marshall K. Wood, with Dantzig as chief mathematician. Project SCOOP was the setting in which the LP structure and the simplex method were proved and introduced to the world. The SCOOP civil service staff of mathematicians, statisticians, and computational experts was responsible for formulating and solving a wide range of Air Force planning and programming problems, as well as installing, in June 1952, the first computer in the Pentagon, a UNIVAC-I for solving Air Force problems. SCOOP also funded the construction and use of the 1950 National Bureau of Standards Eastern Automatic Computer (SEAC), as well as supporting academic researchers who helped to bring the application of LP to industry and business (Gass 2002).

In 1952, Dantzig transitioned from the Air Force to RAND. He joined the Berkeley faculty in 1960 and then Stanford in 1966. President Ford awarded him the 1975 President's National Medal of Science. Dantzig was a founder of OR and made further significant contributions to the field during his career.

By the mid-1950s, the headquarters OA office had 25 professional positions divided among five teams. Two of the teams were primarily concerned with implications of new types of weapons: one with atomic and nuclear weapons, and one with ballistic and cruise missiles. A third team dealt primarily with deriving information about combat operations from tests, exercises, etc. A fourth team integrated inputs from the previous three teams to use in assisting Air Staff planners. The fifth team maintained liaison with the existing field OA offices and helped commanders who wished to establish new field offices where they did not yet exist.

The field OA offices were organized according to the same general principles. There should be analysts available to study combat operations and related problems, as well as others with understanding of new technology and its implications for new weapons. Most of the growth in the OA program at that time came through the establishment of new offices, rather than the enlargement of existing offices.

Force Structure Analysis and Vietnam in the 1960s

In the 1960s, the situation began to change markedly, through the combination of two developments. One came fairly abruptly when the Secretary of Defense McNamara of the Kennedy administration institutionalized systems analysis (used to denote OR on broad systems problems) in the Office of the Secretary of Defense. Many of the RAND analysts became McNamara's whiz kids. Their efforts greatly increased the demand for cost-effectiveness studies from the military services. The other development came throughout the decade as the increase in computer hardware and software capabilities led to great increases in the development, size, and use of computer simulation models.

The headquarters OA office was caught up in both of the above trends, which made it more difficult to devote as much effort as desired to the analysis of operations in Vietnam. A small group of OR professionals worked at the Seventh Air Force Headquarters in Vietnam. This group was involved in both the day-to-day operations of the command and in longer term analyses. Analysts presented daily briefings containing trend analysis, principally truck kill projections, to the Director of Operations and the Commander. They supplemented these with weekly trend analyses to assist decision making for the next week. These analyses investigated truck kill claims and battle damage assessment. In 1970, the air sortie debrief reports were incorporated into Southeast Asia Database (SEADAB) to support better analysis. The principal OR tool used was regression analysis to project future results. This analysis cell also conducted special-purpose studies and explored subjects like subsystem effectiveness, such as the Black Crow, which was a highly sensitive passive sensor deployed on AC-130s that could detect North Vietnamese trucks hidden under the dense jungle canopy along the Ho Chi Minh trail. Finally, the office compiled a comprehensive history of the Southeast Asia war in an annual report termed Commando Hunt.

In the mid-1960s, a new and larger organization of Studies and Analyses was formed in the Pentagon incorporating an office that had been set up in the late 1950s to operate a large (for that time period) computer simulation model. It had been difficult to acquire the data and manpower to make effective use

of that model, and the resources of that office became available to staff the new office created to meet the growing need for cost-effectiveness studies. The newer office of Studies and Analyses and the smaller headquarters OA office (about 35 professionals at that time) both reported at high levels, required the same kind of competent analysts, and used OR techniques. These similarities suggested the merger of the smaller OA headquarters office into the larger office. It was finally accomplished in the first 6 months of 1971. The Studies and Analyses office chose not to continue implementation of AFR 20-7. The immediate consequences were not striking. The field OA offices continued, though a few made slight changes in name. Most of the other trends noted above continued, or even accelerated. There was a proliferation of computer simulation models and of their use in large studies.

The Air Force Studies and Analyses Agency (AFSAA) served informally as an OR research focal point. Technical exchanges across the Air Force continued in the course of business and at meetings of professional societies. Initially, the Air Force analysts held a semi-annual OA technical symposia, however they discontinued these as they made increasing use of the multiservice classified symposia of the Military Operations Research Society (MORS). The Air Force was one of the founding organizational sponsors when MORS was incoporated in 1966. While continuing to participate in MORS, in 1994, the Air Force reinstituted conducting internal technical exchanges with their annual Air Force Operations Research Sympoisium (AFORS); in 2009, this name changed to the Air Force Analyses, Assessment, and Lessons Learned (A2L2) Symposium.

The Cold War in the 1970s and 1980s

Through the 1970s and 1980s, concern related to the Cold War dominated in spite of the hot war in Vietnam. The Air Force Analysis community responded. Three main organizations focused extensive resources on nuclear warfare analyses; Headquarters Strategic Air Command (SAC), AFSAA, and the Joint Staff J8. After WWII, General LeMay had recruited to SAC preeminent operations researchers. The Headquarters at Offutt Air Force Base maintained a centralized civilian analysis organization along with military analysis shops in each of the functional areas. AFSAA dedicated a third of its analysts to evaluating nuclear war. These three analysis offices annually conducted and compared detailed plans of potential Soviet massive nuclear attacks on the U.S. and planned response options. The predominant approaches were LP and discrete-event simulations. These studies provided the foundation for force structure decisions including requirements and acquisitions.

At the Air Staff, the bulk of the studies dealt with future weapon systems and future force posture. The occurrance of many very highly classified studies of black systems began and continues today. Many studies evaluate weapon systems exploiting the latest technology. The difference in emphasis between RAND and the in-house Air Force analytical offices that had prevailed in the 1950s diminished, to a large extent because of the impact of the institutionalization of systems analysis in the Department of Defense (DoD). Lt Gen Glenn Kent (2008), who led AFSAA and later worked at RAND, summarizes several of the analytical approaches in his analytical memoir. The primary war in this period remained the Cold War, until, suddenly, it was won.

During this period, the Air Force began educating personnel in military OR. The United States Air Force Academy offered OR as an undergraduate major beginning in 1978 and has conferred 1,031 degrees to OR majors through 2010. The Air Force Institute of Technology started conferring this specialty for master's degrees in 1973 and doctorates in 1992. Through 2010, they have conferred 1,107 master's in OR and closely related programs and 43 doctorates in OR.

The total number of Air Force analysts generally continued to increase, at a somewhat slower rate, through the mid-1980s. In 1988, an Air Force personnel database showed 476 civilian analysts in the OR analyst career series. With the end of the Cold War in the late 1980s, there began a general decrease in the size of the DoD, including military OR. By the end of 1993 Air Force civilian levels in career series relevant to analysis were about 20% lower than 1988 levels through the 1990s. For military analysts, in 1986, the Air Force had 1,626 military scientists with approximately 60% OR analysts. After the turn of the century, the number of analysts began to increase. The Air Force had

increased to 566 civilian OR analysts in 2010. The Air Force completed 2010 with 499 military OR analysts.

The Middle East Wars in the 1990s through 2010

The end of the Cold War resulted in a significant drawdown in the Air Force, as the federal government reallocated resources to other concerns. This reduction in defense spending was commonly referred to as the peace dividend. The end of the Cold War resulted in an Air Force shift from a primary emphasis on strategic bombing to fighter operations. In 1992, SAC was disestablished and a joint US Strategic Command was established at Offutt Air Force Base. This Combatant Command continues to have a stronger presence and reliance on OR analysts than the other combatant commands. With the Air Force as Executive Agent, these analysts are Air Force civilians and predominately Air Force among the military members. While the major commands were realigned, the Air Staff was also reorganized. In 1991, the OR organization known as the Air Force Center for Studies and Analyses was renamed the Air Force Studies and Analyses Agency (AFSAA), which reported to the Air Staff. This alignment remained through the 1990s. The First Gulf War in 1991 extensively employed members from Air Force Studies and Analyses in build up deliberations and support for the Black Hole team.

The terror attacks on September 11, 2001 accelerated the DoD expansion that had began two years prior. OR experienced more than a decade of growing influence in the Air Force. In 2001, AFSAA became a direct reporting unit to the Air Force Vice Chief of Staff (VCSAF). In 2006, the OR organization became an Air Staff directorate, designated AF/A9, reporting to the Chief of Staff of the Air Force (CSAF). The other services and joint organizations aligned their analysis center under their planning, programming, and budgeting organizations. The equal status within the Air Staff enabled supporting a wide range of decisions across manpower, operations, planning, and resources. The major commands also each established A9 organizations to lead their analysts. Furthermore, combat analysts were deployed into the staffs fighting the wars in Iraq and Afghanistan. These developments have resulted in widespread recognition among the leadership of the role and contributions of OR in supporting their decisions.

In 1993, under Defense Secretary Les Aspin, the DoD completed the Bottom Up Review to adjust the National Defense Strategy following the end of the Cold War. Congress decided to mandate these episodic reports, which became the Quadrennial Defense Reviews (QDRs). The Air Force contributed significant force structure analyses in support of the QDRs of 1993, 1996, 2000, 2006, and 2010. The differences between the Services, Joint Staff, and OSD led to the formulation of standard scenario and campaign model inputs in the Analytical Agenda, which began in 2006. In 2010, the name was changed to Support for Strategic Analysis. The Air Force developed Synthetic Theater Operations Research Model (STORM), a discrete-event simulation of about 2 million lines of C code, has become the standard campaign model for the Air Force, Navy, and Marines by 2010.

Concluding Remarks

The end of the Cold War also precipitated a significant shift in force planning and, consequently, the analysis needed to support force development. Force planning guidance based on a single, peer threat gave way to a new paradigm comprised of multiple, often concurrent commitments. These engagements might occur anywhere on the globe at any time and range in intensity from limited humanitarian operations to full-scale theater warfare. Inherent uncertainty concerning time, place, and adversary led to production and regular revision of many planning scenarios. This evolution of force planning to reflect the new geo-political environment placed new demands on force development analysis. Years of analyzing a single, peer threat produced a large, complex hierarchy of analysis tools. While these tools provided comprehensive, high-fidelity analysis of individual campaigns, they are extremely data- and labor-intensive. The development, or even modification, of a scenario in these tools is a costly and time-consuming process extending far beyond department planning, programming, and budgetary cycle timelines. The analysis community is thus

faced with a difficult analytic challenge. They need to examine many, disparate planning scenarios to hedge against future uncertainty; their primary tools are inflexible on the timescale required by decision processes.

A resolution to this dilemma may be found in the development of new analytic tools guided by a conceptual model for addressing future uncertainty. With a less concrete vision of future conflict, optimal force design for a single scenario is less meaningful. Forces must instead be designed for robustness against unexpected contingencies and with enough inherent flexibility to allow for adaptation to impending shifts in the geo-political environment. Potential force constructs must be tested in a wide variety of scenarios informed by a multi-perspective approach to force development, recognizing no single approach provides a complete solution. Multi-scale tools must be developed to provide variable scope and fidelity necessary to address different problems. The tools must be agile enough to enable testing within decision-relevant time spans. This approach harkens back to the roots of OR: teams of scientists and operators cooperating to examine a variety of problems from the perspective, and at the levels of detail and complexity required, by the situation at hand.

Air Traffic Management

Michael Ball
University of Maryland, College Park, MD, USA

Introduction

The world-wide air transportation system represents an essential component in the operation of the various national economies. Many businesses would degrade to the point of insolvency without air transportation. Because of this high dependency, any deficiency in the performance of the air transportation system imposes a very large cost on the economies of virtually all countries. A recent study commissioned by the U.S. Federal Aviation Administration (Ball et al. 2010) estimated that the cost of air transportation delays to the US economy in 2007 to be $32.9 billion.

Air Traffic Management (ATM) is the process by which an air transportation system is managed. While individual flight operators and operators of large fleets, e.g., airlines, play a large role in ATM, large developed countries typically establish a national air navigation service provider, ANSP, that has responsibility for ATM. ANSP's traditionally are government agencies; however, recently several have adopted a privatized or semi-privatized business model. In either case, the primary systems and procedures for ATM are under the control of ANSP's. At the same time, increasingly, ATM is being viewed as a joint undertaking between the ANSP's and flight operators. Of course, there still remains a broad set of airline planning and control problems that would not be classified as ATM, e.g., fleet and crew planning problems and airline operational control problems that largely are

independent of ANSP decisions and processes. Ball et al. (2006) and Hoffman, Mukherjee and Vossen (2011) provide detailed reviews of ATM.

While the application of operations research to airline planning problems is perhaps the better known part of aviation operations research, the research community has devoted substantial attention in recent years to ATM problems. ATM problems possess particular characteristics that make them particularly challenging but also very interesting from the research perspective. Specifically,

- They are large, e.g., on there are over 50,000 daily scheduled, controlled flights in the U.S. airspace;
- Models and decision support tools should represent dynamic and stochastic elements as weather and other uncertain events greatly impact the capacity of airspace elements and decisions can be updated almost continuously;
- Distributed decision making and control strategies are used as both the ANSP's and flight operators distribute responsibilities among multiple entities;
- On the flight operator side, the decision makers represent competing economic entities so both economic and technical controls must be considered;
- The system requires an extremely high level of safety so that safety concerns can dominate the design of many solution strategies.
- Perhaps less directly related to modeling, but no less important from an implementation perspective, is the broader environment in which aviation is contained, which includes features such as a large unionized controller workforce, a high level of government control with related political influences and the need to achieve international harmonization among national ATM strategies and systems.

Air Traffic Flow Management Background

It is convenient to break down the domain of ATM into a tactical component and a strategic component. The tactical component, Air Traffic Control (ATC), is concerned with controlling individual aircraft on a time horizon ranging from seconds to 30 min for the purpose of ensuring safe separation from other aircraft and from terrain. The strategic component, Air Traffic Flow Management (ATFM) works at a more aggregate level and on a time horizon of up to about 12 h in the United States and 48 h in Europe. Its objective is to insure the efficient flow of aircraft through the airspace. It seeks to avoid congestion and delays and, when delays are unavoidable, to reduce as much as possible their overall impact. ATC problems are largely driven by safety concerns and the operating characteristics of aircraft. Thus, they largely fall within the disciplines of Control and Aeronautical Engineering. ATFM, on the other hand, is a large systems problem involving many stochastic elements and large decision spaces and thus falls within the domain of Operations Research. This chapter focuses on ATFM problems. Odoni (1987) provided an early description of operations research models for ATFM problems.

Air traffic is diverse consisting of individual flights by general aviation pilots, a variety of commercial on-demand and business jet services and the operations of large scheduled air carriers; military air traffic is another category: some military traffic is restricted to separate airspace and some is mixed with other air traffic. The large air carriers dominate the major airports and airspace. ATFM systems tend to be focussed on their needs. Specifically, air carrier schedules represent airspace demand and also serve as the basis for measuring the performance of ATFM systems. The fundamental premise of ATFM is that, roughly speaking, if all operations occurred at their scheduled times and if all airspace elements were in their normal operating states, then there would be little need for any flow management. Under such ideal conditions demand on all airspace elements would be less than capacity and operations would generally proceed as if there were no constraints. ATFM recognizes that the complexity of the airspace system and its susceptibility to weather conditions imply that it is extremely rare that nominal operating conditions exist over extended periods of time and/or large portions of the airspace.

ATFM performance is measured primarily with reference to deviations from schedules. Consequently, ATFM systems generally seek to minimize deviation between the timing of actual operations and scheduled operations. Thus, the key performance indicators usually involve measures of delay.

Before discussing ATFM decisions and controls, it is important to consider the roles and responsibilities of

the various stakeholders. The primary mission of ANSP's is to insure safety. As such they have a very strong role in the tactical (ATC) domain; further, even within ATFM their main responsibilities involve insuring airspace does not become overloaded causing unsafe situations. Over time, they have taken on a greater role in seeking to insure the overall efficient operation of the system, however, one should keep in mind that the air carriers and other flight operators will have strong (perhaps stronger) role in this area. In fact, in the past 15 years a new philosophical approach to ATFM has emerged. This new approach was originally called Collaborative Decision Making (CDM) and more recently is known as Collaborative Air Traffic Management (CATM). Its philosophical tenets include:

- Generating a better knowledge base by merging information provided by flight operators with the data that are routinely collected by an ANSP;
- Creating common situational awareness by distributing the same information to both the ANSP and the flight operators;
- Creating tools and procedures that allow flight operators to respond directly to capacity/demand imbalances and to collaborate with ANSP specialists in the formulation of flow management actions.

There are three basic types of controls used to manage air traffic:

Ground Holding: the simplest way to insure a portion of airspace does not become overloaded is to prevent certain flights from departing at the origin airports; in both the U.S. and Europe ground holding can be issued by way of multiple types of larger initiatives; the ANSP generally explicitly must give a flight operator permission before a flight can depart; a somewhat extreme version of ground holding is a ground stop, where all flights that have not yet departed and are destined for a particular airport are held on the ground until further notice.

Rerouting: a second approach to avoiding congested airspace is to fly around it; rerouting is a fundamental method used to manage congestion; the decision to change a route can occur before departure or after a flight is airborne; generally the flight operator requests a route or route change and this must be approved by the ANSP; however, it is also the case that the ANSP might indicate that only certain route options are available effectively forcing flight operator routing decisions; an extreme version of rerouting is a diversion, where a flight is redirected to an airport other than its scheduled destination.

Airborne Speed Control: once airborne, a certain amount of speed control can be exercised on flights; small changes can be implemented by simply adjusting the actual velocity of the aircraft; greater adjustments can be implemented by various types of maneuvering, e.g., vectoring, which involves flying in an indirect zig-zag pattern, and airborne holding, which involve flying in circular or oval patterns so as to remain in a designated area until progress toward the destination is allowed. Typically a flight operator chooses the speed of its flights to optimize business objectives; speed controls might subsequently be put in place by the ANSP.

These three classes of controls broadly represent the decision space of the ANSP (although as indicated each type of action requires some type of collaborative decision on the part of the flight operator). Another very important control is the decision to cancel a scheduled flight. Canceling certain flights clearly can greatly help relieve congestion but at the expense of a high degree of inconvenience imposed on certain passengers. While ANSP actions might greatly influence which flights are canceled, the final decision on a flight cancelation rests with the flight operator.

Basic Decision Problems and Optimization Models

It is useful to start with a description of three basic ATM problems and models. These problems represent basic functions that underlie higher level ATM processes. Further, at least in their simplest form the underlying models are classic operations research models.

The (Single) Flight Planning Problem

At the heart of a large, complex air traffic plan are the flight plans that individual flights follow from their origin airports to their destination airports. The key elements of a flight plan include the (1) the route the flight will follow, which indicates the points on a two-dimensional map it will fly over, (2) the flight

profile, which indicates the altitude the flight uses over the course of the route, (3) the speed to use over the course of the route, and (4) the trip fuel required for the flight. A controlled flight is one for which an approved flight plan has been filed with the air traffic management (ATM) system. Airline and general aviation operators prepare and file flight plans usually based on criteria that consider each flight in isolation. Air carriers typically employ sophisticated software, including advanced route optimization programs, for this purpose. By accepting a flight plan, an ANSP agrees to take responsibility for the safe separation of that aircraft from all other controlled aircraft in the airspace and to provide many other types of assistance toward the goal of completing the flight safely and expeditiously. Practically all airline flights and a large number of general aviation flights are controlled.

Considering the flight planning problem in unconstrained, three-dimensional space, control-based methods can be brought to bear. These employ aircraft performance characteristics and the relationship among weight, fuel remaining and aircraft performance. This basic approach can have limited applicability because much of today's airspace is highly organized so that many flight plan options are limited to a relatively small number of discrete choices. Thus, dynamic programming and shortest path methods become appropriate. A variety of factors add to the problem's complexity, including the need to take into account weather conditions, restrictions on various portions of airspace, differences in overflight charges among countries to name a few. A common decomposition approach first determines a route and then optimizes the speed and profile in a second step. Solution robustness can also be of interest to account for possible changes in weather or other conditions. While this basic problem is quite challenging and spans multiple domains there is surprisingly little literature on it. Sorensen and Goka (1985) provided an early reference on the topic and Altus (2007) a more recent survey.

Arrival Sequencing Problem

In order to maintain a high level of arrival throughput into an airport one would seek to space successive aircraft as close as safely possible. There are two physical effects that determine this safe separation: one is the long-standing safety requirement that two arriving aircraft cannot occupy the same runway simultaneously and the second is based on the separation requirements related to the *wake vortex* hazard. A wake vortex is a disturbance of the air caused by one aircraft. This disturbance can cause a second trailing aircraft to become unstable and even crash. Thus, there needs to be a certain separation distance or time to allow the wake to dissipate. The required distance depends on the characteristics of the (ordered) aircraft pair, e.g., a very heavy aircraft followed by a very light aircraft is the least stable situation requiring the larger separation distance. The net result of these characteristics is that the arrival throughput in terms of rate of arriving aircraft depends on the types of aircraft and their sequence. For example, a light aircraft followed by two heavies would require less total time to land than a heavy followed by a light followed by a heavy.

Thus, a fundamental problem in air traffic management is determining and arrival sequence for a group of aircraft (Balakrishnan and Chandran 2010; Beasley et al. 2000). The simplest version could be stated as: given n airborne aircraft, all approaching a single runway, determine a sequence of landings so as to minimize the time when the last aircraft lands. Here in the most general form there would be a required separation or distance, t_{ij}, between every possible ordered aircraft pair, (i, j). This is an instance of the well-known Hamiltonian path problem, which is very closely related to the even more celebrated traveling salesman problem.

However, the classic Hamiltonian path problem is a static problem. On the other hand, the problem of sequencing aircraft on a runway is dynamic: over time, the pool of aircraft available to land changes, as some aircraft reach the runway while new aircraft join the arrivals queue. Moreover, minimizing the "latest landing time" (or maximizing "throughput") should not necessarily be the objective of optimal sequencing. Many alternative objective functions, such as minimizing the average waiting time per passenger, are just as reasonable. A further complication is that the very idea of "sequencing" runs counter to the traditional adherence of ATM systems to a first-come, first-served (FCFS) discipline, which is perceived by most as fair.

These observations have motivated a variety of research on the arrival sequencing problem with the

objective of increasing operating efficiency while ensuring that all airport users are treated equitably. It is common to assume that aircraft start in an initial sequence and so both the dynamic aspect and fairness considerations can be modeled by limiting the deviations from this sequence. Other constraints might include adherence to a landing time window for each flight and also precedence constraints. The simplest versions of this problem can be solved in polynomial time, however, more complex versions become more difficult. Nonetheless, because the amount of sequence shifting that can take place can be quite limited, the problem can be effectively solved in practice.

The Slot Assignment Problem

In the U.S. ground holding is most often implemented via a ground delay program (GDP). Here the arrival capacity at a destination airport is reduced due to poor weather and so the rate of flow into the airport is reduced by delaying flights on the ground at their origin airports. The problem can be modeled by defining a set of slots (time intervals) at the destination airport with a capacity in terms of number of arrivals for each such slot. Each flight is assigned to an arrival slot, which can be no earlier than the flight's earliest arrival time. This effectively determines an arrival delay for each flight, which is in turn converted into a departure delay (ground hold). This basic model of assigning flights to slots arises in other contexts as well, for example in the planning of airspace flow programs, which are used in the U.S. to ration the flow through a portion of the airspace.

Model inputs include: set of slot (time intervals) $t(t = 1,2,\ldots,T)$ and set of flights $f\,(f = 1,2,\ldots,F)$. Let

$$b_t = \text{the (reduced) arrival capacity of slot } t,$$

$$e(f) = \text{the earliest time slot at which flight } f \text{ can arrive},$$

$$c_{ft} = \text{the cost of assigning flight } f \text{ to arrive at time interval } t,$$

and the variables:

$$x_{ft} = 1 \text{ if flight } f \text{ is assigned to time interval } t;\ 0 \text{ otherwise.}$$

Then, the slot assignment problem can be formulated as:

Slot_Assign

$$\begin{aligned} \text{Min}: \quad & \sum_{f,t} c_{ft}x_{ft} \\ \text{s.t.} \quad & \sum_{f} x_{ft} \le b_t \quad \text{for all } t, \\ & \sum_{t \ge e(f)} x_{ft} = 1 \quad \text{for all } f, \\ & x_{ft} \ge 0 \text{ and integer} \quad \text{for all } f \text{ and } t. \end{aligned}$$

As can be seen, this is a simple transportation model that can be solved very efficiently. This model was first described in Terrab and Odoni (1993). It has been noted that the definition $c_{ft} = r_f(t - e(f))^{1+\epsilon}$ is attractive since flight delay costs tend to grow with time at a greater than linear rate. In addition, solutions produced using this objective function are attractive from the standpoint of equity or fairness (Vossen and Ball 2006a).

CDM and Resource Allocation and Exchange

The CDM effort grew out of a desire on the part of both the airlines and the FAA for improvements in the manner in which GDPs were planned and controlled (Wambsganss 1996; Vossen and Ball 2006a). The FAA and, more specifically, the air traffic control system command center (ATCSCC) had realized the need for more up-to-date information on the status of flights currently delayed due to mechanical or other problems or even canceled unbeknownst to the ATCSCC. Equally important, the success of GDPs also depends vitally on timely information regarding airline intentions with respect to flight cancelations and delays over the next few hours. At the same time, the airlines did not feel the allocation procedures used by the ATCSCC were always fair and efficient. In addition, each airline wished to gain more control over how delays were allocated among its own flights. Thus, both the airlines and the FAA had specific (although different) objectives that motivated their participation in CDM. These issues bring another dimension to research in this area involving the relationship between resource allocation methods and stakeholder incentives. These topics are more typically considered in the economics literature, e.g., under the domain of mechanism design.

$$\textit{Ration-by-Schedule} \rightleftarrows \textit{Cancelations \& Substitutions} \rightleftarrows \textit{Compression}$$
$$\Leftrightarrow$$
$$\textit{Fair slot allocation} \rightleftarrows \textit{Intra-airline slot exchange} \rightleftarrows \textit{Inter-airline slot exchange}$$

Air Traffic Management, Fig. 1 CDM resource allocation

CDM Resource Allocation

It is instructive to consider CDM slot assignment within a more general framework. Figure 1 illustrates the overall resource allocation process. The basic (initial) slot assignment performed by the ANSP (FAA in this case) employs the ration-by-schedule, RBS algorithm. Each airline, using the cancelations and substitution process, may then cancel flights and modify slot-to-flight assignments for its own flights (intra-airline exchange). Thus, although RBS, in concept, allocates slots to flights, the cancelation and substitution process effectively converts the slot-to-flight assignment into a slot-to-airline assignment. The final step, compression, which is carried out by the ANSP/FAA, maximizes slot utilization by performing an inter-airline slot exchange in order to ensure that no slot goes unused.

RBS defined below is a simple priority rule for findisng a (feasible) solution to SLOT_ASSIGN. In this description, slots are defined so that each has capacity 1, i.e., $b_t = 1$ for all t. The algorithm employs a scheduled arrival time for each flight f, $\hat{e}(f)$, which may be different from the earliest arrival time $e(f)$:

RBS:

Step 1: Order slots by increasing value of slot time (t).

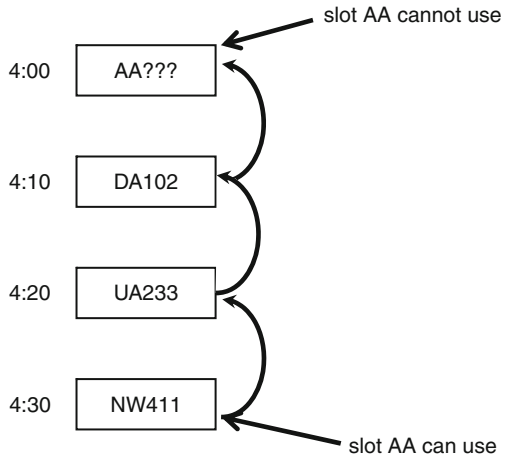
Step 2: For each slot t, choose the unassigned flight f with the earliest scheduled arrival time (value of $\hat{e}(f)$) and assign f to t, i.e., set $x_{ft} = 1$.

The fact that priority is based on scheduled arrival time $\hat{e}(f)$ as opposed to say earliest arrival time $e(f)$ is important. In general $e(f)$ can be larger than $\hat{e}(f)$ as mechanical problems or upstream delays to inbound flights can delay aircraft availability. Earlier (pre-CDM) procedures, which were based on $e(f)$, encouraged airlines to withhold or alter flight status information, as higher values of $e(f)$ led to less desirable slot allocations. By basing the allocation on $\hat{e}(f)$, the resources obtained are independent of the flight status information provided. On the other hand, by using $\hat{e}(f)$, it is quite possible that certain flight-to-slot allocations (instances where $x_{ft} = 1$) are not feasible leading to the need for the intra-airline slot exchange process; it is even possible that airlines will receive slots that are infeasible for all of their flights, which leads to the need for the inter-airline slot exchange.

Airlines can view the intra-airline slot exchange (cancelation and substitution) step as an internal resource allocation process. Specifically, the collection of slots allocated to a given airline's flights can be viewed as a set of slots owned by that airline. The airline could then view the internal problem of assigning its flights to the slots it owns as an optimization problem; again this is a transportation or assignment problem. In this case, each airline could employ its own internal cost function where the cost of the delay assigned to each flight might depend on a variety of internal (possible proprietary) factors unique to that airline. The decision variables in this problem would, in general, include the possibility of canceling certain flights.

Slot Trading Models

As indicated above, the third step of the CDM allocation process, the compression algorithm, can be viewed as a form of inter-airline trading or bartering. Compression is necessary when one or more airlines are assigned slots that they cannot use. Specifically, when a slot time t is earlier than the earliest arrival time $e(f)$ of all of an airlines' unassigned flights, then that airline cannot use the slot t. In such a case, the owner of the slot would be willing to give up the (early) slot for a later one that it can use. As illustrated in Fig. 2, the underlying exchange is not a simple one-for-one trade. Rather, there is a daisy chain of slot reassignments, which results in freeing up the earliest slot usable by the airline that has given up its slot. The compression algorithm is a batch process that identifies all unusable slots and finds for each an appropriate sequence of slot reassignments/exchanges. Research has shown that the problem of finding a set of such exchange sequences is equivalent to finding a set of arc-disjoint cycles in a directed graph (Vossen and Ball 2006a). Viewing the problem in this way leads to the consideration of alternate objective functions and the possibility of



Air Traffic Management, Fig. 2 Compression exchange: AA gives up the 4:00 slot and receives in return the 4:30 slot

including trading mechanism in more complex optimization models.

While the original CDM-based decision support system for GDP's included the batch compression process, later implementations included near-real-time trading mechanisms. The slot credit substitution mechanism is initiated by an airline that wishes to trade an earlier slot for a later one. This mechanism allows an airline to insure it will receive a slot at a particular time before freeing up an earlier slot by canceling a flight. The adaptive compression procedure is initiated by a background process run by the ANSP. The process continuously searches for slots that are in danger of going unused and executes slot exchanges in order to insure that arrival capacity does not go unused.

More recent research (Vossen and Ball 2006b) has focused on implementing more complex slot exchanges, e.g., where an airline gives up two or more slots in exchange for a similar number of other slots. While compression (and its real-time versions) are always motivated by the existence of a slot an airline cannot use, under the more complex trading models, an airline can trade multiple "usable" slots for another set of usable, but higher value, slots. Research has demonstrated that more complex trading schemes can yield an increase in the overall welfare of participating airlines. Additionally, integer programming models have been developed for identifying the best set of trades to execute.

Of course, a very logical further step in the progression of trading mechanisms would be to consider the use of monetary-based exchanges. In fact, it is quite easy to envision the inclusion of side payments with any of the trading mechanisms described above. Research has shown that adding the possibility of side payments can lead to increases in overall welfare over models that do not employ monetary payments. Recent work has developed and analyzed specific mechanisms of this type. However, implementation in practice has yet to take place.

Modeling Equity and Equity Efficiency Tradeoffs

RBS evolved out of a set of human-in-the-loop (war-gaming-like) and consensus-building exercises. It is now accepted as a de facto allocation standard within the U.S. With this background, subsequent research examined its inherent properties as a fair allocation rule. It was also then used as an equity standard in the development of models that considered equity efficiency tradeoffs.

RBS assigns to each flight f a controlled time of arrival $CTA(f)$. ($CTA(f)$ is the time of the slot to which f is assigned, i.e., the t with $x_{ft} = 1$.) The assignment of $CTA(f)$ is equivalent to assigning a delay $d(f)$ to flight f given by $d(f) = CTA(f) - \hat{e}(f)$. Assuming that flight delays, i.e., the $d(f)$ values, are all integer and defining D to be the maximum delay assigned to any flight and $a_i = |\{f : d(f) = i\}|$ for $i = 0,1, 2,\ldots, D$, then the important properties of unconstrained RBS can be defined by,

Property 1: RBS minimizes total delay $= \sum_f fd(f)$.

Property 2: RBS lexicographically minimizes $(a_D,\ldots, a_1, a_0)$. That is, a_D is minimized; subject to a_D being fixed at its minimum value, a_{D-1} is minimized; subject to (a_D, a_{D-1}) being fixed at its lexicographic minimum value, a_{D-2} is minimized; and so on.

Property 3: For any flight f, the only way to decrease a delay value, $d(f)$, set by RBS is to increase the delay value of another flight g to a value greater than $d(f)$.

Property 3, which follows directly from Property 2, expresses a very fundamental notion of equity that has been applied in a number of contexts. It is interesting to note that RBS, which was developed as a practical alternative by means consensus-building exercises, has such elegant and desirable properties. On the

other hand, this may not be surprising in that these properties may represent a large part of the basis for reaching consensus.

These properties show that unconstrained RBS produces a fair allocation. However, RBS is not used in its pure form. Rather, certain flights are exempted from RBS (and given no delay); the flights exempted are "long haul" flights greater than a certain distance away from the GDP (destination) airport. The motivation for these exemptions will be described later when stochastic models are discussed. One then naturally considers whether the exemption policies, in fact, introduce bias (in the sense that certain airlines consistently receive more delay on the average than others). Vossen et al. (2003) showed that exemptions do introduce a bias. In additions, optimization procedures have been developed for mitigating these biases. The approach taken initially computes the unconstrained RBS solution and defines it as the ideal allocation. Optimization procedures are then described that minimize the deviation of the actual allocation from the ideal. The resulting approaches maintain the exemption policies, but take into account the advantages provided to an airline by its exempted flights when allocating delays to its other flights. The principle underlying this work is that equity or fairness can be measured as the deviation from RBS. This basic concept can be applied more generally by considering equity as one objective and another performance criterion, e.g., throughput, as a second objective. One can then consider designing decision support systems that take a multi-objective approach trading off these two objectives.

Resource Allocation Based on User Supplied Priorities

The preceding set of processes can be viewed under a general paradigm in which (1) the ANSP allocates resources to flight operators, (2) each flight operator optimizes the use of the resources it owns, (3) a limited amount of inter-operator trading is supported. An alternative approach to allowing flight operator costs and priorities to be taken into account involves processes in which each flight operator provides priority or tradeoff information to the ANSP and the ANSP takes this information into account in determining resource allocation. This approach underlies the new Collaborative Trajectory Options Program (CTOP), which is now being tested by the FAA for deployment in assigning reroute options to flights competing for common resources. CTOP uses flight operator priority information in determining exactly which resource to give to each flight on a list, but determines priorities among flights based on a variant of RBS. A fundamentally different system could use flight operator inputs to determine the priority order of flights.

One such approach assigns a certain number of credits to each flight operator (Sheth and Gutierrez-Nolasco 2010). These credits constitute a type of artificial currency. Specifically, a flight operator would assign a certain number of credits to each of its flights. These credits would be used in a bidding/negotiation process when competing for access to airspace resources. Simulations and human-in-the-loop experiments have been conducted that show promise for this concept. In concept, it could address some of the tradeoffs that various types of slot trading systems would address, e.g., allowing a flight operator to gain access to an early slot for a highly valued flight by giving up priority for a lesser valued flight. In the end such systems are types of marketplaces, which implies that, in a highly competitive environment, mechanisms must be in place to determine the equivalent of a market clearing price. Research is needed to address such challenges. Another important issue is the design of a fair method for allocating credits to the various flight operators.

Large-Scale Deterministic Optimization Models

There are two broad classes of global air traffic flow models (Bertsimas and Stock Paterson 1998; Helme 1992; Lindsay et al. 1994; Sherali et al. 2002). The first assumes that the trajectory (route) of each flight is fixed and optimizes the timing of the flight's operations. The second allows the route of each flight to vary, as well. While conceptually models of the second type have a much larger decision space, recent research has produced models of the second type with computation times close to those of the first type.

The modeling approach for both cases chooses a time horizon of interest and decomposes it into a discrete set of time intervals. A geographic scope is

also selected. This determines the set of capacitated elements under consideration. Two capacitated elements might include the arrival and departure processes for an airport (or a combined arrival and departure process). Another could be a sector: a volume of airspace with a limit on the number of aircraft that can simultaneously have access. Another could be a waypoint: a point in 3-dimensional space that multiple flights seek to pass through over time. The combination of the model's temporal and geographic scope determines the set of flights to be considered.

For models of the first type, the basic decision variables specify the airspace element occupied by a flight at each time interval, i.e.,

$x_{fte} = 1$ if flight f occupies airspace element e during time interval t; 0 otherwise.

The capacity constraint associated with an element e and time interval t is of the form:

$$\sum_f x_{fte} \leq cap(t, e) \quad \text{for all } t \text{ and } e,$$

where *cap(t, e)* is the capacity of element e during time interval t. For airport arrival and departure capacities and for waypoints, $cap(t, e)$ is equal to the maximum number of flights that could flow through that element during time interval t. For a sector, it is equal to the maximum number of flights that can occupy the sector simultaneously.

The remaining constraints define temporal restrictions on the manner in which each flight can progress through the airspace. For example, they might specify that, once a flight enters a sector, it must remain in the sector for 3, 4 or 5 time intervals. In this case, 3 time intervals would correspond to traversing the sector on a direct path at maximum speed and 5 time intervals might correspond to a longer traversal time based on application of some type of speed control. Since the flight's route is an input, the progression from departure airport through a specific sequence of sectors to a destination airport is a fixed model input, as well.

Models of this type can be solved very efficiently. Of particular note is their use of an alternative set of decision variables. Specifically, the x_{fte} variables are replaced with a set, w_{fte}, defined by:

$w_{fte} = 1$ if flight f arrives at airspace element e by time interval t; 0 otherwise.

While the w variables can be obtained from the x variables through a simple linear transformation ($w_{fte} = \sum_{s=1}^{t} x_{se}$), the w variables are much easier to work with because they produce very simple and natural temporal progression constraints. Further, the associated linear programming relaxations are very strong in the sense that they lead to the fast solution of the associated integer programs (Bertsimas and Stock Paterson 1998). A variety of additional features can be included in models of this type, including the propagation of delays that occurs when a delay in the arrival of a flight causes a delay of an outbound flight that uses the same aircraft. Models can also capture the dependence between an airport's arrival and departure capacities and choose the appropriate combination of the two for each time interval.

A second type of model also allows for flight routes to vary. The most direct way to develop such models would employ variables of the form:

$x_{frte} = 1$ if flight f uses route r and occupies airspace element e during time interval t; 0 otherwise.

Since these variables involve the incorporation of an additional dimension, running times can increase dramatically. While the large-scale models of the previous type, e.g., involving thousands of flights, could be solved to optimality very quickly using commercial integer programming solvers, much smaller instances of problems of the second type could only be addressed uses approximate techniques. Bertsimas, Lulli and Odoni (2011) describe new models with route choice using variables of the first type. This was accomplished by embedding constraints within the formulations that implicitly represent the route choice options.

Stochastic Models

Uncertainty on multiple levels has led to the failure of many attempts at practical implementation of various

air traffic flow management models. To be effective, models must include stochastic components explicitly or they must address problems restricted to limited geographic and time domains for which available information is less subject to uncertainty. The term demand uncertainty describes the possibility that, due to random or unforeseen events, flights may deviate from their planned departure or arrival times or from their planned trajectories. Similarly, capacity uncertainty refers to the possibility that random or unforeseen events will cause changes to the maximum achievable flow rates into and out of airports or through airspace waypoints or to the maximum number of flights that can occupy simultaneously a portion of the airspace. Examples of factors contributing to demand uncertainty include problems in loading passengers onto an aircraft, mechanical problems, queues on the departure airport's surface or in the air and en route weather problems. Examples of factors contributing to capacity uncertainty include weather conditions at an airport or in the en route airspace, failures or degradation of air traffic control equipment, unavailability of air traffic control personnel, and random changes in flight sequences and aircraft mix that require alterations of anticipated flight departure or arrival spacing.

The largest body of work in this area has focused on ground holding models that explicitly take into account uncertainty in airport arrival capacity (Ball et al. 2003; Mukherjee and Hansen 2007; Richetta and Odoni 1993). As discussed in the previous section, optimization models for the ground holding problem subdivide time into an arbitrary number of discrete intervals. Typical time intervals might be 10 or 15 min or even as much as 1 h for the most aggregate models. The rate of arrivals into an airport is called the airport acceptance rate (*AAR*). A GDP is motivated by a reduction in the AAR over a period of time, e.g., four hours, usually due to poor weather. A weather forecast might be characterized by an AAR vector, which specifies the predicted AAR value for a sequence of time intervals into the future. As discussed earlier GDP's must be planned well in advance based on a weather forecast. In a typical GDP caused by a weather disturbance that moves through a region, the AAR would start at its normal level, e.g., 60 arrivals per hour, decrease to one or more degraded levels, e.g., 30 arrivals per hours, for several time intervals, e.g., 4 h, and then return to its original level. If it were known that such a scenario would occur with certainty, then a deterministic ground holding model, such as those discussed earlier, could obviously be used with this scenario providing the capacity constraints input. Of course, in general, there may be significant uncertainty associated with any single AAR vector so that ideally the AAR should be treated as a random variable. The typical stochastic programming modeling approach used takes as input several such scenarios together with associated probabilities. For example, an optimistic scenario indicating no capacity degradation would consist of a vector of hourly AARs of 60 throughout the period of interest, whereas, a more pessimistic scenario might assume that the AAR will be 30 during every hour in the period. Such an input can be characterized as:

$$D_{tq} = \text{AAR for time interval } t \text{ under scenario } q, \quad \text{for } t = 1, \ldots, T \text{ and } q = 1, \ldots, Q.$$

$$p_q = \text{probability of the occurrence of scenario } q, \quad \text{for } q = 1, \ldots, Q.$$

The x_{ft} variables are then defined as in the deterministic ground holding model, but the capacity constraints are replaced with a new set of scenario-based constraints and associated variables. The new variable set is defined by:

$$y_{tq} = \text{number of flights held air from period t to } t+1, \text{ under scenario } q, \text{ for } q = 1, \ldots, Q.$$

The new set of capacity constraints then is:

$$\sum_{f=1}^{F} x_{ft} + y_{t-1q} - y_{tq} \leq D_{tq} \text{ for } t = 1, \ldots, T \text{ and } q = 1, \ldots, Q.$$

Thus, under these constraints, there is a separate capacity for each scenario. However, the y variables allow for flow between time intervals, so the number of flights assigned to land in an interval under a particular scenario can exceed the AAR by allowing excess

flights to flow to a future time interval. Note that this set of capacity constraints defines a small network flow problem for each q, with flights flowing from earlier time intervals to later ones. To be feasible, for each given q, the total arrival capacity for the entire period of interest, $\sum_t D_{tq}$, must be at least as large as the total number of flights (F).

The objective function for the model minimizes the sum of the cost of ground delay plus the expected cost of airborne delay. It requires a parameter, c^a, defined as the cost of holding one flight in the air for one time period:

$$\text{Min}: \quad \sum_{f=1}^{F}\sum_{t=1}^{T} c_{ft}x_{ft} + \sum_{q=1}^{Q} p_q \sum_{t=1}^{T} c^a y_{t-1q}.$$

This class of models has been generalized to address both airport and airspace problems. That is, weather may also cause portions of the airspace to experience capacity reductions or to be blocked entirely. A similar approach to modeling capacity uncertainty can be used.

The models just discussed can be classified as static stochastic models. Specifically, they are two-stage models in which a stage one plan (the x variables – ground delay assignment) is developed but the cost of that plan is measured based on a random stage two process (the realization of the arrival capacity and the ensuing airborne delays). In reality, the stage one decisions can be adjusted in reaction to the random events. For example, if the weather clears early, then most, or even all, flights serving ground delay can be released early. More recent research has modeled the possible adjustment of decisions on ground delays. In general such models can lead to very large scenario trees. However, some research has taken advantage of the fairly simple scenario/capacity structure associated with many GDP plans. Specifically, in many cases there is an onset of bad weather which reduces the AAR from its nominal value, say D^N, to a reduced value, say D^R. Further, it is assumed that the decision to release flights from their assigned ground delay cannot be made until the time at which the AAR switches from D^R to D^N, e.g., this decision will not be made based on a change in the weather forecast, only a change in the actual weather. While this latter assumption might seem like a strong one, it is, in fact, how the system in the U.S. operates today. With this model of the stochastics of the AAR and this dynamic decision regime, a relative simple scenario tree and compact integer program result. Effectively, this dynamic, stochastic model of GDP planning can be cast as a two stage stochastic integer program where the second stage decision variable is the time the weather clears.

Models of this type have been able to formalize the rationale behind giving priority to long-haul flights. As discussed earlier, during GDP's, certain flights are exempt and given no ground delay. The principal set of exempt flights are flights greater than a certain distance from the GDP airport. The heuristic rationale is that such flights would have to be given ground delay well in advance of their arrival at the airport and, therefore, this decision would have to be based on a forecast of weather conditions several hours into the future. Since there is uncertainty there is a (possibly large) likelihood that the ground delay would be applied unnecessarily. Instead these flights are exempt and flights closer to the airport are allowed to absorb the required ground delay if necessary. The formalization of priority based on distance leads to the ration-by-distance (*RBD*) algorithm. RBD is conceptually similar to RBS; the only difference is that Step 2 is replaced by:

Step 2: For each slot t, choose the unassigned flight f the furthest from the GDP airport (with the largest value of L_f) and assign f to t, i.e., set $x_{ft} = 1$.

Here L_f is length of flight f, i.e., the difference between its scheduled arrival time and scheduled departure time. Using a stochastic model of the type just described, i.e., where there is a distribution of possible weather clearance times and a decision to release a flight (or reduce its ground delay) is made as soon as the weather clears, it can be shown that RBD minimizes the total expected delay assigned to all flights in the GDP (Ball, Hoffman and Mukherjee 2010). RBD is not viewed as a practical algorithm since it can assign extreme delays to some short flights; a practical alternative, Equity-Based RBD (*ERBD*), uses the RBD priority principle but ensures the delay assigned to each flight does not deviate beyond a specified limit from the delay RBS would assign.

Stochastic integer programs based on models of this type have also been developed to analyze enroute problems. Since these models have the complexity of 2-stage stochastic programs they are reasonably tractable, while representing what is, from a practical perspective, a multi-stage, dynamic problem.

Concluding Remarks

Air traffic management is of vital importance to the smooth operation of the world-wide economy. The underlying essential problems have a strong systems nature, are large and subject to uncertainty. Moreover, decision-making must dynamically adjust to changing conditions and be distributed throughout multiple diverse organizations. Operations research has much to offer this area.

[2]The University of Auckland, Auckland, New Zealand

Introduction

The dramatic growth of the airline industry over the past thirty years into a highly competitive world-wide transport network has been accompanied by the extensive use of operations research and management science methodology in all areas of airline operations. All airlines make major investments in sophisticated aircraft and employ highly trained and skilled staff. Efficient utilization of such valuable resources is clearly an important objective in the management of a profitable airline.

In 1960, the airline industry recognized the potential benefits of OR/MS by setting up the Airline Group of the International Federation of Operations Research Societies (AGIFORS) as a special interest group. Since that time, annual AGIFORS symposia have been held and the proceedings of these meetings provide excellent documentation of the many applications and problems which have been addressed by the use of OR/MS techniques (Richter 1989). A comprehensive discussion of the direction of OR/MS applications in the airline industry by the late 1980s was given by Teodorovic (1988), and a special issue of *Interfaces* edited by Cook (1989) presented six specific OR/MS airline-industry case studies.

Over the years since then, an extensive range of practical problems involving long-term planning, short-term planning and "day of operation" decision making have been considered and the full range of methods and techniques including forecasting, simulation, heuristics and optimization have been used to provide practical solutions and decision support systems. In particular, such methods as set partitioning and set covering optimization have been widely applied in many airline scheduling problems. In recent years, linear optimization models generated from airline applications have stimulated much research into the development of interior point and improved simplex methods for solving such problems. The following broad application areas of OR/MS in the airline industry can be clearly identified and will be discussed in further detail:

- Flight Scheduling Planning
- Fleet Assignment
- Yield Management
- Crew Scheduling
- Aircraft Maintenance Routing
- Schedule Recovery

Flight Scheduling Planning

The design of a flight schedule is probably the most important and fundamental task for any airline. The schedule which determines the frequency and departure times of flights between airports served by the airline is usually prepared and published many months before it is due to be operated. The preparation of the schedule must take into account forecast passenger demand, the operational limitations of both aircraft and crews, and the access limitations imposed by airports either due to meteorological conditions, airport congestion, operational restricted hours or differential landing tariffs. Besides many constraints on the form of feasible flight schedules, there is also considerable variation in the choice of objective ranging from maximizing profit, maximizing passenger-kilometers, maximizing load factors, minimizing the number of aircraft and minimizing direct and indirect operating costs. A discussion of this problem was given by Soumis and Nagurney (1993).

Two particular forms of schedule also reflect the airlines' mode of operation as either a network or a hub-and-spoke operation. Airlines operating hub-and-spoke systems design schedules that bring many aircraft into a hub airport within a short space of time, thus enabling passengers to transfer to another aircraft before all of the aircraft then depart (on the spokes) from the hub over a short period of time. In both forms of operation, the airline schedule can be represented as a network problem in which one must determine conserved flows of aircraft between ports at times chosen to satisfy operational constraints and optimize a specified objective. Because of the enormous combinatorial complexity of the network model, many heuristic methods have been developed to assist airline schedule planners. The problem continues to motivate the development of improved optimization methods.

Fleet Assignment

Given a predetermined flight schedule, the fleet assignment problem is to determine which aircraft type is assigned to a given flight segment in the carrier's network. The goal of the fleet assignment problem is to assign as many candidate flight-segments as possible in a schedule pattern to specific aircraft types, based on such factors as operating costs, revenues, and operational constraints and capabilities. The problem is formulated and solved as an integer-programming model that permits the assignment of multiple fleet types to a flight schedule simultaneously. The fleet assignment model can be classified as a large multicommodity flow problem with side constraints defined on a time-space network. One of the earliest published articles on the topic of fleet assignment was presented by Abara (1989), who discussed the application of integer linear programming to the fleet assignment problem, and explained how this technique was already being used extensively throughout American Airlines.

Subramanian et al. (1994) presented a solution procedure referred to as Coldstart, which is a fleet assignment methodology developed by Delta Airlines. Coldstart minimizes a combination of operating and passenger spill costs, subject to operational constraints. Hane et al. (1995) outlined a model for the fleet assignment problem and discuss solution problems that often exist with such large problems including degeneracy, that leads to poor performance of standard LP solution techniques. The solution methodology presented incorporates an interior point algorithm, cost perturbation, model aggregation, branching on set-partitioning constraints, and prioritizing the order of branching, in an effort to develop more efficient solution procedures for the problem. Clarke et al. (1996) discussed maintenance and crew considerations in the basic daily fleet assignment problem of Hane et al. (1995), and implementation issues related to its solvability. The solution methodology presented involves the use of the dual steepest edge simplex method and solving the mixed integer problem by branch and bound.

The most recent advances in the fleet assignment problem have included the development of origin-destination based models that incorporate passenger flow issues more accurately into the decision model. These are able to control passenger mix and reflect the upstream and downstream effects of the fleet assignment decision. Jacobs (1999) and Kniker (1998) independently discussed the origin-destination fleet assignment problem.

Yield Management

The yield management process maximizes revenue by selectively accepting and rejecting reservation requests based on its relative value. Excellent reviews with good bibliographies are provided in Weatherford and Bodily (1992) and McGill and van Ryzin (1999). The procedure is designed to manage perishable seat inventory effectively, since an empty seat at flight departure cannot be resold. The control of reservation inventory to maximize revenues is normally accomplished through a series of sequential processes including overbooking, fare mix or discount allocation control, group control and traffic flow control. Overbooking is the process by which additional reservations beyond physical capacity (seats) are sold to compensate for the effects of cancellations, noshows, duplicate bookings and misconnects. The primary objective of discount allocation control is to limit the number of seats sold to lower valued passengers by protecting seats for late booking higher valued passengers. The optimal discount allocation controls result in the optimal onboard mix of full fare, discount, leisure and deep discount passengers to maximize the total onboard revenue. The process of yield management effectively manages the risk associate with this uncertainty and maximizes expected revenues.

Group control is done using a group evaluator that assists in deciding whether to accept or reject the group booking. The group evaluator determines the minimum acceptable fare based on the expected displacement cost of individual passengers, projected group attrition forecast, the size of the group, the peripheral profit, and the number of complementary seats requested by the group.

The process of traffic flow control is very important in an airline network with high levels of connecting traffic. The control of reservation inventory by origin-destination (itinerary) is accomplished using the value of the individual passenger to determine reservation availability. The passenger value is based on several factors including itinerary, departure

date, fare class, actual paid fare, and point of sale. The concept of virtual nesting was developed to approximately control reservation requests by origin-destination. It relies on the aggregation of various origin-destination fare classes that flow over a flight leg into amanageable number of virtual buckets based on reservation value. The value of an origin-destination class is the fare net of up-line and down-line displacement costs. The buckets are serially nested to ensure that as sales build up for a flight, the lower valued classes are automatically closed.

First generation yield management techniques were developed to maximize revenues on a leg-based inventory control scheme. Second generation systems clustered similar origin-destination/fare classes into "buckets" (see Smith et al. 1992, for a comprehensive description of this type of system, with attendant forecasting and performance measurement, at American Airlines), and the current state-of-the-art controls directly at the origin-destination level of detail. In a full origin-destination inventory control environment, reservation inventory is controlled by the actual origin and destination based on reservation value. This is accomplished using a network optimization model that takes the flight schedule, network capacity and the origin-destination demand forecasts and variance by class, to determine the probabilistic bid prices by leg and base compartment (Smith 1998). The bid price can be interpreted as the minimum acceptable fare for a reservation request on a flight leg to be accepted. The bid price for a multiple leg itinerary is the summation of the bid prices on each flight leg. Fares greater than the minimum acceptable fare or the total bid price are open for sale, subject to satisfying the associated fare rules. The fundamental difference between nested controls and origin-destination control is that availability is not prestored, but is dynamically calculated for each reservation request.

Belobaba (1989) discussed the development and application of a probabilistic decision model to airline seat inventory control. The concept referred to as Expected Marginal Seat Revenue (EMSR) takes into account the uncertainty associated with estimates of future passenger demand, as well as the nested structure of booking limits in airline reservation systems. Curry (1990) discussed an optimal airline seat allocation method that handles fare classes nested by origin and destinations. The solution procedure combines concepts from marginal seat revenue methods and mathematical programming to develop equations that find optimal allocation of seats when fare classes are nested on an origin-destination itinerary and the inventory is not shared among origin-destinations.

Williamson (1992) provided a comprehensive review of the application of mathematical programming and network flow models to the origin-destination seat inventory control problem. Belobaba (1998) reviewed the evolution of airline yield management from fare class to origin-destination seat inventory control. The author highlights the major milestones in the airline yield management arena, discusses the origin-destination seat inventory control problem, and outlines a new solution approach that uses the minimum acceptable bid prices derived from leg-based optimization models to control seat availability. Talluri and van Ryzin (1999a) discussed theoretical issues relating to bid prices, including an example of how they can be non-optimal, while also showing that bid prices are asymptotically optimal. A randomized version of the deterministic linear-programming method for computing network bid prices was given in Talluri and van Ryzin (1999b).

Crew Scheduling

The topic of crew scheduling can be subdivided into several categories including crew pairing generation, crew rostering, preferential bidding, and crew recovery. The crew pairing problem consists of constructing a set of pairings that cover at minimum cost a given set of flight segments. Typically all flight legs pertain to the same aircraft fleet and individual crew members are not considered in the problem. Each pairing has to be constructed in accordance with the prevailing collective agreement and airline regulations. The crew rostering problem entails the construction of monthly work schedules that assign pairings and rest periods to each employee, while considering pre-assigned activities such as recurrent training and personal holidays. The preferential bidding problem is a slight variation of the crew rostering problem wherein employee preferences are incorporated into the crew scheduling process. Although a large amount of research has been done

on crew scheduling, the problem of crew recovery in the aftermath of irregular airline operations has only recent surfaced in the research community.

Gershkoff (1989) outlined an optimization model that uses a set-partitioning framework, wherein the rows represent flights to be covered and the columns represent candidate crew trips. The primary objective of the model is to minimize the cost of flying the published airline schedule, subject to operational crew constraints. The crew scheduling problem is formulated as an integer-programming problem and can be solved using a commercial optimization software package. In these early efforts, it was found that a global optimization to the problem was difficult to achieve, and much research focused on the development of efficient heuristic procedures to address the problem. Concepts such as dynamic column generation and LP relaxation play a major role in the ability of researchers to tackle and successfully solve such largescale mathematical programs of crew pairing optimization. Crew pairing optimization has evolved substantially in the last ten years, as advances in computer technology, CPU run time, and the availability of efficient optimization software packages, have given practitioners the ability to solve large problems (Barutt and Hull 1990; Anbil et al. 1991). Innovative methods such as constraint branching (Ryan and Foster 1981), branch and cut (Hoffman and Padberg 1993), and column generation (Lavoie et al. 1988; Desrosiers et al. 1993) have successfully solved problems with very large numbers of feasible pairings.

The rostering problem involves the allocation of pairings to crew members to build a legal and feasible roster for each crew member in a crew rank. Often, such allocations are based on the so-called seniority preferential bidding (SPB) system in which pairings are allocated to crew members in decreasing order of seniority satisfying, whenever possible, each individual crew member's bids for certain types of work or rest periods. Heuristic algorithms of a greedy sequential type are most commonly used to solve this allocation problem, but they usually result in an inequitable distribution of work and often some pairings (referred to as "open flying") remain unallocated. An alternative form of the rostering problem involves the equitable allocation of pairings to all crew members of a crew rank. Measures of equitability are usually based on the notion that all members of a crew rank should do approximately the same amount of work. Equitability rostering problems can again be formulated as specially structured and generalized set partitioning models (Ryan 1992). Many alternative legal and feasible roster lines are generated for each crew member and the optimal solution of the model selects one line for each crew member to cover all pairings with the required number of crews and at a minimal total cost. The cost in this context can reflect an individual's preference for certain types of work. Column generation methods can again be used to reduce the need to generate many roster lines a priori for each crew member.

Aircraft Maintenance Routing

The aircraft routing problem is traditionally solved after the successful completion of the fleet assignment problem. It involves the allocation of candidate flight segments to a specific aircraft tail number within a given sub-fleet of the airline. The process of aircraft routing has traditionally been a manual activity at many carriers, but in recent years, researchers have developed efficient solution procedures that can be applied to the problem. During the normal operations of a carrier, situations often develop wherein modifications have to be made to the existing schedule plan. In addition, due to the inherent variation in passenger demand over the course of the week, airlines find it necessary to adjust their daily flight schedules to adequately meet demand. This will result in the need to make minor modification to aircraft routings and possibly fleet assignments.

Bard and Cunningham (1987) explored aircraft routing, while taking into consideration the benefits of through-flight schedules and the potential for increased revenues. Talluri (1996) describes an algorithm for making aircraft swaps that will not affect the equipment type composition overnighting at various stations throughout the airline's network. He also outlines the application of the swapping procedure in the airline schedule development process. Soumis et al. (1980) presented a model for largescale aircraft routing and scheduling problems which incorporates passenger flow issues. The authors discuss the technique used to transfer

information from the passenger flow problem to the aircraft routing problem. Daskin et al. (1989) discussed a Lagrangian relaxation approach to an integer-linear program model which is used to assign aircraft to routes in a hub and spoke network. Zhu et al. (1995) presented a mathematical formulation for the aircraft rotation problem and discuss its similarity with the asymmetric traveling salesman problem. Kabbani and Patty (1992) discussed aircraft maintenance routing at American Airlines, and the application of mathematical programming techniques to solve the problem. Desaulniers et al. (1994) outlined the daily aircraft routing and scheduling problem and presented two different formulations of the problem. The first is a set partitioning type formulation and the second a time constrained multicommodity network flow formulation.

Schedule Recovery

Schedule recovery in the aftermath of irregularities address how airlines reassign operational aircraft to scheduled flights. The main aspect of recovery for an airline is centered around flight rescheduling. Today, flight rescheduling is typically done manually at airlines, since research on the topic is relatively a recent phenomenon. Teodorovic and Stojkovic (1990) discussed a greedy heuristic algorithm for solving a lexicographic optimization problem which considers aircraft scheduling and routing in a daily schedule while minimizing the total number of canceled flights in the network. Jarrah et al. (1993) presented an overview of a decision support framework for airline flight cancellations and delays. Two separate network flow models provide solutions in the form of a set of flights delays (the delay model) or a set of flight cancellations (the cancellation model), while allowing for aircraft swapping among flights and the utilization of spare aircraft.

Yan and Yang (1996) developed a decision support framework for handling schedule perturbations. The framework is based on a basic schedule perturbation model constructed as a time-space network from which several perturbed network models are established for scheduling following irregularities. Cao and Kanafani (1997a, b) discussed a real-time decision support tool for the integration of airline flight cancellations and delays. They presented a quadratic 0-1 programming model for the integrated decision problem that maximizes operating profit, while taking into consideration both delay costs and penalties for flight cancellations. Arguello et al. (1997) presented a time-band optimization model for reconstructing aircraft routings in response to groundings and delays experienced in daily operations. Clarke (1997) discussed the airline schedule recovery problem that provides a comprehensive framework for reassigning operational aircraft to scheduled flights in the aftermath of irregularities. It is formulated as a mixed-integer linear-programming problem and solved using an optimization-based solution procedure. Lettovský (1997) outlined the airline integrated recovery problem that addresses crew assignment, aircraft routing, and passenger flow. The problem is formulated as a mixed-integer linear-programming problem and solved using Benders' decomposition. The master problem generates a cancellation and delay plan that satisfies imposed landing restrictions and assigns equipment types. The decoupled aircraft and crew subproblems are first solved and then the passenger flow subproblem is solved to determine new itineraries for disrupted passengers.

Concluding Remarks

Over the last forty years, operations research has played an integral role in many of the technological advancements credited to the airline industry. For instance, revenue management was developed using concepts from statistics, forecasting, and linear optimization. The various stages of the airline scheduling process have been modeled and implemented using ideas from network flow theory and mathematical programming. As researchers continue to make advances in these underlying fields of operation research, practitioners will be given added tools to tackle unanswered problems that exist in the industry. The continued improvement in commercial optimization software packages has encouraged and fostered the development of many of the state-of-the-art decision support tools now in use or currently under development. Such improvements, coupled with advances in computer hardware, will continue to push the horizon for OR practitioners in the airline industry.

Algebraic Modeling Languages for Optimization

Robert Fourer
Northwestern University, Evanston, IL, USA

Introduction

Algebraic modeling languages are sophisticated software packages that provide a key link between an analyst's mathematical conception of an optimization model and the complex algorithmic routines that seek out optimal solutions. By allowing models to be described in the high-level, symbolic way that people think of them, while automating the translation to and from the quite different low-level forms required by algorithms, algebraic modeling languages greatly reduce the effort and increase the reliability of formulation and analysis. They have thus played an essential role in the spread of optimization to all aspects to OR/MS and to many allied disciplines.

Background and Motivation

Practical software packages for solving optimization problems emerged in the 1950s, as soon as there were computers to run them. Initially based on linear programming, these solvers were soon generalized to allow for nonlinearities and to accommodate integer variables and other discrete decisions. Despite continuing progress in algorithms and in computing, however, by the beginning of its second decade large-scale optimization had come to be seen as failing to live up to its potential. The key weakness in early optimization systems was not in their algorithms, however, but in their interaction with modelers. The human time and cost of preparing a solver's

input and examining its output often greatly dominated the computer costs of solving. The cause of this difficulty, and its ultimate cure, can best be understood by considering the steps of the optimization modeling process and their interaction with the technical requirements of large-scale optimization.

The process of building practical optimization models involves several interrelated steps. The first and most important is extensive communication with the owner of a decision problem to identify the problem ingredients and to ascertain the extent to which optimization is feasible within the managerial structure of the client organization and the cognitive limitations of the model user. Next is the formulation of a mathematical abstraction of the problem — a model — that offers a sufficiently accurate characterization of the real situation in terms of reasonably available data. Further steps build datasets, generate the corresponding optimization problem instances, feed the problem instances to solvers, run the solvers to produce results that are optimal or near — optimal by the model's criteria, and process the results into descriptions of decisions in forms that clients can understand and analyze. These tasks are carried out repeatedly in a kind of feedback loop, as further communication results in model modifications and data refinements due to invalid assumptions, bad data, programming errors, and (most interestingly) the identification of previously unelucidated policies, constraints and preferences. The success of an optimization application depends critically on how fast one can implement the central feedback loop — formulation, solution, analysis, revision. The faster these steps, the greater the likelihood that the modeling effort will receive sufficient attention from the client in the communication phase to ensure that the model will eventually be adopted and supported. Thus, as the number — crunching solution phase became progressively more efficient with advances in algorithms and computers, the steps involving human analysts became the bottlenecks in this process.

In fact, the optimization development cycle was found to take much more analyst time than expected. The culprit was the awkward and error-prone work of converting an optimization problem between the modeler's conception and the algorithm's representation. Indeed, the natural way for a modeler to think about and express models is in direct conflict with the input requirements of solution algorithms. As detailed in Fourer (1983), whereas the modeler's form is symbolic, general, concise, and understandable to other modelers, the solver's form is contrary in every respect: explicit, specific, extensive, and convenient for computation. For all but the smallest and simplest instances, the only practical way to make the conversion from the modeler's to the algorithm's form is by writing a computer program for the purpose, and it was the continued maintenance and debugging of this program in successive cycles of the development process that unexpectedly soaked up so much analyst time. Whether a program of this kind is working correctly is particularly hard to confirm, as the only detailed evidence of its performance consists of voluminous coefficient lists and other details that are specifically intended for algorithmic efficiency rather than human comprehension.

Optimization modeling languages were conceived as a way of alleviating this bottleneck of conversion. They allow people to convey their formulations to computer systems in much the same way that they would write them out or describe them to colleagues. Computer systems that implement modeling languages also facilitate analysis and reporting using the terminology of the model, thus further speeding the development cycle.

Any convenient form of representation for some class of optimization applications can in principle give rise to a modeling language. Many general-purpose modeling languages, however, are based on the familiar mathematical representation of an optimization problem as the minimization or maximization of a function of decision variables, subject to equations and inequalities in functions of the variables. The most popular languages are founded in particular on familiar expressions — like $\sum_{j=1}^{n} a_{ij} x_j$, $\sqrt{\sum_{s \in S} (g_{rs} - h_s)^2}$, or $G_{km} \cos(\delta_k - \delta_m)$ — that use the operators and functions of elementary algebra, though written in a form that requires only a computer character set. Most such languages have been generalized through the use of notations from logic, computer programming, and other disciplines, but in recognition of their origins they are widely known as algebraic modeling languages (Bisschop and Meeraus 1982).

The initial popularity of algebraic modeling languages derived in part from their users' familiarity with mathematical optimization theory. They quickly became recognized as offering a valuable tradeoff between the convenience of highly application-specific representations and the power of informal natural-language problem descriptions. Their combination of precision and generality enabled them to support optimization as a paradigm for modeling and decision making in diverse applications of operations research and throughout engineering, science, economics, and management. At the same time, their flexibility enabled them to accommodate the unique features that distinguish individual applications in realistic situations.

Example. To give a further view of the issues involved in designing, selecting, and using an algebraic modeling language, a modest example of a model of optimal multiperiod transportation of a single commodity is presented. The presentation describes the model first in words and mathematical formulas, and then equivalently in one of the widely used modeling languages, concluding by describing three major aspects of working with the model: the specification of data, the invocation of solvers, and the examination of results.

Mathematical formulation. To begin describing an algebraic model for transportation, it may be said that there is a set I of cities where supply of a product originates, and a set J of cities where demand must be met. A set of links $L \subseteq I \times J$ specifies those origin-destination pairs (i,j) for which shipments from i to j are possible. The goal to plan for the next T weekly time periods.

The objective of this model is to decide how much to ship from each origin to each destination in each week, so as to minimize the total cost of all shipments. Decision variables $x_{ijt} \geq 0$ and parameters $c_{ijt} \geq 0$ for each $(i,j) \in L$ and $t = 1, \ldots, T$ are introduced, representing respectively the amounts to be shipped (which will be determined by optimization) and the costs per unit of shipment (which are supplied as data). In terms of these quantities, the objective may be written algebraically as

$$\text{Minimize} \sum_{(i,j)\in L} \sum_{t=1}^{T} c_{ijt}\, x_{ijt}$$

The essential constraints on the decision variables are next described in terms of parameters a_{it} for each $i \in I$ and $t = 1, \ldots, T$, representing the amount that becomes available for shipment at origin i in week t, and b_{jt} for each $j \in J$ and $t = 1, \ldots, T$, representing the amount required to meet expected demands at destination j in week t. The possibility of week-to-week fluctuations in shipping costs suggests that not all supply should be shipped out in the week that it becomes available. Decision variables y_{it} for each $i \in I$ and $t = 1, \ldots, T$ are also introduced, to represent the amount of product in inventory at origin i at the end of week t. The following algebraic constraints then serve to express the limitations on shipping out of each origin and the requirements of meeting demand at each destination:

$$\sum_{j\in J:(i,j)\in L} x_{ijt} + y_{it} \leq a_{it} + y_{i,t-1}, \text{ for each } i \in I, t = 1, \ldots, T$$

$$\sum_{i\in I:(i,j\in L)} x_{ijt} = b_{jt}, \text{ for each } j \in J, t = 1, \ldots, T$$

For the sake of this simple model the possibility of initial inventories is disregarded, thus implicitly setting to zero all terms y_{i0} in the origin constraints for $t = 1$.

The shipment plan is also commonly subject to certain operational considerations. As just one example, the amount shipped over link (i,j) in all weeks may be required to sum to at least a certain amount, given by a parameter $d_{i,j,}$ if that link is used in any period at all. A quite general way of implementing this restriction through algebraic constraints is by defining a corresponding collection of decision variables z_{ij} that can only take the values 0 or 1. Then it may be written:

$$d_{ij}Z_{ij} \leq \sum_{t=1}^{T} x_{ijt} \leq \min\left(\sum_{t=1}^{T} a_{it}, \sum_{t=1}^{T} b_{jt}\right) z_{ij}, \text{ for each } (i,j) \in L$$

which forces shipments to be zero when z_{ij} is zero, or to be at least $d_{i,j}$ (and at most some implied upper bound) when z_{ij} is one.

Modeling language formulation. The representation of this model in an algebraic modeling language is fundamentally the same as this mathematical formulation, with the differences deriving mainly from the need to communicate the model unambiguously and to use a standard character

set. Thus for instance in the AMPL modeling language (Fourer et al. 1990) the sets and parameters that describe the data might be specified as follows:

```
set ORIG; # origins
set DEST; # destinations
set LINKS within {ORIG,DEST};
param T integer > 0;
param supply {ORIG,1..T} >= 0;
param demand {DEST,1..T} >= 0;
param cost {LINKS,1..T} > 0;
param minShip {LINKS} >= 0;
```

AMPL defines a standard indexing expression such as {ORIG,1..T} to correspond to a statement like "for each $i \in I, t = 1, \ldots, T$" in the mathematical formulation (though the i and t need be included only where actually used). The use of more meaningful names like ORIG for I and supply for a, while not required, often proves useful for keeping models understandable as they grow in complexity. Models can also be more thoroughly documented through a variety of comments, which are seen here for the first two sets but will be otherwise omitted in this description for the sake of brevity.

Decision variables are next defined in much the same way as parameters:

```
var Ship {LINKS,1..T} >= 0;
var Inv {ORIG,1..T} >= 0;
var Use {LINKS} integer >= 0, <= 1;
```

Indeed the only difference between parameters and variables is that the former are specified as part of the data while the latter are given their values by the solver so as to optimize the objective. Given the definitions in this example, AMPL's statement for the objective of the model is as follows:

```
minimize TotalCost:
  sum {(i,j) in LINKS, t in 1..T} cost
  [i,j,t] * Ship[i,j,t];
```

This is the same algebraic expression as in the mathematical formulation, adapted for input to a computer system; sum {...} corresponds to the sigma expressions, while cost[i,j,t] and Ship[i,j,t] are the AMPL representations for c_{ijt} and x_{ijt}. An explicit operator * is introduced to represent the multiplication that is customarily implicit in mathematical expressions.

Constraints are similarly converted to algebraic expressions in the modeling language. They are somewhat more complex than the objective because they come in indexed collections and use relational operators for equalities and inequalities:

```
subject to Supply {i in ORIG, t in
1..T}:
  sum {(i,j) in LINKS} Ship[i,j,t] +
  Inv[i,t]
    <= supply[i,t] + (if t > 1 then Inv
    [i,t-1] else 0);
subject to Demand {j in DEST, t in
1..T}:
  sum {(i,j) in LINKS} Ship
  [i,j,t] = demand[j,t];
subject to ZeroMin1 {(i,j) in LINKS}:
  minShip[i,j] * Use[i,j] <= sum
  {t in 1..T} Ship[i,j,t];
subject to ZeroMin2 {(i,j) in LINKS}:
  sum {t in 1..T} Ship[i,j,t] <=
    min (sum {t in 1..T} supply[i,t],
      sum {t in 1..T} demand[j,t]) *
      Use[i,j];
```

The emphasis is on keeping the original forms of the constraints as much as possible, while letting the AMPL translator automate the work of evaluating coefficient expressions, collecting terms on the left, and other regularizations that may be required by solvers. Each modeling language does introduce some changes; here AMPL requires the double-inequality constraint to be split in two, but streamlines the specifications of the supply and demand constraints by interpreting {(i,j) in LINKS} so that it specifies indexing over only whichever index has not already been fixed. Also the assumption of zero initial inventories must be made explicit, in this example by using an if-then-else construct to handle inventories at the end of "week 0" specially.

Specification of data. Each modeling language offers its own format for associating actual data values with the sets and parameters in the symbolic model. A small collection of data for our example could be specified by an AMPL text file that begins as follows:

```
set ORIG := YYZ LAF CVG PIT CLE;
set DEST := ABE ORF;
set LINKS := (YYZ,ABE) (YYZ,ORF)
(LAF,ABE) (CVG,ORF)
  (PIT,ABE) (PIT,ORF) (CLE,ABE)
  (CLE,ORF);
param T := 5;
```

```
param demand: 1 2 3 4 5 :=
  ABE 1000 1200 1900 2500 2000
  ORF 2100 3000 4900 7700 5000;
param supply: 1 2 3 4 5 :=
  YYZ 2100 2250 3190 3120 3500
  LAF 1400 1250 1320 1220 1100
  CVG 1650 1250 2290 2120 2300
  .......
```

Model and data together specify a particular instance of an optimization problem for which a solution can be sought.

Modeling language systems typically also offer facilities for exchange of data with popular databases, spreadsheets, and other repositories of data for decision support. Indeed there is a close correspondence between the way that data values are described in algebraic models and the way they are organized in relational databases (Fourer 1997). Close interaction with data management software is often important to the integration of optimization into business operations.

Invocation of solvers. Modeling language software automatically reads and interprets a model and data, generates an instance, and conveys the instance to a solver in the required form. In AMPL it suffices to give only a few commands for these purposes:

```
ampl: model multiEORMS.mod;
ampl: data multiEORMS.dat;
ampl: option solver cplexamp;
ampl: solve;
  73 variables:
     8 binary variables
     65 linear variables
  51 constraints, all linear;
  221 nonzeros
  1 linear objective; 40 nonzeros.
  CPLEX 12.2.0.2: optimal integer
  solution; objective 288503.5
  65 MIP simplex iterations
  2 branch-and-bound nodes
```

The solver software is a separate product for which there may be many alternatives. For this model, a different mixed-integer programming solver might have been used instead:

```
ampl: model multiEORMS.mod;
ampl: data multiEORMS.dat;
ampl: option solver gurobi;
ampl: solve;
  Gurobi 4.0.1: optimal solution;
  objective 288503.5
  71 simplex iterations
  plus 52 simplex iterations for
  intbasis
```

Also a full variety of options, specific to each solver, are accessible as needed to set algorithmic options and report progress of long runs.

Examination of results. Once the solver has returned a solution, the same expression forms that are so convenient in describing the model to the computer system can also be used to describe the results to be viewed. For example to show for each link the ratio of total shipments to minimum shipment over all periods, one can simply ask AMPL to display the appropriate sum, adapting the same summation syntax that was used in the model:

```
ampl: display {(i,j) in LINKS}
ampl? sum {t in 1..T} Ship[i,j,t] /
minShip[i,j];
: ABE    ORF :=
CLE 0    1.69032
CVG .    1.48992
LAF  1.38636 .
PIT 0    0
YYZ 1    2.99143
```

Simple displays of this kind do much to support the cycle of development, by speeding the modeler's aggregation, transformation, and analysis of solutions. For later deployment of the model, facilities are also available for writing more precisely formatted text and for sending results off to other software for analysis.

Advantages

The fundamental concept of algebraic modeling languages — that the entire optimization modeling cycle is best carried out at the level of the model formulation — makes possible the creation of modeling systems that have a number of desirable characteristics. This article has already described how such systems promote optimization modeling by making the entire process more efficient and reliable. The modeling language concept has proven to have other benefits as well. Principally these relate to independent treatment of distinct aspects of

optimization, and to extensions well beyond linear optimization.

Independence. In contrast to the highly integrated design common of software for mathematical and statistical modeling and for simulation, modeling language systems for optimization have promoted an independence of model, data, and solvers. This property has proved to be of benefit of users in several ways.

Because the sets and parameters of a model are described symbolically along with the variables, objectives, and constraints, the same model readily describes any number of problem instances of different sizes and purposes. This model-data independence allows prototypes to be scaled up quickly to larger and more realistic scenarios through changes to the data files alone. Equally it provides flexibility to experiment with different formulations on the same data, as is often essential for finding tractable approaches to difficult mixed-integer modeling applications. Following the initial development stages, model-data independence is also beneficial, allowing the model to be frozen while deployment focuses on periodically generating data for new runs. The full symbolic model description remains accessible, however, whenever modifications are necessary to accommodate new circumstances or analyses.

Because modeling languages are designed to describe models and their data in an abstract way, they are not tied to particular software for optimization or even to particular methods. This model-solver independence allows instances to be benchmarked over a range of solvers. The choice of a solver for deployment can then be based on a tradeoff between price and performance, and can be revisited as optimization technology evolves. The very substantial changes in linear optimization packages that have occurred over recent decades have thus not required corresponding changes in modeling language design.

Another virtue of model-solver independence is to relieve the analyst of much tedious work of converting between the modeler's form and the various algorithms' forms. Originally this work consisted mainly of generating coefficient lists and bound vectors. But as languages have become more sophisticated it has come to include conversions to linear representations from other forms that may be closer to the original model conception, such as piecewise-linear formulations and network node-arc descriptions.

Extensions. Algebraic languages can express nonlinear optimization problems as easily as linear ones, simply by permitting expressions that are nonlinear in the variables. Thus for instance in our transportation example if it is desired to encourage shipments of moderate size, neither too small nor too large, the objective could be changed to

$$\text{Minimize} \sum_{(ij)\in L} \sum_{t=1}^{T} c_{ijt} \frac{x_{ijt}^{\alpha}}{1 - x_{ijt}/l_{ij}}$$

where $0 < \alpha < 1$ and l_{ij} is some positive link capacity. To specify this in a modeling language it suffices to write the corresponding nonlinear expression:

```
minimize TotalCost:
  sum {(i,j) in LINKS, t in 1..T}
    cost[i,j,t] * Ship[i,j,t]^alpha / (1 - Ship[i,j,t]/
    lim[i,j]);
```

After the model and data have been processed, a representation of each nonlinear objective and constraint expression is included as part of the instance representation passed to the solver interface. The interface then uses this representation to compute function values at successive points generated by the solver as it iterates toward the optimum; the interface also provides analytical (not approximate) first and second derivatives automatically by methods that avoid the overhead of symbolically differentiating each nonlinear expression (Rall and Corliss 1996; Griewank and Walther 2008). This approach is considerably more efficient and less error-prone than working directly with the nonlinear solver, which would require writing, debugging, and maintaining a program for each nonlinear expression and its derivatives.

The technology for recognizing and processing conventional nonlinear expressions extends moreover to virtually any kind of expression that can be written in terms of functions and operators. Thus, it is possible to substantially extend the range of models that can be expressed naturally through algebraic modeling languages. Current implementations allow for example the specification of complementarity conditions, and the description of logical restrictions

using operators like "or" and "not" rather than through the introduction of zero-one variables. Also special cases like quadratic objectives and constraints can be detected and transformed automatically.

The algebraic expressions that are useful in describing individual objectives and constraints are also useful in describing manipulations of models and transformations of data. Thus almost as soon as modeling languages became available, users started finding ways to adapt model notations to implement sophisticated solution strategies and iterative schemes. These efforts stimulated the evolution within algebraic modeling languages of scripting features, which include statements for looping, testing, and assignment. Thus, for instance, to test the sensitivity of our multiperiod transportation model to the minimal-shipment thresholds, the modeler could write a simple loop:

```
for {k in 1..10} {
  let {(i,j) in LINKS} minShip[i,j] := minShip[i,j]
  + 250;
  solve;
  if solve_result = "infeasible" then break;
}
```

Industrial and research applications now commonly employ scripts involving many hundreds of lines. The efficiency and convenience of algebraic modeling is thus extended to situations much more complex than the solving of individual optimization problems.

Alternatives

The ideas and benefits of algebraic modeling languages are available to various extents in several kinds of software.

General-purpose algebraic modeling languages embody model-data-solver independence to the greatest degree, supporting links to numerous independently-developed solvers and data-management systems. The most widely used commercial systems in this category are AIMMS (Paragon Decision Technology 2011), AMPL (AMPL Optimization 2011), GAMS (GAMS Development 2011), and MPL (Maximal Software 2011); for noncommercial uses, GNU MathProg (Free Software Foundation 2011) and Zimpl (Zuse Institute 2011) are open-source alternatives licensed under the GNU GPL. All base their language designs on the same fundamental ideas, though with varying specifics in some key respects. They differ more substantially in aspects of their user, solver, and data management interfaces.

Solver-specific algebraic modeling languages offer similar designs but have been implemented to be used mainly or exclusively with one solver developer's products. By forgoing solver independence, they can offer more complete and integrated support for one suite of solvers, often including ones that go beyond the traditional algorithmic approaches for linear and smooth nonlinear problems. Among the best-known are LINGO (LINDO Systems 2011a), Mosel (Fair Isaac 2011), and OPL (IBM Corporation 2011b).

An algebraic modeling framework for optimization can also be implemented within a general object-oriented modeling language. Specialized object types are defined to represent common model entities such as parameters, variables, and constraints; then all of the standard operators and functions are overloaded to act specially when applied to these types. Thus for example using the CPLEX Optimization Studio's Concert C++ library (IBM Corporation 2011a) one can make definitions such as

```
IloEnv env;
IloNumArray supply(env);
IloNumVarArray Use (env, nOrig, 0, 1, ILOINT);
IloExpr totalShipFrom(env);
```

and then express, for example, some supply-limit constraints by writing

```
for (i = 0; i < nOrig; i++) {
  for (j = 0; j < nDest; j++) {
    totalShipFrom += Ship[i][j];
  }
  mod.add(totalShipFrom <= supply[i] * Use[i]);
}
```

What appear to be arithmetic and comparison operations are in fact interpreted as instructions to build up a constraint data structure for an affiliated solver. A similar Concert interface is available for Java and .NET, and the same idea with more general-purpose solver support has been carried through by, among others, FLOPC++ (COIN-OR 2011), OptimJ (Ateji 2011) for Java, and Pyomo (Sandia 2011) for Python. Compared to languages specially designed for algebraic modeling, these object-oriented tools have less natural representations — particularly in the use of indexing

sets — and require more user involvement in the lower-level aspects of programming. They can, however, offer the advantages of a much richer programming environment than is afforded by the scripting facilities of specialized modeling languages; also they hold out the possibility of simplifying the integration of optimization models into broader applications.

Several kinds of modeling language integration with general-purpose analytical tools have also proved popular. Some general-purpose modeling languages have connections to solvers running under MATLAB (Mathworks 2011), and there is a MATLAB-based connection from AMPL to many independent solvers through the TOMLAB environment (Tomlab Optimization 2011). The AMPL-like OPTMODEL language (SAS Institute 2011) supports SAS/OR solvers as an integrated part of the SAS business analytics system. By far the most popular are modeling languages implemented as Microsoft Excel add-ins, notably the Frontline Premium Solver (Frontline Systems 2011) and What'sBest (LINDO Systems 2011b), with a variety of solver options. Because these languages are closely tied to Excel spreadsheet data forms, they are very limited in power and expressiveness. They offer, however, the very substantial benefit of being able to integrate optimization into the most widely used environment for all kinds of business analyses.

Extensions

Enhancements to algebraic modeling languages are basically of two kinds: extensions to the languages themselves, and improvements to the ways in which the languages interact with other systems.

Modeling language extensions tend to be driven by solver developments. Whenever algorithms are developed to effectively solve new forms of optimization problems, modeling language developers are challenged to provide more convenient support. Operators and syntaxes may be added to let modelers describe new forms in the most natural ways, as happened, for example, with the advent of more effective solution strategies to handle complementarity conditions (Ferris et al. 1999). Alternatively, additional logic may be introduced to detect special cases that are significant to new algorithms, as occurred with the discovery of efficient methods for second-order cone problems that were equivalent to several common kinds of nonlinear constraints (Lobo et al. 1998); here the recognition technology is still in the process of being developed. Ferris et al. (2009) survey a variety of such problems including also bi-level and generalized nonlinear optimization. Constraint programming solvers have motivated a variety of extended forms for logical and discrete optimization (Lustig and Puget 2001) which have also proved to be valuable for describing discrete optimization more naturally to other kinds of solvers.

Enhancements to the interfaces and interoperability of modeling language systems tend to be driven by more general developments in computing. This has been seen in the creation of more sophisticated user interfaces for model building, more powerful object-oriented programming interfaces for embedding models within larger applications, and closer links to data management systems. Popularity of Python-based optimization modeling tools is an example of such a trend. Another is the growing attractiveness of optimization "software as a service" — as pioneered by the NEOS Server (Czyzyk et al. 1998; Dolan et al. 2002) — which seems likely to motivate widespread access to algebraic modeling languages "in the cloud" in ways that will foster even more efficient and convenient development cycles for optimization.

Analytic Hierarchy Process

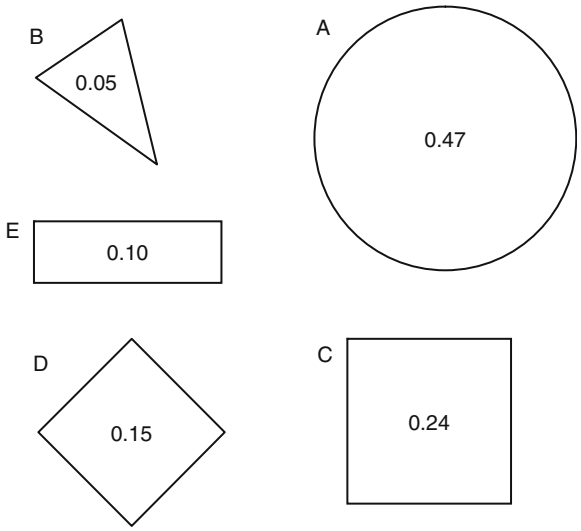
Thomas L. Saaty
University of Pittsburgh, Pittsburgh, PA, USA

Introduction

It is safe to say that people in general think that to measure something is to apply a scale with an arbitrary unit to it designed to measure things with respect to some property. One would then read the numbers on the scale to get the measurement. Such scales are hard physical scales or soft ones like the ones that are used to measure IQ and creativity. What is clear is that whatever is measured must sustain the property being measured long enough to get a reading. Human behavior varies with the circumstance and thus eludes measurement. That is not all. Some things can happen only if other things happen and how strongly they happen depends not only on the strength of those other things but also on their number and variety. How can one capture and measure something whose measurement constantly changes because it depends on a myriad other things that may also need to be measured? What kind of special scale is used to take such measurements? Money, weight, or speed? Hardly.

It is possible to measure in another fundamentally different way. Before showing how, we need to answer the one question: What use do we intend to make of the measurements? Clearly no number speaks to us directly. We must interpret what it means out of our experience or that of an expert who can interpret it for us according to the need or purpose for which it is taken. In other words, to use measurement we need experience and judgment. It appears that our own and other people's subjective perceptions are the bottom line for the meaning and the use of measurements even in spite of how people speak of the objectivity of science. Presumably, objectivity means we will arrive at the same conclusions when we start with the same assumptions if we reason logically, or we will obtain the same measurement if we all follow the same rules. But logic itself is a linear process that goes from assumption to conclusion and cannot be used to synthesize the outcome of many interdependent causes that produce effects that may themselves be part of the causes, so a new way is needed to think about and draw conclusions in such complexity.

In the end, we must depend on our collective understanding to deal with the world. Since it is expert and subjective judgment that interprets what measurements mean and how important they are, can we turn this around and instead associate numbers directly with judgments in such a way that we can derive scales whose readings tell us about the priority or relative importance of what we think we want to measure in some cases without the need for making measurements? If we can do that then we can also ask the expert to use judgment to prioritize intangibles: things or ideas for which we have no measurements. Perhaps we can deal with the meaning of all properties tangible or intangible using priorities so long as we use experienced and informed judgment. The physical sciences are based on formulas that deal with



Analytic Hierarchy Process, Fig. 1 Area example

variables and their measurements from observations that are made and on the interpretation by experts of what the numbers after they are combined in a formula mean. Can we extend the use of expert judgment in a mathematically credible way to thinking in the nonphysical sciences? Let us begin by illustrating how a process that involves expert judgments works with a simple example.

Consider a person who would like to estimate the relative area of the five geometric shapes given in Fig. 1. For the purpose of this illustration, the relative area inside each shape obtained from actual measurement by using a ruler and dividing each measurement by the sum of all five measurements is also provided. Of course, in real-life situations the relative areas would not be known to the person. He must estimate the relative sizes of the figures by comparing them in pairs. A pairwise comparison consists of identifying the figure with the smaller area of the two, and estimating numerically how many times larger the area of the larger one is than the area of the smaller one using the scale in Table 1. The smaller figure is then assigned the reciprocal value when compared with the larger one. These comparisons are arranged in a 5×5 matrix as given in Table 2. By convention, the item on the left side of the matrix is compared with that on top. If it is larger, the whole number corresponding to the judgment is put in that cell. If it is smaller, the reciprocal value is put in the cell. Finally, one derives priorities of the relative sizes of the areas from all the judgments. Table 2 also gives the estimated and actual relative areas resulting from this exercise in the last two columns. They are very close.

The Fundamental Scale

Paired comparison judgments are applied to pairs of homogeneous elements. The fundamental scale of values to represent the intensities of judgments is shown in Table 1. This scale has been validated for effectiveness, not only in many applications by a number of people, but also through theoretical comparisons with a large number of other scales.

There are many situations where elements are close or tied in measurement and the comparison must be made not to determine how many times one is larger than the other but by what fraction it is larger than the other. In other words, there are comparisons to be made between 1 and 2, and what is desired is to estimate verbally the values such as 1.1, 1.2,. . ., 1.9. There is no problem in making the comparisons by directly estimating the numbers. What is proposed here is to continue the verbal scale to make these distinctions so that 1.1 is a "tad," 1.3 indicates moderately more, 1.5 strongly more, 1.7 very strongly more, and 1.9 extremely more. This type of refinement can be used in any of the intervals from 1 to 9 and for further refinements if one needs them, for example, between 1.1 and 1.2 and so on.

An area represented on the left side of the matrix is compared with each area at the top as to how many times it is larger or more dominant. If it is not, the reciprocal value is entered in that position. The judgments are made based on feeling and converted by using the Fundamental Scale. Because the areas are visible to the eyes it is sometimes possible to express the judgments with fractional values. It is known that a small change in the numbers leads to a small change in the final priorities. The next to last priority column can be obtained as an approximation to the priorities given here by adding the numbers in each column (there are five columns) of the judgment matrix, dividing each number in the column by the total obtained, then averaging the first entries in the five columns (adding them and dividing their sum by 5), and then doing the same for the second entries in the

Analytic Hierarchy Process, Table 1 The fundamental scale

Intensity of importance	Definition	Explanation
1	Equal Importance	Two activities contribute equally to the objective
2	Weak or slight	
3	Moderate importance	Experience and judgment slightly favor one activity over another
4	Moderate plus	
5	Strong importance	Experience and judgment strongly favor one activity over another
6	Strong plus	
7	Very strong or demonstrated importance	An activity is favored very strongly over another; its dominance demonstrated in practice
8	Very, very strong	
9	Extreme importance	The evidence favoring one activity over another is of the highest possible order of affirmation
1.1–1.9	When activities are very close a decimal is added to 1 to show their difference as appropriate	A better alternative way to assigning the small decimals is to compare two close activities with other widely contrasting ones, favoring the larger one a little over the smaller one when using the 1–9 values
Reciprocals of above	If activity *i* has one of the above nonzero numbers assigned to it when compared with activity *j*, then *j* has the reciprocal value when compared with *i*	A logical assumption
Real numbers between the above integers		When appropriate according to the person making the comparisons because of special knowledge that person has
Ratios of measurements on a ratio scale		When measurements are available and one interprets their ratios to be equivalent to judgments (not usually recommended)

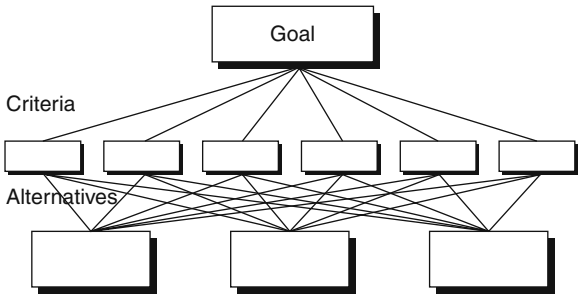
Analytic Hierarchy Process, Table 2 Pairwise comparison judgments of the different areas

Figure	Circle	Triangle	Square	Diamond	Rectangle	Priorities (eigenvectors)	Actual relative size
Circle	1	9	2	3	5	0.462	0.471
Triangle	1/9	1	1/5	1/3	1/2	0.049	0.050
Square	1/2	5	1	3/2	3	0.245	0.234
Diamond	1/3	3	2/3	1	3/2	0.151	0.149
Rectangle	1/5	2	1/3	2/3	1	0.093	0.096

five columns and so on to the fifth entries in the five columns. This only illustrates the use of judgments in a problem where the answer is known to give a little credibility to the idea that it may also work with things that are not visible, but one can think about them and so on.

It has been observed that in general comparisons with respect to the dominance of one object over another with respect to a certain attribute or criterion take three forms: importance or significance that includes all kinds of influence, physical measurements in science, engineering, and economics fall under this category; preference as in making decisions; and likelihood as in probabilities. If there is adequate knowledge, one can compare anything with anything else that shares a common attribute or criterion. Thus, comparisons go beyond ordinary measurement to include intangibles for which there are no scales of measurement.

The Analytic Hierarchy Process (AHP) is a general theory of measurement. It is used to derive relative



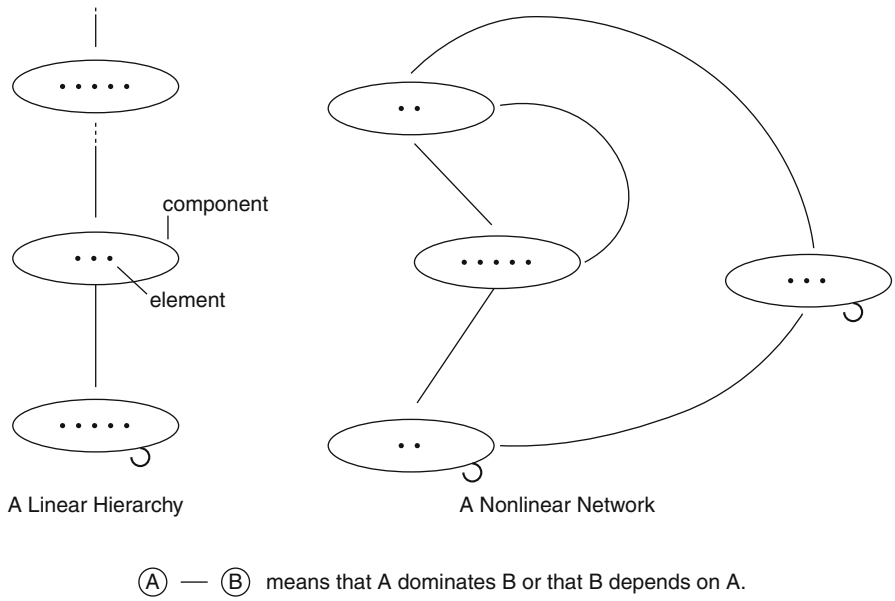
Analytic Hierarchy Process, Fig. 2 A three-level hierarchy

scales of absolute numbers from both discrete and continuous paired comparisons in multilevel hierarchic structures. These comparisons may be taken from actual measurements or from a fundamental scale that reflects the relative strength of preferences and feelings. The AHP has a special concern with departure from consistency and the measurement of this departure, and with dependence within and between the groups of elements of its structure. It has found its widest applications in multicriteria decision making, in planning and resource allocation, and in conflict resolution (Saaty and Alexander 1989). In its general form, the AHP is a nonlinear framework for carrying out both deductive and inductive thinking without use of the syllogism by taking several factors into consideration simultaneously and allowing for dependence and for feedback, and making numerical trade-offs to arrive at a synthesis or conclusion (Figs. 2 and 3).

For a long time, people have been concerned with the measurement of both physical and psychological events. By physical it is meant the realm of what is fashionably known as the tangibles insofar as they constitute some kind of objective reality outside the individual conducting the measurement. By contrast, psychological means the realm of the intangibles, comprising the subjective ideas, feelings, and beliefs of the individual and of society as a whole. The question is whether there is a coherent theory that can deal with both these worlds of reality without compromising either. The AHP is a method that can be used to establish measures in both the physical and social domains.

From the neurological sciences, it is known that sense data are mixed with temperature and other information by the thalamus, before they are recorded in memory. In the end, what we sense is what we are and not fully what is out there. Performance tests indicate that an individual not experienced in ranking objects according to size may well say that one apple which is three times larger than another apple is the same as the smaller one. Only by being exposed to many apples and asked to make careful distinctions in size will the individual begin to show an improved ability to sort and rank apples according to size. What the person does is to adjust sensation and impression with what he or she observes. It is not the real apples that one compares, but the impressions one forms about them. One needs such real experiences to institute early in one's mind the possibility of comparing things in pairs. This applies equally to more abstract ideas and their relative importance to a higher-order property or goal. He or she would then be able to say that one idea is more important than another in terms of the satisfaction of the goal and whether, according to his or her understanding and experience, it is much more important or slightly more important. The lesser of the two is always used as the unit in terms of which the more important one is compared as to how much more important it is, and also how many times more, because the feeling of importance is converted to magnitudes on numerous sense experiences. Thus, there is transfer from the concrete to the abstract, so that the two can be combined to make trade-offs when needed, which happens frequently in daily experience. It is not possible to compare the lesser element with the greater one, because it must first be used as a unit to determine the magnitude of the greater one. Therefore, there is bias in human thinking in using the smaller of two elements as the unit. It is impossible a priori to ask how much less the smaller element is than the larger without first involving it as the unit of measurement. Thus, priorities of many objects can only be derived on the basis of dominance, and their reciprocal is automatically calculated to determine, in a meaningful way, the relative priorities of being "dominated."

In using the AHP to model a problem, one needs a hierarchic or network structure to represent that problem, as well as pairwise comparisons to establish relations within the structure. In the discrete case, these comparisons lead to dominance matrices and in the continuous case to kernels of Fredholm operators (Saaty and Vargas 1993), from which ratio scales are derived in the form of principal eigenvectors or



Analytic Hierarchy Process, Fig. 3 Structural difference between a linear and a nonlinear network

eigenfunctions, as the case may be. These matrices, or kernels, are positive and reciprocal, for example, $a_{ij} = 1/a_{ji}$. In particular, special effort has been made to characterize these matrices (1993). Because of the need for a variety of judgments, there has also been considerable work done to deal with the process of synthesizing group judgments (Saaty 1994). The axiomatic foundations of the AHP may be found in Saaty (1986).

Absolute and Relative Measurement and Structural Information

Cognitive psychologists have recognized for some time that there are two kinds of comparisons: absolute and relative. In absolute comparisons, alternatives are compared with a standard in one's memory that has been developed through experience; in relative comparisons, alternatives are compared in pairs according to a common attribute. The AHP has been used with both types of comparisons to derive ratio scales of measurement. Such scales are called absolute and relative measurement scales. Relative measurement w_i, $i = 1,\ldots, n$, of each of n elements is a ratio scale of values assigned to that element and derived by comparing it in pairs with the others. In paired comparisons, two elements i and j are compared with respect to a property they have in common. The smaller i is used as the unit and the larger j is estimated as a multiple of that unit in the form $(w_i/w_j)/1$ where the ratio w_i/w_j is taken from a fundamental scale of absolute values.

Absolute measurement (sometimes called scoring) is applied to rank the alternatives in terms of the criteria or else in terms of ratings (or intensities) of the criteria, for example, excellent, very good, good, average, below average, poor, and very poor, or A, B, C, D, E, F, and G. After setting priorities for the criteria (or subcriteria, if there are any), pairwise comparisons are also made between the ratings themselves to set priorities for them under each criterion and dividing their priorities each by the largest rated intensity (the ideal intensity). Finally, alternatives are scored by checking off their respective ratings under each criterion and summing these ratings for all the criteria. This produces a ratio scale score for the alternative. The scores thus obtained of the alternatives can in the end be normalized by dividing each one by their sum.

Absolute measurement has been used to rank cities in the United States according to nine criteria as judged by six different people (Saaty 1986). Another appropriate use for absolute measurement is that of schools admitting students (Saaty et al. 1991). Most schools set their criteria for admission independently of the performance of the current crop of students seeking admission. Their priorities are then used to determine whether a given student meets the standard set for qualification. In that case absolute measurement should be used to determine which students qualify for admission.

Comments on Cost-Benefit Analysis

Often, the alternatives from which a choice must be made in a choice-making situation have both costs and benefits associated with them. In this case, it is useful to construct separate costs and benefits hierarchies, with the same alternatives on the bottom level of each. Thus one obtains both a cost-priority vector and a benefit-priority vector. The cost-benefit vector is obtained by taking the ratio of the benefit priority to the costs priority for each alternative, with the highest such ratio indicating the preferred alternative. In the case where resources are allocated to several projects, such cost-to-benefit ratios or the corresponding marginal ratios prove to be very valuable.

Wrong decisions may be made in some cases where only one structure is used for the purpose of generating priorities for the alternatives. In general, one needs two or more of four separate structures: one for benefits, one for costs, one for opportunities, and a fourth for risks. Because one must ask what dominates what in the paired comparisons and by how much (homogeneous elements with clusters and pivots are used for widely spread alternatives), in the end one multiplies the benefits of each alternative by the opportunities it creates and divides by the costs times the risks.

For example, in evaluating three types of copying machines, one represents in the benefits hierarchy the good attributes one is looking for and one represents in the costs hierarchy the pain and economic costs that one would incur in buying or maintaining the three types of machines. Note that the criteria for benefits and the criteria for costs need not be simply opposites of each other but may be totally different. Also note that each criterion may be regarded at a different threshold of intensity and that such thresholds may themselves be prioritized according to desirability, with each alternative evaluated only in terms of its highest priority threshold level. Similarly, three hierarchies can be used to assess a benefit/(cost × risk) outcome.

The Eigenvector Solution for Weights and Consistency

There is an infinite number of ways to derive the vector of priorities from the matrix $\boldsymbol{A} = (a_{ij})$, but emphasis on consistency leads to an eigenvalue formulation.

If a_{ij} represents the importance of alternative i over alternative j and a_{jk} represents the importance of alternative i over alternative j and a_{ik}, the importance of alternative i over alternative k must equal $a_{ij}a_{jk}$ for the judgments to be consistent. Without a scale at all, or not available conveniently, as in the case of some measuring devices, one cannot give the precise values of $a_{ij} = w_i/w_j$ but only an estimate. The problem becomes $\mathrm{A}'\mathrm{w}' = \lambda_{\max}w'$ where $\lambda_{\max}$ is the largest or principal eigenvalue of $A' = \left(a'_{ji}\right)$, the perturbed value of $\boldsymbol{A} = (a_{ij})$, with $a'_{ji} = 1/a_{ij}$ forced. To simplify the notation, write $\boldsymbol{A}\boldsymbol{w} = \lambda_{\max}w$ where $\boldsymbol{A}$ is the matrix of pairwise comparisons.

The solution is obtained by raising the matrix to a sufficiently large power, then summing over the rows and normalizing to obtain the priority vector $w = (w_1,\ldots, w_n)$. The process is stopped when the difference between components of the priority vector obtained at the kth power and at the $(k + 1)$st power is less than some predetermined small value.

An easy way to get an approximation to the priorities is to normalize the geometric means of the rows. This result coincides with the eigenvector for $n \leq 3$. A second way to obtain an approximation is by normalizing the elements in each column of the judgment matrix and then averaging over each row.

For important applications one should use only the eigenvector derivation procedure because approximations can lead to rank reversal in spite of the closeness of the result to the eigenvector. It is easy to prove that for an arbitrary estimate x of the priority vector

$$\lim_{k\to\infty} \frac{1}{\lambda_{\max}^k}\boldsymbol{A}^k x = cw$$

where c is a positive constant and w is the principle eigenvector of $\boldsymbol{A}$. This may be interpreted roughly to say that if we begin with an estimate and operate on it successively by $\boldsymbol{A}/\lambda_{\max}$ to get new estimates, the result converges to a constant multiple of the principal eigenvector.

A simple way to obtain the exact value (or an estimate) of $\lambda_{\max}$ when the exact value (or an estimate) of w is available in normalized form is to add the columns of $\boldsymbol{A}$ and multiply the resulting vector by the vector w. The resulting number is $\lambda_{\max}$ (or an estimate). This follows from

Analytic Hierarchy Process, Table 3 Random consistency index

n	1	2	3	4	5	6	7	8	9	10
Random Consistency Index (R.I.)	0	0	0.52	0.89	1.11	1.25	1.35	1.40	1.45	1.49

$$\sum_{j=1}^{n} a_{ij}w_j = \lambda_{\max}w_i \quad \text{and} \quad \sum_{i=1}^{n}\sum_{j=1}^{n} a_{ij}w_j = \sum_{j=1}^{n}\left(\sum_{i=1}^{n} a_{ij}\right) w_j = \sum_{i=1}^{n} \lambda_{\max}w_i = \lambda_{\max}$$

The problem now is how good is the principal eigenvector estimate w. Note that if one obtains $w = (w_1,\ldots, w_n)^{\mathrm{T}}$, by solving this problem, the matrix whose entries are w_i/w_j is a consistent matrix which is our consistent estimate of the matrix $\boldsymbol{A}$. The original matrix $\boldsymbol{A}$ itself need not be consistent. In fact, the entries of $\boldsymbol{A}$ need not even be transitive; that is, $\boldsymbol{A}_1$ may be preferred to $\boldsymbol{A}_2$ and $\boldsymbol{A}_2$ to $\boldsymbol{A}_3$ but $\boldsymbol{A}_3$ may be preferred to $\boldsymbol{A}_1$. What is desired is a measure of the error due to inconsistency. It turns out that $\boldsymbol{A}$ is consistent if and only if $\lambda_{\max} = n$, and that the quantity $\lambda_{\max} - n$ is always available. This suggests using $\lambda_{\max} - n$ as an index of departure from consistency. But

$$\lambda_{\max} - n = -\sum_{i=2}^{n} \lambda_i;\ \lambda_{\max} = \lambda_1$$

where λ_i, $i = 1,\ldots, n$ are the eigenvalues of $\boldsymbol{A}$. Thus, the index adopted is the average value $(\lambda_{\max} - n)/(n-1)$, which is the (negative) average of λ_i, $i = 2,\ldots, n$ (some of which may be complex conjugates).

It is interesting to note that $(\lambda_{\max} - n)/(n-1)$ is the variance of the error incurred in estimating a_{ij} . This can be shown by writing

$$a_{ij} = (w_i/w_j)\varepsilon_{ij},\ \varepsilon_{ij} > 0 \quad \text{and} \quad \varepsilon_{ij} = 1 + \delta_{ij},\ \delta_{ij} > -1$$

and substituting in the expression for $\lambda_{\max}$. It is δ_{ij} that is of interest, as the error component and its value $|\delta_{ij}| < 1$ for an unbiased estimator. The measure of inconsistency can be used to successively improve the consistency of judgments.

The consistency index of a matrix of comparisons is given by $\mathrm{CI} = (\lambda_{\max} - n)/(n-1)$. The consistency ratio (CR) is obtained by comparing the CI with the appropriate one of the following set of numbers each of which is an average random consistency index (RI) derived from a sample of size 500 of randomly generated reciprocal matrices using the scale 1/9, 1/8, . . .,1, . . ., 8,9 (Table 3). A CR = CI/RI less than or equal to 0.10 is considered acceptable. If CR is larger than 0.10, the problem should be reanalyzed and the judgments revised.

The consistency index for an entire hierarchy is defined by

$$C_H = \sum_{j=1}^{j}\sum_{i=1}^{n_{i_{j+1}}} w_{ij}\mu_{ij+1}$$

where $w_{ij} = 1$ for $j = 1$, and $n_{\ i\ j-1}$ is the number of elements of the $(j + 1)$st level with respect to the ith criterion of the jth level.

Let $|C_k|$ be the number of elements of C_k and let w_{hk} be the priority of the impact of the hth component on the kth component, that is, $w_{hk} - w_k(C_h)$ or w_k: $C_h \to w_{hk}$.

Labeling the components of a system along lines similar to those followed for a hierarchy and denoting by w_{jk} the limiting priority of the jth element in the kth component,

$$C_s = \sum_{k=1}^{s}\sum_{j=1}^{n_k} w_{jk}\sum_{h=1}^{|C_k|} w_{hk}\mu_k(j,h)$$

where $\mu_k\,(j, h)$ is the consistency index of the pairwise comparison matrix of the elements in the kth component with respect to the jth element in the hth component.

How to Structure a Hierarchy

Perhaps the most creative part of decision making that has a significant effect on the outcome is the structuring of the decision as a hierarchy. The basic principle to follow in creating this structure is always to see if one can answer the following question: "Can

I compare the elements on a lower level in terms of some or all of the elements on the next higher level?"

A useful way to proceed is to come down from the goal as far as one can and then go up from the alternatives until the levels of the two processes are linked in such a way as to make comparison possible. Here are some suggestions for an elaborate design.

1. Identify overall goal. What are you trying to accomplish? What is the main question?
2. Identify subgoals of overall goal. If relevant, identify time horizons that affect the decision.
3. Identify criteria that must be satisfied to fulfill subgoals of the overall goal.
4. Identify subcriteria under each criterion. Note that criteria or subcriteria may be specified in terms of ranges of values of parameters or in terms of verbal intensities such as high, medium, low.
5. Identify actors involved.
6. Identify actor goals.
7. Identify actor policies.
8. Identify options or outcomes.
9. For yes-no decisions take the most preferred outcome and compare benefits and costs of making the decision with those of not making it.
10. Do cost-benefit analysis using marginal values. Because we are dealing with dominance hierarchies, ask which alternative yields the greatest benefit, and for costs, which alternative costs the most.

Software programs such as *superdecisions* and *Expert Choice* incorporate the AHP methodology and enable the analyst to structure the hierarchy and resolve the problem using relative or absolute measurements, as appropriate.

Hierarchic Synthesis and Rank

Hierarchic synthesis is obtained by a process of weighting and adding down the hierarchy leading to a multilinear form. The hierarchic composition principle is a theorem in the AHP that is a particular case of network composition which deals with the cycles and loops of a network.

What happens to the synthesized ranks of alternatives when new ones are added or old ones deleted? The ranks cannot change under any single criterion, but they can under several criteria depending on whether one wants the ranks to remain the same or allows them to change. Many examples are given in the literature showing that allowing rank to change is natural. In 1990, Tversky et al. concluded that the primary cause of preference reversal is the "failure of procedure invariance." In the AHP there is no such methodological constraint (Tversky et al. 1990).

In the distributive mode of the AHP, the principal eigenvector is normalized to yield a unique estimate of a ratio scale underlying the judgments. This mode allows rank to change and is useful when there is dependence on the number of alternatives present or on dominant new alternatives which may affect preference among old alternatives thus causing rank reversals (see phantom alternatives—Saaty 1993). In the ideal mode of the AHP, the normalized values of the alternatives for each criterion are divided by the value of the highest rated alternative. In this manner, a newly added alternative that is dominated everywhere cannot cause reversal in the ranks of the existing alternatives (Saaty 1994).

Examples

Relative Measurement: Choosing the Best House

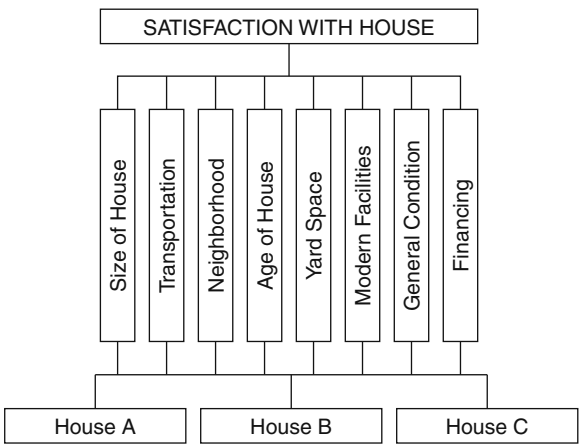
When a family of average income is being advised on buying a house, the family identifies eight factors that they think they have to look for in the house. These factors fall into three categories: economic, geographic, and physical. Although one might begin by examining the relative importance of these clusters, the family feels they want to prioritize the relative importance of all the factors without working with clusters. The problem is to decide which of three candidate houses to choose. In applying the AHP, the first step is decomposition, or the structuring of the problem into a hierarchy (Fig. 4). On the first (or top) level is the overall goal of Satisfaction with House. On the second level are the eight factors or criteria that contribute to the goal, and on the third (or bottom) level are the three candidate houses that are to be evaluated in terms of the criteria on the second level. The definitions of the factor and the pictorial representation of the hierarchy follow.

The factors important to the individual family are:

1. *Size of house*: Storage space, size of rooms, number of rooms, total area of house

2. *Transportation*: Convenience and proximity of bus service
3. *Neighborhood*: Degree of traffic, security view, taxes, physical condition of surrounding buildings
4. *Age of house*: Self-explanatory
5. *Yard space*: Includes front, back, and side space, and space shared with neighbors
6. *Modern facilities*: Dishwashers, garbage disposals, air-conditioning, alarm system, and other such items
7. *General condition*: Extent to which repairs are needed; condition of walls, carpet, drapes, wiring; cleanliness
8. *Financing*: Availability of assumable mortgage, seller financing, or bank financing

The next step is comparative judgment. Arrange the elements on the second level into a matrix and elicit from the people buying the house judgments about the relative importance of the elements with respect to the overall goal, Satisfaction with House.



Analytic Hierarchy Process, Fig. 4 Decomposition of the problem into a hierarchy

The questions to ask when comparing two criteria are of the following kind: Of the two alternatives being compared, which is considered more important by the family buying the house and how much more important is it with respect to family satisfaction with the house, which is the overall goal?

The matrix of pairwise comparisons of the factors given by the home buyers in this case is shown in Table 4, along with the resulting vector of priorities. The judgments are entered using the Fundamental Scale, first verbally as indicated in the scale and then associating the corresponding number. The vector of priorities is the principal eigenvector of the matrix. This vector gives the relative priority of the factors measured on a ratio scale. That is, these priorities are unique to within-a-positive-similarity transformation. However, if one insures that they add up to unity, they are always unique. In this case financing has the highest priority, with 33% of the influence.

In Table 4, instead of naming the criteria, use the number previously associated with each.

Now consider the pairwise comparisons of the houses on the bottom level, comparing them pairwise with respect to how much better one is than the other in satisfying each criterion on the second level. Thus there are eight 3×3 matrices of judgments since there are eight elements on level two, and three houses to be pairwise compared for each element. The matrices (Table 5) contain the judgments of the family involved. In order to facilitate understanding of the judgments, a brief description of the houses is given below.

House A: This house is the largest of them all. It is located in a good neighborhood with little traffic and low taxes. Its yard space is comparably larger than that of houses B and C. However, its general condition is not very good and it needs cleaning and painting.

Also, the financing is unsatisfactory because it would have to be financed through a bank at a high rate of interest.

House B: This house is a little smaller than House A and is not close to a bus route. The neighborhood gives one the feeling of insecurity because of traffic conditions. The yard space is fairly small and the house lacks the basic modern facilities. On the other hand, its general condition is very good. Also an assumable mortgage is obtainable, which means the financing is good with a rather low interest rate. There are several copies of B in the neighborhood.

House C: House C is very small and has few modern facilities. The neighborhood has high taxes, but is in good condition and seems secure. The yard space is bigger than that of House B, but is not comparable to House A's spacious surroundings. The general condition of the house is good, and it has a pretty carpet and drapes. The financing is better than for A but not better than for B.

Table 5 gives the matrices of the houses and their local priorities with respect to the elements on level two.

The next step is to synthesize the priorities. In order to establish the composite or global priorities of the houses, lay out in a matrix (Table 6) the local priorities of the houses with respect to each criterion and multiply each column of vectors by the priority of the corresponding criterion and add across each row, which results in the composite or global priority vector of the houses. Under the distributive mode, House A is preferred if, for example, copies of B matter. Under the ideal mode, House B is the preferred house if the family wanted the best house regardless of other houses and how many copies of it there are in the neighborhood. In a large number of situations with ten criteria and three alternatives, the two modes gave the same best choice 92% of the time (Saaty 1994).

Absolute Measurement: Evaluating Employees for Raises

Employees are evaluated for raises. The criteria for Dependability, Education, Experience, and Quality. Each criterion is subdivided into intensities, standards, or subcriteria as shown in Fig. 5. Priorities are set for the criteria by comparing them in pairs, and these priorities are then given in a matrix. The intensities are then pairwise compared according to priority with respect to their parent criterion (as in Table 7) and their priorities are divided by the largest intensity for each criterion (second column of priorities in Fig. 5). Finally, each individual is rated in Table 8 by assigning the intensity rating that applies to him or her under each criterion. The scores of these subcriteria are weighted by the priority of that criterion and summed to derive a total ratio scale score for the individual. This approach can be used whenever it is possible to set priorities for intensities of criteria, which is usually possible when sufficient experience with a given operation has been accumulated.

Concluding Remarks

The Analytic Hierarchy Process is widely applied in business and government on a global scale. Applications include strategic planning, R&D and innovation, capital planning, IT and product portfolio management, trade studies, vendor selection, and site selection, to name a few. Notable government organizations applying AHP include the US Joint Chiefs of Staff; US Navy, Air Force, and Army;

Analytic Network Process

Thomas L. Saaty
University of Pittsburgh, Pittsburgh, PA, USA

Introduction

There are at least five important criteria that a reliable decision theory should satisfy. They are: (1) having the potential to cope with full fledged complexity, including scenarios, stakeholders, criteria, subcriteria and the like; (2) validation in practice through prediction of decision outcomes in complex situations; (3) measuring intangible factors along similar lines as the theory does with tangibles; (4) including the possibility to deal with dependence and feedback among the elements of the decision; and (5) allowing for group decision making within the assumptions and mathematical workings of the theory by including the power of each member of a group in a scientifically justified way and not simply through consensus or other arbitrarily chosen criteria.

The Analytic Network Process (ANP) is a new theory that extends the Analytic Hierarchy Process (AHP) to cases of dependence and feedback and generalizes on the supermatrix approach introduced by Saaty for the AHP. It allows interaction and feedback within clusters (inner dependence) and between clusters (outer dependence). Feedback can better capture the complex effects of interplay in human society. The ANP provides a thorough framework to include clusters of elements connected in any desired way to investigate the process of deriving ratio scale priorities from the distribution of influence among elements and among clusters. The AHP becomes a special case of the ANP. Although many decision problems are best studied through the

ANP, it is not true that forcing an ANP model always yields better results than using the hierarchies of the AHP. There are examples to justify the use of both. It is not yet known when the shortcut of the hierarchy is justified, not simply on grounds of expediency and efficiency, but also for reasons of validity of the outcome.

The ANP is a coupling of two parts. The first consists of a control hierarchy or network of criteria and subcriteria that control the interactions in the system under study. The second is a network of influences among the elements and clusters. The network varies from criterion to criterion and a supermatrix of limiting influence is computed for each control criterion. Finally, each of these supermatrices is weighted by the priority of its control criterion and the results are synthesized through addition for all the control criteria.

In addition, a problem is often studied through a control hierarchy or system of benefits, a second for costs, a third for opportunities, and a fourth for risks. The synthesized results of the four control systems are combined by taking the quotient of the benefits times the opportunities to the costs times the risks to determine the best outcome.

Feedback Networks

Many decision problems cannot be structured hierarchically because they involve the interaction and dependence of higher-level elements on lower-level elements. Not only does the importance of the criteria determine the importance of the alternatives as in a hierarchy, but also the importance of the alternatives themselves determines the importance of the criteria.

The feedback structure does not have the linear top-to-bottom form of a hierarchy but looks more like a network, with cycles connecting its clusters of elements, which can no longer be called levels, and with loops that connect a cluster to itself. A decision problem involving feedback arises often in practice. It typically has many interactions, which in the limit converge toward the goal. Our minds need a tool to manage this complexity. The ANP provides that tool.

At present, in their effort to simplify and deal with complexity, people who work in decision making use mostly very simple hierarchic structures consisting of a goal, criteria, and alternatives. Yet, not only are decisions obtained from a simple hierarchy of three levels different from those obtained from a multilevel hierarchy, but also decisions obtained from a network may be different from those obtained from a more complex hierarchy. The question is: How much would one like to trade off the effort in creating and following through an elaborate structure against the desired degree of accuracy of the outcome? We one cannot collapse complexity artificially into a simplistic structure of two levels, criteria and alternatives, and hope to capture the outcome of interactions in the form of highly condensed judgments that correctly reflect all that goes on in the world. We one must learn to decompose these judgments through more elaborate structures and organize our reasoning and calculations in sophisticated but simple ways to serve our understanding of the complexity around us. Experience indicates that it is not very difficult to do this, although it takes more time and effort. Indeed, one must use feedback networks to arrive at the kind of decisions needed to cope with the future.

We will lay out the theoretical foundations for the kinds of structures and matrices of derived ratio scales associated with feedback networks from which we obtain the priorities for a decision. Let us summarize what we will do in anticipation of what will be coming later on. Each ratio scale, derived from a paired comparison matrix, is appropriately introduced as part of a column in a matrix to represent the impact of elements in a component on an element in another component (outer dependence) or on elements of the component itself (inner dependence). Not every element of a component need impact an element in another component. In that case those elements that make no impact are given a zero value for their contribution. The resulting matrix of components with their elements displayed vertically on the left side of the matrix and horizontally at the top of the matrix must be stochastic (each column sums to one) to obtain meaningful limiting results. To ensure that this matrix, called the supermatrix, is stochastic, we need to compare the components themselves (rather than their elements) that are on the left with respect to their impact on each component at the top according to an attribute represented in a separate control hierarchy for that system. The resulting priorities of the

components are then used to weight the column vectors. Each block of column vectors defines an entry of the supermatrix. All the column vectors in the block are multiplied by the single priority of the corresponding component on the left. The process is repeated by deriving a vector of impact of all components on the left on each component at the top. The columns of the supermatrix corresponding to the impacts on the elements of the component at the top now sum to one. The resulting supermatrix is column stochastic. What is desired, is the long-run or limiting priority of impact of each element on every other element.

Contributions to this impact are obtained in many ways. They are be obtained directly from the matrix or indirectly for any two elements by taking the impact of the first on some third element and then multiplying it by the impact of that element on the second. One must consider every such possibility of a third element. All such possibilities are obtained from the square of the matrix. Again the impact can be obtained by considering a third element that impacts a fourth element, which in turn impacts the second element. All such impacts are obtained from the cubic power of the matrix, and so on. Thus we have an infinite number of impact matrices: the matrix itself, its square, its cube, etc. If we sum all these matrices, does the result converge? Does the limit exist, and how do we compute it to obtain the desired priorities? The supermatrix may not be positive and may have zeros in certain positions where there is no direct impact of an element on another. Alternatively, the matrix may be positive or may become positive after raising it to powers. What theory do we have to deal with this problem?

Note that if the matrix is positive or if, after raising it to some power, it becomes positive, it turns out that one can obtain a unique answer. But when no power of the matrix is strictly positive, we need to examine what happens closely because even in those situations where every element can be reached from every other element, we may not have a unique limit. For example, powers of the matrix may oscillate, and different limits are obtained. Also, if it is not possible to reach every element from every other, then the graph representing the connections of the components and even the elements them-selves may be divided into subgraphs, in some of which every element can be reached from every other, but not in others. How then does one obtain the desired results? The graph of a decision system must always be connected. It cannot be divided into two or more disjoint parts.

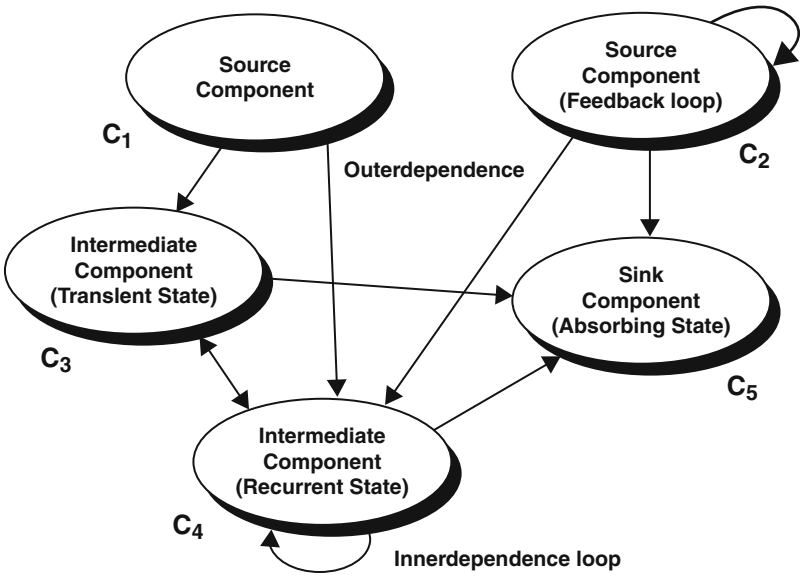
When the criteria do not depend on the alternatives, the latter may be kept out of the supermatrix and evaluated according to the ideal or distributive modes of the AHP, after the limiting priorities of the criteria are obtained from the limiting supermatrix. Otherwise, if some criterion depends on the alternatives or if there is inner dependence among the alternatives, they must be included in the supermatrix.

To test for the mutual independence of the criteria, one proceeds as follows: construct a zero-one matrix of criteria against criteria using the number one to signify dependence of one criterion on another, and zero otherwise. A criterion need not depend on itself, just as an industry, for example, need not use its own output. For each column (criterion) of this matrix, construct a pairwise comparison matrix only for the dependent criteria, derive an eigenvector, and augment it with zeros for the excluded criteria. If a column consists of only zeros, then as-sign a zero vector. The question in the comparison would be: For a given criterion, which of two criteria depends more on that criterion with respect to the goal or with respect to a higher-order control criterion?

The Supermatrix of a Feedback System

This section introduces different examples of graphs and their matrices. Assume that there is a system of N clusters or components whereby the elements in each component interact or have an impact on or are influenced by some or all of the elements of another component with respect to a property governing the interactions of the entire system, such as energy or capital or political influence. Assume that component h, denoted by C_h, $h = 1, \ldots, N$, has n_h elements, denoted by $e_{h1}, e_{h2}, \ldots, e_{hn\ k}$. The impact of a given set of elements in a component on another element in the system is one represented by a ratio scale priority vector derived from paired comparisons in the usual way.

In Fig. 1, no arrow feeds into a source component, no arrow leaves a sink component, and arrows both leave and feed into a transient component. Each such priority vector is now introduced in the appropriate



Analytic Network Process, Fig. 1 Feedback network

position as a column vector in a supermatrix of impacts displayed as follows:

$$
W = \begin{array}{c|cccc}
 & C_1 & C_2 & \cdots & C_N \\
 & e_{11}e_{12}\cdots e_1n_1 & e_{22}e_{22}\cdots e_{2n_2} & & e_{N1}e_{N2}\cdots e_Nn_N \\

\end{bmatrix}
$$

each of whose columns is a principal eigenvector that represents the impact of all the elements in the i th component on each of the elements in the j th component.

The discussion of this section will focus on deriving limiting priorities for the supermatrix. It must first be reduced to a matrix, each of whose columns sums to unity. As already mentioned, such a matrix is known as a column stochastic or simply a stochastic matrix. If the matrix is stochastic, the limiting priorities depend on the reducibility, primitivity, and cyclicity of that matrix. Interaction in the supermatrix may be measured according to several different criteria. To display and relate the criteria, there is a need for a separate control hierarchy that includes these criteria with their priorities. For each criterion, a different supermatrix of impacts is developed, and in terms of that criterion the components are compared according to their relative impact (or absence of impact) on each other component at the top of the supermatrix, thus developing priorities to weight the block matrices of eigenvector columns under that component in the supermatrix. The resulting supermatrix would then be a stochastic matrix. Hereafter, W is usually a stochastic matrix.

In general, the supermatrix is rarely stochastic because, in each column, it consists of several eigenvectors that each sum to one, and, hence, the entire column of the matrix sums to an integer greater

than one. The natural thing to do is to determine the influence of the clusters on each cluster with respect to the control criterion. This yields an eigenvector of influence of all the clusters on each cluster. The priority of a component of such an eigenvector is used to weight all the elements in the block of the supermatrix that corresponds to the elements of both the influencing and the influenced cluster. The result is a stochastic supermatrix. This is not a forced way to make the matrix stochastic. It is natural. Why? Because the elements are compared among themselves and one needs information about the importance of the clusters to which they belong, to determine their relative overall weight among all the elements in the other clusters. Normalization would be meaningless, and such weighting does not call for normalization. Here is an example of why it is necessary to weight the priorities of the elements by those of their clusters: If one shouts into a room, "Ladies and Gentlemen, the President," everyone is alerted and somewhat awed to expect to see the president of the United States because he is in the news so often. But if the announcement is then followed by, "of the Garbage Collection Association," the priority immediately drops according to the importance of the group to which that president belongs. There is a need for such consideration.

The Control Hierarchy

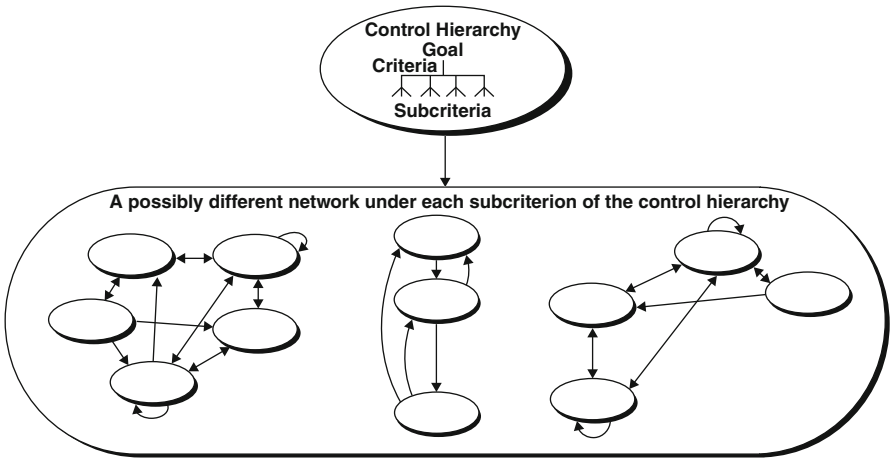
Analysis of priorities in a system can be thought of in terms of a control hierarchy with dependence among its bottom-level subsystem arranged as a network (Fig. 2). Dependence can occur within the clusters and between them. A control hierarchy at the top may be replaced by a control network with dependence among its clusters. More generally, one can have a cascading set of control networks, the outcome of one used to synthesize the outcomes of what it controls. For obvious reasons relating to the complexity of exposition, apart from a control hierarchy, we will not discuss such complex control structures here. A control hierarchy can also be involved in the network itself with feedback involved from the criteria to the elements of the network and back to the criteria to modify their influence. This kind of closed-circuit interaction between the operating parts and the criteria that drive the parts is likely to be prevalent in the brain.

A component or cluster in the AHP is a collection of elements whose function derives from the synergy of their interaction and, hence, has a higher-order function not found in any single element. A component is like the audio or visual component of a television set or like an arm or a leg, consisting of muscle and bone, in the human body. A mechanical cluster has no synergy value but is simply an aggregate of elements and is not what is meant by a component or cluster. The clusters of the system should generally be synergistically different from the elements themselves. Otherwise, they would be a mechanical collection with no intrinsic meaning.

The criteria in the control hierarchy that are used for comparing the components are usually the major parent criteria whose subcriteria are used to compare the elements in the component. Thus the criteria for comparison of the components need to be more general than those of the elements because of the greater functional complexity of the components. Sometimes for convenience, interactions of both components and elements are examined in terms of the same criteria in the control hierarchy. Although one does that to economize on the effort spent, it is more meaningful to compare the clusters with respect to control criteria and to compare the elements with respect to subcriteria of the control criteria. Otherwise the process can lead to asking difficult questions in making the paired comparisons.

The control hierarchy, critical for ANP analysis, provides overriding criteria for comparing each type of interaction that is intended by the network representation. There are two types of control criteria (subcriteria). A control criterion may be directly connected to the structure as the goal of a hierarchy if the structure is in fact a hierarchy. In this case the control criterion is called a comparison-linking criterion. Otherwise a control criterion does not connect directly to the structure but induces comparisons in a network. In that case the control criterion is called a comparison-inducing criterion.

An example of dependence between components is the input-output of materials among industries. The electric industry supplies electricity to other industries including itself. But it depends more on the coal industry than on its own electricity for operation and also more on the steel industry for its turbines.



Analytic Network Process, Fig. 2 A control hierarchy

To summarize, a control hierarchy is a hierarchy of criteria and subcriteria for which priorities are derived in the usual way with respect to the goal of the system being considered. The criteria are used to compare the components of a system, and the subcriteria are used to compare the elements. The generic question is: Given an element (in the same component or in another component) of the system or given a component of that system, how much more does a given element (component) of a pair influence that element (component) with respect to a control subcriterion (criterion)? The weights of the components are used to weight the blocks of the supermatrix corresponding to the component being influenced. The limiting priorities in each supermatrix are weighted by the priority of the corresponding subcriterion and the results are synthesized for all the subcriteria. If it should happen that an element or a component has no input, a zero is entered in the corresponding priority vector.

In each block of the supermatrix, a column is either a normalized eigenvector with possibly some zero entries, or all of its elements are equal to zero. In either case it is weighted by the priority of the corresponding cluster on the left. If it is zero, that column of the supermatrix must be normalized after weighting by the cluster's weights. This operation is equivalent to assigning a zero value to the cluster on the left when weighting a column of a block with zero entries and then renormalizing the weights of the remaining clusters.

Figures 3 and 4 and their accompanying supermatrices represent a hierarchy and a holarchy whose bottom level is connected to its top level of criteria and has no single element goal as in a hierarchy. Note the difference between the two.

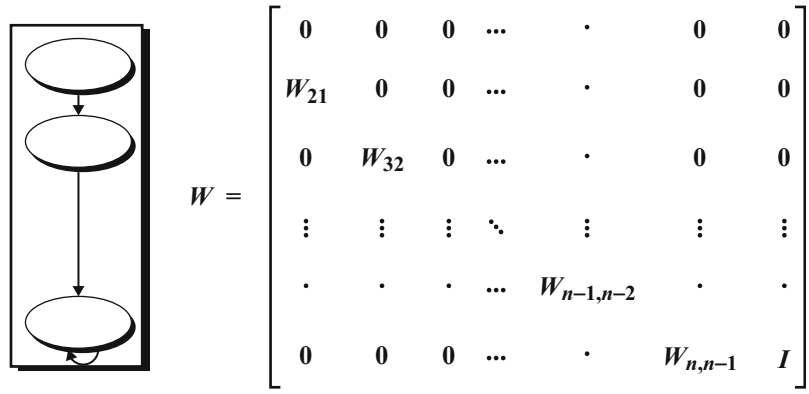
Note from Fig. 3 that the entry in the last row and column of the supermatrix of a hierarchy is the identity matrix I. The limiting results obtained by raising W to powers and by following the theoretical route described here turn out to be the same.

For Fig. 4 a system may be generated from a hierarchy by increasing its connections gradually so that pairs of components are connected as desired and some components have an inner dependence loop. What follows is an illustration of how feedback and the supermatrix work in a pharmaceutical marketing decision problem.

Drug-Marketing Decision

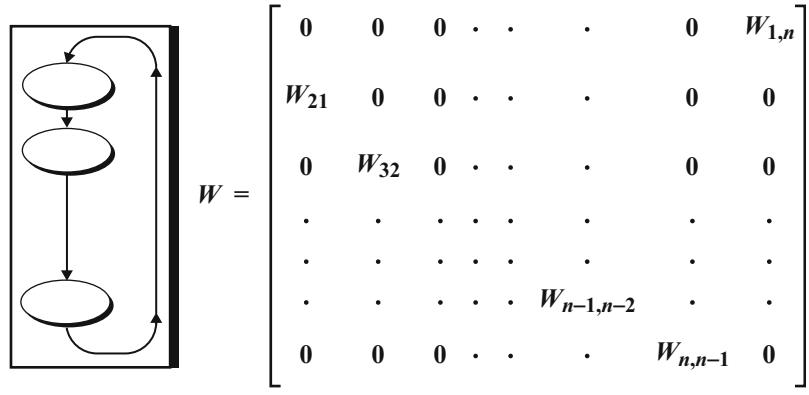
The problem faced by a large pharmaceutical company was how should the company market a new drug, given the pending patent expiration of an already existing drug it had been marketing? The ANP model used to make the decision illustrates two important ideas. First, it uses a very simple control hierarchy involving the aggregate criteria of benefits, costs, and risks (Fig. 5). For each of these controlling considerations, a separate network model of interactions was created. Thus there were three submodels, one for each control criterion. Second, the outcomes of the three sub-models were computed.

This ANP model was a real case in that the company was actually in the process of making the decision



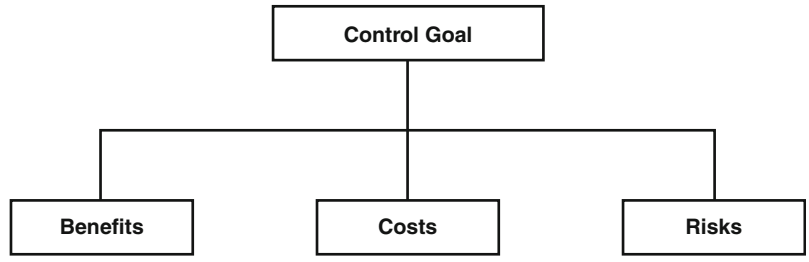
$$W = \begin{bmatrix} 0 & 0 & 0 & \cdots & \cdot & 0 & 0 \\ W_{21} & 0 & 0 & \cdots & \cdot & 0 & 0 \\ 0 & W_{32} & 0 & \cdots & \cdot & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ \cdot & \cdot & \cdot & \cdots & W_{n-1,n-2} & \cdot & \cdot \\ 0 & 0 & 0 & \cdots & \cdot & W_{n,n-1} & I \end{bmatrix}$$

Analytic Network Process, Fig. 3 The structure and supermatrix of a hierarchy



$$W = \begin{bmatrix} 0 & 0 & 0 & \cdot & \cdot & \cdot & 0 & W_{1,n} \\ W_{21} & 0 & 0 & \cdot & \cdot & \cdot & 0 & 0 \\ 0 & W_{32} & 0 & \cdot & \cdot & \cdot & 0 & 0 \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot & \cdot & W_{n-1,n-2} & \cdot & \cdot \\ 0 & 0 & 0 & \cdot & \cdot & \cdot & W_{n,n-1} & 0 \end{bmatrix}$$

Analytic Network Process, Fig. 4 The structure and supermatrix of a holarchy

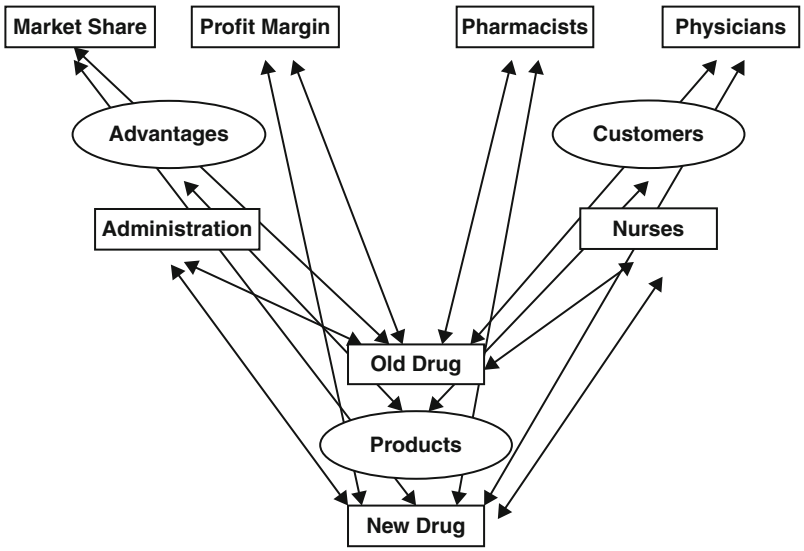


Analytic Network Process, Fig. 5 The control hierarchy

when the study was conducted. With the pending expiration of the current market offering, their objective was clearly to launch the new drug successfully before the patent for the old drug expired.

However, the company had to decide whether to market the new drug over the old. The questions were: Should the old drug be phased out slowly or entirely replaced by the new drug? How much of the marketing budget should be devoted to each strategy? Other important questions were also considered. Although the old drug would be facing stiffer competition, its brand recognition would continue to bring in revenue. The new drug was chemically improved over the old but needed greater promotion to be successful. There was also the risk that the new drug would be rejected by the HMOs and by customers. Moreover, with the added costs of promotion and the existing competition, the company could be facing slimmer profit margins, making these marketing decisions more critical.

The first step in building the model was to identify the stakeholders: HMO administrators, physicians, pharmacists, and nurses. Interviews with these stakeholders facilitated identifying the relevant clusters and the elements in each cluster and their



Analytic Network Process, Fig. 6 The benefits submodel

interdependencies. The interviews also yielded invaluable information and knowledgeable judgments for the model.

The second step was to partition the decision by using the control model approach. This allowed the participants to focus on each aspect of the larger problem. When considering benefits alone, for example, factors such as market share and profit margin were identified. Their importance may vary for the different stakeholders, and these are precisely the dependencies and priorities the model seeks and measures. For the costs side, the factors identified included marketing expenses, production costs, and market share loss. Factors for the risks model included product acceptance, production backlog, patient expiration, and sales incentives. Figure 6 illustrates the submodel corresponding to the benefits control criterion (note there that an oval represents a cluster and a rectangle represents an element belonging to a cluster).

The last step was to synthesize the ANP submodels. The best outcome derived from the ANP was the decision to proceed to market the new drug but also continue to market the old one. The new drug would incur higher marketing expenses compared with the old, but the brand recognition of the old drug would continue to provide a healthy return even with a lower marketing effort.

The actual decision of the company was to proceed to market the new drug and continue to market the old drug (Table 1). However, the company decided to eliminate the sales incentives and marketing expenses for the old drug and to increase the sales incentives and marketing expenses for the new drug. These decisions were consistent with the ANP model of Fig. 5.

Analytic Network Process, Table 1 The ratio of benefits/(costs × risks)

Market share	0.4845
Physicians	0.5901
Profit margin	0.3416
Administration	0.1739
Pharmacists	0.2905
Nurses	0.1193
Old drug	1.8180
New drug	2.6692

The final outcome is given in Table 1. It suggests marketing the new product in the ratio of 2.6692 to 1.8180, or 1.47 to 1, obtained by dividing the ratio scale numbers for the two drugs.

Approximate Dynamic Programming

Michael C. Fu
University of Maryland, College Park, MD, USA

Introduction

Stochastic dynamic programming models provide a rich framework for modeling sequential decision making under uncertainty. However, for many problems of practical interest, finding a tractable solution of the resulting models faces many potential challenges, including

- large state space;
- large action space;
- unknown state transition function/probabilities;
- costs or rewards that must be estimated.

The so-called curse of dimensionality refers to the computational intractability resulting from a large state space or a large action space (or both). Traditional methods for solving dynamic programming assume that the model is completely specified and that the corresponding expectations can be computed exactly. Even in cases where the state transition function/probabilities and probability distributions on costs/rewards are fully specified, analytical calculations may be computationally prohibitive if the state or action space is large.

Approximate dynamic programming (ADP) is the name given to approaches for providing practically implementable computational solutions to dynamic programming problems facing one or more of the challenges just described (Powell 2011; Si et al. 2004). In the artificial intelligence (AI) community, ADP methods are usually referred to as reinforcement learning (Sutton and Barto 1998), and in the stochastic control community, ADP is often called neuro-dynamic programming (Bertsekas and Tsitsiklis 1996). Simulation-based ADP approaches are described in Chang et al. (2007) and Gosavi (2003). ADP generally does not refer to the process of trying to estimate the transition probabilities directly. For expositional purposes, a discounted reward Markov decision process (MDP) model will be used throughout this entry. However, the state and action spaces will not be restricted to be finite or even countable, as the most general ADP approaches handle uncountable settings.

Problem Setting

The MDP is defined by the respective state and action spaces S and A, along with the one-stage rewards $r(s, a)$, $s \in S$, $a \in A$, which will be assumed to be stationary, and a probabilistic mechanism (which could be a simulation model) for transitioning from a state given an action taken. For the usual MDP with a finite or countable state space, this is specified in the form of state transition probabilities $\{p_{ij}(a), i, j \in S, a \in A\}$ that give the probability of going from state i to state j when action a is taken. Given an initial state (or more generally a probability distribution over the initial state), the optimization or control problem is to sequentially choose actions in each stage to maximize the expectation of the total discounted reward given by

$$\sum_{t=0}^{T} \beta^t r(s_t, a_t), \tag{1}$$

where $0 < \beta < 1$ is the discount factor, T is the number of stages (horizon length, so taking $T \to \infty$ corresponds to the infinite-horizon problem), a_t is the action taken in stage t, and s_t is the state reached in stage t. To simplify notation, it is assumed that all actions are feasible in all states; otherwise, one would write $A(s)$, $s \in S$ for the feasible action space in state s.

The action a_t taken in each stage is assumed to be specified by a Markov policy $\pi = \{\pi_0\ \pi_1 \ldots \pi_T\}$ that specifies for each possible state the action to be taken, i.e., a policy is a sequence of decision rules π_t: $S \to A$, where t is the stage. A stationary policy does not

depend on the stage, in which case π will be used to indicate both the policy and decision rule, which is the same for any stage. In the infinite-horizon setting, the usual objective is to find an optimal stationary policy (if one exists), for which there are three main approaches: value iteration, policy iteration, and linear programming.

Value Function and the Optimality Equation

Critical to ADP is the concept of a value function, which is defined for a given policy π from any stage n and state s_n to the end of the horizon:

$$V_n^{\pi}(s_n) = E\left[\sum_{t=n}^{T} \beta^{t-n} r(s_t, \pi_t(s_t)) \middle| s_n\right]. \quad (2)$$

The optimal value function achieves the maximum:

$$V_n^* = \sup_{\pi} V_n^{\pi},$$

and the problem of maximizing the expectation of (1) becomes that of finding $V_0^*(s_0)$ for a given starting state s_0, with an optimal policy given by

$$\arg\sup_{\pi} V_0^{\pi}(s_0).$$

According to the principle of optimality in dynamic programming, the optimal value function satisfies the Bellman optimality equation:

$$V_n^*(s) = \sup_{a \in A} \left\{E[r(s,a)] + \beta E[V_{n+1}^*(s')]\right\},\ s \in S, \quad (3)$$

where s' represents the state (a random variable) reached in stage $n + 1$ when taking action a from current state s in stage n, and the reward $r(s, a)$ is also allowed to be random. The form of the optimality equation given by (3) is convenient for the ADP setting, generalizing the usual form for the countable state space MDP with nonrandom rewards given by

$$V_n^*(s) = \sup_{a \in A} \left\{r(s,a) + \beta \sum_{j \in S} p_{sj}(a) V_{n+1}^*(j)\right\},\ s \in S.$$

Two Approaches

The computational challenges that may arise in (stochastic) dynamic programming are evident from inspection of the optimality equation in the form given by (3). First, the equation has to be solved for every state in the state space S over the action space A. Thus, for a given state, the optimization problem over a huge action space could be intractable, and/or the number of optimization problems that have to be solved could be impractical. Furthermore, the expectations in (3) may be analytically intractable and must be estimated from sampled simulation output or from actual (e.g., online) data. This may arise even in the finite state space nonrandom reward setting, e.g., if the transition probabilities are not readily available, so that state transitions can only be sampled using a simulation model or observing a real system.

This entry briefly describes the two most frequently employed ADP approaches:

- Value (or cost-to-go) function approximation;
- Q-learning.

The former addresses the state space curse of dimensionality, whereas the latter addresses the setting where the expectations in (3) must be estimated. Other approximations not described here include purely greedy (myopic) algorithms, one-step look-ahead algorithms, rollout algorithms, linear programming methods, policy parameterization, and numerous aggregation (state and/or action) methods.

For further expositional simplicity, the infinite-horizon case will be considered, so that the value function (for a given policy π) and optimal value function are defined by

$$V^{\pi}(s) = E\left[\sum_{t=0}^{\infty} \beta^t r(s_t, \pi(s_t)) \middle| s\right], \quad (4)$$

$$V^*(s) = \sup_{\pi} V^{\pi}(s), \quad (5)$$

where a stationary policy π is assumed. The optimal value function V^* in (5) then satisfies the following Bellman optimality equation:

$$V^*(s) = \sup_{a \in A} \left\{E[r(s,a)] + \beta E[V^*(s')]\right\},\ s \in S, \quad (6)$$

which is a fixed point equation over the state space S (again s' represents the random state reached when taking action a from current state s). Value function approximation uses a compact representation for the value function (4), which should satisfy (6) if optimal. Applying value function approximation thus involves two steps if used to find optimal policies: approximating the optimal value function and then finding an approximately optimal policy.

A common value function approximation is a linear combination of a set of basis functions:

$$\widehat{V}^{\pi}(s,\mathbf{r}) = \sum_i r_i \phi_i(s) = \mathbf{r}\boldsymbol{\phi},$$

where $\mathbf{r} = [r_1\ r_2\ \ldots]$ is a (row) vector (set) of parameters and $\boldsymbol{\phi} = [\phi_1\ \phi_2\ \ldots]^T$ is a (column) vector (set) of basis functions. The basis functions and parameterization are usually chosen based on some domain knowledge of the problem setting, which can be expressed in terms of features of the problem. However, in many settings this may be more art than science.

Instead of working with the value function directly, Q-learning works with the so-called Q-factors, which are the functions being optimized in the Bellman equation (6), i.e.,

$$Q(s,a) = E[r(s,a)] + \beta E[V^*(s')], \tag{7}$$

which depends on both the state and action. If all the Q-factors are known, then the value function can be found simply by taking

$$V^*(s) = \sup_{a \in A} Q(s,a),$$

so that (7) becomes

$$Q(s,a) = E[r(s,a)] + \beta E[\sup_{a' \in A} Q(s',a')]. \tag{8}$$

Note that in (8) the optimization operator (supremum) is inside the expectation, whereas it appears outside the expectation in (6). However, now the curse of dimensionality in both the state and action spaces comes directly into play, since a two-dimensional lookup table is required to keep track of the Q-factors that will be estimated using Q-learning. Similar to value function approximation, one could also seek a compact (approximate) parametric representation of the Q-factors to reduce the dimensionality.

The basic idea of Q-learning is to use outputs from the model (real or simulated) to iteratively update the estimate of the Q-factors as follows:

$$\begin{aligned} Q_{n+1}(s,a) &= Q_n(s,a) \\ &\quad + \alpha_n \left[(r(s,a) + \beta \sup_{a' \in A} Q_n(s',a')) - Q_n(s,a) \right] \\ &= (1-\alpha_n) Q_n(s,a) + \alpha_n \left[r(s,a) + \beta \sup_{a' \in A} Q_n(s',a') \right], \end{aligned}$$

where n denotes the iterate number and α_n is called the learning rate. Q-learning is a form of the AI machine learning approach called temporal-difference (TD) learning, because the Q-factor update in the first expression uses the difference between the predicted Q-factor value based on a sampled version of (8) for a single next state s' (simulated or from real online data) and the current Q-factor value. In the second form of the update iteration, the Q-factors are expressed as a convex combination of these two values. The desire is that with increasing n, the estimated Q-factors approach the true Q-factors, i.e., $Q_n(s, a) \to Q(s, a)$ for all states $s \in S$ and actions $a \in A$. Since the first form of the iterative updating also puts Q-learning in the class of stochastic approximation algorithms, for which there is a large body of research, convergence analysis can use machinery developed for those methods, and the choice of the learning rate parameter sequence $\{\alpha_n\}$, which greatly affects the practical performance of the algorithm, can also find guidance there.

Successful Applications

The earliest success stories for ADP are applications in computer programs for playing games, from checkers (Samuel 1959) to backgammon (Tesauro 1995). The program TD-Gammon, which reached the level of the best human backgammon players at the time, used an artificial neural network to approximate the value function, where the state space is estimated to have over 10^{20} states (close to the estimated number of grains of sand in the world's beaches). ADP ideas were also implemented in the computer system

"Watson" that was designed to play the television quiz show *Jeopardy!* and in 2011 beat the two best human players; Tesauro was a member of the IBM team that developed "Watson."

Other successful applications of ADP have been found in financial engineering, although the term ADP is not generally used or recognized there. For example, the pricing of financial derivatives for American-style options is an optimal stopping problem, where at each decision stage there are two possible actions: "Hold" or "Exercise" (and stop). Generally the exercise value can be calculated easily, so calculating the price of the derivative reduces to calculating the value of holding (taking the "Hold" action), which is also called the continuation value and can be represented by $Q(s, \text{Hold})$ using the Q-factor notation introduced previously, with

$$V^*(s) = \max\left\{Q(s, \text{Hold}), \text{Value of Exercising at } s\right\}.$$

Now either of the two ADP approaches described in the previous section could be used to estimate the continuation values $Q(s, \text{Hold})$: Q-learning or function approximation. Regression based on a large number of simulated paths is a popular way of carrying out the function approximation. See (Glasserman 2004, Chapter 8) for more details on this approach.

A real-world large-scale application of ADP received the 2010 Daniel H. Wagner Prize for Excellence in Operations Research Practice, which "emphasizes the quality and coherence of the analysis used in practice" (as stated on the INFORMS Web site, accessed October 2010). The application addressed logistics and transportation planning for a large trucking company, reported in Simão et al. (2010): "Schneider National needed a simulation model that would capture the dynamics of its fleet of over 6,000 long-haul drivers to determine where the company should hire new drivers, estimate the impact of changes in work rules, find the best way to manage Canadian drivers, and experiment with new ways to get drivers home. It needed a model that could perform as well as its experienced team of dispatchers and fleet managers. In developing our model, we had to simulate drivers and loads at a high level of detail, capturing both complex dynamics and multiple forms of uncertainty. We used approximate dynamic programming to produce realistic, high-quality decisions that capture the ability of dispatchers to anticipate the future impact of decisions. The resulting model closely calibrated against Schneider's historical performance, giving the company the confidence to base major policy decisions on studies performed using the model. These policy decisions helped Schneider to avoid costs of $30 million by identifying problems with a new driver-management policy, achieve annual savings of $5 million by identifying the best driver domiciles, reduce the number of late deliveries by more than 50 percent by analyzing service commitment policies, and save $3.8 million annually by reducing training expenses for new border-crossing regulations."

Concluding Remarks

Historically, ADP can be traced all the way back to the very roots of dynamic programming itself, from function approximations in Bellman and Dreyfus (1959) to the machine learning-based checkers-playing program of Samuel (1959). Q-learning was introduced by Watkins in his 1989 Ph.D. dissertation, with a convergence proof published in Watkins and Dayan (1992). An online and continually updated version of the research-oriented Chap. 6 on ADP in Volume II of the two-volume book by Bertsekas (2007) is made freely available for download by the author at his MIT Web site.

Although the setting considered here is stochastic, the idea of approximating the value function in dynamic programming can also be applied to completely deterministic settings, which might be appropriate when the state and/or action space is huge.

- ▶ Military Operations Research

Arrival Process

A random point process or marked point process with marks denoting some aspects of the stream of customers arriving to a queue or some aspects of the queue itself at the times of arrival, with points representing the precise instants of arrivals. For example, in the marked point process $(\boldsymbol{X}^a, \boldsymbol{T}^a)$, the $\boldsymbol{X}^a$ process may represent the sequence of customer priority classes arriving to a queue, while the $\boldsymbol{T}^a$ process would be the sequence of actual arrival times.

[3]George Mason University, Fairfax, VA, USA

Introduction

Both artificial intelligence (AI) and operations research (OR) have roots in the early years of computer science, both matured during the 1950s and 1960s, and both have undergone major changes in the last few decades as a result of the explosive power and affordability of computers. Operations research is an interdisciplinary approach to problem solving, generally using mathematical models to represent a system. Artificial intelligence involves making computers perform functions that are generally believed to require intelligence. Although the meaning of intelligence is subject to debate, one ingredient, which relates to OR, is being able to solve complex problems.

Recent years have seen considerable overlap between OR and AI with a number of conferences and journals devoted specifically to areas of overlap such as heuristic search and data mining. Indeed some similar techniques have followed parallel paths, for example, A* search within AI and branch and bound within OR. Problem areas involving big data that arise particularly through the development of the Internet give rise to new opportunities and problems for both AI and OR, with data mining and machine learning techniques, which are generally regarded as AI approaches, becoming increasingly prominent within the OR community.

In developing computer systems capable of complex problem solving, the AI community has adopted a wide variety of approaches that range from very strong cognitive models of human problem solving to very strong computational models that have little internal resemblance to human problem solving. The more cognitively oriented models focus on knowledge representation and reasoning, while the more computationally oriented methods focus on efficient techniques for representing and searching large, complex spaces.

The AI techniques that are likely to be most useful to the OR researcher and practitioner are those of weak AI, which consists of those AI techniques which are targeted at solving specific problems, and form the primary focus of this article. Strong AI research aims to find a more general-purpose computer intelligence at a similar level to that of human or at least animal intelligence. This appears to be an extremely difficult goal and problems requiring this general-purpose intelligence are often referred to as AI-hard. To illustrate this, consider the Deep Blue chess computer, which built upon decades of research on computer hardware, software and chess AI to beat the human world champion, Garry Kasparov, in 1997. While Deep Blue was arguably the strongest chess playing entity on the planet at that time, Deep Blue was incapable of doing almost all of the everyday activities of a human, such as talking about the weather or filling in a tax return. One of the ongoing problems of AI research is the so-called AI effect that once a precise algorithm is known for performing a task that appeared to require intelligence, then it can be argued that it does not require intelligence. Some AI methods, however, such as neural networks, can be encoded on a computer but the precise mechanism by which solutions are generated is not readily understood.

In the past there has been overoptimistic extrapolation of the triumphs of weak AI research to the possibility of general intelligence. Recent success in AI approaches to steering a road or air vehicle in real time point to a substantial increase in the generality of problems which AI can solve, but still leave the goals of strong AI some way off. One exciting possibility for strong AI is the computational neuroscience approach to directly modeling the processing methods of the human brain (Feng 2003). While this approach is still in its infancy, it provides a method which might lead to very flexible and powerful problem-solving approaches in the future.

AI as Search

It would seem at first glance that the obvious way to build intelligent systems is to use as a starting point

properties of human problem solving. Articulating and implementing human capabilities, however, has proven to be an exceedingly difficult task. This is perhaps best illustrated by the efforts to build game playing programs for chess (Hsu 2004) and Go (Lucas 2011), where approaches that aim to emulate the thought processes of a human expert are much weaker than those that are able to search through millions of alternative move sequences before selecting a move.

Unlike OR, AI has the dual mission of producing a solution and providing a laboratory tool to test explanatory theories of intelligent behavior. This dual role creates a difference in how AI approaches search. An OR design always seeks an optimal solution with a minimum of computational effort and, for complex problems, must trade-off solution quality with computational effort. An AI design is additionally concerned with the meaning of the heuristic in relation to human reasoning, and the trade-off between solution quality and computational effort can be different. For example, humans generally construct satisfactory solutions to problems such as "what route will I take home tonight," and do not spend much time thinking about optimality. Historically, OR has focused on computational efficiency by exploiting mathematical structures in a relatively narrow class of problems, while AI has focused on heuristics for broader class of problems. In recent years, however, OR and AI approaches have become more intermingled.

Modern AI approaches (Russell and Norvig 2010) generally objectify a computational problem-solving approach as an agent. Often the computational decision making approach is closely integrated into a physical system, or robot. The agent receives sensory information about the current state, and chooses between the set of possible actions at that state to move to a new state, and to continue selecting actions until a goal state is reached. Such a problem is known as a planning problem in the AI literature. A planning problem may be represented as a directed graph with states as nodes, actions as arcs and goal states as optimal solutions (or at least solutions of acceptable quality). This mapping allows search approaches from AI and OR to be used interchangeably for a wide range of problems.

The difficulty with modeling complex problems as spaces to be searched is that most such spaces are known to present NP-hard search problems, that is, there are no known polynomial-time algorithms for finding the answer. As a consequence considerable effort has gone into the development of efficient heuristic search procedures capable of finding solutions in acceptable amounts of search time. A heuristic is simply a rule of thumb that expresses some problem-specific knowledge that can be used to improve search efficiency.

A heuristic search strategy consists of a problem representation, a database of points in the search space, a set of heuristic rules and a control strategy. At any point during the search, the database contains subsets of candidate solutions. Using this database the control strategy selects a heuristic that generates a new candidate to be tested. Examples of control strategies are depth-first and breadth-first search. Testing a candidate, such as a partial solution to a traveling salesman problem, can be as simple as evaluating the length of the sub tour. A heuristic can be as simple as choosing the next link to be a nearest neighbor of an endpoint of the partial solution, or it can be more computationally intensive, such as solving a linear-programming relaxation problem that provides a bound on the completion of the partial solution.

An important AI paradigm for node selection in a search tree is the A* algorithm. This is a family of algorithms designed to find an optimal or high-quality solution guided by a heuristic function. For each node, n, in the search tree, such as at a partial solution to a traveling salesman problem, the cost to reach that node is denoted by $g(n)$, and the estimated minimum cost to complete the solution is the heuristic function, denoted $h(n)$. The control strategy selects the node having the minimum value of $g + h$.

In this family of algorithms, if the heuristic function is admissible: i.e., $h(n) \leq h^*(n)$, where $h^*(n)$ is the actual minimum cost to complete the solution from node n, then the resulting solution is guaranteed to be optimal. In words, if the heuristic function $h(n)$ is optimistic, then the resulting A* search finds an optimal solution. If h is admissible, the search tree can be pruned below node n when $g(n) + h(n) \geq g(n')$ for some complete solution n' already found (in OR, this is called fathoming a node).

A special case is breadth-first search, where $h \equiv 0$ and $g(n)$ is defined to be the depth of node n. Another special case is OR's branch-and-bound for general integer

programming, where $g + h$ is the objective value of the linear relaxation at a node.

When using a non-admissible heuristic estimate h, optimality is no longer guaranteed, although the time taken to find a solution of sufficient quality may be very greatly reduced. For example, this approach may be taken in applications such as finding paths for a very large number of units in a computer simulation or game, and is used in a variety of search local approaches which do not have optimality guarantees.

Models for AI problems are often less well-defined than in OR, in areas such as machine vision or vehicle guidance, and it is difficult to define a priori a heuristic search approach for such a problem. As a consequence, an important subarea of AI focuses on algorithms that construct models from sampled data provided a priori or dynamically acquired during the problem solving process. These techniques are generally labeled as machine learning algorithms (Mitchell 1997; Alpaydin 2004) and have been successfully applied to a variety of difficult problems including classification (e.g., support vector machines for image processing) and sequential decision problems (e.g., reinforcement learning techniques for robot control).

Machine learning approaches have proven their worth in conjunction with OR heuristics and algorithms, for example in finding good parameters for another search approach or in choosing which heuristic approach to use at each step of search. The use of machine learning approaches to choose between other heuristics was christened a hyperheuristic in (Cowling et al. 2001), and this approach has gained in popularity as an approach for solving difficult optimization problems (Chakhlevitch and Cowling 2008). Hyperheuristics are examples of a more general approach to machine learning where an ensemble of learning methods are combined using some kind of voting method to yield an approach which is greater than the sum of its parts (Polikar 2006). Recent years have seen considerable success for ensemble approaches, particularly for classification problems arising in data mining (Nisbet et al. 2009).

Another theme in AI is the design and application of biologically-inspired techniques. A well-developed subarea focuses on artificial neural networks (ANNs) (Bishop 1995). ANNs are very loosely based on a connectionist model of the mammalian brain and have proven extremely useful when dealing with problems where it is necessary to provide a mechanism for approximating a complex function. An ANN is a weighted digraph with identified sets of input, hidden, and output nodes. Values are applied to the input nodes which are then propagated though the ANN to generate values at the output nodes which approximate the given function. The values at each hidden node and the output nodes are obtained by applying a nonlinear squashing function to the sum of the inputs at each node, weighted using the arc weights. These values are then propagated forward to subsequent hidden nodes and ultimately to output nodes. The function to be approximated may be highly complex, for example to estimate the probability that a luggage contains an explosive device by using an ANN to analyze the pixels of an X-ray photograph of the luggage. Appropriate weights are determined by supervised or unsupervised learning. In supervised learning a large number of examples where the function value is known are considered and the variance between ANN outputs and true outputs is minimized by treating the problem of changing weights as a nonlinear optimization problem. Back propagation is often used to improve the weights, proceeding backwards from output nodes to input nodes, iteratively adjusting weights so as to reduce the error arising for each example. Unsupervised learning is also used, where the arc weights are often adjusted using an Evolutionary Algorithm (EA) and the ANN is evaluated by considering its performance directly in an application (e.g., the time taken to drive around a track for an ANN which controls vehicle steering).

Evolutionary Algorithms (EAs) (Michalewicz and Fogel 2004; De Jong 2006) are another well-developed area of biologically-inspired techniques. EAs use analogies with natural evolutionary processes. They maintain a population of candidate solutions, and local search operators which modify single solutions (mutation) and pairs of solutions (crossover). EAs attempt to find a solution with a high objective function value (generally known as fitness within an EA) by using selection processes modeled on Darwin's "survival of the fittest" principal. EAs have proven effective in a number of problems where it is difficult or impossible to use a large amount of problem knowledge, so that they may be regarded as relatively general-purpose approaches.

In game theoretic problems involving more than one participant, machine learning and evolutionary algorithm approaches have proven effective. In particular, Monte Carlo Tree Search (MCTS) (Lucas 2011) has recently provided much stronger players for the game of Go, a game that has for a long time been considered as one of the more intractable problems of AI research. Since 2009, MCTS approaches using highly parallel algorithms on many computer cores have started to compete at, or near human world champion level for small-board Go. MCTS algorithms selectively build a search tree, starting from the current state, by trading off exploration of unseen areas of the tree, and exploitation of known good areas, by considering the decision as to where to progress at each node/state as a multi-armed bandit problem. It seems likely that MCTS approaches will become increasingly important in a wide variety of decision applications.

There are many other approaches to heuristic search which have been explored by researchers and practitioners in OR and AI, known as metaheuristics (Michalewicz and Fogel 2004; Gendreau and Potvin 2010). Generally these approaches guide a local search operator to avoid poor local optima. Metaheuristics are often inspired by natural metaphors. They include: simulated annealing, inspired by the second law of thermodynamics; tabu search, inspired by connections between intelligence and memory; and swarm intelligence algorithms, inspired by the foraging behavior of insects.

AI as Logic

At the other end of the AI spectrum are techniques for solving problems by capturing the knowledge of human experts and using a reasoning approach analogous to that of a human problem-solver. Generally, this involves expressing a problem as a theorem to be proved using a particular system of logic and providing a computational procedure for proving such theorems. This is generally referred to as logic programming.

The most elementary form uses propositional logic. A set of propositions and logical expressions is given. The satisfiability problem is to find an assignment of truth values for the propositions such that the logical expressions are true. In logical inference, the given expressions are facts about how propositions relate to each other. Consider, for example, a project selection problem, where proposition $P_j = TRUE$ means project j is selected, and $P_j = FALSE$ means project j is not selected. Projects might be related by a simple precedence constraint, $P_i \rightarrow P_j$, which says that if project i is selected, project j must also be selected (or the selection of project i must precede the selection of project j).

A feasible truth assignment exists when the facts, which comprise one form of a knowledge base, are consistent. Redundant facts occur when some logical expression is implied by the others. For example, if the knowledge base contains $P_i \rightarrow P_j$ and $P_j \rightarrow P_k$, then $P_i \rightarrow P_k$ is a redundant fact (from transitivity of implication). The knowledge base contains circular reasoning if it contains the implication $P_i \rightarrow P_i$ through a chain of implications. For example, the expressions, $P_i \rightarrow P_j$, $P_j \rightarrow P_k$ and $P_k \rightarrow P_i$, are circular. This means that projects i, j and k form an equivalence class: all are selected, or all are rejected. In managing a knowledge base, one wishes to know if it is consistent, non-redundant, and non-circular, particularly when new facts are entered into it. In some cases, violations can mean an error in the rule entry. If, for example, precedence constraints are supposed to form a partial ordering, as in job scheduling, a circular chain implies that there is no feasible schedule. Similarly, a redundancy can be due to a subtle implication that the users of the rule base should know to avoid a false perception of what an inference means.

The satisfiability problem can be represented by a system of linear inequalities with binary-valued variables. Let x_j be 1 or 0, according to whether P_j is true or false, respectively. A simple implication, $P_i \rightarrow P_j$, is true if, and only if, $x_j \geq x_i$. More complex logical expressions can also be represented by linear inequalities, but the effort to derive the inequalities is, itself, a difficult problem unless special forms are assumed.

The difficulty with propositional logic is that it not sufficient to express many important pieces of knowledge such as "all men are mortal." To do so requires logics with more expressive power such as the first-order predicate calculus. Unfortunately, this increase in expressibility comes at a high price: the inability to implement efficient computational theorem

provers. One of the important developments in this area was the development of PROLOG, a logic programming system based on a restricted form of the predicate calculus that maintained considerable expressive power while providing an efficient theorem prover (inference engine). This was achieved by restricting the semantics of negation and restricting propositions to one special form, a Horn clause. This is where the antecedent is a conjunction of propositions and the consequent is only one proposition: $P_1 \wedge P_2 \wedge \ldots \wedge P_n \wedge P_0$. This can be represented by $x_0 \geq x_1 + x_2 + \ldots + x_n - n + 1$.

To see if a particular proposition can be inferred from a set of facts, the logic programming problem becomes one of combinatorial optimization. Suppose the truth value of P_i for i in I is given, where I is some index reference set over the propositions, in order to determine if P_j can be inferred from the knowledge base (where j is not in I). x_i is set to 1 or 0, according to whether P_i is true or false, respectively, for $i \in I$ and minimum and maximum values of x_j are determined subject to the logical constraints. The maximum of x_j is 1 if, and only if, P_j can be true, and the minimum of x_j is positive if, and only if, P_j must be true. Then, the facts imply P_j if P_j can be true (i.e., max $x_j = 1$) and P_j cannot be false (i.e., min $x_j > 0$). The facts are inconsistent if P_j cannot be true (i.e., max $x_j < 1$) and P_j cannot be false.

Logic programming has been successfully used to build many AI systems, particularly expert systems designed to give advice about a particular problem, in areas such as medical diagnosis. A substantial effort has been made to encode common sense in the database of a very large, multi-contextual knowledge base and inference engine developed by Cycorp using the rules of logical inference to provide a general way to make everyday decisions. Evidence so far suggests that such an expert system is effective for specific tasks, but not likely to work as a method for attacking the strong AI problems of general intelligence.

Knowledge representation in an expert system can include forms other than logical expressions and uncertainties can be represented by a variety of calculi. Alternative logics arise naturally in both human reasoning and in AI. For example, it may be accepted that birds fly and deal with special cases, like penguins, without disturbing the main value of logical reasoning (key terms to investigate are non-monotonic and default logics).

One area that bring together search and logic-based approaches to problem solving is constraint programming (Van Hentenryck and Michel 2009). Constraint programming software allows a user to express a rich variety of constraints, which link decision variables. These include constraints such as "all these variables take distinct values from a given set" which are often difficult to model using other techniques. Powerful solution approaches are then often able to find solutions which satisfy all constraints (and which may also be required to maximize an objective function). Constraint programming techniques have been used with considerable success in a variety of planning and scheduling applications. Their drawback is that they often cannot guarantee to find a solution at all, so that metaheuristics are often used instead of, or in conjunction with, constraint programming approaches for very difficult problems.

Further Reading

A broad selection of AI textbooks are available. One widely used AI text is Russell and Norvig (2010). Michalewicz and Fogel (2004) introduces evolutionary algorithms and metaheuristic methods alongside OR techniques in a problem-solving style, based on the classic Polya book. Traditional heuristic search is well covered by Pearl (1984). A number of journals are specifically devoted to the links between Computer Science and OR, where AI is the aspect of Computer Science most strongly represented, including the *INFORMS Journal on Computing* and *Computers and Operations Research*. The Conference on Integration of AI and OR (CPAIOR) brings together AI and OR researchers with a common interest in constraint programming. More generally a great number of AI and OR journals and conferences specifically ask for contributions which bridge the gaps between these disciplines.

Artificial Variables

A set of nonnegative variables added temporarily to a linear program to obtain an initial basic (artificial) feasible solution. If the original constraints are $\boldsymbol{Ax} = \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}$, than adding an artificial variable y_i to each equation yields the system $\boldsymbol{Ax} + \boldsymbol{Iy} = \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}, \mathbf{y} \geq \boldsymbol{0}$, where $\boldsymbol{y}$ is a column vector of artificial variables. Assuming the vector $\boldsymbol{b} \geq \boldsymbol{0}$, this system has an obvious basic (artificial) feasible solution, with $y_i = b_i$ being the basic variables and the x_i the nonbasic variables. To obtain a basic solution to the original constraints, the artificial variables must be driven to zero. One way to do this is to solve an auxiliary linear program (known as Phase I) where the objective is to minimize the sum of the artificial variables. If the new system has no solution with all artificial variables equal to zero, then the original constraints are infeasible.

Assignment Problem

The problem of optimally assigning m individuals to m jobs, so that each individual is assigned to one job, and each job is filled by one individual. The problem can be formulated as a linear-programming problem

with the objective function measuring the (linear) utility of the assignment as follows:

$$\text{Maximize} \sum_i \sum_j c_{ij} x_{ij}$$

subject to

$$\sum_i x_{ij} = 1 \qquad j = 1, \ldots, m$$

$$\sum_j x_{ij} = 1 \qquad i = 1, \ldots, m$$

$x_{ij} = 1$ if person i is assigned to job j

$x_{ij} = 0$ if person i is not assigned to job j

$c_{ij} =$ utility of person i assigned to job j

The problem is a special form of the transportation problem and, as such, has an optimal solution in which each variable is either zero or one. The problem can be solved by the simplex method, but special assignment problem algorithms tend to be computationally more efficient.

Auction and Bidding Models

Ronald M. Harstad
University of Missouri-Columbia, Columbia, MO, USA

Introduction

Models to assess and guide bidding and auction design have proliferated, broadened, and become more game-theoretic. Usage of auctions for major sales by governments, most notably of rights to the electromagnetic spectrum for digital transmission, have been a major impetus for these developments; Internet auctions and combinatorial procurement auctions have also stimulated and supported modeling advances. In 1997, William Vickrey shared the Nobel Prize in Economic Science for his pioneering development of auction theory; the Prize in 2007 was awarded to Leo Hurwicz, Eric Maskin, and Roger Myerson for closely related work in Mechanism Design.

Why hold an auction? The literature has focused on two reasons: because a bid-taker lacks the information needed to fix an apt price, and because a method is needed to harness competition. Research has also pointed to a need to organize the allocation of interrelated, heterogeneous assets or contracts so as to accommodate bidder synergies across packages of assets or contracts (Harstad and Pekec 2008). Auctions are also employed to reduce the flexibility of an agent assigned to attain a sale or procurement, or when legitimacy of a transaction and its pricing needs to be secured or to be made transparent (Rothkopf and Harstad 1994). All these reasons, and indeed, virtually all of the analyses of auctions and bidding, straightforwardly apply and adapt whether bidders are seeking to buy or to sell; for more concrete exposition, the bid-taker is here treated as a seller of an asset or assets (with but few and narrow exceptions, the literature models a seller and ignores any noncongruence of interests between an auctioneer and a consignor).

Given these reasons for auctioning, auctions and bidding have become the most extensive and most noted application of the theory of games of asymmetric information: it is because potential buyers have information about asset values that a less informed seller cannot simply fix a price and thus conducts an auction; it is because a winning bidder both uses and protects the bidder's private information against rivals who have differing information that winning an auction is on average profitable when bidding rationally, despite best efforts of rivals to compete and best efforts of a seller to extract some of this profit in the form of higher revenue.

In the face of myriad practical problems, however, models of bidding and auctions far too frequently make assumptions in service of elegant,

general results at far too high a cost in relevance; key limits to applicability are noted in the following.

Environments Modeled

Vickrey (1961) introduced auction theory under the assumptions that each bidder privately knew the auctioned asset's value, and that rivals' values were independent of each other. While appropriate for such a pioneering study, it is hard to justify the frequent tendency to continue to base theoretical analysis on this independent private-values model. Any durable asset presumably has a value to a bidder related to how useful it would be to rival bidders now or to potential purchasers in the future, and thus is not private. Even for a perishable commodity, a fancy dessert at a charity auction, a bidder rationally expects more serious competitive bids for a more mouth-watering cake—defeating the independence assumption. Independent-private-values models exhibit the simple characterization that a bidder facing more rivals bids more aggressively, and a far-from-robust revenue equivalence result that any auction in which the efficient acquirer always wins and any bidder with a zero chance of winning is indifferent over participating attains expected revenue equal to the expected opportunity cost (the second-highest value).

More useful is the polar opposite: a common-value model (Rothkopf 1969; Wilson 1977). In it, asset value is the same for all bidders, unknown to any at the time of the sale, and each bidder has privately acquired an estimate of the common value. A generalization to affiliated-values auctions allows asset values to incorporate a common resale value, as well as a private possession value. Where the common-value component is significant, facing more rivals raises the important "winner's curse" (Capen et al. 1971): if a bidder did not anticipate before bidding that winning likely implies rivals observed lower estimates, then the appropriate reassessment of asset value may well cause the winning bidder to feel miserable for winning. In particular, this leads to the conclusion that each extra rival past the first should lead the bidder to bid less aggressively for any given asset value estimate. (Even with participating in hundreds of auctions, sharp experimental subjects in economics laboratories cannot systematically learn to survive the winner's curse, the toughest problem economics experimenters have posed, see Kagel, Levin, and Harstad (1995).

Auction Forms

Many auction models consider any method of reaching an allocation—via communications from bidders to a seller who has an a priori commitment to functions specifying bidders' payments and probabilities of winning that depend on the profile of communications sent—to be an auction. In practice, auctions follow simpler rules and can be considered minor variants on a few basic forms.

Standard sealed bidding, commonly called a first-price auction, features a single round of simultaneous bids, with the highest bid winning and setting the price. It continues to be somewhat common, used for many procurement auctions, government sales of mineral rights, and in circumstances where congregating bidders in time and space is unjustifiably expensive. The bidder's problem is a complicated one, exhibiting a tradeoff between the probability of winning (enhanced by bidding more aggressively) and the expected profit in the event of winning (diminished by aggressiveness). Published solutions presume the set of assumptions {A}: a single, isolated auction; symmetric aggressiveness of a known, fixed number of rational rivals; all bidders risk-neutral; and that each bidder's information about asset value can be completely summarized by a single real number.

Vickrey auctions, that is, sealed bidding under second-price rules, in which the seller is committed to selling to the highest bidder at a price set by the highest losing bid (no matter how much higher the winner bid), are rare, but are an important benchmark to understanding auctions and bidders' incentives. Since a bid may only determine whether the bidder wins, but not how much the payment will be if the bidder wins, the feature that a bidder should submit the bid that separates prices at which the bidder would prefer to win from prices at which the bidder would rather lose is quite general. Outside private-values models, this pivotal bid depends on the information about asset value that can be inferred from having to pay a particular price (because the highest-bidding rival bid that price).

Most auctions feature dynamic pricing, starting at a level with more bidders than assets and becoming less attractive, with bidders repeatedly deciding whether to continue competing or cease (exit). The last remaining bidder wins, paying a price equal to, or some modest fixed increment above the last price where the bidder faced competition. Such auctions allow bidders to reevaluate as they observe diminishing competition; upon such reevaluation, the last two bidders effectively engage in a second-price auction. The literature commonly calls these English auctions; the game-theoretic model of English auctions usually considered the standard, assumes a continuous rise in prices with all exits public and irrevocable (Milgrom and Weber 1982). Under irrevocable, public exits, and assumptions {A}, expected revenue in the Bayesian Nash equilibrium of the English auction exceeds that of other auction forms. Relative to second-price auctions, this stems from the greater problem the winner has in protecting the winner's information, as revelation of exit prices, and thus inferences about losing bidders' information, makes the last rival's evaluation a better substitute for the winner's.

Auctions with dynamic pricing seldom cleanly provide the final bidders this much information. In part, this is because bidders are reluctant to let winning bids in auctions reveal their private information, let alone losing bids. In part, it is because an auctioneer does not need to learn how many bidders are still competing to raise the price; excess demand is sufficient. So it is common for an auctioneer to recognize two willing bidders, raising the price as they alternately affirm continuing excess demand. When one bidder ceases doing so, the auctioneer must find another bidder willing at that price to pair up, reestablishing the excess demand that raises the price. This aspect may slow the auction enough to reveal an exit price, but Harstad and Rothkopf (2000) find that a second-price auction model may more closely estimate revenue when some bidders' exits are silent and unobserved.

The Dutch auction starts with a high price unacceptable to any bidder and adjusts it down until a bidder ends the auction by accepting the current price (the term Dutch auction tends to be used in financial markets in a very different way). As this faces a bidder with the same probability of winning-expected profit if winning tradeoff, auction theorists who have never witnessed a Dutch auction assume it can be analyzed via the same model as the first-price auction. (As witnessed by the author, the auction's video-game speed explains its usage in flower and fish markets in the Netherlands; for flowers, each of 13 auctioneers sell a lot of flowers every 4.25 seconds).

Revenue Maximization

If n bidders will compete no matter what auction is used, a seller maximizes expected revenue via monopolistic inefficiencies that take the form of refusing to sell in some circumstances where a bidder offers more than keeping the asset is worth to seller. The reserve price that mainstream models focus on is a binding commitment never to part with the asset if no bid exceeds the reserve. Such a blunt instrument is used only in auctions of perishables; to auctioneers, a reserve price is the lowest price at which the asset will be sold today, but with later negotiations or auctions with a lower reserve possible.

A more realistic model treats the number of competitors as an endogenous variable, responding to the expected profitability of bidding. For this expected profitability to be predictable, potential bidders' private information, and their bidding aggressiveness, must be symmetric. In such a model, forcing inefficiencies is costly for a seller; the main conclusion is that aspects of different auction situations that are not modeled—e.g., costliness of congregating bidders, or bidders' preference for dynamic pricing—can be accommodated without necessarily sacrificing revenue.

Concluding Remarks

Sets of assumptions such as {A} seriously limit practical relevance by treating bidding for an asset as an isolated occurrence; this is more the exception than the rule. Firms in an industry may repeatedly bid to sell contracts or acquire key inputs, with repetition adding issues of reputation or collusion, not yet well treated by modelers. Also, the outcome of an auction may affect later negotiations or industrial competition; rational bidders anticipate such

follow-up impacts and adjust their bidding for the conjoint expected profitability of the auction and the aftereffects.

It is also common for collections of assets to be sold simultaneously or in rapid succession. When identical, as financial asset shares, attempting to have sales priced at opportunity costs (as indicated by rival bids) becomes much more complicated if an individual bidder is allowed to win multiple shares; most auction models prohibit multiple purchases, but few auctioneers do. If K identical assets are sold sequentially, expected profitability of competing in the last auction reduces bidding for the (K-1) asset, dollar-for-dollar, if winning at that stage would lead the bidder not to compete for the last asset.

Simultaneous auction of heterogeneous but related assets, rare until the mid-1990's, has arisen widely and attracted much attention, primarily in governmental sales of rights to use electromagnetic spectrum for digital transmissions, in privatization of factories and contractual responsibilities, and in firms' procurements of services, primarily logistics. Early attention focused on spectrum auctions by the U.S. Federal Communications Commission, but the key feature of potential synergies from winning particular collections of assets fits all these areas. If bidders can only compete asset-by-asset, synergies may go unbid and unattained; if bidders can make single bids on arbitrary packages of assets, the auction may be computationally unmanageable (in that both the problem of determining the revenue-maximizing collection of bids, and the bidder's problem of finding the minimal bid on a desired package to place it into the tentative winning set, become unboundedly complex). Opportunities to structure the set of permitted package bids so as to keep the auction computationally manageable have been illustrated. Package auctions have been implemented in all three situations.

Although the Internet has altered the patterns of auction usage, of general interest is the descriptive book on auctions and auctioneering by Cassady (1967), and the sociological interpretation of auctions by Smith (1990). Surveys include Wilson (1992) and Klemperer (2000); critical perspectives are given in Rothkopf and Harstad (1994); Klemperer (2002, 2003); and Harstad and Pekec (2008).

Automation in Manufacturing and Services

Kalyan Singhal[1], Vijay K. Agrawal[2] and Matthew J. Liberatore[3]
[1]University of Baltimore, Baltimore, MD, USA
[2]The University of Nebraska at Kearney, Kearney, NE, USA
[3]Villanova University, Villanova, PA, USA

Introduction

Automation has affected both manufacturing and services. Automation's roots are in mechanization, which can be defined as the transfer of skills and manual activities to machine operation. Automation differs from mechanization in that it includes feedback for controlling the system (Odrey 1992). Automation is a dynamic technology that has been evolving for decades.

Automated reasoning is rarely included explicitly in the definition of automation, although machine learning, heuristics, and knowledge-based systems are increasing the scope of automation activities. But the industrialized world is moving towards building highly automated systems that are intelligent and operate in real time, with self-defined capabilities for carrying out pre-defined objectives over long periods of time in an uncertain environment (Kim and Chung 1991). Automation is defined here as the use of technological-based systems that replace routine physical labor and human reasoning by machines that perform operations with minimal or no human intervention. These machines should be as self-activated, self-acting, self-determining, self-regulating, and self-reliant as is practical. Automated systems can provide a heretofore unmatched level of performance along the four strategic dimensions of cost, quality, delivery, and flexibility (Singhal 1987). Parts of this presentation are based on Singhal et al. (1987) and Singhal (2011).

Automated Manufacturing

A typical automated manufacturing system can perform such operations as machining, welding, inspection, and assembly in industries as diverse as heavy machinery and light electronics. Its elements include computer-interfaced machine tools, robots, and automated material-handling and storage devices. The processing instructions stored in the computer memory of a machine tool enable it to perform customized operations automatically on each workpiece. Sensory devices in the machines and robots perform automatic inspection. The machines are linked by an automated material handling system and a central computer. The central computer provides the overall control of the system. This control includes routing and sequencing jobs, tracking their status, down-loading instructions to machine tools, and taking corrective actions. Other components of the system include a tool delivery system, and a common central buffer or local buffers at individual work stations. Applications of automation in manufacturing include a variety of technologies:

- Automatic machine tools: They include computer-numerical-controlled (CNC) tools that are controlled by software that is fairly easy to reprogram.
- Automatic materials-handling and storage systems: They include automatic storage and retrieval systems (AS/RS) and automatic guided vehicle (AGV) systems.
- Industrial robots: These are reprogrammable multi-function manipulators, often arm like in appearance, perform a variety of tasks.
- Flexible manufacturing systems (FMSs): These are manufacturing cells designed for mid-volume and mid-variety ranges of production (Stecke 1985, 1992). Typical FMSs consist of 5–25 machines that are linked together by common computer controllers and by automated material handling

devices. Because of the versatility of machine tools, for example, and the quick (seconds) cutting tool interchange capability, these systems are quite flexible with respect to the number of part types that can be produced simultaneously and in low (sometimes unit) batch sizes.

- Fixed automation: This is used when the sequence of operations is fixed, for example, high-volume assembly.
- Computer-aided design (CAD): CAD relies on computer graphics for designing products, and a full system includes databases of documentation and stored images of parts and assemblies. The designer can create new designs or modify existing designs on a CRT by using a light pen, a keyboard, or a joystick.
- Computer aided manufacturing (CAM): CAM includes various forms of manufacturing automation such as those listed above (Considine and Considine 1989; Odrey 1992).
- Computer-aided process planning (CAPP): CAPP uses computers to develop detailed process plans for producing parts or assemblies, and, as such, links CAD and CAM.

The use of CAD in contemporary engineering projects is especially important. CAD has been used to design products as simple as potato chips, kitchen cabinets, and customized swimsuits, and such complex products as the Boeing 777. Boeing's CAD system employed nine IBM mainframes, a Cray supercomputer, and 2,200 workstations and stored 3,500 billion bits of information. Boeing reduced its engineering design errors by more than 50% and designing and building a 777 plane took 10 months as compared to 18 months for Boeing's earlier planes, the 747 and the 767 (Laudon and Laudon 1998, pp. 618–621). CAD eliminates such activities as drawing blue prints and building prototypes, reducing costs, which was all quite critical in the Boeing efforts. More generally, CAD permits designers to make changes quickly and at very low cost. The designer can rotate the design to examine it from various angles, can split it apart to get a view of the inside, or zoom in on portions of the computer screen for close-ups.

An engineering perspective of automation in manufacturing is given in Chryssolouris et al. (2009). Radio frequency identification (RFID) has enormous potential for automated traceability in manufacturing systems. According to Ngai et al. (2007), its advantages include improved lead time; ability to offer customers timely information about an item's status and job completion time, improved maintenance operations; reduction in human errors, improved inventory management, automatic capture of data and resulting lower costs, and improved customer relationships.

Many automated manufacturing systems integrate several production stages resulting in interactions among many hardware and software components. Many of the benefits of automated systems accrue from this integration. For a number of reasons, this integration can dramatically increase the complexity of managing a manufacturing system. First, many automated manufacturing systems have several hierarchical levels, a large number of candidate decisions, and large data requirements. Second, management of these systems requires balancing multiple objectives with quantifiable and nonquantifiable trade-offs. Finally, the high degree of integration makes the management of automated manufacturing systems especially vulnerable to the stochastic variability of machine failures, operator absences, material shortages, and production requirements.

Since mathematical models can offer insights into the nature of the interactions among components in complex systems, OR/MS professionals can play a major role in the design, operation, and control of complex automated systems. Although these systems are complex, the central role played by computers enables low cost data collection for a wide range of events that occur within the system. The resulting availability of information greatly facilitates the use of OR/MS models in these computer-controlled systems. The contribution of models and other decision-making aids can be substantial because the large investments these systems require make the opportunity cost of suboptimal design and operation high. Time, talented professionals, and good data are also crucial to success.

Traded off against the costs of the capital investment and the human resources are a wide range of benefits attributed to automated manufacturing systems. These benefits include lower direct manufacturing costs resulting from reductions in setup time, processing time, labor requirements, lead time, inventory, and factory space; improved product conformance (quality); a greater variety of products at

little additional cost (economies of scope); the ability to respond rapidly to changes in design and demand, and flexibility in scheduling around equipment breakdowns.

Managers can sometimes obtain many of the benefits in improved quality and lead time that are attributed to automated systems by paying attention to problems in these areas, irrespective of the technology in place. Adopting total quality management, just-in-time practices, and design-for-manufacturability, for example, may achieve many of those benefits at a fraction of the capital cost. If this is the case, one must ask whether the additional benefits that can actually be attributed to automation can justify the cost. In the 1980s, an IBM printer manufacturing facility in Kentucky dramatically redesigned and simplified its product and process to pave the way for 100% automated assembly. IBM discovered that the redesigned printer was so simple that it could achieve high quality manual assembly at a lower cost than automated assembly.

It is useful to partition the issues related to analyzing and modeling automated manufacturing systems according to the following phases: choice of technology; design of the physical system; design of the production planning, scheduling, and control system; installation and start-up; and steady-state operation and improvements (Singhal et al. 1987):

The Choice of Technology — Conceptually, the decision rule for investing in an automated manufacturing system is like that for any other investment decision; the net benefits, tangible and intangible, should result in positive net present value to the firm. Because many of the benefits of automated manufacturing systems are difficult to quantify, the firms should first calculate the net present value on the basis of quantifiable benefits. If this value is negative, firms should use managerial judgment to decide whether the intangible benefits are greater than the shortfall. Analysts also use multicriteria approaches, such as the analytic hierarchy process or multiattribute utility theory, to compare different automation options. Canada and Sullivan (1989) and Liberatore (1990) reviewed models for investment in automated manufacturing systems and related issues.

It is crucial that a firm's technology acquisition decisions be consistent with its manufacturing strategy. Once the firm has established that the acquisition is congruent with its manufacturing strategy, it must consider several other issues. First, in addition to hardware costs, the investment cost includes the cost of software and training. Second, in a changeover from conventional manufacturing, the firm should include in its analysis the cost of changeover and the reduction in work-in-process and finished-goods inventory. Third, it cannot extrapolate the tangible benefits from the performance of a conventional manufacturing system; it must evaluate an initial design of the system to measure these benefits.

During the technology evaluation process, the firm should identify sources of risk and uncertainty related to the automated manufacturing system project. The stochastic variability of market demand, component supply, and competitive interaction will all affect the contribution of an automated manufacturing system to a firm. An additional source of uncertainty is organizational learning. In automated systems, as in most manufacturing systems, learning continues beyond the start-up phase into the steady-state operation phase. Learning increases equipment utilization, reduces the number of workers, increases flexibility in meeting changes in product demands and designs, improves quality, and increases variety.

Benefits that are difficult to quantify economically should be identified. These benefits include better and more consistent quality, economies of scope, shorter lead times, and flexibility in responding to changes in product designs and product demands. Some of these benefits derive from the firm's ability to do things not previously possible and to build new strategies to exploit the new capabilities.

The firm should not assume a static environment when comparing the option of investing in automated technologies with the option of retaining its old technologies. Whether or not a firm chooses to invest in automated technologies, its competitors may do so.

Another issue is whether the firm should acquire islands of automation in stages and then link them or whether it should go for complete automation in one step. With the former approach the firm can evaluate what it has implemented before proceeding with the next step. This approach also provides more scope for learning and mastering technology in stages. However, it will realize many of the benefits related to flexibility and product variety only when it links these islands. This may make the latter approach more desirable.

The Design of the Physical System — For most automated manufacturing systems, the output and flexibility requirements determine the basic design: the types and number of machines, robots, material handling devices, information processing capabilities, and human resources. Important decisions in the design of automated manufacturing systems concern the specifications of the structure of the control system and the sizes and locations of inventory and capacity buffers. Although most automated manufacturing systems are large and complex, they tend to be organized in hierarchical structures, allowing the designer to break up the computational and data requirements up so that modeling the system is possible. The higher levels of the hierarchical models have long horizons and use aggregated data. The lower levels have shorter horizons and use more detailed data. Queueing models (Buzacott and Yao 1986a, 1986b) can be used for the basic design. They are robust and computationally efficient, and they can predict the main output measures within 10% accuracy. Thus, the designer can explore a wide range of alternatives before selecting a small subset of designs for detailed evaluation.

Viswanadham and Narahari (1992, p.163) point out that "Markov chains constitute the basic model of discrete event systems and therefore of automated manufacturing systems." They further note (p. 7) that the "underlying stochastic process of most high-level models such as queues, queueing networks, and stochastic Petri nets turns out to be a Markov chain."

The detailed design of the system determines the layout, the number of pallets, the type and number of fixtures, the required accuracy of machines, the types of tool-changing systems, and the methods of feeding and locating parts at machines. The designer should integrate the planning, scheduling, and control of operations with the detailed design. Simulation, because of its versatility, is the tool most frequently used for detailed design. The designer plans the details of a common data base at this stage. In an ideal system, all decision makers in the organization have access to the same data so that engineering changes in products and processes can be entered as soon as they are finalized. The development of such a database for an automated manufacturing system is a major task requiring considerable effort and resources. For an application of analytical approaches to the design of an automated production line, see Burman, Gershwin, and Suyematsu (1998).

Design of the Production Planning, Scheduling, and Control System — Production planning consists of deciding when to produce which products; allocating machines, pallets, fixtures, operators, and tools; and determining policies for preventive maintenance and inspection. Scheduling problems include establishing work-releasing, sequencing, and priority rules. Control problems include determining policies for defect detection, equipment breakdown, repair, and real-time allocation of resources. The operations of an automated manufacturing system are under the control of a computer system that makes decisions, such as which parts to load into the system next and what workstations a particular batch is to visit next. Human intervention becomes necessary only when unusual or unanticipated events take place, such as machine failures, non-availability of materials, human errors, unscheduled maintenance, and changes in the operating environment. Some of the resulting resource/reallocation decisions require a combinatorial number of complex computations that need to be done quickly. In most cases, these computations cannot be done optimally in real time with the present speed of computers and current OR/MS models and artificial intelligence (AI). Combining OR/MS models and AI approaches seems promising. Crama, Oerlemans, and Spieksma (1996) review models for planning and scheduling.

The objectives for the models at each level of the control system hierarchy depend on the operating characteristics of the system and, thus, cannot always be specified without evaluating the alternatives at lower levels. Hence, system designers use detailed simulations to determine the appropriate planning, scheduling, and control system before its implementation.

Installation and Start-up – Many shortcomings in design and planning are exposed during installation and start-up. The systems may be incompatible with product design, the database may be inadequate, and the operators, managers, and support staff may not have the required skills. The models developed for steady-state operation of an automated manufacturing system are usually not applicable to its transient behavior during start up and shutdown. Equipment breakdowns may also cause transient behavior that interrupts steady-state operation. During start up,

however, one can expect frequent shutdowns and one can expect devote a good deal of effort to debugging and tuning the system.

Steady-State Operation and Improvements – There is considerable scope for learning during steady-state operation, and learning is facilitated if those who design and install the system also operate it. The learning objectives will be to increase equipment utilization, to reduce labor costs, to increase flexibility in meeting changes in product design and demand, to improve quality, to discover opportunities for improving product design, and to increase product variety. The firm can achieve these objectives by improving production planning, scheduling, and control; by developing preventive maintenance and repair policies; by devising strategies to cope with the consequences of equipment breakdowns; and by integrating the various functions in the firm, especially manufacturing and engineering. Two major determinants of learning are planned efforts and the existing skills of the operators, managers, and support staff. The firm can use total quality management and business process redesign to make some of these improvements.

Automated technologies are becoming capable of learning from experience and making decisions with little or no human intervention to optimize operations and minimize costs. For example, in manufacturing automation, artificial intelligence (AI) will become increasingly important in the move toward a true computer-integrated-manufacturing (CIM) environment, in which all of the organization's activities are linked through computers: order entry and customer billing, product design, manufacturing planning, and manufacturing control.

Services

The impact of automation on service is visible in everyday life: TV remote control, automated telephone answering systems, automated teller machines (ATMs), the World Wide Web, electronic commerce, and so forth. Such technologies as electronic imaging, electronic data interchange (EDI), and expert systems are having a major effect on work-flow automation. Electronic imaging involves scanning and digitizing documents (e.g., routine reports, expense-account reimbursements, and purchase orders) so that they can be stored in a database and retrieved. EDI allows information to be transmitted and shared electronically. Expert systems are programs that incorporate knowledge of experts concerning a particular set of decisions. Some examples of automation in services are noted below.

Food Service — In Arby's, Inc., an automated ordering machine asks the customers whether they intend to dine or take out and what they want, keeps a running tally of the cost, and if the customer does not order a drink, it suggests one. The machine has reduced order times by about 50% and improved accuracy. In McDonald's restaurants, an automated fry-maker drops fries into the basket, lowers the basket into the cooking oil, shakes them intermittently, and dumps the finished fries into a tray.

Retail Sales – Bar codes save time at the cash register and automatically update the store's inventory records as items are sold. Electronic commerce on the internet saves customers' time and reduces administrative and other retailing costs.

Financial Services – ATMs improve customer service and reduce the costs of transactions; electronic fund transfer systems have made possible direct payroll deposit and debit cards; and optical scanning in credit card and check processing operations reduces processing time and improves accuracy. Other applications include expert systems for loan applications, insurance underwriting, and security analysis.

Interorganizational Coordination – EDI speeds the exchange of information between locations by eliminating the time taken by regular mail and for data entry. Buyers in a retail chain, for example, decide which items are to be purchased and the automated system can them sort them and place orders with suppliers. Srinivasan, Kekre, and Mukhopadhyay (1994) reported that EDI technology facilitates the accurate, frequent, and timely exchange of information to coordinate the movement of materials between trading parties. Organizations implementing EDI must cooperate closely and establish coordination between the organizations (Cohen and Apte 1997).

Office automation – Automation includes word processing, spreadsheets, optical scanning, electronic mail, teleconferencing, and voice mail.

United States Postal Service – Optical character systems can read and sort 5,000 pieces of mail per hour as compared to 800 per hour for a human sorter and 1,650 per hour for a mechanical sorter.

Healthcare – CAT scanners, laboratory diagnosis machines, pacemakers, and expert systems help physicians to make diagnosis and prescribe treatments.

Education – Automation includes distance learning, bibliographic databases in libraries, and computer assisted instructions.

Hospitality Industry – Automation includes revenue management, electronic reservation systems, and message and wake-up call systems.

Most parts of the framework described earlier for automated manufacturing are also applicable to automated services, as are the OR approaches used for automated manufacturing. As in manufacturing, it is crucial that a firm's decisions about process design and technology acquisition are consistent with its strategy. The firm must make sure that its systems and procedures are properly designed or redesigned before introducing automation. A redesigned process is not always simpler than its predecessor (Davenport 1993). For example, a new underwriting process developed by Phoenix Home Life Mutual Insurance (Hartford, Connecticut) substantially reduced under writing time by making activities parallel rather than serial. But the new system turned out to be much more complex than the one it replaced.

In making decisions about automating service, one must consider both tangible and intangible benefits and risks and uncertainties associated with them. To justify investment in electronic imaging, the firm must assess its potential impact on work flow and the performance of the overall system. Firms use a number of multicriteria approaches to evaluate costs and benefits. The United States Postal Service used simulation to evaluate facilities and equipment for automating postal operations (Cebry et al. 1992) and a decision tree to choose between two alternatives for one of its automation plans (Ulvila 1987). A number of OR approaches, including queueing theory and mathematical programming, are used for designing the physical systems and operations planning, scheduling, and control systems in automated services. Kolesar (1984) described a queueing analysis of ATMs. Other examples of OR studies on automation in the service sector include studies to measure the effect of ATMs on branch labor productivity, to manage investment portfolios, to trade fixed-income securities, and to process loan applications. The continuing importance of improving productivity in the service sector will lead to further automation and to OR studies to improve automated systems.

Implementation: Human and Organizational Dimensions

To implement automation, firms must change their technology, their operations, the design of their organization, and the tasks people perform. An organization adopting and implementing automation must often retrain workers, invest in computer hardware and software, and deal with start-up problems until it stabilizes the manufacturing process and the organization.

Workers operating automated systems must be highly skilled. The organization must be designed to facilitate interaction among many departments – manufacturing, engineering, purchasing, marketing, and accounting. In a changeover from conventional system, the firm must plan for the redeployment of its workforce and the restructuring of the organization. For such pervasive organizational changes, the firm must bring all parties, including top management, all departments, professional staff, union leaders, and workers, into the discussion.

Upton and McAfee (1998) suggested that automation should be designed and implemented to broaden the roles of workers instead of constraining them. The implementation of automated technologies in manufacturing inflicts stress on workers and this can hinder the process. Karuppan and Schniederjans (1995) suggested a number of steps for three different categories of workers in automated design and automated manufacturing. For CAD/CAM workers, they suggest increased participation in project teams and early and thorough training, preferably cross-training in designing different products or different tools and in programming a variety of numerically controlled (NC) machines. This can improve workers' flexibility, enhance their ability to handle fluctuating workloads, and break the monotony in most work situations. For manufacturing-control-system employees, they suggest broadening the scope of workers' responsibilities (articulating critical success factors

for software enhancements and hardware upgrades and redesigning the layout of the manufacturing floor according to work flow), making their workstations more private and personal, teaching them proper posture in front of the screen, and investing in equipment with ergonomic features. For NC machine and robot operators, they suggest educating workers about safety, ensuring proper ventilation, providing adequate rest areas, cross training for different NC machines or robots, and broadening their responsibilities (machine programming, maintenance, quality control, keeping and analyzing breakdown records, evaluating the present equipment, and formulating criteria for improvements). Many of the steps suggested for implementation of automation in manufacturing are also useful in facilitating implementation of automation in services.

Concluding Remarks

Analysts routinely combine OR with the methods of AI approaches to take advantage of their synergy. AI helps automate the selection, development, and use of OR tools and models through intelligent modeling and decision support systems. For example, AI can be used to determine whether a mathematical programming model has a special structure that can be exploited by a more efficient algorithm. In addition, AI can be used to develop new models when knowledge about operations is complex and qualitative, e.g., by combining expert systems (intelligent computer programs that can solve difficult problems using knowledge and inference) with OR approaches in such areas as process planning and scheduling.

Availability

Igor Ushakov
Qualcomm Inc., San Diego, CA, USA

Availability is a property of a system requiring it to be ready for performing its required operation or task at time t. (It is often also referred to as readiness.) This is clearly related to the main system property, reliability. The main measure of availability is the availability coefficient, $A(t)$, which is equal to the probability of finding the system in the operational state at the needed moment of time t.

If the process of the system's functioning is described in terms of an alternating sequence of lifetimes (i.e., times to failure) $\{X_i\}$ and repair times $\{Y_i\}$, then at any moment t, the availability coefficient can be determined as

$$A(t) = \Pr\{t \in X_i, i = 1, 2, \ldots\}.$$

For stationary processes, i.e., where t goes to ∞, the stationary availability coefficient is defined as

$$A = \lim_{t \to \infty} A(t) = \frac{E[X]}{E[X] + E[Y]}.$$

Backward Chaining

An approach to reasoning in which an inference engine endeavors to find a value for an overall goal by recursively finding values for subgoals. At any point in the recursion, the effort of finding a value for the immediate goal involves examining rule conclusions to identify those rules that could possibly establish a value for that goal. An unknown variable in the premise of one of these candidate rules becomes a new subgoal for recursion purposes.

Backward Kolmogorov Equations

In a continuous-time Markov chain with state $X(t)$ at time t, define $p_{ij}(t)$ as the probability that $X(t+s) = j$, given that $X(s) = i$, $s, t \geq 0$, and r_{ij} as the transition rate out of state i to state j. Then Kolmogorov's backward equations say that, for all states i, j and times $t \geq 0$, the derivatives $dp_{ij}(t)/dt = \sum_{k \neq i} r_{ik}\, p_{kj}\,(t) - v_i\, p_{ij}(t)$, where v_i is the transition rate out of state i, $v_i = \sum_j r_{ij}$.

► Markov Chains
► Markov Processes

Backward-Recurrence Time

Suppose events occur at times $T_1, T_2, \ldots$ such that the interevent times $T_k - T_{k-1}$ are mutually independent, positive random variables with a common cumulative distribution function. Choose an arbitrary time t. The backward recurrence time at t is the elapsed time since the most recent occurrence of an event prior to t.

Balance Equations

(1) In probability modeling, steady-state systems of equations for the state probabilities of a stochastic process found by equating transition rates. For Markov chains, such equations can be derived from the Kolmogorov differential equations or from the fact that the flow rate into a system state or level must equal the rate out of that state or level for steady state to be achieved. (2) In linear programming (usually referring to a production process model), constraints that express the equality of inflows and outflows of material.

Banking

Stavros A. Zenios
University of Cyprus, Nicosia, Cyprus
University of Pennsylvania, Pennsylvania, PA, USA

Introduction

OR/MS techniques find applications in numerous and diverse areas of operation in a banking institution. Applications include the use of data-driven models to measure the operating efficiency of bank branches through data envelopment analysis, the use of image recognition techniques for check processing, the use of artificial neural networks for evaluating loan applications, and the use of facility location theory for opening new branches and placing automatic teller machines (e.g., Harker and Zenios 1999). A primary area of application is that of financial risk control in developing broad asset/liability management strategies. Papers that summarize these areas are Zenios (1993), Jarrow et al. (1994), and Ziemba and Mulvey (1998). This work can be classified into three categories: (1) pricing contingent cashflows, (2) portfolio immunization, and (3) portfolio diversification.

Pricing Contingent Cashflows

The fundamental pricing equation computes the price of a contingent cashflow as the expected net present value of the cashflows, discounted by an appropriate discount rate. In discrete time the pricing equation takes the form

$$P_T = E_S\left\{\sum_{t=0}^{T}\frac{C_{t+1}^S}{1+r_t^S}\right\} \tag{1}$$

where E denotes expectation over the set of scenarios indicated by index s, C_t^S denotes the cashflow received at period t under scenario s, r_t^S is the spot rate for the same period under the scenario s, and T denotes the maturity date. The vector (r_t) is known as the term structure of interest rates. For risk-free cashflows, the appropriate discount rate is the rate implied by the Treasury yield curve. At any given point in time, vector (r_{0t}^S) can be obtained using market data; this is the current term structure scenario. However, the temporal variation of the term structure is stochastic. This stochastic interest rate behavior, together with potential uncertainties in the level of the cashflows (i.e., the scenarios C_t^S) are the primary challenging issues behind the evaluation of (1).

One major strand of research is devoted to the development of stochastic models for the term structure of interest rates. Cox, Ingersoll and Ross (1985) first described the interest rate dynamics via the (continuous) diffusion process

$$dr = \kappa(\mu - r)dt + \sigma\sqrt{r}d\omega \tag{2}$$

Here, μ is the mean and σ the variance of the stochastic interest rate process, and $d\omega$ is the differential of a standard Wiener process. This model exhibits mean reversion with a drift factor $\kappa(\mu - r)$, and guarantees that interest rates remain positive. It is, however, a single factor model: the term structure of interest rates is represented by a single state variable, namely the spot rate, r.

A two-factor model for bond prices was developed by Brennan and Schwartz (1979). They considered two state variables, the spot rate r and a long-term (consol) rate L. The dynamics of these two variables are described by

$$\begin{cases} dr = b_1(r,L,t)dt + a_1(r,L,t)d\omega_1 \\ dL = b_2(r,L,t)dt + a_2(r,L,t)d\omega_2 \end{cases} \tag{3}$$

Here, the drift factors are denoted by the functions $b_1(r, L, t)$ and $b_2(r, L, t)$, and the variance terms are expressed by $a_1(r, L, t)$ and $a_2(r, L, t)$. The elements $d\omega_1$ and $d\omega_2$ are differentials of standard Wiener processes.

Despite the elegance of continuous-time models, since most practical applications deal with discrete time cashflows, there is interest in the development of discrete models. A popular choice of discrete models is based on binomial lattices. Such models typically assume that interest rates can move to one of two possible states, up or down, from period t to $t + 1$. The probability and magnitude of each step are calibrated using the Treasury yield curve and the volatility implied by the prices of traded option instruments. Ho and Lee (1986) and Black, Derman and Toy (1990) proposed some fundamental models. For example, the Black, Derman and Toy model described the spot rates by the process

$$r_t^{\sigma} = r_t^0(\kappa_t)^{\sigma}.$$

Here r_t denotes the spot rate that takes values r_t^{σ} with possible states $\sigma = 0,1, \ldots, t$; r_t^0 is the ground state; and κ_t is the volatility of the spot rate in period t.

Models such as those described above generate the discount rates used in the pricing of riskless cashflows. For risky contingent cashflows (e.g., cashflows with credit, default, lapse, prepayment, and other such risks), the discount rates must be adjusted with a suitable riskpremium. Such premiums can be computed from the observed market prices of actively traded securities with comparable risks through the use of option adjusted analysis (Babbel and Zenios 1992).

Another important modeling issue in evaluating (1) is the forecasting of the cashflow stream (C_t). Statistical analysis and econometric modeling can be used in this context, especially when dealing with the various complex securities that have emerged in the 1980s and 1990s, like callable corporate bonds, mortgage and other assetbacked securities, and a range of insurance products. This kind of modeling was represented for insurance products by Asay, Bouyoucos and Marciano (1993), and for mortgage-backed securities by Kang and Zenios (1992).

Portfolio Immunization

This is a portfolio management strategy for locking in a fixed rate of return during a prespecified horizon. It assumes that all risk in the returns of the securities is systematic, that is, all risks are due to some common underlying factor(s). Portfolio immunization aims at eliminating this systematic risk. In the case of fixed-income securities, systematic risk is primarily due to changes in the term structure. Portfolio immunization traditionally deals with this type of risk.

The actuary F.M. Reddington (1952) was the first to introduce the notion of immunization, and also specified conditions for immunization. Portfolio immunization became a popular strategy in the 1970s at the aftermath of interest rate deregulation in the U.S. and the volatility of the fixed-income markets that followed. Fisher and Weil (1971) defined immunization as follows:

> A portfolio of investments is immunized for a holding period if its value at the end of the holding period, regardless of the course of rates during the holding period, is at least as large as it would have been had the interest rate function remained constant throughout the holding period.

A portfolio of assets used to fund a stream of liabilities can be immunized if the following conditions are met: (1) The present value of the assets is equal to the present value of the liabilities, and (2) the duration of the assets is equal to the duration of the liabilities. The first condition guarantees that the target liabilities are funded if the interest rates remain constant throughout the target period. The second condition guarantees that assets and liabilities have identical sensitivities to parallel shifts of the interest rates. Hence, the target liabilities will be funded even if the term structure experiences parallel shifts. A general overview of portfolio immunization was given in Fabozzi (1991). Linear programming formulations are often used to structure immunized portfolios, as in Zenios (1993).

Briefly, let r_i be the yield of the ith security, and C_{it} be the cashflow of security i at time t. From the fundamental pricing (1), obtain the price of the ith security by

$$P_i = \sum_{t=1}^{T} C_{it}(1 + r_i)^{-t}.$$

The sensitivity of the price — or *dollar duration* — of security i is obtained by differentiating with respect to cashflow yield, $(\partial P_i / \partial r_i)$, to get

$$k_i = -\sum_{t=1}^{T} tC_{it}(1 + r_i)^{-(t+1)}.$$

Given the present value P_L and dollar duration k_L of its liabilities, an immunized portfolio can be structured by solving the linear program

$$\begin{aligned} \text{Maximize} \quad & \sum_i k_i r_i x_i \\ \text{s.t.} \quad & \sum_i P_i x_i = P_L \\ & \sum_i k_i x_i = k_L \\ & x_i \geq 0 \end{aligned}$$

The objective function above maximizes an approximation to the portfolio yield, obtained as the dollar duration-weighted average yield of the individual securities in the portfolio. Several variations exist on the theme of portfolio immunization. One extension is to structure a portfolio that matches not only present value and duration of assets with those of the liabilities, but that also matches convexity, i.e., second partial derivatives $(\partial^2 P_i / \partial r_i^2)$ as well. Another approach is to compute the sensitivity of the prices to more than one factor, than just to parallel shifts of interest rates. The precise form of these factors (i.e., parallel shifts, steepening of the term structure, or term structure inversions) can be obtained using factor analysis of market data. Factor analysis of the term structure was first proposed for the U.S. market by Litterman and Scheinkman (1988). The use of linear programming for factor immunization was proposed by Dahl (1993) and D'Ecclesia and Zenios (1994).

Portfolio Diversification

The principle of diversification — based on the adage "do not put all your eggs in one basket" — remains a universal strategy for portfolio management. It provides a systematic way for dealing with residual risk, assuming that residual risk is accurately represented by a function of the mean and variance in the return of the securities. It also assumes that investors have an (implied) utility function over the mean and variance of portfolio returns, favoring portfolios with higher means and lower variances. The efficient portfolios for an investor are those that achieve the highest expected return for a given level of variance or the smallest possible variance for a given level of return. Such portfolios are called mean-variance efficient portfolios. Mean-variance optimization models were proposed by Markowitz in the 1950s; Ingersoll (1987) gives an advanced textbook treatment.

Minimum variance portfolios, i.e., portfolios with the lowest level of variance for a given target expected return, can be structured using nonlinear quadratic programming. Define

Q as the covariance matrix $\{q_{ij}\}$ between securities i and j,
μ_i as the expected return of security i,
μ_p as the target expected return of the portfolio, and
X_i as the fraction of the portfolio in security i.

Assuming that no short sales are allowed ($x_i \geq 0$ for all i), formulate the problem as

$$\begin{aligned} \text{Minimize} \quad & x^T Q_x \\ \text{s.t.} \quad & \sum_i \mu_i x_i = \mu_p \\ & \sum_i x_i = 1 \\ & x_i \geq 0 \end{aligned}$$

Other constraints, like limits on portfolio turnover, on minimum holdings, or limits of investments in different market segments, etc., can be captured with more complex formulations. These issues have been addressed by Perold (1984). See also the articles in Zenios (1993) and Ziemba and Mulvey (1998).

The major area of investigation in implementing minimum variance models in practice is in the estimation of the covariance matrix. Factor models that relate the returns and variances of individual securities to a set of common factors are widely used in practice (Elton and Gruber 1984).

Mean-variance models have traditionally been used in managing portfolios of equities and for strategic asset allocation. By contrast, fixed-income portfolio management has traditionally been based on the principles of portfolio immunization. In the 1980s,

however, there was a convergence of portfolio management tools towards the ideas of portfolio diversification. More complex fixed income securities (e.g., corporate callable bonds, high-yield bonds, mortgages and other asset-backed securities) have very volatile returns. The notion of duration, as a measure of sensitivity, is extremely restrictive for such instruments. Mulvey and Zenios (1993) advocated the use of diversification models for fixed-income portfolios, indicating how pricing models can be developed to generate scenarios of holding period returns in order to calibrate the models, and illustrating that such models produce better results than traditional portfolio immunization strategies.

Another development deals with the asymmetric returns of fixed-income securities, especially those with embedded options. Mean-variance models are valid assuming a symmetric distribution of return. Furthermore, they penalize both upside and downside deviations from a target return. Development of more practical models for dealing with asymmetric returns and penalizing differentially upside from downside risk include the mean-absolute deviation model of Konno and Yamazaki (1991), the expected utility optimization models of Grauer and Hakkanson (1985), and the dynamic, multiperiod models of Kallberg, White and Ziemba (1982), Mulvey and Vladimirou (1992), and Golub et al. (1995).

Barrier Functions and their Modifications

Roman A. Polyak
George Mason University, Fairfax, VA, USA

Introduction

In the mid-1950s and the early 1960s, Frisch (1955) and Carroll (1961) proposed the use of Barrier Functions (BFs) for constrained optimization. Since then, the BFs have been extensively studied, with particularly major work in the area due to Fiacco and McCormick (1968) who developed the Sequential Unconstrained Minimization Technique (SUMT). Currently, methods based on barrier functions make up a considerable part of modern optimization theory.

Barrier Functions

Consider the constrained optimization problem

$$x^* \in X^* = \arg\min\{f(x) | x = \in \Omega\} \tag{1}$$

where $\Omega = \{x: g_i(x) \geq 0, i = 1, \ldots, m\}$, $f: \Re^n \to \Re$ is convex, all $g_i: \Re^n \to \Re$ are concave, $m > n$, and X^* is the set of values minimizing $f(x)$ on Ω. Frisch's logarithmic barrier function F: int $\Omega \times \Re_{++} \to \Re$ is defined by formula

$$F(x, \mu) = f(x) - \mu\Sigma \ln g_i(x) \tag{2}$$

and Carroll's hyperbolic barrier function C: int $\Omega \times \Re_{++} \to \Re$ is defined as

$$C(x, \mu) = f(x) + \mu\Sigma \ln g_i^{-1}(x).$$

Assume that X^* is bounded and $\ln t = -\infty$ for $t \leq 0$; then for any $\mu > 0$, there exists a minimum of $F(x, \mu)$ in $\Re^n$, denoted by

$$(x, \mu) = \arg\min\{F(x, \mu) | x \in \Re^n\}. \tag{3}$$

Therefore

$$\begin{aligned} \nabla_x F(x, \mu), \mu) &= \nabla f(x(\mu)) - \Sigma\mu g_i^{-1}(x(\mu))\nabla g_i(x(\mu)) \\ &= \nabla f(x(\mu)) - \sum \lambda_i(\mu)\nabla g_i(x(\mu)) \\ &= \nabla_x L(x(\mu), \lambda(\mu)) = 0 \end{aligned} \tag{4}$$

where $L(x, \lambda) = f(x) - \sum \lambda_i g_i(x)$ is the Lagrangian for the problem (1). Also $g_i(x(\mu)) > 0, i, = 1, \ldots, m$ and

$$\lambda_i(\mu) = \mu g_i^{-1}(x(\mu)) > 0, \quad i = 1, \ldots, m. \tag{5}$$

Hence $x(\mu) \in$ int Ω, $\lambda(\mu) = (\lambda_i(\mu), i, = 1, \ldots, m) \in \Re^m{}_{++}$ and due to (4)

$$L(x(\mu), \lambda(\mu)) = \min\{L(x, \lambda(\mu) | x \in \Re^n\}.$$

Consider the dual problem to (Eq. 1)

$$\lambda^* \in L^* = \text{Arg}\max\{d(\lambda) | \lambda \in \Re_+^m\} \tag{6}$$

where $d(\lambda) = \min\{L(x, \lambda) \mid x \in \Re^n\}$ and L^* is the set of maxima of $d(\lambda)$ on $\Re^m$. The vector $x(\mu)$ is interior primal, the vector $\lambda(\mu)$ is interior dual, and due to (Eq. 5) the primal-dual gap is

$$\begin{aligned} \Delta(\mu) = f(x(\mu)) - d(\lambda(\mu)) &= f(x(\mu)) - L(x(\mu), \lambda(\mu)) \\ &= \Sigma\lambda_i(\mu)g_i(x(\mu)) = m\mu. \end{aligned}$$

Therefore

$$\mu \to 0 \Rightarrow \Delta(\mu) \to 0 \Rightarrow f(x(\mu)) \to f(x^*) \text{ and } d(\lambda(\mu)) \to d(\lambda^*).$$

The primal barrier trajectory $\{x(\mu)\}$ and the primal-dual trajectory $\{x(\mu), \lambda(\mu)\}$ are critical elements in both SUMT (Fiacco and McCormick 1968) and recent developments in Interior Point Methods (IPMs).

Interest in barrier and distance functions was revived after N. Karmarkar (1984) published his polynomial projective scaling method for linear programming (LP) calculations. The connection between Karmarkar's method and the Newton log barrier method for LP calculations was discovered by Gill, Murray, Saunders, Tomlin and Wright (1986). Since then the interest to BFs grew dramatically and IPMs became the main stream in modern optimization. Hundreds of papers and several books have been published recently on the matter (see Nesterov and Nemirovsky 1994; Roos et al. 1997; Wright 1997; Ye 1997).

The main idea of the path-following IPMs (see Gonzaga 1992; Renegar 1988) is to replace in a sense the unconstrained minimization problem (Eq. 3) by one Newton step for solving the system $\Delta_x F(x, \mu) = 0$. The basic path-following IPM consists of performing a Newton step toward the solution $x(\mu)$ of the system

$$\nabla_x F(x, \mu) = 0 \tag{7}$$

followed by the barrier parameter update.

For a given $\mu > 0$ one finds an approxmation x for $x(\mu)$, the so-called "warm" start. The warm start belongs to the area where Newton method for the system (Eq. 7) is well-defined (Smale 1986), that is, from x as a starting point the method

$$\hat{x} = x - (\nabla^2_{xx} F(x, \mu))^{-1} \nabla_x F(x, \mu) \tag{8}$$

converges to $x(\mu)$ quadratically. The step of the path-following method consists in replacing x by $\hat{x}$ and μ by $\hat{\mu} = \mu(1 - \alpha/\sqrt{m})$ where $\alpha > 0$ is independent on $m > n$.

In the late 1980s Nesterov and Nemirovsky (1994) discovered the self-concordant property of the function $F(x, \mu)$ for important classes of constrained optimization problems including LP, QP, and QP with quadratic constraints. A function ϕ: int $\Omega \to \Re$ is self-concordant if it is convex, three times differentiable, and for any $x \in$ int Ω any $h \in \Re^n$ on the interval $I = \{t/x + th \in \text{int } \Omega\}$, the function ϕ: $I \to R$ defined by $\phi(t) = \phi_{x,\, h}(t) = \phi(x + th)$ satisfies the following inequality

$$\varphi'''(0) \le 2(\varphi''(0))^{3/2}.$$

The self-concordant property guarantees that if x is well defined for the system $\Delta_x F(x, \mu) = 0$ then $\hat{x}$ will be well defined for the system $\nabla_x F(x, \hat{\mu}) = 0$. The polynomial complexity of the path-following method for LP follows immediately from the fact that each Newton step shrinks the primal-dual gap by $(1 - \alpha/\sqrt{m})$, where $\alpha > 0$ is independent on m.

The primal-dual algorithms have emerged as the most important and useful class of IPMs (see Wright 1997). On the computational side, the most successful implementation (see Lustig et al. 1992) is based on the Mehrotra predictor-corrector algorithm (Mehrotra 1992). The BFs became the basic tool in the IPM, but the BFs still have their inherent drawbacks: these function, as well as their derivatives, do not exist at the solution; and they grow infinitely large together with the condition number of their Hessians when the approximation approaches the solution and the area where the Newton method is well-defined shrinks to a point.

To eliminate the drawbacks, while still retaining the nice properties of the barrier functions, modified barrier functions (MBFs) were introduced in the early 1980s for both LP and NLP calculations (Polyak 1986, 1992, 1996). The MBFs are particular cases of the Nonlinear Rescaling Principle, which consists of transforming the objective function and/or the constraints into an equivalent problem and using the classical Lagrangian for the equivalent problem in both theoretical analysis and numerical methods (Polyak 1986).

Modified Barrier Functions

Consider the constrained optimization problem

$$g_i(x) \ge 0, i = 1, \ldots, m \tag{9}$$

is equivalent to $\mu \ln(\mu^{-1} g_i(x) + 1) \geq 0$, $i = 1, \ldots, m$. Therefore problem (1) is equivalent to

$$x^* \in X^* = \operatorname{Argmin}\{f(x) / \mu \ln(\mu^{-1} g_i(x) + 1) \geq 0, \quad i = 1, \ldots, m\} \tag{10}$$

where the constraints are transformed by $\psi(t) = \ln(t + 1)$, and rescaled by $\mu = 0$. The classical Lagrangian for the equivalent problem (10)

$$F(x, \lambda, \mu) = f_0(x) - \mu \Sigma \lambda_i \ln(\mu^{-1} g_i(x) + 1),$$

is the logarithmic MBF which corresponds to Frisch's log-barrier function (2). For any $\mu > 0$, the system (9) is equivalent to

$$\mu[(\mu^{-1} g_i(x) + 1)^{-1} - 1] \leq 0, i = 1, \ldots, m$$

where the constraints transformation is given by $v(t) = (t + 1)^{-1} - 1$. The classical Lagrangian for the equivalent problem is the hyperbolic MBF

$$C(x, \lambda, \mu) = f_0(x) + \mu \Sigma \lambda_i [(\mu^{-1} g_i(x) + 1)^{-1} - 1],$$

which corresponds to Carroll's hyperbolic barrier function (3).

The MBF's properties make them fundamentally different from the BFs. The MBFs, as well as their derivatives, exist at the solution, and for any Karush-Kuhn-Tucker pair (x^*, λ^*) and any $\mu > 0$, the following critical properties hold:

P1. $F(x^*, \lambda^*, \mu) = C(x^*, \lambda^*, k) = f_0(x^*)$;

P2. $\nabla_x F(x^*, \lambda^*, \mu) = \nabla_x C(x^*, \lambda^*, \mu) = \nabla_x L(x^*, \lambda^*) = 0$;

P3. $\nabla_{xx} F(x^*, \lambda^*, \mu) = \nabla_{xx} L(x^*, \lambda^*) + \mu^{-1} \nabla g^T(x^*) \Lambda^* \nabla g(x^*)$,

$\nabla_{xx} C(x^*, \lambda^*, \mu) = \nabla_{xx} L(x^*, \lambda^*) + 2\mu^{-1} \nabla g^T(x^*) \Lambda^* \nabla g(x^*)$.

where $\wedge = \operatorname{diag}(\lambda_i)$ and $\Delta g(x) = J[g(x)]$ is the Jacobian of the vector-function $g(x)^T = (g_i(x), i = 1, \ldots, m)$.

The MBF's properties resemble that of augmented Lagrangians (Bertsekas 1982; Golshtein and Tretyakov 1974; Hestenes 1969; Mangasarian 1975; Polyak and Tretyakov 1973; Powell 1969; Rockafellar 1973). One can consider the MBFs as interior augmented Lagrangians. At the same time, MBFs have some distinctive features, which make them different from both quadratic augmented Lagrangian (Rockafellar 1973) and nonquadratic augmented Lagrangian (Bertsekas 1982). The MBFs' properties lead to the following multipliers method.

Let $\mu > 0$, $\lambda^0 = e = (1, \ldots, 1) \in \Re^m$ and $x^0 \in \Omega_\mu = \{x | g_i(x) \geq -\mu, i = 1, \ldots, m\}$. The logarithmic MBF method consists of generating two sequences $\{x^s\}$ and $\{\lambda^s\}$:

$$x^{s+1} \in \arg\min\{F(x, \lambda^s, \mu) | x \in \Re^n\} \tag{11}$$

and

$$\lambda^{s+1} = \operatorname{diag}[\mu^{-1} g_i(s^{s+1}) + 1]^{-1} \lambda^s. \tag{12}$$

There is a fundamental difference between the logarithmic MBF method and SUMT or other IPM that is based on BFs. The MBF method converges to the primal-dual solution with *any* fixed $\mu > 0$ for any convex programming which has bounded optimal primal and dual solutions (Jensen and Polyak 1994). Moreover, for LP calculations, M. Powell proved that for any fixed barrier parameter, the MBF method produces such primal sequences that the objective function tends to its optimal value and constraints violations tend to zero with R-linear rate (Powell 1995).

If the second order optimality conditions hold then the primal-dual sequence converges with Q-linear rate:

$$\max\{\| x^{s+1} - x^* \|, \| u^{s+1} - u^* \|\} \leq c\mu \| u^s - u^* \| \tag{13}$$

where $c > 0$ is the condition number of the constrained optimization problem, which depends on the input data and the size of the problem, but it is independent on $\mu > 0$ (Polyak 1992).

The numerical realization of the MBF method leads to the Newton MBF. The Newton method is used to find an approximation for x^s, followed by the Lagrange multiplier update. Due to the convergence of the MBF method under the fixed barrier parameter $\mu > 0$, both the condition number of the MBF Hessian and the area where the Newton method is well defined remain stable. These properties contribute to both numerical stability and complexity, and they lead to the discovery of the "hot" start phenomenon in constrained optimization. It means that from some

point on for large classes of nondegenerate-constrained optimization problems including LP, QP and QP with quadratic constraints, the approximation for the primal minimizer will remain in the Newton area after each Lagrange multipliers update (Polyak 1992; Melman and Polyak 1996).

Due to (13) from the "hot" start on it takes only (ln ln ε^{-1}) Newton steps to improve the primal-dual approximation by a given factor $0 < q < 1$ as soon as $\mu \leq qc^{-1}$. The neighborhood of (x^*, λ^*) where the "hot" start occurs can be characterized by the condition number $c > 0$. Using the IPM with the Shifted Barrier Function (SBF) $S(x, \mu) = f(x) - \mu \sum \ln(\mu^{-1} g_i(x) + 1)$, which is self-concordant for the same classes of problem as $F(x, \mu)$, it takes $0(\sqrt{m} \ln c)$ to reach the "hot" start.

Combining the IPM based on SBF with the Newton MBF method, it is possible to improve substantially the complexity bounds for nondegenerate LP, QP and QP with quadratic constraints. In particular, for nondegenerate QP the total number of Newton step sufficient to obtain an approximation for (x^*, λ^*) with accuracy $\varepsilon = 2^{-L}$ is

$$N = 0(\sqrt{m} \ln c) + 0((L - \ln c) \ln m),$$

where L is the input length, $c > 0$ is the condition number of QP and $n < m$ (Melman and Polyak 1996).

The MBF method has an interesting dual interpretation. Assuming that the dual function $d(\lambda)$ is differentiable,

$$\Delta d(\lambda) = -g(x(\lambda))$$

where $x(\lambda) = \arg\min\{L(x, \lambda) | x \in \Re^n\}$ and $g(x(\lambda)) = (g_i(x(\lambda)), i = 1, \ldots, m)$, that is,

$$\nabla d(\lambda^{s+1}) = -g(x^{s+1}). \tag{14}$$

From the formula (12) for the Lagrange multipliers update

$$\begin{aligned} g_i(x^{s+1}) &= \mu \psi'^{-1}(\lambda_i^{s+1}/2\lambda_i^s) \\ &= \mu \psi^{*\prime}(\lambda_i^{s+1}/2\lambda_i^s), i = 1, \ldots, m \end{aligned} \tag{15}$$

where $\psi^*(s) = \inf\{st - \psi(t)\} = 1 - s + \ln s$ is the Legendre transformation of $\psi(t) = \ln(t + 1)$. Using (15), rewrite (14) as

$$\nabla d(\lambda^{s+1}) + \mu \Sigma \psi^{*\prime}(\lambda_i^{s+1}/\lambda_i^s) e_i = 0$$

where $e_i = (0, \ldots, 1, \ldots, 0)$. Hence,

$$\begin{aligned} \lambda^{s+1} &= \arg\max\{d(\lambda) + \mu \Sigma \lambda_i^s \psi^*(\lambda_i/\lambda_i^s)/\lambda \in \Re_+^m\} \\ &= \arg\max\{d(\lambda) - \mu D(\lambda, \lambda^s)/\lambda \in \Re_+^m\} \end{aligned} \tag{16}$$

where $D(\lambda, \lambda^s) = \sum \lambda_i^s \varphi(\lambda_i/\lambda_i^s)$ – a ϕ -divergence entropy-like distance with the kernel $\phi = -\psi^*$. Note that (16) is an IPM for the dual problem (see Teboulle 1993; Polyak and Teboulle 1997).

The formula (12) is in fact a method for solving the dual problem (6). It can be rewritten as

$$\lambda_i^{s+1}(1 - \mu^{-1} \nabla_{\lambda_i} d(\lambda_i^{s+1})) = \lambda_i^s, i = 1, \ldots, m. \tag{17}$$

Such a method is a well-known multiplicative image reconstruction algorithm for positron emission tomography (Eggermont 1990). On the other hand, it is nothing but the implicit Euler method for numerical solution of the following system of ordinary differential equations

$$\frac{d\lambda_i}{dt} = \mu^{-1} \lambda_i \frac{\partial d(\lambda)}{d\lambda_i}, \lambda(0) = \lambda_0, \ i = 1, \ldots, m$$

and $\lim_{t \to \infty} \lambda(t) = \lambda^*$, which is the solution of following nonlinear complementarity problem

$$\begin{aligned} \nabla d(\lambda) \leq 0, \ \lambda \leq 0 \\ \lambda^T \nabla d(\lambda) = 0. \end{aligned}$$

Basic Feasible Solution

A nonnegative basic solution to a set of $(m \times n)$ linear equations $\boldsymbol{Ax} = \boldsymbol{b}$, where $m \leq n$. The major importance of basic feasible solutions is that, for a linear-programming problem, they correspond to extreme points of the convex set of solutions. The simplex algorithm moves through a sequence of adjacent extreme points (basic feasible solutions).

See

- ▶ Adjacent (Neighboring) Extreme Points
- ▶ Basic Solution
- ▶ Linear Programming

Basic Solution

For a set of $(m \times n)$ linear equations $\boldsymbol{Ax} = \boldsymbol{b}$ $(m \leq n)$, with rank m, a basic solution is a solution obtained by setting $(n - m)$ variables equal to zero and solving for the remaining m variables, provided that the column vectors associated with the m variables form a linearly independent set of vectors. The m variables are called basic variables, and the remaining $n - m$

variables that were set equal to zero are called nonbasic variables. The vectors associated with the basic variables form an $(m \times m)$ basis matrix $\boldsymbol{B}$.

See

► Linear Programming

Basic Variables

The set of variables corresponding to the columns of a basis matrix in a linear system $\boldsymbol{Ax} = \boldsymbol{b}$.

See

► Basic Solution
► Basis
► Linear Programming

Basis

A nonsingular square matrix $\boldsymbol{B}$ obtained by selecting linearly independent columns of a full row rank matrix $\boldsymbol{A}$. The matrix $\boldsymbol{B}$ is then a basis matrix for the system $\boldsymbol{Ax} = \boldsymbol{b}$. The components of $\boldsymbol{x}$ associated with $\boldsymbol{B}$ are called the basic variables, and the remaining components are called the nonbasic variables. The term basis also refers to the set of indices of the basic variables.

Battle Modeling

Dean S. Hartley III
Oak Ridge National Laboratory, Oak Ridge, TN, USA

Introduction

The ideal battle model completely, accurately, quickly, and easily predicts the results of any postulated battle from the initial conditions. Several factors prevent the existence of an ideal battle model.

One factor is computational complexity. For example, medical planners could use such a battle model to determine the size of treatment facilities, the breakdown of physician skills needed, and the medical supply inventory requirements. It is reasonable to suppose a battle model would track individuals and their separate wounds for engagements of a dozen participants on a side; however, maintaining that level of detail for engagements of tens of thousands of people would be prohibitively expensive in time and hardware requirements. Thus the requirement for complete predictions competes with the requirements for generality and speed of computation.

The second factor preventing the existence of an ideal battle model is the fact that not enough is known about battle dynamics to model it accurately. Where components can be modeled accurately (e.g., firing disciplines for weapons and probabilities of kills given hits), it is not known how the components fit together (e.g., when do soldiers fire their weapons and

how do conditions modify their ideal performance). Further, it is not known when, where, and why battles are joined or when and how they stop. The ignorance is not absolute, but is relative to the desired accuracy for the battle models.

A third factor also proceeds from ignorance. It is not known which initial conditions are significant for determining battle results. In general, those battle models that deliver massive details about the model results require extremely large quantities of input data. Thus, perceived accuracy of results is a competitor of ease and rapidity of use.

Battle Model Classification

Although the ideal battle model cannot be built, many individual battle models can be built, each conceived to fulfill a particular set of objectives. These models of combat may be classified by their position along several dimensions; however, they all have one feature in common, and that is the object that is modeled is some aspect of combat. These dimensions are listed below with illustrative examples of positions along the dimension.

DOMAIN	Land; air; naval; space; combinations.
SPAN (size of conflict)	Platoon battle; division combat; theater-level combat; global combat.
SCOPE (type of conflict)	Politico-military; special operations; low intensity conflict; urban warfare; conventional warfare; theater-level nuclear, chemical, and biological conflict; strategic nuclear conflict.
SCORING (adjudication topics and methodology)	Measures of merit: attrition, movement, tons of bombs dropped, supplies delivered, victory; methodologies: weapon weights (simple or complex, as in anti-potential potential, which uses eigenvalues to value weapon by the value of the weapons it can kill), process simulations.
RANDOMNESS	Deterministic or stochastic calculations.
COMBAT ACTIVITIES AND FORCE COMPOSITION (military assets and mission areas)	Small-arms; armor; aircraft; artillery; engineer; logistics; signal; command and control; intelligence; surface navy; submarine; electronic warfare; space assets; missiles.
LEVEL OF RESOLUTION OR DETAIL (smallest item modeled as a separate entity)	Bullet; soldier; tank; platoon; company; battalion; brigade; division; corps.
ENVIRONMENT	One-dimensional terrain (pistonmodel); two-dimensional terrain (including ocean or air), latitude-longitude or hexagonal grid-based; three-dimensional terrain; weather; day-night; smoke.
PURPOSE (design purpose or users' purpose)	Training; weapon system employment; force composition decisions; operations plans testing.
LEVEL OF TRAINING (training audience)	Individual skills; platoon leaders' skills; division staff skills; commanders' skills; combinations.
MODEL TREATMENT OF TIME	Linear code with no time representation or algorithmically computed time (generally analytic combat models); time-stepped simulations; event-driven simulations; expected value models; stochastic simulations.
HUMAN INTERACTION	Data preparation and output interpretation; interruptible with modification and restart; computer-assisted human participation on one or more sides; continuous human participation on all sides.
SIDEDNESS	One-sided (e.g., strategic nuclear strike damage effects); two-sided; multi-sided; hard-coded identical properties for each side, hard-coded different properties for each side (e.g., U.S. vs Soviet-style tactics), or data-driven properties for each side.
COMPUTER INVOLVEMENT	None; moderate; complete.
SIZE COMPUTER REQUIRED	PC; mini-computer; mainframe; supercomputer; peripheral equipment required; large run-times, small run-times.
EXTERNAL INTERACTIONS (interfaces with parts of the real world)	None; distributed processing; interfaces with weapon simulators; interfaces with real equipment; sand tables, scripting.

Battle modeling started the first time someone scratched a battle plan in the dirt and tried to conceive of the consequences. Sand tables, with miniature troops and landscaping, added discipline to the modeling process; however, the modeling remained essentially qualitative. Sand table models were used as war games, in which opposing players took turns moving the pieces and used rules to

adjudicate the results of the moves. Modern war games include sand table games and computer adjudicated games.

Attrition Laws

Lanchester (1916) introduced the concept of a quantitative model of attrition. (Osipov in Russia and Fiske in the U.S. introduced similar concepts at virtually the same time; however, most Western works refer to Lanchester's Laws and Lanchestrian attrition.) Lanchester showed that one could express the value of concentration of forces precisely, using mathematics, and thus evaluate what forces would be needed for victory before a battle. Engel (1954) provided what many took to be proof that Lanchester's square law was correct.

Lanchester's simple concepts have been elaborated to the extent that Taylor (1983) required two volumes to discuss the many uses and implications of Lanchester theory. The computational power of computers has permitted this elaboration. First, heterogeneous Lanchester equations could be solved without undue manual labor. Once, heterogeneous equations were admitted, the coefficients could be represented as functions of other factors, such as weather, firing discipline, and distance to the target. Bonder and Farrel (in Taylor 1983) introduced rigorous thinking into this area by observing direct fire activities and creating a mathematical model of those activities.

Dupuy (1985) argued that there are many important factors in combat that were not being included in the physics-based combat models. Morale, training, and leadership are at least as important as force sizes according to Dupuy. He proposed a model based on quantified judgments of these and other "soft" factors. His Quantified Judgment Model (QJM) stirred considerable controversy. Regardless of the merits of the QJM itself, the quantified judgments of soft factors is currently receiving more favorable reviews. The difference in public opinion at home during the Vietnam and Gulf wars and the impact on troop morale and the outcomes of the wars provides some justification for increased emphasis on soft factors.

Computers also made the computation of stochastic processes possible. The differential equations of Lanchester attrition were viewed as approximations to a random process model of the actual killing process that should be correct for large numbers. Stochastic duels addressed the results for small numbers. Ancker and Gafarian have made significant contributions in this area (Ancker 1994).

Helmbold has made contributions to both the theoretical and the practical aspects of battle modeling. His empirical studies of attrition (1961, 1964), breakpoints (1971), and movement (1990) injected the element of reality into the sometimes rarefied atmosphere of theoretical battle modeling. Hartley (1991) continued in this vein with results indicating that the best description of attrition (using a homogeneous approximation) is not the Lanchester square or linear law, but an intermediate form between the linear law and a logarithmic law. Speight (1995, 1997) and Speight and Rowland (1999) have continued the process, introducing duels (mini-battles) and simulations of combat exercises (trials) and showing the impact of firing on dead targets on the formulation of attrition equations.

With computer battle models also came a proliferation of structural types of models. Battle models involving anti-submarine warfare have a peculiar requirement of finding the enemy before the battle can be prosecuted. Search theory must be implemented in such models, just as it is used in actual battles or exercises (Shudde 1971). In some types of war, the proper allocation of resources or mix of strategies provides an easily defined variable (e.g., strategic nuclear targeting or allocation of combat air forces to mission types). Because game theory deals with optimal strategies considering both sides' options, it provided an obvious technique for addressing the problem and providing prescriptive models (Bracken et al. 1974; HQ USAF/SAMA 1974).

Dimension, Data, and Output

In earlier times, land warfare models were one-dimensional: the forward edge of the battle area (FEBA) advanced or retreated. More sophisticated versions allowed one-dimensional structures for each sector (piston-models). More powerful computers now permit two-dimensional representations of the battlefield, using either x, y (or latitude, longitude) coordinates or (rectangular or hexagonal) grid structures. Some models are now three-dimensional, having terrain elevation and playing the effects of

flying aircraft at different altitudes. [See, for example, the Research Evaluation and Systems Analysis (RESA) model (Naval Ocean Systems 1992), which plays aircraft at different altitudes and submarines at different depths].

Most large models have extremely large input and output data sets and require sophisticated database management systems to keep track of the data. These large output data sets also stress the human ability to understand the results. Sophisticated graphics are necessary adjuncts to most large models today. The graphics are required to define realistic scenarios and to understand the process and results of the model.

Advances in computer power have resulted in the capability for human interfaces that are qualitatively different from past capabilities. Such interfaces include real-time depictions of a battlefield from a human perspective and auditory and tactile interfaces. The first full-scale example of this kind of interface, called virtual reality, in a battle model was SIMNET (HQ US Army Armor School 1987). SIMNET is a network of tank and other vehicle simulators, each participating in a shared virtual battlefield. Work is proceeding to tie virtual reality battle models to other, more conventional battle models. The success of connecting simulators has motivated recent work in connecting interactive training models. The connection of these battle models permits distributed processing and cost sharing among users.

The history of battle modeling has not been a smooth process of constant improvements. It has been beset with controversies in many areas. Some of the controversies have involved the standard resource allocation question: where do you spend the money? One of the first of these concerned documentation. Early (1960–1970s) computer models were usually undocumented and, because of frequent modifications, had virtually indecipherable code. The need for proper documentation was obvious but the need for better (or at least more complex) models appeared overriding. While the readability of the documentation of today's models may be variable, most models are documented.

Verification, Validation, and Accreditation

One controversy probably began with the first model that produced a result someone did not like: is the model right? During the 1960s and early 1970s, it was said there were two kinds of generals: those for whom computer printout was the gospel and those who would believe nothing produced by a computer. The problem in dealing with the first type was in conveying that there were caveats. All results had to be retyped manually to disguise their origin for the second type of general. Today's generals (and politicians) grew up with computers. They want to understand to what extent the results are believable. They require verification, validation, and accreditation. Although progress is being made, no one knows how to completely verify, validate, or accredit the general battle model.

Other Controversies

There have also been technical controversies in battle modeling. Notable controversies have included the proper interpretation (and thus use) of the differences between the Lanchester linear and square laws, the connection between attrition and advance rates (if any), the value of force ratios, the connection between deterministic Lanchester formulations and stochastic attrition formulations and which should be used. There is a precept that states that a force ratio of 3-1, attacker-defender is required for a successful attack. Numerous studies have criticized this precept, yet it is still heard.

There are disagreements about the proper level of detail in deterministic models, despite agreement on the principle that what is appropriate depends on the uses to be made of a model. High resolution models of large span require tremendous quantities of data and run slowly. One camp advocates small, fast "roughly right" models as better than high resolution models. Another camp protests that such models will miss the critical points that differentiate the issues in question. The stochastic process camp protests that both the large, high resolution and the small, low resolution models are not grounded in the reality of stochastic battles, and cannot thus be even roughly right.

There have also been disagreements about the proper uses of models. At one time prescriptive battle models were popular (finding optimal strategies, where the definition of optimal varied with the model). Lately they have been out of favor. Complaints about the misuse of models have ranged from the use of models designed for other purposes and failing to understand the resulting mismatch of assumptions to charges of advocacy modeling. Advocacy modeling, in the

pejorative sense, entails fiddling with input parameters until a combination is found that gives the desired result. Most large models have sufficient numbers of parameters with sufficiently tenuous connections to physical factors that plausible values can be found that generate almost any result.

One controversy involves the discovery that very simple deterministic battle models can exhibit chaos (Dewar et al. 1991). The question of the impact of chaos on the more complex models that are actually used is obvious. Most issues are settled by point estimates. For example, suppose the impact of weapon X is being investigated. Model runs with 25% X, 50% X, 75% X, and 100% X are executed. The runs with 75% X and 100% X are found to have superior results. It is assumed that such results are valid for values between 75% and 100%. If the results are chaos driven, such an assumption is unwarranted. The question has not been finally answered; however, investigations with one of the currently used complex models indicates that any uncertainty due to chaotic behavior in that model is no larger than a few percent. Because this is within the uncertainty that was already present in the model, the impact of possible chaotic behavior was claimed to be minimal (Herndon 1993).

Concluding Remarks

Despite all controversy, battle modeling remains the only method of answering some questions and is widely used. Battle models are used to inform decisions on weapons' procurement issues (balancing costs against effectiveness), to test strategies and tactics, and to train personnel. Battle training models provide inexpensive tools for training commanders because the large numbers of combat personnel maneuver in the computer rather than on the ground. As military funding is reduced, this supplement to traditional training methods has become indispensable. New models continue to be created as the requirements for greater scope arise. The insertion of information technology into combat has necessitated new models that can discriminate among the effects of different Command, Control, Communications and Intelligence (C^3 I) systems, such as the Joint Warfare System (JWARS) for analysis and the Joint Simulation System (JSIMS) for training.

Bayes Rule

When a decision maker receives data bearing on an uncertain event, the probability of the event can be updated by computing the conditional probability of the uncertain hypothesis given the new evidence. The derivation of the revised or a posteriori probability can be easily derived from fundamental principles and its discovery has been attributed to the Reverend Thomas Bayes (1763). The result is therefore known as Bayes rule or theorem:

$$\Pr\{H_1|E\} = \frac{\Pr\{E|H_1\}\Pr\{H_1\}}{\sum_i \Pr\{E|H_i\}\Pr\{H_i\}}$$

In this equation, H_1 refers to the specific, uncertain hypothesis entertained by the decision maker, the $\{H_i\}$ are the complete set of possible hypotheses, and E refers to the new evidence or information received.

Bayesian Decision Theory, Subjective Probability, and Utility

Kathryn Blackmond Laskey
George Mason University, Fairfax, VA, USA

Introduction

In every field of human endeavor, individuals and organizations make decisions under conditions of uncertainty and ignorance. The consequences of a decision and their value to the decision maker often depend on events or quantities which are unknown to the decision maker at the time the choice must be made. Such problems of decision under uncertainty form the subject matter of Bayesian decision theory. Bayesian decision theory has been applied to problems in a broad variety of fields, including engineering, economics, business, public policy, and artificial intelligence.

A decision-theoretic model for a problem of decision under uncertainty contains the following basic elements:

- A set of options from which the decision maker may choose;
- A set of consequences that may occur as a result of the decision;
- A probability distribution that quantifies the decision maker's beliefs about the consequences that may occur if each of the options is chosen; and
- A utility function that quantifies the decision maker's preferences among different consequences.

Subjective Probability

Decision theory applies the probability calculus to quantify a decision maker's beliefs about uncertain events or quantities, and to update beliefs upon receipt of additional information. De Finetti (1974) showed that any decision maker who acts on degrees of beliefs not

conforming to the probability calculus can be exploited by a series of gambles guaranteed to result in a net loss. Such a bet is called a dutch book. The Dutch Book Theorem and other related derivations of probability from axioms of rationality have been used to justify probability as a calculus of rational degrees of belief (De Groot 1970; Pratt et al. 1965).

Bayes Rule

When a decision maker receives information bearing on an uncertain hypothesis, degrees of belief are updated by computing the conditional probability of the uncertain hypothesis given the new evidence. The equation expressing how beliefs change with new evidence has been attributed to the Reverend Thomas Bayes (1763) and is known as Bayes Rule. The odds-likelihood form of Bayes Rule is:

$$\frac{\Pr\{H_1|E\}}{\Pr\{H_2|E\}} = \frac{\Pr\{E|H_1\}\Pr\{H_1\}}{\Pr\{E|H_2\}\Pr\{H_2\}}$$

In this equation, H_1 and H_2 refer to two uncertain hypotheses entertained by the decision maker and E refers to the new evidence or information received by the decision maker. Bayes rule quantifies how evidence is used to obtain the relative posterior probabilities $\Pr\{H_i|E\}$ of the hypotheses given the evidence. The ratio of posterior probabilities is determined by two factors. One is the ratio of prior probabilities $\Pr\{H_i\}$: all other things being equal, the stronger the prior belief in H_1 relative to H_2, the stronger the posterior belief in H_1 relative to H_2. The other is the likelihood ratio, or ratio of the probabilities $\Pr\{E|H_i\}$ of the evidence given each of the hypotheses. Again, all other things being equal, the better H_1 accounts for the evidence relative to H_2, the stronger the posterior belief in H_1 relative to H_2.

Other Interpretations of The Probability Calculus

There has been considerable debate about how to interpret the concept of probability. The term Bayesian, after Bayes Rule, is used to refer to the subjective interpretation. A subjective probability distribution represents an individual's degrees of belief about the likelihood of uncertain outcomes. Alternative interpretations of probability include the classical, the logical, and the frequentist approaches (Fine 1973). Much of standard statistical theory is based on the frequentist approach. Frequentists argue that probability models are appropriate only for repeatable phenomena exhibiting inherent randomness. For such phenomena, it is argued, there exist objectively correct probabilities intrinsic to the process producing the uncertain outcomes. Subjectivists apply probability theory to any outcomes about which a decision maker is uncertain. For subjectivists, no objectively correct probabilities need exist. Different decision makers are free to have different opinions about the probability of an outcome.

The only constraint subjective theory places on a probability distribution is that it be coherent, that is, that degrees of belief conform to the probability calculus. Within this constraint, decision makers are free to choose any probability distribution to model their uncertainty about a problem. Its inherent subjectivity has been a persistent criticism of the subjectivist approach. This is often of little practical consequence for problems that can be said to exhibit inherent randomness. The subjectivist draws inferences about the posterior distribution of the unknown parameter, while the frequentist draws inferences about the distribution of the data given different values of the unknown parameter. Nevertheless, it can be shown that when there are sufficient data to draw accurate inferences, the subjectivist and the frequentist will usually agree on the implications of the results. Thus, the major difference of practical import between the subjectivist and the frequentist is their attitudes toward problems for which there are too little data to estimate parameters accurately or for which the assumption of intrinsic objective frequencies is problematic. The frequentist maintains that probability models are in-appropriate for such problems; the subjectivist argues that probabilities are appropriate and that it is legitimate for rational people to disagree until there are sufficient data to bring them to agreement.

Utility Theory

Decision theory quantifies preferences by a utility function. It is assumed that the decision maker can

assign a numerical utility to each possible consequence of each option being entertained. Consequences with higher utilities are preferred to consequences with lower utilities. When there is uncertainty, the decision maker selects the option for which the expected value of the utility function is the largest. For some problems it is customary to deal with losses, or negative utilities. Smaller losses are preferred to larger losses.

The concept of utility appears to have been first introduced by Daniel Bernoulli (1738) in his solution to a puzzle known as the St. Petersburg Paradox. Bernoulli considered the problem of what price to pay for the opportunity to play the following gamble. A fair coin (probability 0.5 of landing heads) is tossed repeatedly until the first head appears. If the first head appears on the *n*th toss, the decision maker receives a prize of 2^n units of currency. The decision maker's expected monetary prize is

$$2(0.5) + 2^2(0.5)^2 + 2^3(0.5)^3 + \ldots,$$

which is infinite. A decision maker who maximized expected monetary value should be prepared to pay an arbitrarily large sum of money for the opportunity to play this gamble. As Bernoulli noted, most people would be willing to pay only a modest amount. Bernoulli suggested that the resolution to this apparent paradox was that a prize's worth to a decision maker was a nonlinear function of the monetary value of the prize. For example, replacing 2^n with $\log 2^n$ in the above equation yields a finite expected monetary prize.

Von Neumann and Morgenstern (1944) were the first to present a formal axiomatic development of utility theory. They defined the utility of a consequence in terms of a comparison between two options, one sure and one uncertain. The sure option is the consequence itself; the uncertain option is a lottery between two standard reference prizes, one worth more and one worth less than the consequence in question. If the reference prizes are assigned utility one and zero, then the utility of the consequence in question is defined as the probability at which the decision maker is indifferent between the two lotteries. Several similar axiom systems can be shown to lead to the maximization of expected utility as a principle of rational decision making (De Groot 1970; Pratt et al. 1965).

Concluding Remarks

It has been observed that people systematically violate the axioms of expected utility theory in their everyday behavior. Some of these violations can be reversed by informing people of the implications of their stated preferences. In other cases, many people resist changes to their original judgments. Even when the decision maker regards expected utility theory as a norm of rational behavior, it cannot be assumed that unaided judgments will be consistent with the theory. The field of decision analysis applies theories and methods from decision theory and the psychology of human information processing to construct decision theoretic models for practical decision problems (Clemen 1996).

Interest has been growing in decision theoretic formulations of statistical problems. For example, to formulate an hypothesis testing problem, one defines a prior probability for the null and alternative hypotheses. One also defines losses associated with accepting a false alternative hypothesis and rejecting a true null hypothesis. The optimal decision rule is to accept or reject the hypothesis according to which decision yields the lower posterior expected loss given the observed sample. Similarly, decisions of whether to gather information and how large a sample to draw can be formulated as decision problems that consider both the cost of gathering information and the benefit of obtaining the information. Some problems that are quite complex when viewed from a frequentist perspective become straightforward when viewed from a Bayesian perspective. Examples include hierarchical models and problems of missing data (Gelman et al. 1995).

An area of application is the field of intelligent systems (Haddawy 1999). Utility theory is being applied to planning and control of reasoning in expert systems. Diagnostic expert systems based on probability theory have achieved performance comparable to human decision makers (e.g., the Pathfinder system for diagnosing lymph node pathology, Heckerman 1991). Perhaps the most important and challenging aspect of decision analysis is the creative process of model formulation. Decision theory takes options, consequences, and their interrelationships as given. Automated decision model generation is an open research area of great importance to application of decision theory to the field of intelligent systems (Haddawy 1994).

Bellman Optimality Equation

Dynamic programming equation that the optimal value (or cost-to-go) function must satisfy, according to the principle of optimality. One simple form is the following finite-action, finite-state, finite-horizon version for a minimization problem:

$$f_n(i) = \min_a \{c_n(i,a) + \Sigma_j p_{ij}(a) f_{n+1}(j)\},$$

where $f_n(i)$ represents the optimal cost-to-go function in state i for stage (period) n, $c_n(i,a)$ is the one-period cost in stage n for state i and action a, and $p_{ij}(a)$ is the probability of transitioning from state i to state j when action a is taken.

Bilevel Linear Programming

Bilevel linear programming (BLP) is a hierarchical, decentralized, multilevel mathematical programming problem in which the objective functions and constraints are linear. It can be stated in terms of upper and lower problems as follows:

$$\underset{x}{\text{Maximize}} f_1(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{c}_1\boldsymbol{x} + \boldsymbol{d}_1\boldsymbol{y}$$

where $\boldsymbol{y}$ solves:

$$\underset{y}{\text{Maximize}} f_2(\boldsymbol{x}, \boldsymbol{y}) = \boldsymbol{c}_2\boldsymbol{x} + \boldsymbol{d}_2\boldsymbol{y}$$

subject to

$$\boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{y} \leq \boldsymbol{b}$$
$$\boldsymbol{x}, \boldsymbol{y} \geq 0$$

where $\boldsymbol{c_1}, \boldsymbol{c_2}, \boldsymbol{d_1}, \boldsymbol{d_2}$, and $\boldsymbol{b}$ are constant vectors, $\boldsymbol{A}$ and $\boldsymbol{B}$ are constant matrices; $\boldsymbol{x}$ and $\boldsymbol{y}$ are vectors of the decision variables of the upper and lower problems, respectively; f_1 and f_2 are the objective functions of the upper and lower problems, respectively.

Bin-Packing

Nastaran Coleman[1] and Pearl Wang[2]
[1]Federal Aviation Administration, Washington, DC, USA
[2]George Mason University, Fairfax, VA, USA

Introduction

The bin-packing problem is concerned with the determination of the minimum number of bins that are

needed to pack a given set of input data items. The problem has numerous applications in operations research, computer science, and engineering, where the items and bins to be packed can be of varying shapes or multi-dimensional in size. These applications include industrial manufacturing, container loading, stock cutting, vehicle routing, television commercial scheduling, job scheduling on multiple processors, file backup creation in removable media, integrated circuit manufacturing and fault detection, and location testing in linear circuits. Since the bin-packing problem is known to be NP-hard (Garey and Johnson 1979), it is of interest to find efficient heuristics that obtain near-optimal solutions to the problem.

Problem Definition

The classical one-dimensional bin-packing problem (1DBPP) is defined as follows: Given a positive bin capacity C and a list of items $L = (p_1, p_2, \ldots, p_n)$, where p_i has size $s(p_i)$ satisfying $0 \leq s(p_i) < C$, determine the smallest integer m such that there is a partition of $L = B_1 \cup B_2 \cup \ldots \cup B_m$ where the sum of the sizes of the items $p_i \in B_j$ do not exceed the capacity C. Each set B_j is usually viewed as the contents of a bin of capacity C. In much of the literature, C is taken to be 1.

Several versions of two-dimensional bin-packing problems have also been studied. For example, if L is a set of rectangles p_i having heights h_i and widths w_i, one type of bin packing problem requires that the rectangles of L be packed into a single two-dimensional bin of width C and infinite height. The goal is to determine a minimum height packing of the pieces into this bin. These problems are referred to as strip-packing problems.

For an alternative form of the two-dimensional packing problem, the rectangles of L are to be packed into a minimum number of rectangular bins. A common version of the problem concerns packing a list of squares into m unit squares with the objective being to minimize m. When the rectangles to be packed are not square, restrictions might be made on the types of allowable placements of the rectangles within the bins. Depending on the application, rotations of the items may not be permitted; packings may also require that the items are placed parallel to the sides of the bins.

The items being packed in two-dimensional problems do not need to be rectangular in shape. Circular and polygonal shapes may also be packed into circular or rectangular bins.

Three-dimensional bin-packing problems have goals that are similar to their lower dimensional counterparts. For example, given the set L of rectangular prisms having widths w_i, height h_i, and depth d_j, a common problem is to pack the items into a minimum number of bins of width W, height H, and depth D. In the case of container packing, the pieces are not rotated and must be placed parallel to the sides of the bins.

Cutting stock problems are variants of bin packing problems because the amount of wasted space within stock sheets is to be minimized while the pieces are being cut from stock sheets. Similarly, if just a single bin of fixed size is to be packed and each item is characterized by both a volume and a value, the problem of maximizing the total value of a subset of items that can fit into the bin by volume is known as the knapsack problem.

Approximation algorithms for bin-packing problems were among the earliest algorithms studied in the literature. In the 1970s, it was shown that near-optimal solutions could be guaranteed for some frequently used one-dimensional packing techniques. Since then, many heuristics have been proposed for obtaining approximate solutions to both the one and two-dimensional problems for sequential and parallel models of computation. Three-dimensional problems were initially studied to a lesser degree, but recent work now appears regularly in the literature. The performance of a given heuristic (i.e., the computational time and resources needed to find a packing), as well as the quality of the packing that is constructed by the heuristic are important considerations that have been analyzed by many researchers.

Surveys of many classical bin-packing algorithms can be found in Coffman et al. (1996). A bibliography of cutting and packing research was presented by Sweeney and Paternoster (1992), while a more recent typology that characterizes cutting and packing problems is described in Wäscher et al. (2007). Recent probabilistic analyses of approaches for solving one-dimensional bin-packing problems are discussed in Coffman et al. (2000). Two-dimensional packing problems are surveyed by Lodi et al. (2002)

and meta-heuristic algorithms for strip packing problems are reviewed in (Hopper and Turton 2001). Recent work that addresses three-dimensional packing problems includes (Martello et al. 2000), (Faroe et al. 2003), and (Parreño et al. 2008). Heuristic approaches for solving irregular and polygonal packing problems are presented by Jakobs (1996) and Burke et al. (2010).

Algorithms for solving the problem on various parallel models of computation can be found in Anderson et al. (1989), Fenrich et al. (1989), Berkey (1990), and Coleman and Wang (1992). The EURO Special Interest Group on Cutting and Packing maintains a website for research activities related to cutting and packing.

Characterizations of Bin-Packing Algorithms

Many types of bin-packing algorithms have been proposed and analyzed for both sequential and parallel systems. Sequential heuristics can be classified as either on-line or off-line algorithms. On-line algorithms assign data items to bins in the same order as originally input, without utilizing any global knowledge of the data list. For example, the Next-Fit packing and Sum of Squares heuristics are on-line algorithms that perform one-dimensional packing. Off-line algorithms preprocess the data, usually by sorting. Well-known examples are the First-Fit Decreasing and Best-Fit Decreasing algorithms. Alternatively, other methods may preprocess the input data by partitioning the items by size into subintervals, and then pack the data using those sub-intervals. These techniques are described in more detail below.

Approximation algorithms for solving the one-dimensional bin-packing problem on various models of parallel computation have been reported. It has been shown that several frequently used sequential bin packing strategies such as First-Fit Decreasing are P-Complete. Thus, it is unlikely that these heuristics can be parallelized into efficient algorithms for the theoretical Parallel Random Access Machine (PRAM) model of computation. However, other well-known sequential strategies such as Harmonic packing can be parallelized efficiently. In the previous decade, experimental studies of similar heuristics were performed on Single-Instruction, Multiple-Data (SIMD) and Multiple-Instruction, Multiple-Data (MIMD) parallel computers.

Theoretical Studies

Performance metrics have been formulated as a means to compare these different packing algorithms when executed on random data. Theoretical analyses typically include worst-case and average-case packing performance of the heuristics. The asymptotic worst-case performance can be defined as the limiting ratio of an algorithm's worst instant packing to its optimal packing. For example, if $A(L)$ and $OPT(L)$ are the number of bins packed by an algorithm A and the optimal number of bins needed for a list L, respectively, then the asymptotic performance ratio can be defined as

$$R_A^{\infty} = \inf\{r \geq 1 : \text{ for some } N > 0, A(L)/OPT(L) \leq r \text{ for all } L \text{ with } OPT(L) \geq N\}$$

Two measures of average-case packing performance that have been studied are the expected values $E(R_N)$ and $E(U)$ where R_N is the ratio of the average number of bins packed by the algorithm to the average size of all data items and U is the difference between these quantities. Further, an algorithm is often said to exhibit perfect packing if $E(R) = 1$, where $E(R)$ is the limiting distribution of $E(R_N)$, or when $E(U) = O(\sqrt{N})$.

These metrics are studied analytically as well as by simulation. The input data are usually assumed to come from a uniform distribution $U[a, b]$. Coffman et al. (2000) introduced the perfect packing theorem and show that the optimal expected wasted space for a random list is either $o(n)$, $o(n^{0.5})$ or $o(1)$. These researchers have also shown that the average case can differ substantially between discrete and continuous uniform distributions.

An alternative measure of packing performance is to determine the expected waste of the packing. If $L_n(F)$ denotes a list of n items drawn according to a probability distribution F and $P_n^A(F)$ denotes a packing resulting from the application of algorithm A, then the expected waste is defined as $EW_n^A(F) = E\left[W\left(P_n^A(F)\right)\right]$ where expectation is taken over the random variable $L_n(F)$.

Theoretical studies of bin packing problems are often aimed at determining whether asymptotic approximation schemes can be constructed. In this

case, researchers seek to determine if for every $\varepsilon > 0$, there is a polynomial time algorithm A_ε having an asymptotic approximation ratio of $1 + \varepsilon$.

Some One-Dimensional Packing Heuristics

The Next-Fit algorithm packs one-dimensional items into one-dimensional bins in the simplest fashion. The data items are processed one at a time, beginning with p_1, which is put into bin B_1. If item p_i is to be packed and B_j is the highest indexed nonempty bin, then p_i is placed into bin B_j if it fits into B_j; that is, $p_i + size(B_j) \leq C$. Otherwise, a new bin B_{j+1} is started and p_i is placed into it. In this manner, each successive piece is packed into the most recently used bin, and previously packed bins are not considered. Next-Fit is a fast on-line algorithm whose time complexity is $O(n)$. Its worst-case performance ratio is bounded by 2, and its average performance by 3/2. Variants of Next-Fit have been proposed and include Next-Fit-Decreasing, Next-1-Fit, and Next-K-fit. The basic approach is also used to obtain level-oriented heuristics for solving two-dimensional bin packing problems.

The Harmonic packing algorithm begins by partitioning the unit interval into the set of intervals $I_k = (1/(k + 1), 1/k]$, $1 \leq k < m$ and $I_m = (0, 1/m]$. The bins are divided into m categories and an I_k-bin packs at most kI_k data. The packing of each I_k piece into an I_k-bin is done using the Next-Fit Algorithm. At any given time, an active list of all unfilled I_k-bins is kept. The Harmonic algorithm has a worst-case performance bound of 1.69; some modified versions of the approach have been shown to have lower performance bounds.

The Sum-of-Squares (SS) algorithm is an online method for packing items with integral sizes into bins of capacity C. It has time complexity $O(nC)$. If the amount of unpacked space in a bin is called its gap, g, and $N(g)$ is the number of bins in a current packing with gap g, then this algorithm puts an item p_i into a bin such that after placing the item, the value of $\sum_{g=1}^{C-1} N(g)^2$ is minimized.

Theoretical analysis of this algorithm demonstrates that for any perfectly packable distribution F, that $EW_n^{SS}(F) = O(\sqrt{N})$ and if F is a discrete uniform distribution $U(j, C)$ where $j < C - 1$, then $EW_n^{SS}(F) = O(1)$. For all lists L, it is further demonstrated that $SS(L) < 3OPT(L)$. Csirik et al. (2006) survey other online algorithms including randomized variants of sum-of-squares. Bender et al. (2007) propose two variants of the sum-of-squares algorithm and Seiden (2002) presents a survey as well as an online algorithm based on the Harmonic approach.

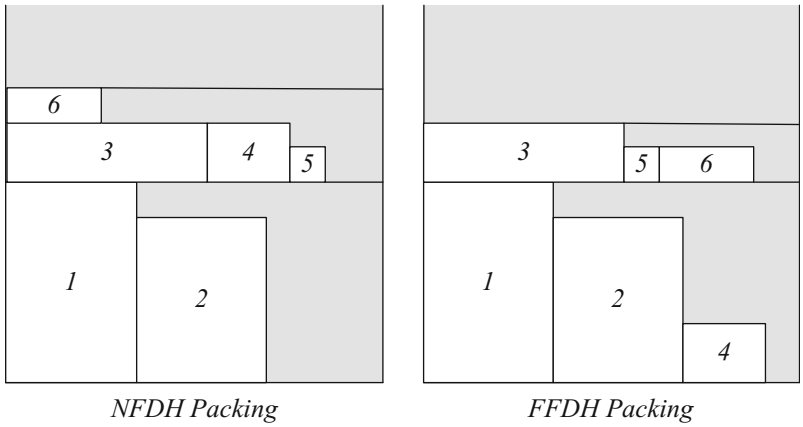
The First-Fit (FF) heuristic packs each successive data item p_i into the lowest indexed bin B_j into which it fits. When this is not possible, a new bin is created. Thus, it is necessary to maintain a list of all partially filled bins. For the worst-case, average case, and lower bound performance of First-Fit, it has been shown that the numberof bins used by this algorithm is 17/10 $OPT(L) \pm 2$, where OPT is the number of bins used by the optimal solution. Xia and Tan (2010) decreased the upper bound for the asymptotic performance ratio to 17/10 OPT + 7/10 for First-Fit and for the absolute performance ratio– to 12/7 OPT. The time complexity of First-Fit is $O(n \log n)$.

If the items are initially sorted in non-increasing order before packing proceeds, the heuristic is referred to as First-Fit Decreasing, and the performance bound decreases to 11/9 OPT + 6/9. Other algorithms that are based on this approach include Best-Fit (where the "best" bin is chosen if there is more than one possibility), Best-Fit Decreasing, Worst-Fit, Almost Worst-Fit, Revised First-Fit, and Modified First-Fit Decreasing bounded by 71/60 OPT + 1. When the data items are drawn from a uniform distribution, then $E(A(L)) - n/2 = O(n)$ for the First-Fit Decreasing and Best-Fit Decreasing algorithms. Asymptotic polynomial-time approximation schemes show that it is possible to find a solution for any $0 < \varepsilon \leq 1/2$ in polynomial time using at most $(1 + 2\varepsilon)OPT + 1$ bins.

Some Multi-Dimensional Packing Heuristics

Two-Dimensional Packing

The Two-Dimensional Bin-Packing Problem requires packing a finite set of small rectangles into the minimum number of rectangular bins without overlapping. The problem is strongly NP-hard, and has several industrial applications. Other variants of two-dimensional bin-packing problems occur in real-world applications, especially in the manufacturing industries. Additional constraints may include orientation where items can be rotated by 90°



Bin-Packing, Fig. 1 Level-oriented packings

or have to stay fixed. For example, rotation is not allowed when the items are articles to be paged in newspapers.

Researchers have applied one and two-phase algorithms that make use of upper and lower bounds on the number of bins needed to pack the input rectangles. These approaches are often integrated into greedy heuristics and tabu searches. One-phase algorithms directly pack the items into the finite bins. Two-phase algorithms start by packing the items into a single strip, i.e., a bin having width W and infinite height. In the second phase, the strip solution is used to construct a packing into finite bins. Lodi et al. (2002) survey advances obtained for the two-dimensional bin and strip packing packing problems, with emphasis on exact algorithms whose goal is to find an optimal solution, as well as effective heuristic and metaheuristic approaches.

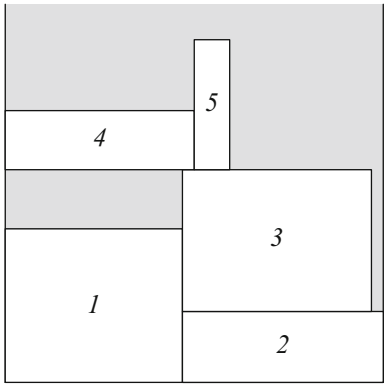
Level-oriented packing heuristics pack rectangles into a single two-dimensional bin (or strip) that has infinite height. In these approaches, the rectangles to be packed are first ordered by non-increasing height. The packing is constructed as a sequence of levels, whose heights are defined by the heights of the first rectangles placed in the respective levels. The Next-Fit or First-Fit approaches can be used to define and fill these levels of the bin. The asymptotic performance bounds of the Next-Fit Decreasing Height (NFDH) and First-Fit Decreasing Height (FFDH) heuristics are 2 and 1.7, respectively. Figure 1 illustrates these packing heuristics.

Similar approaches in which the heights of the levels are preset by a parameter yield a variety of shelf heuristics, where these levels can be packed in a similar fashion. Next-Fit Shelf and First-Fit Shelf are examples of these heuristics. Their corresponding execution times are $O(n)$ and $O(n^2)$. If the parameter that dictates the shelf heights is defined by r, then these methods have asymptotic performance bounds of $2/r$ and $1.7/r$, respectively.

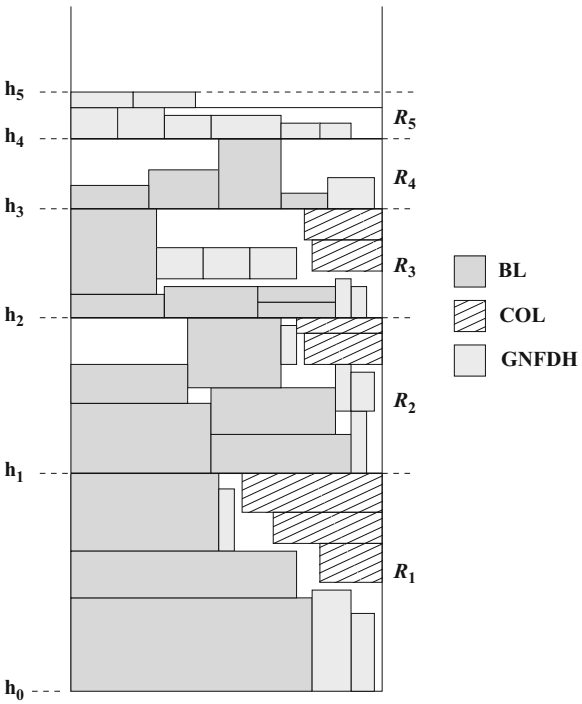
Bottom-Left (BL) packing approaches pack rectangles into an infinite height bin by successively placing each item into the bottom-most, left-most position in which it fits without overlapping any rectangles that have already been packed. If the items are preordered by non-increasing width, then the worst case bound of this heuristic indicates that the height of the packing does not exceed twice the height of an optimal packing. The algorithm can be implemented in $O(n^2)$ time and a sample packing is shown in Fig. 2.

Alternative methods may divide the set of items being packed into sublists that are used to obtain a split packing. In this case, the infinite height bin is also divided into subregions where one-dimensional heuristics are used to pack the rectangles. Classical techniques include Split-Fit, Mixed Fit, and Up-Down (see Fig. 3) which require $O(n \log n)$ time. Performance ratios of 2, 1.33, and 1.25, respectively, have been proven for these approaches. Other similar methods appear in the literature. Coffman and Shor (1993) discuss asymptotic average-case analysis for two-dimensional bin-packing.

One particular heuristic that uses a split packing approach addresses the problem of packing squares into a two-dimensional strip of unit width. The squares whose widths are greater than 1/2 are first

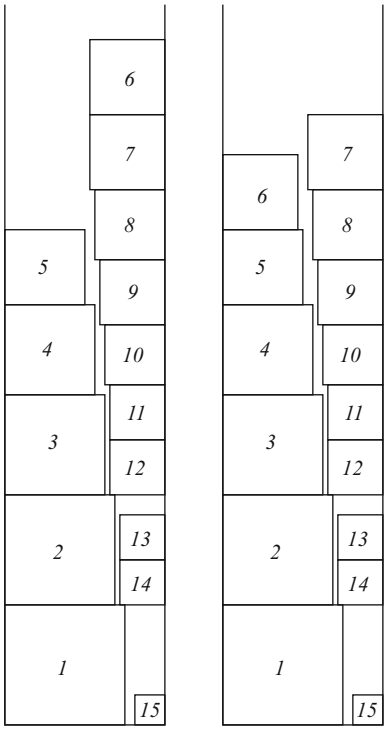


Bin-Packing, Fig. 2 BL packing



Bin-Packing, Fig. 3 Up-down packing

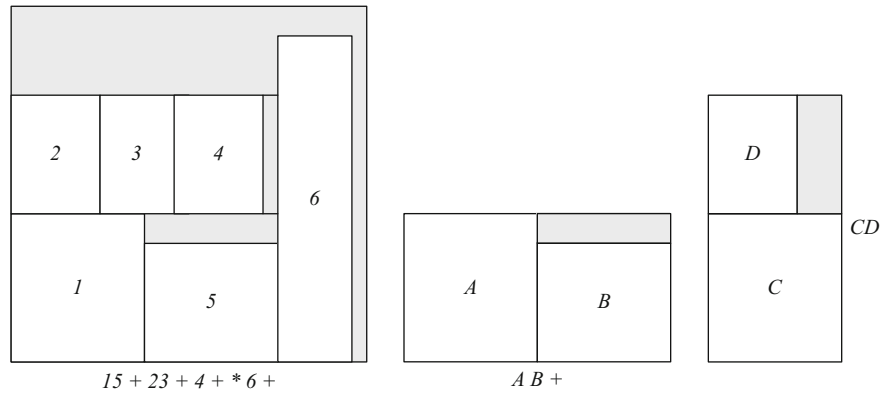
stacked along the left edge of the strip in order of decreasing width. Starting at the height, $H_{1/2} = \sum_{w_i > 1/2} h_i$, where the sum of the sizes of packed squares exceeds 1/2, the remaining squares are stacked along the right edge of the strip in order of decreasing width. This stack slides downward until



Bin-Packing, Fig. 4 Packing squares

it either rests on the bottom of the strip, or a square in the right stack comes in contact with a square in the left stack, whichever occurs first. Finally, all the squares lying entirely above $H_{1/2}$ are repacked into two stacks, one against the left edge of the strip and the other against the right edge. This is done in decreasing order of size, placing each successive square on the shorter of the two stacks already created. A sample packing is shown in Fig. 4. It can be shown for this algorithm, that $E(A(L)) = E(OPT(L)) + O(1)$.

When multi-dimensional objects are to be packed into a minimum number of multidimensional bins, the vector packing approach can be used. This technique is a direct generalization of the one-dimensional problem. For example, if rectangles are to be packed into square bins, then the only types of packing that are permitted are those where the rectangles are diagonally placed corner-to-corner across the bins. In general, if a vector packing algorithm is such that no two nonempty bins can be combined into a single bin, then the ratio of the number of bins packed to the optimal solution does not exceed $d + 1$, where d is the number of dimensions. Extensions of the First-Fit and First-Fit Decreasing



Bin-Packing, Fig. 5 Postfix GA encoding

heuristics to this multi-dimensional case have yielded approaches whose asymptotic worst case ratio is $d + 7/10$ and $d + 1/3$, respectively.

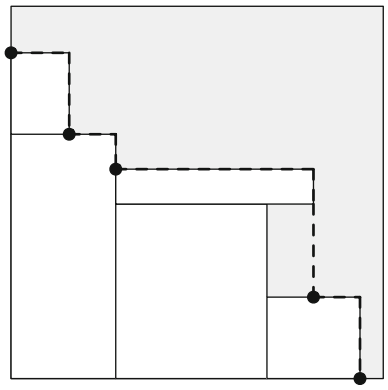
Metaheuristic algorithms have been used extensively in recent years to solve two-dimensional bin-packing problems. In short, metaheuristic methods are general frameworks that try to improve the direction of the search for the best solution, thus finding a better solution at every iteration. There are no guarantees of finding an optimal solution, but many metaheuristics implement some form of stochastic or linear optimization. Genetic algorithms, simulated annealing, and tabu search are examples of metaheuristic algorithms.

Hopper and Turton (2001) review several approaches developed to solve two-dimensional packing problems with metaheuristic algorithms. Genetic algorithms (GAs) were first used in the mid-1980s to solve strip and bin-packing problems. Many employ a two-step approach referred to as a hybrid genetic algorithm. Encoded solutions corresponding to physical layouts are manipulated by GAs that evaluate the solutions using decoding algorithms. In some cases, these decoded layouts correspond to non-overlapping packings that are obtained using a bottom-left packing heuristic. Other researchers have used a sliding principle that gives priority to the downward shifting of the rectangle being packed for the decoding routine.

Other genetic algorithms incorporate layouts directly into the encoding technique. For example, postfix strings corresponding to packing layouts can be manipulated by GAs. In the example shown in Fig. 5, the A B + and CD* substrings correspond to placements of two rectangles that are horizontally or vertically adjacent, respectively.

It is also possible for genetic algorithms to operate without encodings. An initial layout can be modified by rotating, translating, and/or relocating an item (or subset of items) in the layout. These operators correspond to hill-climbing and the mutation and recombination features of GAs. Hopper and Turton (2001) compare some meta-heuristic algorithms to two-dimensional random search and heuristic packing routines. The comparison is made in terms of the solution quality and the computation time for a number of packing instances of different sizes.

Simulated annealing, tabu search and exact algorithms have also been used to compute solutions to two-dimensional bin and strip packing problems. See (Lodi et al. 2002) for a survey of some of these approaches. A simulated annealing approach was first applied to a pallet loading problem (i.e., a three-dimensional packing problem that has been reduced to its two-dimensional footprint). Simulated annealing is a hill-climbing approach where solutions that are worse may be accepted as dictated by a cooling schedule which is determined by a given probability function. For the pallet loading problem, the number of feasible solutions for a box is equated with multiples of the item length. Neighborhoods are defined by moving each item in a solution to another position (with some restrictions). As a result, the simulated annealing heuristic would allow both legal and illegal packings as it attempted to improve the solution quality. The objective function must then minimize any overlaps that occur in the packing layout.



Bin-Packing, Fig. 6 Defining corner points

The tabu search strategy utilises a search scheme and a candidate neighborhood that is consturcted from a feasible solution: a heuristic recombines a subset of items currently packed into k different bins along with one item packed into a bin that is likely to be emptied. The value of k is also updated during the search to escape from local optima. A mechanism (i.e., the use of memory) must be built into the tabu search to prevent the heuristic from returning to recently examined packings.

Lower bounds are used to guide search strategies in exact algorithms whose goal is to find optimal solutions. For example, in one branching scheme, each node in the search tree represents a subset of packed rectangles which define a set of corner points for the bottom-left placement of unpacked items (see Fig. 6). The use of bounds to traverse a search tree corresponds to the selection of branches to investigate or ignore.

The average performance of exact algorithms and metaheuristics are typically evaluated through extensive computational experiments using benchmark data sets as described in (Parreño et al. 2008). Other more recent two-dimensional and three-dimensional examples include Bekrar and Kacem (2009) and Puchinger et al. (2010).

Three-Dimensional Packing

Algorithms for obtaining heuristic solutions to three-dimensional packing problems in which boxes are to be packed into a minimum number of identical three-dimensional bins have been characterized as either local-search or construction heuristics (Faroe et al. 2003). Analgous to the two-dimensional case, local-search methods iteratively seek better packings of the boxes by examining neighborhoods of solutions, while constructive heuristics add boxes to a packing using strategies such as First-Fit or Best-Fit. Examples of recent heuristics that have employed these methods include guided local search (GLS), a two-level tabu search (TS^2PACK), and a greedy randomized adaptive search procedure (GRASP) that is combined with a variable neighborhood descent (VND) structure.

The GLS strategy has roots in constraint-satisfaction applications and uses memory (typical of tabu search methods) to guide the search of the solution space by augmenting the objective function with penalties for previously visited solutions. It begins with an upper bound calculated from an initial greedy solution and then iteratively removes one bin from the feasible solution. Translation of boxes within one bin or between bins defines the neighborhood of the local search algorithm. To speed up the search process, some boxes are temporarily fixed in position. As before, the objective function additionally reflects the total volume of an overlap between boxes.

The TS^2PACK heuristic uses a first-level tabu search that addresses the optimality of the packing problem and a second-level tabu search that finds feasible solutions for the items assigned to the bins. An initial solution is computed using a Next-Fit Decreasing packing based on box volumes and the extreme points that are identified for a given box – these indicate positions where an additional item can be accommodated with respect to the given box. Then the TS^2PACK heuristic iteratively discards the bin with the worst fitness function value (defined as the weighted sum of the volume used by the items in the bin and the number of items). Each discarded item is packed into one of the remaining bins which yields the maximum fitness function value (i.e., minimizes the height of the new packing with bin size constraints relaxed). If this packing is not feasible due to bin size violations, a second heuristic is employed to optimize the packing with respect to the bin size constraints. This heuristic is a tabu search that uses interval graphs to represent the layout. By manipulating the graphs, alternate layouts can be generated that correspond to moving boxes by locating them in different positions.

The packing performance of these and other heuristics is compared against the GRASP/VND

approach summarized in (Parreño et al. 2008). Large sets of test cases are studied that include both two and three-dimensional problem instances. The results indicate that this method obtains comparable or better solutions to the other algorithms.

The GRASP/VND heuristic is an iterative method that combines a randomized constructive phase and an improvement phase. The constructive phase iteratively fills one bin with boxes by considering the maximal spaces created by placing boxes near corners of the bin. Boxes to be packed are selected based on best-volume or best-fit criteria. This is repeated until all boxes are packed into bins.

Attempts may be made to improve the packing by moving boxes in the bins that have first been sorted by volume. Four improvement moves were proposed: move the last k percent of boxes, move a percentage of boxes in every bin that has below average occupancy, move different parts of the bins to be emptied, or combine subsets of boxes in complementary bins and refill both with the remaining boxes.

The application of improvements (i.e., the movements of the chosen boxes) was dictated by several strategies. One of these applied the VND strategy to explore the solution neighborhood defined by the four possible moves. If the GRASP/VND heuristic appeared to be stuck at a local solution, diversification iterations are applied in the constructive process which require packing the most frequently remaining boxes first.

Recent Theoretical Studies of Multi-Dimensional Packing

Several theoretical analyses have been performed for multi-dimensional bin-packing heuristics that provide performance guarantees for packing quality as well as for algorithm execution time. One example is the recent work related to polynomial time approximation schemes (APTAS) for the three-dimensional strip packing problem. It has been shown that APTAS's exist for one-dimensional bin-packing and two-dimensional strip packing problems, but an APTAS will only exist for two-dimensional bin-packing problems if P = NP. These results are reviewed by Bansal et al. (2007) who also develop two approximation schemes: one for packing three-dimensional strips with arbitrarily sized boxes and a second for packing boxes with square bases.

Their first algorithm initially applies a Harmonic transformation (i.e., using intervals similar to those defined in the 1DBPP Harmonic heuristic) to the box widths, then it creates slabs of items to form two-dimensional strip packing instances. The two-dimensional strip is then cut into slices to produce new items that are placed on top of each other in the height dimension of a three-dimensional strip. The authors prove that this algorithm has an asymptotic approximation ratio that is arbitrarily close to the Harmonic number $T_\infty \approx 1.69$. The second algorithm A packs of set I of three-dimensional boxes with square bases so that the height of the packing does not exceed $(1 + 12\varepsilon)OPT(I) + O(K)$ where $K = \varepsilon^{-O(2^{1/\varepsilon})}$.

An APTAS for packing d-dimensional cubes into a minimum number of unit cubes has been developed by Correa and Kenyon (2004) who also present a scheme for packing rectangles into at most OPT square bins whose sides have length $1 + \varepsilon$ and OPT denotes the minimum number of unit bins required to pack the rectangles.

Parallel Algorithms

Many parallel algorithms have been proposed and studied for solving the cutting stock and knapsack variants of the bin-packing problem. Heuristics have also been proposed that obtain approximate solutions to the one-dimensional bin-packing problem on various models of parallel computation.

For the shared-memory Exclusive-Read Exclusive-Write PRAM model of computation, a heuristic based on First-Fit Decreasing has been proposed which runs in $O(\log n)$ time on $n \log n$ processors (Anderson et al. 1989). This approach divides the data items into two groups. Items in the first group are partitioned into sublists that are packed into "runs" of bins. The bins are then filled using items in the second group. The algorithm relies on parallel prefix, merging, and parenthesis matching operations, and has a worst-case performance bound of 11/9.

Practical one-dimensional bin-packing algorithms (including parallelizations of the Harmonic algorithm) have also been proposed and implemented on parallel architectures such as systolic arrays, SIMD arrays, and MIMD hypercubes. Quantitative studies

and theoretical analyses have been performed on some of these approaches. The Systolic packing algorithm, for example, has a worst-case performance bound of 1.5 and executes in $O(n)$ time. Similar results were reported in Berkey (1990).

Coleman and Wang (1992) formulated an online heuristic for massively parallel systems that used interval partitioning. The average case behavior of the heuristic could be predicted when the input have a symmetric distribution. The method is asymptotically optimal, yields perfect packings, and achieves the best possible average case behavior with high probability.

Birth-Death Process

A stochastic counting process that satisfies the following is called a birth-death process: (1) changes from state n (sometimes written more generally as state E_n) may only be to states $n+1$ or $n-1$ (i.e., changes can only be ± 1 unit); (2) the probability of a birth (death) occurring in the "small" interval of time, $(t, t+dt)$, given that the process was in state n at the start of the interval, is $\lambda_n dt + o(dt)[\mu_n dt + o(dt)]$, where $o(dt)$ is a function going to 0 faster than dt. Such processes are in fact Markov chains in continuous time. The system size of an M/M/1 queueing system is an example of a birth-death process where $\lambda_n = \lambda(n = 0, 1, 2, \ldots)$ and $\mu_n = \mu(n = 1, 2, \ldots)$. Markov chains; Markov processes.

Bland's Anticycling Rules

A set of pivot rules, the application of which to linear-programming (degenerate) problems, prevents cycling in the simplex algorithm. Their basic principle is that whenever there is more than one eligible candidate in selection of the variable entering the basis, or the variable leaving the basis, the candidate with the smallest index is chosen.

Blending Problem

The linear-programming problem of blending raw materials, for example, crude oils, meats, to produce one or more final products, for example, fuels, sausages, so that the total cost of production is minimized. The problem is subject to restrictions on material availability, blending requirements, quality restrictions, etc.

- ▶ Activity-Analysis Problem
- ▶ Stigler's Diet Problem

Block Pivoting

The process of entering several nonbasic variables simultaneously into the basis in the simplex algorithm.

See

- ▶ Simplex Method (Algorithm)

Block-Angular System

A linear system of equations for which its matrix of coefficients A can be decomposed into k separate blocks of coefficients A_i, where each A_i represents the coefficients of a different set of equations. This structure typically represents a system consisting of k subsystems whose activities are almost autonomous, except for a few top-level system constraints whose variables couple the k blocks of the subsystems. Such systems can also have a few variables external to the blocks that couple the blocks.

- ▶ Large-Scale Systems
- ▶ Weakly-Coupled Systems

Block-Triangular Matrix

A matrix which is lower (upper) triangular except for a number of blocks along the diagonal.

See

- ▶ Triangular Matrix

Bonferroni Inequality

Result in basic probability that provides a general lower bound on the intersection of events $E_1,\ldots,E_n$:

$$P(\bigcap_{i=1}^{n} E_i) \geq 1 - \sum_{i=1}^{n} P(E_i^c).$$

Note that the events need not be independent (nor mutually exclusive).

Applied in stochastic simulation output analysis to make statements about the overall confidence level of multiple performance measures (simultaneous confidence intervals). For example, for three output performance measures each with 99% confidence levels, the overall confidence level would be at least 97%.

Bootstrapping

In forecasting, the term bootstrapping refers to models that have been developed by regressing an individual's (or group's) forecasts against the inputs that the individual used to make the forecasts.

Introduction

Researchers typically encounter many situations in which parametric statistical techniques are less than ideal. The t-statistic, for example, assumes that the data were sampled from a normal distribution. Of course, much real-world data follow distributions that are far from normal, and may in fact be quite skewed. Suppose a researcher is investigating data that is known to follow an exponential distribution. Clearly, it would take an extremely large sample and a great deal of manipulation (e.g., averages of averages), for the central limit theorem to apply. In many cases, there is no parametric test for the measurement of interest because the sampling distribution of that measurement may be unknown and thus there would be no tractable analytic formulas for estimating such measures, for example, the difference between two medians (Mooney and Duval 1993, p. 8).

There are a number of nonparametric statistical techniques that do not rely on distributional assumptions and often may be used in place of the more traditional parametric tests. Many nonparametric techniques, however, work only with the median as a measure of central tendency (e.g., Mann-Whitney-Wilcoxon). This may present a problem for researchers who are more interested in the mean as the measure of interest.

The bootstrap statistic (Efron 1981, 1982; Mooney and Duval 1993) is a nonparametric, computer-intensive resampling technique, which makes no distributional assumptions and may be used for estimation and hypothesis testing. The bootstrap, jackknife, and other related resampling methods are beginning to generate interest among management scientists. Indeed, these tools can be very useful for the type of data that is frequently encountered by management scientists.

The Bootstrap Method

With traditional parametric inference, a sample is taken and a statistic, often the sample mean, is computed. This statistic is assumed to follow a known distribution (normal, t-distribution, F-distribution, χ^2-distribution, etc.), which then allows the researcher to perform hypothesis tests and/or estimate confidence intervals. With bootstrapping, which was developed mainly to determine the standard error for other types of estimates (Efron and Tibshirani 1991), the sample itself is used to construct a sampling distribution by selecting from it many resamples, or pseudo-samples.

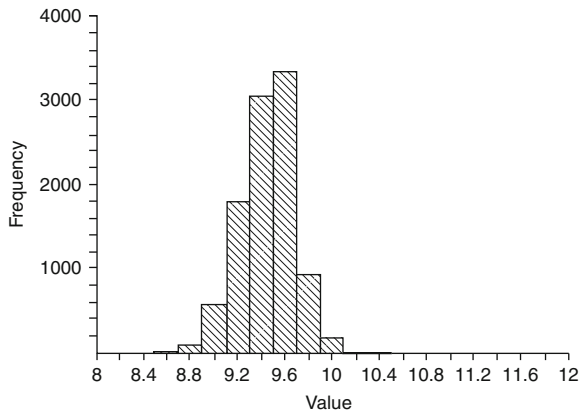
Resampling from the sample is done with replacement. Thus, it is like sampling from an infinite population with a composition that exactly matches that of the sample that was originally drawn. After resampling a great number of times one may construct a sampling distribution for a statistic of interest, such as the mean, median, or any percentile. This distribution, which is entirely based on the original sample and not on any theoretical distribution, may then be used to test hypotheses about measures of interest and to construct confidence intervals.

To illustrate the method, two illustrative examples are presented. The first is a hypothesis test for a sample from a single population; the second, for samples from two presumably different populations.

Bootstrapping: Resampling Methodology, Table 1 Sample data and statistics, Example I

Life	Frequency
8.0	3
9.0	5
10.0	6
11.0	2

$\bar{x} = 9.438$, $s = 0.964$, $n = 16$



Bootstrapping: Resampling Methodology, Fig. 1 Histogram of mean lifetimes, 10,000 resamples, Example I

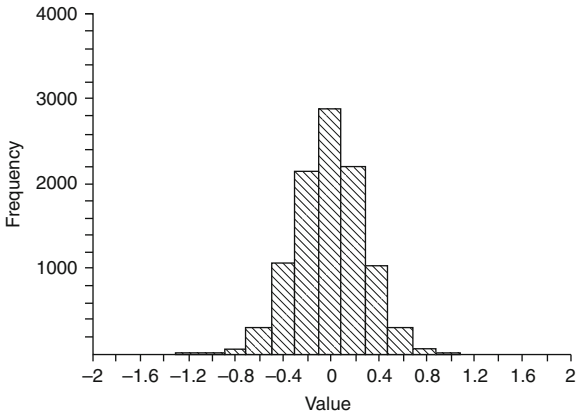
Example I A company claims that the average life of a part that it manufactures is at least 10 hours. A sample of 16 parts is taken in order to test this claim. The sampled data is summarized in Table 1.

A parametric analysis using the t-statistic would have to assume that the underlying population is normally distributed since the sample is too small to rely on the central limit theorem. Moreover, this type of data is usually not normally distributed, or even symmetrical.

Using the bootstrap method, 10,000 resamples, each of size $n = 16$, were taken from the original data. Figure 1 is a histogram of the 10,000 resampled means. One can see that the means seem to be hovering about the values 9.3 to 9.7 hours, and very few are actually above 10.0. Table 2 confirms that only a small fraction of the means were above 10.0. As a matter of fact, the 95 percent one-sided confidence interval is bounded by the value of 9.8125 hours. This means that only 5 per cent of the resamples had mean values above 9.8125. Clearly, the claim that the average life of these parts is at least 10 hours should be rejected.

Bootstrapping: Resampling Methodology, Table 2 Frequency distribution of mean lifetimes, Example I (note that each category covers all values within 0.1 of its center)

Center value	Frequency	Percent	Cum percent
8.6	7	0.1	0.1
8.8	92	0.9	1.0
9.0	583	5.8	6.8
9.2	1798	18.0	24.8
9.4	3057	30.6	55.4
9.6	3342	33.4	88.8
9.8	920	9.2	98.0
10.0	184	1.8	99.8
10.2	16	0.2	100.0
10.4	1	0.0	100.0



Bootstrapping: Resampling Methodology, Fig. 2 Histogram of mean lifetimes, 10,000 resamples, Example II

Bootstrapping: Resampling Methodology, Table 3 Sample data and statistics, Example II

Group 1	Group 2
13.8	12.6
13.3	12.4
13.7	12.9
13.6	13.3
15.2	14.2
14.4	13.0
13.6	13.4
13.3	12.9
13.6	13.5
13.8	13.6
$\bar{x}_1 = 13.83$	$\bar{x}_2 = 13.18$
$s_1 = 0.57$	$s_2 = 0.53$
$n n_1 = 10$	$n_2 = 10$

Bootstrapping: Resampling Methodology, Table 4 Frequency distribution of mean lifetimes, Example II (note that each category covers all values within 0.1 of its center)

Center value	Frequency	Percent	Cum percent
21.2	1	0.0	0.0
21.0	4	0.0	0.1
20.8	42	0.4	0.5
20.6	273	2.7	3.2
20.4	1065	10.6	13.9
20.2	2164	21.6	35.5
0.0	2876	28.8	64.3
0.2	2189	21.9	86.1
0.4	1026	10.3	96.4
0.6	305	3.0	99.4
0.8	50	0.5	99.9
1.0	5	0.1	100.0

Example II A similar type of analysis can be done for a two-sample test. Consider the data in Table 3, representing the life (in weeks) of similar parts from two different manufacturers or two different production processes. As in Example I, a parametric test would require an assumption of normally distributed lifetimes, which again may be unrealistic.

With the bootstrapping approach, first combine the two groups of data into one (i.e., under the assumption that H_0 is true). Then, this combined group is resampled to produce two groups of data items, and the mean difference of the two groups $\bar{x}_1 - \bar{x}_2$ is recorded. This resampling is done many times, and the resulting mean differences are compared with the observed mean difference in the original set of data.

In the above example, the observed mean difference is 0.65 weeks (13.83–13.18). The question is, what is the likelihood that this difference occurred by chance? Since this is a two-tailed test, consider resamples for mean differences greater than 0.65 or less than -0.65. Figure 2 contains the histogram of the mean differences of 10,000 re-samples, in which each resample produced two groups of size $n = 10$ each. Examination of this histogram and of Table 4 shows that almost all of the mean differences fall between–0.5 to 0.5. Actually, only 1.85% of the resampled mean differences were either greater than 0.65 or below–0.65. At a significance level of 0.05, reject the hypothesis that the two population means are the same.

Concluding Remarks

Bootstrapping is clearly a technique that is very useful to researchers. It should, however, be pointed out that this technique is totally dependent on the integrity of the original sample of data. If the sampled data is indeed a good representation of the underlying distribution, inferences based on resampling this data will be valid. On the other hand, if the original sample, say, over represents high values of the output distribution, then the resamples and inferences based on them cannot be trusted. If the sample is biased, the resampling technique may reflect and possibly magnify these biases.

Some areas in operations research and management science that have made use of bootstrapping and other resampling techniques include: quality control (Jeske 1997; Seppala 1995), analysis of simulation output (Friedman and Friedman 1995; Kim et al. 1993), neural networks (LeBaron 1998; Shimshoni 1998), performance evaluation (Cho 1997), and production (Jochen 1997).

Mooney and Duval (1993) describe how the bootstrap procedure may be used with SAS and RATS. Resampling Stats (Simon 1995), a simple computer package for bootstrapping, is user-friendly, relatively inexpensive, and comes with numerous examples. Fan and Jacoby (1995) describe a SAS/IML program for performing the bootstrap resampling technique in regression analysis. Bootstrapping can also be done with spreadsheets (Willemain 1994).

► Linear Programming

Branch

To move and analyze a new computational path (i.e., branch) based on the results obtained from a previous path.

See

► Branch and Bound

Branch and Bound

A method for solving an optimization problem, by successively partitioning (branching) the set of feasible points to smaller subsets, and solving the problem over each subset. The resulting problems are called subproblems or nodes in the enumeration tree. The idea in branch and bound is that the optimal solution to the problem is the best among the optimal solutions to the subproblems. To reduce the number of subproblems solved, best-case bounds are computed by solving relaxed problems defined at the nodes. If the best-case bound on a solution to a subproblem is worse than the best available solution, the subproblem is eliminated from consideration (fathomed). Branch and bound techniques are frequently used to solve integer-programming problems, as well as in global optimization.

Brownian Motion

A one-dimensional Brownian motion $\{B(t),\ 0 \leq t\}$ is a continuous-time, Markovian, real-valued stochastic process having continuous sample paths; its distribution is Gaussian with mean function $E[B(t)] = \mu t$ and covariance function $\mathrm{Cov}[B(s), B(t)] = \sigma^2 \min(s, t)$. An n-dimensional Brownian motion is a stochastic process on $\mathbb{R}^n$ whose n components are independent one-dimensional Brownian motions. Named after Scottish botanist Robert Brown. Also known as the Wiener process, named after mathematician Norbert Wiener.

See

► Markov Processes

BTRAN

The procedure for computing the dual variables in a simplex iteration, when the *LU* factors of the basis matrix are given in product form. The name BTRAN (backward transformation) derives from the fact that the eta file is scanned backwards in the solution process.

See

► Eta File

Buffer

The queue or the waiting room in a queueing system. Most often used for networks, especially tandem networks or series queues.

See

► Queueing Theory

Bulk Queues

Arrivals to a queueing system may consist of more than one customer at a time, and/or service might process more than one customer simultaneously.

See

► Queueing Theory

Bullwhip Effect

► Supply Chain Management

Burke's Theorem

The steady-state departure process of a stable M/M/*c* queueing system is a Poisson process with the same rate as the arrival process, irrespective of the service rate.

Business Intelligence

Paul Gray
Claremont Graduate University, Claremont, CA, USA

Introduction

Business Intelligence (BI) systems are sophisticated analytical tools that present complex organizational and competitive information in a way that allows decision makers to decide quickly and appropriately. While the term Business Intelligence is relatively new (it was introduced in 1989, popularized in the 1990s), computer-based BI systems existed, in one guise or another, decades prior to that. BI-type functionality was available previously to varying degrees in Financial Planning Systems (4GLs), Executive Information Systems (EIS), Decision Support Systems (DSS), Data Mining, and On Line Analytic Programming (OLAP). With each new iteration, capabilities increased as enterprises grew ever-more sophisticated in their computational and analytical needs and as computer hardware and software matured. This article explores the capabilities of state-of-the-art BI, their benefits to adopters, and the role of Analytics in BI.

BI describes data-driven decision support systems (Power 2005) for managers. In its initial form, it involved business analysts who refined (mostly internal) business data to create input for management. Such systems have been marketed commercially since the 1960's, if not earlier. BI is now closely linked to Analytics, the use of quantitative methods for solving organizational problems. BI is broader than Analytics because it involves soft methodologies and information systems, as well as Operations Research (OR).

Objective and definition of BI: The objective of BI is to improve the timeliness and quality of the input to the decision process.

To achieve this objective, BI systems combine:

Data gathering		
Data storage	with	Analysis
Knowledge management		

to evaluate complex organizational and competitive information and present the results to planners and decision makers.

The first three operations are inputs, typically performed by people with information systems and data analysis skills. The skills of Analytics are brought to the table by people trained in OR, statistics, and other quantitative disciplines.

Implicit in its definition is the idea that BI systems provide actionable information and knowledge at the right time, at the right place, and in the right form.

Problems to which BI is Applied: BI aims to convert data available to the organization into

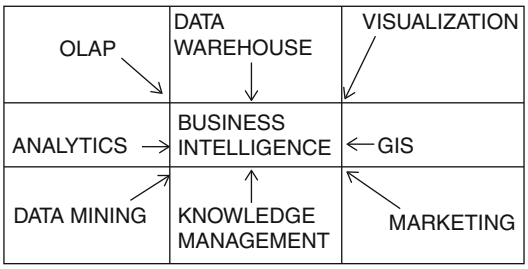
information and, through analysis, into knowledge. Among the many tasks that BI performs are:

- Examine the opportunities for
  - proposed products,
  - mergers and acquisitions,
  - acquiring new customers, and
  - locating sites for new branches.
- Create forecasts based on historical data, current performance, and estimated future performance. Futures methodologies such as Delphi and cross-impact analysis are discussed in Glenn and Gordon (2008).
- Monitor key performance indicators (KPI) both for the organization and its competitors.
- Do "what if" analysis to examine the impacts of changes and of alternative scenarios.
- Ad hoc access to data to answer specific, non-routine questions.

These examples cover both regular, repetitive scheduled reporting (e.g., monthly reports on sales by region, department, or strategic business unit), and special investigations aimed to solve specific problems. Forecasting and many of the specific problem studies involve OR modeling that uses the organization's data warehousing capabilities for the underlying information. For example, specific studies undertaken in response to a crisis or an opportunity such as a contract proposal.

BI vs. Competitive Intelligence: Business Intelligence uses technologies, processes, and applications to analyze mostly internal, structured data, and business processes, while Competitive Intelligence (discussed below) gathers, analyzes, and disseminates information from both external and internal sources to provide a framework for assessing the organization's position relative to its industry and non-industry competitors and its vulnerability to disruptive technologies.

Previous Systems: Present-day BI systems reflect a series of iterations to obtain their present functionality. These included (1) 3rd Generation financial planning languages that allowed writing relations in words rather than symbols. (For example, rather than saying S = M*MS, one could write Sales = market*market share.) (2) Executive information systems that can create PowerPoint charts to brief management on the current state of the business. (3) On-Line Analytic Processing in which data warehouses that store data in the form of 2-dimensional relational data bases are used to create multidimensional data cubes (see below). Although each of these elements is more sophisticated than the one before, they were individual systems, while the hallmark of current BIs is the integration of such systems.



Business Intelligence, Fig. 1 Software Components of Inputs to Business Intelligence

BI Input Software

BI is deeply tied to the ability to store data bases and to compute at the organizational or departmental level. Key elements include data warehouses and data marts. As shown in Fig. 1, many software capabilities are involved.

The software components used in BI include:

- A *Data Warehouse* is a collection of data bases that contain both current and historical information about the organization. The warehouse is separate from operational systems that support on-line transaction systems. It contains "a single version of the truth" and is intended to support understanding of the organizational data over time. It is particularly important for BI.

To create the single version of the truth, data goes through a process known as ETL (extract, transform, load). The ETL applies procedures that extract data from selected sources, transforms it into the format of the data warehouse that is consonant with the warehouse's rules, and then stores the data into the warehouse or mart. ETL is important for BI because it standardize the data and eliminates redundancies and inaccuracies.

Data warehouses come in two sizes:

- A data warehouse, which support an entire organization or one of its major portions.
- A data mart that is a smaller version of a data warehouse but has all features of a warehouse. It can

Business Intelligence, Table 1 Characteristics of the Data Warehouse

Characteristics	Description
Subject oriented	Data are organized by how users refer to it.
Integrated	Inconsistencies are removed in both nomenclature and conflicting information, i.e, combining of all related data around a common identifier/key
Non-volatile	Read-only data are not updated by users
Time Series	Data are time series, not current value. A typical data warehouse has 5 to 10 years of data.
Summarized	Operational data are aggregated into decision usable form where appropriate
Larger	Much more data is retained than in transaction systems because it offers time series.
Non-normalized	Data can be redundant for ease of retrieval and use.
Metadata	Data about the data are available to users and to warehouse personnel.
Input	Include both operational data and external data

Source: Gray and Watson (1998)

be dependent or independent. If dependent, it contains a subset of the data warehouse needed by specific groups, such as Analytics. But, multiple independent data marts cannot substitute for a data warehouse because data integrity is not maintained among them.

Over time, a number of specialized data warehouses have evolved. They include operational data stores, real time warehouses, prototype warehouses, and exploration warehouses discussed below.

The characteristics of the data warehouse are listed in Table 1. These characteristics assume that the data warehouse is physically separated from operational systems and that its databases are not used for on-line transaction processing (Inmon 1992).

- *OLAP* (**o**n-**l**ine **a**nalytic **p**rocessing) is used to analyze multidimensional data for a BI. It is used for such tasks as sales analysis, budgeting, forecasting, and financial reporting where it is necessary to manipulate and consolidate data from multiple sources. Data are specially configured for OLAP into data cubes to allow complex questions to be answered more quickly than for relational data bases. OLAP has subdivided into relational, multidimensional, hybrid, and other forms, which are typically referred to as ROLAP, MOLAP, and HOLAP.
- *Analytics* refers to the use of quantitative and statistical methods together with extensive computing and modeling to make sense of the data. It is the area of BI that attracts operations researchers. Mathematics is the base for Analytics. The objective is to obtain realistic and, if possible, optimal alternatives for decision making about the future. Analytics is discussed in more detail below.
- *Data Mining* [also referred to as knowledge data discovery (KDD)] is a form of predictive analytics discussed below. It is a set of analytical techniques to obtain new insights from the data in the data warehouse that an analyst or a manager had not thought to ask. It is used to find answers that reports and queries do not reveal effectively. KDD seeks to find patterns in data and to infer rules. Data mining differs from conventional hypothesis testing in that it looks at data for the relationships it contains to form hypotheses that can be tested. KDD techniques include neural networks, expert systems, fuzzy logic, intelligent agents, multidimensional analysis, data visualization, and decision trees. Data mining is used in wide range of topics, e.g., to identify where people are likely to take vacations, detect fraud, analyze loan quality, and the reported (but apocryphal) association that men who buy diapers on Friday night also buy beer.
- *Knowledge Management*. Knowledge can be tacit and explicit. Tacit knowledge is what is in one's head but cannot usually be expressed, although there are techniques for obtaining some tacit knowledge. Explicit knowledge is about what can be written down, stored, and retrieved. Knowledge management is about knowing what the organization knows and finding new knowledge that is needed when the organization does not know. It focuses on creating, sharing, and applying knowledge. In BI, the explicit information in the data warehouse and in reports is merged with the tacit knowledge in the heads of analysts and professionals.
- *Geographic Information Systems*. These systems link data bases to geographic maps of physical locations. They are used to analyze spatial phenomena. For example, they allow overlaying of customer, distribution center, retailer, and other information about a firm's and its competitor's products.

- *Marketing*. Analytics are used to understand the implications of existing and proposed policies in the marketplace. For example, data from aggregators and from the firm are used to create forecasts of market size and market size.
- *Visualization*. Visualization refers to methods to present information on-screen in a form comprehensible to non-technical managers. It does not replace Analytics; it focuses the analytic results. By exploiting visuals, it provides an overview of complex data sets and allows for identifying relationships and trends in data and in analytical results.

BI Outputs: Dashboards and Reports

Dashboards. In BI, a dashboard is way of communicating results in a form that is easily understood by managers. A dashboard is a visual screen that shows the key performance indicators. The data, drawn from internal information systems and analyses, not only summarize the current status, but also provide historical data, warning levels, next steps, and notices. It includes financial and non-financial measures.

The idea of a dashboard has been in use since the 1960's. At that time, summarized data for managers was displayed on color slides at regular management meetings. For example, the experience at AT&T from color slides was that if the dashboard slides presented the current data in the same format at each meeting, managers would rapidly find and be sensitive to changes that required action.

Introducing the computer provided an instant display device, improved visualization, and provided data on the desktop tailored to each user. For example, the VP for manufacturing and the VP for human resources can see results specifically oriented to their issues. Furthermore, the displays allow drill down; that is they start with a broad view and then let the user see greater and greater detail..

The three main applications are:

- *monitoring* information at a glance. Usually involves key performance indicators (KPI) in graphical, symbol, or symbolic form.
- *analysis* of exceptions to find root causes of problems. Summarized multi-dimensional data and drill down in "slice and dice" fashion are used.
- *Identify actions* to solve problems based on access to detailed operational data, queries, and reports.

Reports include:

- regular, repetitively scheduled documents (e.g., monthly sales by region, department, or strategic business unit),
- exception reports which are produced whenever parameters are outside pre-specified bounds,
- documents presenting the results of special investigations (often in response to requests from BI users), and
- custom data cubes based on specific requests from analysts.

Forecasting and many of the specific studies involve OR modeling that uses the organization's data warehousing capabilities for the underlying information. For example, specific studies are undertaken in response to a crisis or an opportunity such as a contract proposal.

BI Architecture

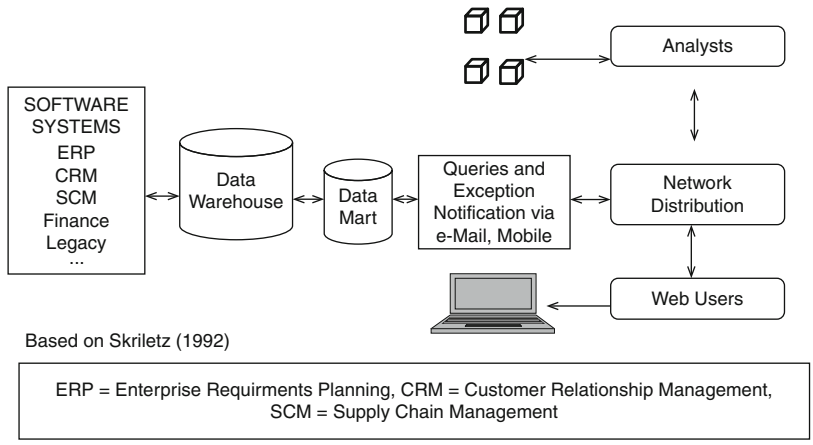
Figure 2 (based on Skriletz 2002) is typical of the architecture for a large installation that centers on the use of Web technology for distribution. As shown, the input data come from a variety of systems into the data warehouse. The specific data needed for BI is downloaded to a data mart used by planners and executives.

As shown, the specific applications used for BI include the organizational focus and the audience (Skriletz 2002).

The left side of Table 2 shows the business focus of the technologies, while the right side shows the levels of people in the organization who are the consumers of the intelligence. At the bottom of the hierarchy is transaction processing based on application-specific data in the warehouse or in ERP or in sales systems. The next level involves processing the data so that it is useful to first level managers. Here, Analytics and pattern analysis are performed and data are presented in visual form. At the top level, predictions, compilations of competitive analyses, and summary presentations for executives are created.

Tools. Many of the tools for BI are used for other applications as well. They include:

- simple querying and reporting,
- on-line analytic processing (OLAP),



Business Intelligence, Fig. 2 BI Architecture

Business Intelligence, Table 2 Business Intelligence Aplications

Organizational focus				Audience
Strategy	Predictive and Prescriptive Analytics	Competitive Intelligence	Intelligence Presentation and Visualization	**Top executives**
Operations Analysis	Data Analytics			**Operations Directors**
Operations Monitoring		Heuristic Pattern Analysis		**Operations Supervisors**
Transaction Processing	Platform for BI - Manage Through Metadata Application-Specific BI (e.g., SAS, IBM, Oracle, SAP)			**Operations staff**

- statistical analyses and data mining,
- forecasting, and
- geographic information systems and visualization.

In addition, the extraction, translation, and loading (ETL) tools of data warehousing are important for BI because they help standardize the data so it can be analyzed with accuracy and provide a single truth. When operational data is used, as from an Operational Data Store (ODS), the objective is to get dynamic data that reflects the current situation.

The key dissemination method for business technology is internet technology, whether it be an intranet within the firm or an extranet connected to suppliers and/or clients. The idea is to reach everyone who needs specific data, rather than a few at corporate headquarters.

Business Analytics

In the 20th century, most information systems were used to standardize routine business processes to minimize cost and time. Fairly sophisticated decision support systems and data warehouses were in use, but these systems rarely directly affected the ways decisions were made (Drucker 1999). BI was mostly the province of the information systems groups in organizations. It centered on providing inputs for data-based decision making. It was only after the turn of the century that it was generally realized that applying Analytics would improve to data-based decision making. This realization was reinforced by leading vendors, such as IBM, Microsoft, Oracle, and SAP, acquiring major BI software firms and investing in expanding BI software capabilities. It became clear that the analytic skills and the methods of OR analysts are needed to exploit information technology capabilities.

The definition of business Analytics is still in flux. Davenport and Harris (2007) defined it as "the extensive use of data, statistical and quantitative analysis, explanatory and predictive models, and fact-based management to drive decisions and actions." In this definition, Analytics is a subset of BI, that is, technologies and processes that use data to understand and analyze performance. A broader

definition comes from IBM who uses it to refer to both software applications and analytic solutions (Lustig et al. 2010). In their view, software includes BI, performance management, prediction, optimization, enterprise information management, content, and collaboration. Analytic solutions involve finance, risk, fraud, customer relations, human capital, and supply chain. Underlying Analytics is the idea that data and information are strategic assets.

Analytics can be divided into three categories (Lustig et al. 2010):

- Descriptive analytics
- Predictive analytics
- Prescriptive analytics

All three categories start with the underlying idea that data and information are strategic assets.

Descriptive analytics is the classic form of BI. It starts by examining, consolidating, and classifying data. Data sources include information from departments (marketing, sales, operations, accounting), enterprise systems (ERP, CRM, and Supply Chain Management SCM), as well as spreadsheets, other databases, and external data from 3rd parties. The outputs are ad hoc and exception reports, dashboards, KPI, statistical analyses, drill down, and answers to ad hoc queries about business performance. These outputs allow for the managing and monitoring of business processes. Descriptive analytics are often inputs to predictive and prescriptive analytics.

Predictive analytics combines the data within a wide variety of mathematical procedures to create models that explain and/or predict performance. It is based on inherent relations between the data inputs and outcomes. Predictive analytics uses data on what happened in the past to detect patterns and relations to make forecasts. Its methods include, among others (Lustig, et al. 2010):

Data mining	Correlations among data
Forecasting	Extrapolations of trends into the future
Monte Carlo simulation	What may happen if changes occur
Root-cause analysis	Evaluation of why things happened
Pattern recognition	Alerts when unusual situations occur
Predictive modeling	Forecasts by Delphi or other methods

Prescriptive analytics refers to mathematical techniques that provide understanding of alternative courses of actions when there are competing objectives, requirements, and constraints. It involves both static and stochastic optimization. The former leads to determining the best outcome, while the latter considers the effects of data uncertainty to improve decisions. Given the increase in computer speed and memory, improved algorithm performance, and in data quality, prescriptive analytics can be run in near-real-time so they can affect operational as well as strategic decisions.

Integrating Analytics and BI

Where traditional BI depends principally on aggregating, evaluating and manipulating the information in the data warehouse, Analytics adds modeling and optimization. Irrespective of which type of Analytics (descriptive, predictive or prescriptive) is used, the results need to be communicated to the user community.

This communication capability involves a series of steps (Shapiro 2010):

- Develop models to optimize decisions for key performance indicators.
- Select the right modeling system. It may be customized or off the shelf.
- Define the database needed for the optimization model. It may be customized or off-the-shelf
- Create the decision database. This may require new ETL routines and descriptive models
- Link the database and the outputs from the optimization model to the organization's reporting tools to be able to communicate results to users.
- For strategic and tactical decisions, reuse criteria for alerts and redo modeling studies at regular intervals. For operational decisions, exercise the operational models in real-time with current data.

Competitive Intelligence

The notion of competitive intelligence (CI) as spy vs. spy, fed by such examples as Japan and China allegedly stealing U.S. industrial secrets, is far from the real situation. That does not mean that companies do not try to find out as much as possible about their current and potential competitors. The people involved, however, claim that they do so in a legal and ethical manner. CI is defined by the Society for

Competitive Intelligence Professionals (SCIP) as the process of monitoring the competitive environment. To do so, analysts systematically gather, analyze, and manage information that can affect a company's plans, decisions, and operations.

The competitive intelligence cycle includes:

- Determine the intelligence needs of decision makers
- Collect information to meet these needs
- Analyze the data and recommend actions
- Present results to the decision makers
- Use the response to the findings to refine collection.

The focus is on determining both the current activities and the likely intentions of other firms and of governments. It also includes looking for the possible appearance of disruptive technologies and finding out about how competitors are responding to your actions.

The collected raw data (facts, statistics) are organized and then analyzed to find patterns, trends, and relationships. The tools used include:

- Simulations of alternative scenarios to test what if conditions
- Data mining of information about both competitors and the firm
- Assessing competitor technologies by tracking (and extrapolating from) patent filings.
- Attending trade shows and conferences
- Scanning publicly available data: public records, the Internet, press releases, and mass media.
- Talking with customers, suppliers, partners, industry experts

Much of the data gathering work is terribly dull and routine. To be effective, it has to be someone's (or some group's) responsibility.

For many organizations, the only basis for evaluating their competitors is by applying the SWOT technique: **S**trengths, **W**eaknesses, **O**pportunities and **T**hreats. SWOT, as taught in business schools, is often done qualitatively based on individuals intuitively assessing a particular competitor. The technique can and should be done using Analytics.

True competitive analysis goes far beyond SWOT. Table 3 shows the results of a survey of the use and effectiveness of CI analysis techniques.

Since this table was compiled, an important new source of competitive data has come to the forefront. That is the analysis of social media data. People do put things on social media (e.g., Facebook, Twitter) that they would not put in writing in e-mail or other forms.

Business Intelligence, Table 3 CI Analysis Tools

Tool	Percent Using	Tool	Effectiveness Percentage
Competitor profiles	88.9	SWOT analysis	63.1
Financial analysis	72.1	Competitor profiles	52.4
SWOT analysis	55.2	Financial analysis	45.5
Scenarios	53.8	Win/loss analysis	31.4
Win/loss analysis	40.4	Gaming	21.9
Gaming	27.5	Scenarios	19.2
Conjoint analysis	25.5	Conjoint analysis	15.8
Simulation	25.0	Simulation	15.4

Source: Powell and Allgaier (1998)
Note: The two columns of table on the *left* shows the percentage of respondents using the technique. The two columns of the table on the *right*, which list the same techniques, shows the percentage of those who believe the technique is effective.

Some companies that practice competitive analysis realize that just as they gather data about competitors, competitors are likely to gather data about them. They therefore try to protect their own information by becoming secretive about their plans. They control their press releases, approve speeches by their executives, provide security training for their employees, and more to avoid leaks about their intentions.

Busy Period

A time interval that starts when all the servers of a queueing system become busy and ends when at least one server becomes free. May also refer to a time interval that starts when a previously completely idle system begins serving any customer and ends when the system becomes idle again. The two definitions (sometimes distinguished as full and partial busy periods, respectively) coincide for a single-server queue.

Calculus of Variations

Stephen G. Nash
George Mason University, Fairfax, VA, USA

Introduction

The calculus of variations is the grandparent of mathematical programming. From it came such concepts as duality and Lagrange multipliers. Many central ideas in optimization were first developed for the calculus of variations, then specialized to nonlinear programming, all of this happening years before linear programming came along.

The calculus of variations solves optimization problems whose parameters are not simple variables, but rather functions. For example, how should the shape of an automobile hood be chosen so as to minimize air resistance? Or, what path does a ray of light follow in an irregular medium? The calculus of variations is closely related to optimal control theory, where a set of controls are used to achieve a certain goal in an optimal way. For example, the pilot of an aircraft might wish to use the throttle and flaps to achieve a particular cruising altitude and velocity in a minimum amount of time or using a minimum amount of fuel. The modern world is full of devices designed using optimal control — in cars, elevators, heating systems, stereos, etc.

Brachistochrone Problem

The calculus of variations was inspired by problems in mechanics, especially the study of three-dimensional motion. It was used in the 18th and 19th centuries to derive many important laws of physics. This was done using the Principle of Least Action. Action is defined to be the integral of the product of mass, velocity, and distance. The Principle of Least Action asserts that nature acts so as to minimize this integral. To apply the principle, the formula for the action integral would be specialized to the setting under study, and then the calculus of variations would be used to optimize the integral. This general approach was used to derive important equations in mechanics, fluid dynamics, and other fields.

The most famous problem in the calculus of variations was posed in 1696 by John Bernoulli. It is called the Brachistochrone ("least time") problem, and asks what path a pellet should follow to drop between two points in the shortest amount of time, with gravity the only force acting on the pellet. The solution to the Brachistochrone problem can be found by solving

$$\underset{y(t)}{\text{minimize}}\ \frac{1}{\sqrt{2g}} \int_{t_1}^{t_2} \sqrt{\frac{1+y'(t)^2}{y(t)}}\,dt$$

where g is the gravitational constant. If this were a finite-dimensional problem then it could be solved by setting the derivative of the objective function equal to zero, but seventeenth-century mathematics did not know how to take a derivative with respect to a function.

The Brachistochrone problem was solved at the time by Newton and others, but the general techniques that inspired the name calculus of variations were not developed until several decades

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

later. The first major results were obtained by Euler in the 1740s. He considered various problems of the general form

$$\underset{y(t)}{\text{minimize}} \int_{t_1}^{t_2} f(t, y(t), y'(t))dt.$$

The Brachistochrone problem is of this form. Euler solved these problems by discretizing the solution $y(t)$ — approximating the solution by its values at finitely many points. This gave a finite-dimensional problem that could be solved using the techniques of calculus. Euler then took the limit of the approximate solutions as the number of discretization points tended to infinity. This approach was difficult and restrictive, because it had to be adapted to the specifics of the problem being solved, and because there were restrictions on the types of problems for which it was successful.

Far more influential was the approach of Lagrange. He suggested that the solution be perturbed or varied from $y(t)$ to $y(t) + \varepsilon\, z(t)$, where ε is a small number and $z(t)$ is some arbitrary function that satisfies $z(t_1) = z(t_2) = 0$. For the Brachistochrone problem this latter condition ensures that the perturbed function still represents a path between the two points.

If $y(t)$ is a solution to the problem

$$\underset{y(t)}{\text{minimize}} \int_{t_1}^{t_2} f(t, y(t), y'(t))dt,$$

then $\varepsilon = 0$ will be a solution to

$$\underset{\varepsilon}{\text{minimize}} \int_{t_1}^{t_2} f(t, y(t) + \varepsilon z(t), y'(t) + \varepsilon z'(t))dt$$

This observation allowed Lagrange to convert the original infinite-dimensional problem to a one-dimensional problem that could be analyzed using ordinary calculus. Setting the derivative of the integral with respect to $\in$ equal to zero at the point $\varepsilon = 0$ leads to the equation

$$\frac{d}{dt}\frac{\partial f}{\partial y'} - \frac{\partial f}{\partial y} = 0.$$

This final condition is a first-order optimality condition for an unconstrained calculus-of-variations problem. It was first discovered by Euler, but the derivation here is due to Lagrange.

The name "calculus of variations was chosen by Euler and was inspired by Lagrange's approach in varying the function $y(t)$. The optimality condition is stated as the first variation must equal zero by analogy with the condition $f'(x) = 0$ for a one-variable optimization problem. Euler was so impressed with Lagrange's work that he held back his own papers on the topic so that Lagrange could publish first, a magnanimous gesture by the renowned Euler to the then young and unknown Lagrange.

There are additional first-order optimality conditions for calculus of variations problems. The theory is more complicated than for finite-dimensional optimization, and the necessary and sufficient conditions for an optimal solution were not fully understood until the 1870s, when Weierstrass studied this topic. A discussion of this theory can be found in Gregory and Lin (1992).

Multipliers

Constraints can be added to problems in the calculus of variations just as in other optimization problems. A constraint might represent the principle of conservation of energy, or perhaps that the motion was restricted in some way, for example that a planet was traveling in a particular orbit around the sun.

Both Euler and Lagrange considered problems of this type, and both were led to the concept of a multiplier. In the calculus of variations the multiplier might be a scalar (as it is in finite-dimensional problems) or, depending on the particular form of the constraint, it might be a function of the independent variable t. They have come to be called Lagrange multipliers; but, as with the optimality condition, Euler discovered them first.

In his book *Mécanique Analytique*, Lagrange includes an interpretation of the multiplier terms. He writes that they can be considered as representing the moments of forces acting on the moving particle, and serving to keep the constraints satisfied. This point of view is the basis for duality theory, although Lagrange does not seem to have followed up on this idea.

Duality

Duality theory did not become fully developed until early in this century, with many of the important steps

coming from the calculus of variations. At first there were only isolated examples of duality. That is, someone would notice that a pair of problems — one a maximization problem, one a minimization problem — would have optimal solutions that were related to each other. An early example of this type was published in 1755, and is described in Kuhn (1991). In the nineteenth century various other examples were noticed, such as the relationship between currents and voltages in an electrical circuit. Gradually it was understood that duality was not an accidental phenomenon peculiar to these examples but rather a general principle that applied to wide classes of optimization problems. By the 1920s techniques had been developed for obtaining upper and lower bounds on the solutions to optimization problems by finding approximate solutions to the primal and dual problems. Duality as a general idea is described in the book by Courant and Hilbert (1953).

Euler and Lagrange only considered problems with equality constraints, but later authors allowed inequality constraints as well. When specialized to finite-dimensional problems, the optimality condition is referred to as the Karush-Kuhn-Tucker condition. Kuhn and Tucker derived this result in a 1951 paper. It was later discovered that Karush had proven the same result in his master's thesis (1939) at the University of Chicago under the supervision of Bliss. There are two aspects to the result: its treatment of inequality constraints, and the assumption or constraint qualification that was used to prove it. The first idea can be traced to Weierstrass and the second to Mayer (1886), and both are outgrowths of the calculus of variations.

In the 1870s Weierstrass studied the calculus of variations and presented the results of his investigations in lectures. Weierstrass did not publish his work and it only became widely known years later through the writings of those in attendance. According to Bolza (1904), Weierstrass converted the inequality constraint

$$g(y) \leq 0$$

to an equivalent equality constraint

$$g(y) + s^2 = 0$$

using a squared slack variable s. This technique is described in many sources from 1900 onward. Bolza later became a professor at the University of Chicago, establishing a connection from Weierstrass to Bliss to Karush. Karush used this technique in his thesis.

The constraint qualification used by Karush, Kuhn and Tucker relates feasible arcs (paths of feasible points leading to the solution) and the gradients of the constraints at the solution. This same condition was used by Mayer (1886), although applied to a calculus of variations problem with equality constraints, and then in a chain of papers by various authors (including Bliss) leading to Karush's thesis. In these papers it is called a normality condition, and it is equivalent to requiring that the matrix of constraint gradients at the solution be of full rank. The implicit function theorem can be used to relate this to the condition on feasible arcs, an observation that is explicit in Mayer's work.

Concluding Remarks

The calculus of variations has influenced many areas of applied mathematics. It is a technical tool for solving optimization problems whose parameters are functions, and in this way it continues to be used in optimal control. It was the setting for the development of the most important concepts in optimization, such as duality and the treatment of constraints. And, when coupled with the Principle of Least Action, it was the vehicle for deriving the fundamental laws of physics.

Call and Contact Centers

Vijay Mehrotra[1], Thomas A. Grossman[1] and Douglas A. Samuelson[2]
[1]University of San Francisco, San Francisco, CA, USA
[2]Infologix, Inc., Annandale, VA, USA

Introduction

All companies have direct and indirect means of contacting customers, potential customers, or other clients. The basic ways include postal mail, email, and, of course, the telephone. Of special importance and interest is the ability of a company's representatives (agents) to talk with call-in clients or called parties on a large scale, that is, via call centers. Call centers are an important channel for businesses to interact with customers and stakeholders. Such centers generate large transaction volumes and can have a significant impact on client attitudes towards a company and its products. Examples include commercial software support, outbound sales prospecting, customer service, internal company help desk services, municipal information dissemination, emergency services dispatch, and financial transaction processing.

Many call centers have expanded to become contact centers that communicate with clients and called parties through a variety of means such as voice calls, planned callbacks (sometimes through virtual queueing), voice mail, cellular text messaging, and email. Like call centers, these types of contact centers are used by organizations to provide a wide variety of services.

Historically, A. K. Erlang, by his paper, "On the rational determination of the number of circuits," written in 1924 and first published in Brockmeyer et al. (1948), is considered the founder of call center analysis. Call and contact centers (hereafter collectively referred to as centers) are a large global industry. In 2008, the U.S. had an estimated 47,000 centers and 2.7 million agents; Europe, the Middle East, and Africa had 45,000 centers and 2.1 million agents; and Canada and Latin America had 35,000 centers and 730,000 agents. Since then, the industry continued to grow rapidly worldwide.

Centers can be inbound, outbound, or blended. Inbound centers receive calls and other contacts from clients. Outbound centers, which normally rely on voice, generate calls that are usually for telemarketing or collections. Blended centers do both and typically deploy agents who perform outbound work when inbound arrival rates are low. Inbound centers provide staff based on advance predictions of call rates and duration; poor predictions can cause serious degradation in performance. Thus, inbound centers need high-quality forecasts of arrival rates and service times that are random and non-stationary.

Outbound center managers have the luxury of choosing when to initiate contact and closely map their actions to the number of agents on duty. Computers are used to generate outbound calls and are programmed to pace calls such that a called party picks up the phone just as an agent ends a call. Hence, outbound centers need predictions of the expected length of contact, and the time interval between a computer-placed call and when the called party answers the phone. Otherwise, the system generates a nuisance call by abandoning the call when the called party answers, or the called party hangs up because there is no one on the line. U.S. law prescribes penalties for generating large numbers of calls abandoned by the system.

Ongoing improvements in information technology and reductions in telecommunications costs allow multiple physical locations to be managed as a single very large virtual center, thus enhancing pooling effects. Contacts can be given complex routings depending on the client's identity, product, need, or service history. Information can be obtained from clients via interactive voice response. Centers maybe off-shored to locations with lower labor costs; they can be run in-house or outsourced to a contractor.

Contact center business and operations issues are discussed in the following surveys and related studies: Aksin et al. (2007a), reviews opportunities for OR to improve practice; Gans et al. (2003) cites 164 papers associated with call centers; an expanded Web-based bibliography by Mandelbaum includes over 450 papers, as well as case studies; and Koole and Mandelbaum (2002) survey queuing models, while L'Ecuyer (2006) surveys optimization models; multi-skill centers are reviewed by Koole and Pot (2006) and Aksin et al. (2007a, b). OR/MS models applied within this domain tend to not consider human resources issues, although these issues are reviewed by Holman (2005) and Aksin et al. (2007b).

Much of the OR/MS knowledge and research related to centers is proprietary and unpublished. Trade magazines and patent filings can be important sources of information.

Inbound Systems

Inbound centers serve clients who initiate contact with an organization to receive service. Such centers need to react to calls that arrive randomly. Typically, after initiating contact, the client is connected to an agent or placed into a queue for later connection. Upon connection, the client receives service for some random amount of time. There can be other outcomes, such as when all incoming phone lines are in use and the call is blocked (the client is given a busy signal) or the client may decide to abandon the call. In some centers, a client may be connected to another agent with different skills, or wait in that agent's queue. The client might call back or otherwise reinitiate contact if the issue was not satisfactorily resolved. See Cleveland (2006) for further details on how inbound call centers operate.

Managers of inbound call centers seek to provide high-quality client service while keeping costs under control. Cost is straightforward, with the largest expense being labor. Cost performance is generally measured using labor cost, for which agent utilization (percent of time an agent is engaged with clients) serving as a proxy. Labor costs typically constitute 60% to 80% of a call center's operating expense. Telephone (or for contact centers, the Internet) costs have been a concern when queues or service times were high. These pressures are diminishing in most developed countries due to rapidly declining telephone and Internet rates. An issue of labor costs is that centers with excessive agent utilization or low pay may experience high employee turnover with concomitant expenses for recruitment and training.

In contrast to labor cost, service quality is a more complex measure. Service quality can include issues such as agent training and professionalism, and the ability to resolve client problems on the first call. Operationally, service quality is often measured by some function of the amount of time a client waits prior to talking to an agent. As the waiting time experienced by an individual client is a random variable, performance measures are typically some function of the waiting time distribution. The two most common measures are the average client waiting time (ASA) and percentage of calls answered within a designated time, the service level (SL).

When clients hang up before talking to an agent, they are said to abandon the queue, an example of queueing's concept of reneging. An important measure of interest is the client abandonment rate (CAR). A client who abandons the queue is presumably dissatisfied, an undesirable event, but this reduces the waiting time for subsequent clients in the queue, which enhances the center's waiting time measures (Mandelbaum and Zeltyn 2007).

Many call centers are able to track whether an issue is successfully resolved by the first phone call or requires one or more follow-up calls. The metric associated with this data is known as the first call resolution (FCR) rate.

Creating Agent Schedules

Managers schedule agents into time blocks that are typically 15 minutes to one hour in length. A 24-hour center with 15-minute time blocks has 96 time blocks each day. They try to keep staff costs low while having enough agents on duty to meet quality targets. The first OR/MS application of this tradeoff was for toll booth staffing, Edie (1954).

The process for scheduling agents is typically performed in five steps, as follows:

Step 1: Forecast call arrivals. Centers use standard statistical and forecasting techniques such as regression, exponential smoothing and its variants, and the time series models of ARIMA. Difficulties in making accurate forecasts are caused by noisy data due to small time blocks. In centers that have

complex routings with multiple queues, each queue requires a forecast. Further, call patterns can be complex in that those that are blocked or abandoned can affect future arrivals, as can call backs caused by inadequate problem resolution. Gans et al. (2003) discusses opportunities to improve center forecasts.

Step 2: Develop an estimate of operational performance measures. To plan effectively, managers must be able to estimate the impact of their decisions on operational performance measures to trade-off cost and client experience. Cost measures typically include total labor cost and average agent utilization. Client experience measures typically include ASA, SL and CAR. These measures can be estimated using analytic models or discrete-event simulation. The most common method is to apply the Erlang C formula (for determining the waiting probability in a queue) to produce estimates for ASA and SL. Arrival rates are assumed to be homogeneous and come from the Step 1 forecast.

Advanced call centers are characterized by complex routing arrangements that shunt clients among multiple queues. Skill-based routing sends calls initially to a queue that processes the most basic client inquiries and routes more challenging calls to better trained and more highly paid agents in a different queue. The task of estimating operational performance measures is thus complicated because arrivals in later queues depend upon performance, including other agent pools. Discrete-event simulation is the tool of choice in these circumstances; see Mehrotra and Fama (2003).

Step 3: Determine the number the number of agents to assign. The manager must set (or staff) the number of agents to be on duty in each time block. This is an aggregate decision, and does not consider the identities or work schedules of individual agents, which are addressed in Steps 4 and 5. Typically, the manager assigns agents to a time block to minimize total agents, while meeting a target performance measure, usually ASA or SL.

Step 4: Develop multi-time block shifts. The manager must take the number of agents assigned to each time block in Step 3 and back out a set of individual, multi-time block shifts that, in aggregate, sum up to the number of assigned agents in each time block, while honoring work rules, contract requirements, and labor laws. This can produce an infeasible or a difficult-to-apply solution, and approximations with high cost are often required.

Step 5: Assign individual agents to each shift. The manager makes final shift schedules, that is, rosters of named agents. This creates challenges of managing total hours worked per day and week to conform to labor laws, as well as managing personal preferences for work schedules and days off.

Integration of the Five Steps. The agent scheduling process is often executed step-by-step. There are obvious interactions across steps with opportunities to integrate the steps (Aksin et al., 2007a, b). Avramidis et al. (2009) show that integrating the staffing and scheduling steps in a center with skill-based routing can lead to better results. Cezik and L'Ecuyer (2008) used linear programming combined with simulation for a center with skills-based routing.

Outbound Systems

In outbound systems, a computer automatically calls designated parties from a given list. The computer recognizes and processes busy signals, no-answers, and telephone company messages. Answered calls are routed to call center agents. Typically, the computer predicts when agents will become free and dials in anticipation of agent availability, thereby reducing the time agents wait between connections.

A key analytical challenge is to determine the pacing, that is, when to dial the next call. If the pacing is too slow, agent time is wasted. If the pacing is too fast, a called party answers when no agent is available, creating a nuisance for the called party (who usually hangs up), a wasted expense for the system. Research in this area is mostly proprietary; there is scant research literature. The solution resulted in the first U.S. patent based on queueing theory (Samuelson 1989). This method estimates service durations, times from dialing to answer, and proportions of dial attempts that result in answers, and uses these statistics, updated frequently, to synchronize dialing attempts to finish shortly after predicted agent service completions (Samuelson 1999). Other patents, such as David (1997), expand and extend this method.

Other proprietary procedures establish call centers based on cloud computing. This approach drastically reduces facility costs, as agents can work from home. It also presents a new version of the predictive dialing problem: the situation is more complex and more subject to quick changes, but the huge computational resources readily available can be employed to do massive parallel simulations in real time to compute the required predictive parameters (Kaiser-Nyman et al. 2011).

Blended Systems

Blended call centers allow agents to be switched in real time between inbound and outbound calls. Bhulai and Koole (2003) discuss a queueing model which yields a threshold policy for assigning agents to outbound calls. Deslauriers et al. (2007) provide a set of Markov chain models for a call center where outbound agents can be diverted to serve inbound calls. Call center managers believe that frequent switching between inbound and outbound calls degrades agent performance for both types of calls, and common practice is to make reassignments for blocks of time rather than call by call. This added constraint makes the performance modeling and scheduling problem substantially more difficult.

Operational Trends and Research Opportunities

Forecasting and Workload Requirements

Some traditional call center assumptions have been questioned by OR/MS researchers, e.g. (Aksin et al. 2007a). One area concerns replacing the standard point-forecast of arrival rates for a short-time block with a stochastic forecast. It is possible to relax the assumption of independent time block call arrivals and model correlation of arrivals across time blocks. More general assumptions on arrival rates can affect the scheduling and rostering problems, see Steckley et al. (2009), Robbins and Harrison (2010), and Gans et al. (2009). Bassamboo et al. (2009) proposed a methodology for capacity planning and dynamic system control in the presence of random arrival rates and multiple inbound call types.

Also, significant research attention has been paid to developing and applying advanced statistical techniques to call center arrival forecasts, with many of these approaches being used to generate not only a point estimate, but also distributional forecasts. Channouf et al. (2007) tested different forecasting models for an emergency medical system. Weinberg et al. (2007) provides a model for forecasting for the short-time blocks commonly found in practice. Avramidis et al. (2004) examined how call volumes correlate across time blocks within a day, and suggested that call arrival data from early in the day can be used to update forecasts for later in the day. Shen and Huang (2008) developed a singular value decomposition model for updating same-day forecasts based on early data, and show it to be superior to benchmarks commonly used in practice. Soyer and Tarimcilar (2008) applied a Bayesian approach for modeling and analyzing call center arrival data.. Aldor-Noiman et al. (2009) developed a Gaussian mixed-model framework that allows for exogenous variables to model the contribution of specific events to forecasted call volumes.

Scheduling

Call center workforce scheduling is more complex than shift scheduling for many other service delivery organizations, such as hospitals (nurses) or transportation (bus drivers), because of the possible need to shift workload quickly to match skills required by the incoming customer to skills of the available agents. That is, call center workforce scheduling decisions are dynamic. As updates on call arrivals and agent availability become available, short-term forecasts and agent schedules can be adjusted. Mehrotra et al. (2010) developed a methodology for intra-day forecast and schedule updating, while Gans et al. (2009) suggest a stochastic-programming model with recourse to account for both random arrival rates and intra-day schedule updates.

Resource Acquisition

Call center resource acquisition is an important and continuing area of interest. Additional research is needed on long-term forecasting, personnel planning for general multi-skill call centers in the presence of both learning and attrition (Ryder et al. 2008), and for complex networks of service providers (Aksin et al. 2007a, Section 2.2). Companies routinely outsource

call center operations to third party service providers. Ren and Zhou (2008), and Milner and Olson (2008) explore issues associated with establishing and managing these relationships.

Use of Real-Time Data

Call center models generally have had to assume that agents' service times are identically distributed for a given class of client. This was due to limited computational resources that necessitated updating parameters at intervals (ten minutes is common) much longer than the typical call duration. Outbound models have similar limitations with respect to the proportion of called parties who answer. Actual call center data, however, indicate persistent differences among agent service times, even for probabilistically identical clients, and runs of high or low proportions of good contacts and of live answers. Therefore, using real-time data to adjust call center operations could produce improvement in performance, although call center managers are quick to point out that efficiency must be balanced against robustness. Kaiser-Nyman et al. (2011) report significant performance improvement from methods that do use the real-time capabilities of cloud computing.

Performance of Outbound Systems

Despite the amount of time that has passed since the solution of the basic predictive dialing problem, many interesting unsolved problems remain, as research has largely concentrated on inbound systems. For systems running multiple simultaneous outbound campaigns and applying multiple predictive dialing systems in parallel, a common tactic is to switch agents from one campaign to another as answer rates change This impairs productivity if agents are switched too abruptly or too often, hence pacing that takes human factors into account would be valuable.

Balancing the utilization of agents in blended systems, where agents could serve both inbound and outbound parties, is generally done with heuristics that tend to under-optimize productivity to ensure that high-priority, high-value inbound calls always get handled quickly. Again, the available heuristics under-optimize and overlook significant human factors.

In some outbound systems, the protocol is to have the first conversation introduce playing a recorded message to a called party who agrees to listen to it, then to have an agent (not necessarily the same one who had the first conversation) conduct a second live conversation. If agents can be switched between first and second conversations quickly, there is an opportunity for greater productivity with a predictive dialing method, but the synchronization problem is quite complex. Also, again, human factors considerations may add additional constraints.

Research Data

Available operational data tend to be aggregated into time-based averages, which is problematic from a queueing science perspective. Fortunately, the Web-based DataMOCCA Project provides a clean source of high-granularity, call-based client call data from several sources that can be used to test proposed center advances in a research environment.

Call Routing

Skill-based routing, in which different agents are capable of handling different subsets of calls in an environment with multiple call types, is a major trend in the call center industry (L'Ecuyer 2006). These systems route clients to different agents depending on their needs and support the creation of a hierarchy of agents with highly skilled personnel handling only the most challenging calls. There is an opportunity for research regarding design and appropriate performance measures in such systems, and in the dependency and interaction among staffing, scheduling, and routing. When there are multiple types of calls and multiple types of agents, performance modeling, staffing, scheduling, and rostering problems all become significantly more complex, which leads to many interesting and important research problems, see Fukunaga et al. (2002) and Avramidis et al. (2009, 2010).

Concluding Remarks

Call and contact center managers do not view models and algorithms as intrinsically appealing. Successful OR solutions need to integrate tightly with a center's existing software systems for data collection, analysis, decision support, and schedule creation. The OR value proposition can extend beyond just cost savings. Managers value OR professionals who can reduce future call volumes using process management

techniques, such as call content analysis, that collects structured data on caller issues and performs Pareto analysis to direct the organization to improve product quality, user manuals, and agent training (Mehrotra and Grossman 2009). Managers also value reduced service time, reduced labor headaches from improved scheduling, and, in some centers, sales made or clients retained. In addition to the technical aspects of the subject, there is room for more study of how to assess and address the business needs.

Capital Budgeting

Reuven R. Levary
Saint Louis University, St. Louis, MO, USA

Introduction

The desired end result of the capital budgeting process is the selection of an optimal portfolio of investments

from a set of alternative investment proposals. An optimal portfolio of investments is defined as the set of investments that makes the greatest possible contribution to the achievement of the organization's goals, given the organization's constraints. The constraints faced by a corporation in the capital budgeting process can include limited supplies of capital or other resources as well as dependencies between investment proposals. A dependency occurs if two projects are mutually exclusive, acceptance of one requires rejection of the other, or if one project can be accepted only if another is accepted. Assuming that the organizational goals and constraints can be formulated as linear functions, the optimal set of capital investments can be found using linear programming (LP).

Capital Budgeting Under Capital Rationing

Capital rationing is a constrained capital budgeting problem in which the amount of capital available for investment is limited.

Pure Capital Rationing, with No Lending or Borrowing Allowed — Consider a firm that has an opportunity to invest in several independent projects. It is assumed that both the future cash flows associated with each project and the firm's future cost of capital can be forecast. These forecasts enable calculation of the net present value for each project, assuming that the firm expects to be affiliated with the projects for a period of N years. It is also assumed that the firm has a given fixed budget for funding the projects for each of the N years, with both the budget and the cost of capital in future periods being unaffected by investments made in previous periods. Finally, it is assumed that any portion of the budget not used in one year cannot be carried over to future years.

The basic model for capital budgeting under pure capital rationing is as follows:

$$\text{maximize} \quad \sum_{i=1}^{M} P_i x_i \tag{1}$$

$$\text{subject to} - \sum_{i=1}^{M} f_{it} x_i \leq b_i \quad \text{for } t = 1, 2, \ldots, N \tag{2}$$

$$0 \leq x_i \leq 1 \quad \text{for i} = 1, 2, \ldots, M \tag{3}$$

where P_i is the net present value for the ith project (calculated based on forecasts of future cash flows), f_{it} is the expected cash flow for project i during year t (cash flow is defined to be positive if it is inflow and negative if it is outflow), b_t is the available budget for year t, M is the number of alternative projects and x_i is the fraction of project i to be funded.

The objective function (1) represents the total expected net present value of the investment proposals that should be funded. Constraints (2) represent restrictions on the available yearly budget. Constraints (3) ensure that no more than one project of a given type will be included in the optimal portfolio. By adding the constraint that x_i be integer for $i = 1, 2, \ldots, M$, the problem becomes an integer program. In this case, no fractional projects will be allowed; a project is either accepted or rejected. Constraints on scarce resources, mutually exclusive projects, and contingent projects can easily be added to the above model when necessary.

Capital Budgeting Where Borrowing and Lending are Allowed — In this model, the amount available for lending in a given year is the "left-over" money for that year. This amount can be carried over to the next year at a given rate of interest r. Consider the case when the interest rate for borrowing, or cost of funds, depends on the amounts borrowed. The cost of borrowing is assumed to have the shape of a step function; that is, the larger the amount borrowed, with limits, the higher the interest rate. Let r_j be the interest rate that applies to borrowing an amount greater than C_{j-1} and less than or equal to C_j. A firm will borrow at interest rate r_j if it exhausts the limits placed on its borrowing at lower interest rates.

If the firm expects to be affiliated with the proposed projects for N years, then the objective is to maximize the total related cash flows at the end of the Nth year, that is, the horizon. Let α_t and β_t be, respectively, the amount lent and the amount borrowed (at interest rate r_j) in year t. Also, let f_{it} be the cash flow in year t resulting from approval of project i. All flows in this model are current values, that is, not present values. Revenues and expenditures are defined, respectively, to be positive and negative cash flows. A given project can generate cash flows after the Nth year as well. Let $\hat{f}_i$ be the present value of total cash flows at the horizon (i.e., year N) that are expected to be generated by project i at years following year N. These flows are

discounted to year N, assuming an interest rate equivalent to the firm's weighted average cost of capital. The model is formulated as follows:

$$\text{maximize} \quad \sum_{i=l}^{M} \hat{f}_i x_i + \alpha N - \sum_{j=l}^{m} \beta_{jN} \tag{4}$$

$$\text{subject to} \quad -\sum_{i=l}^{M} f_{il} x_i + \alpha l - \sum_{j=l}^{m} \beta_{jl} \le b_l \tag{5}$$

$$-\sum_{i=1}^{M} f_{il} x_i - (1+r)\alpha_{l-1} + \alpha_l + \sum_{j=1}^{m} (1+r_j)\beta_{jl-1} - \sum_{j=1}^{m} \beta_{jl} \le b_l \quad \forall \; t = 2,\ 3,\ \ldots,\ N \tag{6}$$

$$\beta_{jt} \le C_{jt} \quad \forall \; t = 1,\ 2,\ \ldots,\ N;\ j = 1,\ 2,\ \ldots,\ m \tag{7}$$

$$0 \le x_i \le 1 \quad \forall \, i = 1,\ 2,\ \ldots,\ M \tag{8}$$

$$\alpha_t,\ \beta_{jt} \ge 0 \quad \forall \; t = 1,\ 2,\ \ldots,\ N;\ j = 1,\ 2,\ \ldots,\ m \tag{9}$$

where m represents the number of different interest rates in the supply of funds schedule. The limit on borrowing during year t, at interest rate r_j, is denoted by C_{jt}. Objective function (4) represents the total flows resulting from the proposed projects at the end of the Nth year. The first component $\sum_{i=1}^{M} \hat{f}_i x_i$ of the objective function represents the present value at the horizon of the cash flows expected to be generated by the projects in years following the horizon year N. The second component $\sum_{j=1}^{M} \beta_{jN}$ is the amount lent minus the amount borrowed during the horizon year N. Inequality (5) and inequalities (6) represent the constraints on the available budget for a given year. The limits on borrowing are represented by constraints (7). This model can be extended by adding constraints on scarce resources and by incorporating mutually exclusive and contingent projects when applicable.

Fractional Projects

All LP models can result in an optimal portfolio of projects composed of fractional projects. Weingartner (1967) showed that the number of fractional projects in the optimal solution set of the basic LP model [described by relations (1)–(3)] cannot exceed the number of time periods for which constraints are imposed. Additional constraints such as mutual exclusion, contingency, and scarce resources can increase the maximum number of fractional projects. Each additional constraint increases the maximum number of fractional projects by one. Weingartner (1967) also showed that the number of fractional projects in the optimal solution of the model where borrowing and lending are allowed is no larger than the number of time periods during which the firm does not lend or borrow money.

Because solutions to LP models can include fractional projects, these models are only an approximation of the exact solution. The exact solution can be obtained by applying integer programming solution procedures. The fractions of mutually exclusive projects, which can be the solution of an LP model, may have a useful interpretation. Fractional projects may suggest the possibility of a partnership. For example, one might interpret the decision to fund the expenses of building a fraction of a shopping center to mean that it would be beneficial for the company to engage in a partnership arrangement.

Dual Linear Programming and Capital Budgeting

Consider the basic model for capital budgeting under pure capital rationing formulated by relations (1)–(3). To evaluate the profitability of various projects, a discount factor must be incorporated into the capital budgeting analysis. Define d_t as the discount factor for period t: $d_t = (1 + r_t)^{-1}$ where r_t is the interest rate at period t. The net present value for project i is

$$P_i = \sum_{t=l}^{N} f_{it}\, d_t. \tag{10}$$

Substitution of Equation (10) into (1) results in the following formulation, called Problem **P**:

$$\text{maximize} \quad Z = \sum_{i=l}^{M} \sum_{t=l}^{N} f_{it}\, d_t\, X_i$$

$$\text{subject to (2) and (3).} \quad (\mathbf{P})$$

Let y_t be the dual variable associated with the budget constraint for year t. The value of y_t at the optimal solution, y_t^*, represents the increase in the total combined net present value of the projects that results from an addition of $1 to the budget for year t.

Assume that V dollars are added to the budget in period t. This results in an increase of the net present value (the objective function) by $v \times y_t^*$. The net present value of v is $v \times d_t$. This implies that the discount factor d_t should be equal to the dual variable y_t^* at the optimal solution (Baumol and Quandt 1965). Problem **P** is called consistent if its optimal solution has the property $d_t = y_t^* \quad \forall t$. A solution to a capital budgeting problem under pure capital rationing where dual variables do not equal the discount factor is not optimal. Therefore, such a problem is inconsistent.

Ananalysis of consistent solutions helps clarify the relationship between Capital budgeting discount factors in discount factors and dual variables, as well as the choice of an objective function. Several properties of consistent solutions were summarized by Freeland and Rosenblatt (1978) and are:

1. The value of the objective function of Problem **P** equals zero if there are no upper bounds on the decision variables (i.e., in the case when the X_i are not restricted to be less than one).
2. When the value of the objective function is zero, the only way to obtain a consistent solution is by having all discount factors equal zero. This is a meaningless situation.
3. To ensure a meaningful consistent solution, the decision variables must have upper bounds. Furthermore, some projects must be fully accepted.
4. For a consistent solution to be meaningful, the optimal value of the objective function must be positive and the budget vector must include both positive and negative components.
5. If unused funds cannot be carried forward, the discount factor in period t may exceed the discount factor in period $t + 1$.

Finding the "Right" Discount Factors

Because different optimal solutions to Problem **P** are obtained for various values of the discount factor, it is necessary to find the right discount factor for the pure capital rationing case before Problem **P** is solved. Freeland and Rosenblatt (1978) reported that most of the proposed iterative procedures for finding the right discount factors described in the literature do not work properly. Problems involved in finding the right discount factors are avoided by using horizon models, such as (4)–(9). Center for Naval Analyses (CNA) origin of The horizon value of the model where borrowing and lending are allowed is $\alpha_N - \sum_{j=1}^{M} \beta_{jN}$ [see relation (4)] when there are no cash flows beyond the horizon. In this case, no discount rate is used in maximizing the horizon value and therefore the problem of finding the right discount factor is irrelevant. In the case where there are cash flows beyond the horizon, management must estimate the respective discount rates using financial and economic forecasting. The calculation of these estimates is external to the LP models used in capital budgeting decisions, and therefore is not linked to the solution procedure of the LP model.

Alternative Capital Budgeting Models

Some capital budgeting problems have multiple objectives. Such problems can be formulated as goal programming problems. In many cases, the values of variables affecting the cash flows of the projects are not known with certainty. Such variables include future interest rates, length of useful economic lives, and salvage values. Computer simulation can be used to handle the uncertainty surrounding capital budgeting decisions (Levary and Seitz 1990). Simulation can also be used to analyze the risk consequences of various capital budgeting alternatives. Decision tree analysis is a widely used method for analyzing risk associated with a single investment alternative (Levary and Seitz 1990). Expected return on investments can be adjusted for risk using the capital asset pricing model (CAPM). CAPM was generalized by Richard (1979) to include environmental uncertainty.

Applications of chance-constrained programming to capital budgeting problems have been reported in the literature. Byrne et al. (1967, 1969) incorporated payback and liquidity constraints into chance-constrained programming models for capital budgeting. The payback is represented in these models in the form of chance-constraints that filter acceptable from unacceptable risks. The liquidity constraints handle risks related to situations such as unplanned demand for cash and unplanned technological breakthroughs. Hillier (1969) formulated the net cash flows in each time period of a capital budgeting model as probabilistic constraints.

The objective function in the model is to maximize the expected utility of the shareholders at the horizon period. Näslund (1966) extended the horizon model [relations (4)–(9)], by including risks. Näslund assumed that the yearly cash flows were independent, normally distributed random variables having known means and standard deviations. He also assumed that no other random variables existed in his model. The adjusted model is a chance-constrained programming model. Näslund developed a deterministic equivalent to his chance-constrained programming model.

Relationships among investments contribute to portfolio risk and can be measured by covariances. Quadratic programming models for capital budgeting can be used in situations where the covariances between returns of various projects can be estimated. Various characteristics of a specific capital budgeting problem, like tax consequences, can be modeled using mathematical programming.

Center for Naval Analyses

Carl M. Harris
George Mason University, Fairfax, VA, USA

Introduction

In the pre-World War II year of 1940, many scientists believed that organizing the nation's scientific research would strengthen national defense. As a result, the National Defense Research Committee (NDRC) was established by Presidential Executive Order.

The NDRC was placed under the direction of the newly created Office of Scientific Research and Development (OSRD), which reported directly to the president. NDRC's contact with British researchers indicated that studying actual operations was an essential part of any assessment process. Because the need for operations research was particularly pressing

in the area of antisubmarine warfare (ASW), the Navy created the Antisubmarine Warfare Operations Research Group (ASWORG). In 1942, comprising at first fewer than a dozen scientists, it was the first civilian group engaged in military operations research in the United States. The Center for Naval Analyses (CNA) traces its origins to ASWORG.

Today, CNA analysts provide the Navy and Marine Corps with objective studies of a wide variety of operations, systems and programs. Such studies range from the support of training and testing activities to the evaluation of new technologies and alternative force structures for top-level decision-makers. The following short history of CNA recounts the high-lights of its evolution and contribution to national security.

World War II

During the 1940s, the United States was preoccupied first with the war in Europe and then with the war in the Pacific. As soon as the United States entered the war, German submarines began to patrol the U.S. East Coast and Atlantic shipping lanes in earnest. The Navy's immediate focus was on the U-boat threat and the Battle of the Atlantic.

In Britain, Professor P.M.S. Blackett had demonstrated the value of operations research in solving military problems. Captain Wilder Baker, leader of the newly formed U.S. Navy Antisubmarine Warfare Unit in Boston, was inspired by Blackett's paper, "Scientists at the Operation Level" (see *Blackett's later work*, 1962). Baker believed that a cadre of civilian scientists could also help the U.S. Navy. He asked Professor Philip M. Morse of MIT to head such a group. ASWORG was formed in April 1942 with a mission to help defeat the German U-boats. The contract for ASWORG was administered by Columbia University, which already had an existing contract with the NDRC that focused on anti-submarine warfare.

ASWORG set a major precedent when it required its analysts to gather field data firsthand. Sending civilian experts to military commands was a delicate matter. In June 1942, the field program began when an ASWORG analyst assisted the Gulf Sea Frontier Headquarters in Miami. Shortly afterward, several analysts were assigned to the Eastern Sea Frontier in New York. The field analysts quickly became accepted; most of ASWORG's noteworthy work was achieved in the field.

In June 1942, ASWORG was assigned to the Head-quarters of Commander in Chief, U.S. Fleet (CominCh). Admiral Ernest J. King was both CominCh and the Chief of Naval Operations (CNO). The Tenth Fleet was formed in 1943 to consolidate U.S. ASW operations. In July 1943, ASWORG became part of the Tenth Fleet.

In October 1944, because of the decrease in enemy submarine activity and the increase in operations research requirements on subjects other than ASW, ASWORG was transferred from the Tenth Fleet to the Readiness Division of the Headquarters of CominCh. It was also renamed the Operations Research Group (ORG) as its analysis efforts had become more diversified.

By the end of the war, ORG had about 80 scientists whose scope of study was all forms of naval warfare. During most of World War II, about 40% of the group was assigned to various operating commands. These field analysts developed immediate, practical answers to tactical and force allocation questions important to their commands. Concurrently, they fed back practical experiences and understanding to the central Washington group, a practice still continued a half century later.

Among its many World War II contributions, ORG devised more effective escort screening plans; determined the optimum size of convoys; developed ASW tactics, such as optimum patterns and altitudes for flying AWS patrol aircraft; developed counter measures to German acoustic torpedoes and snorkeling U-boats; and contributed to the use of airborne radar.

Post-War Period

In August 1945, Admiral King, in a letter to Secretary of the Navy James V. Forrestal, recommended and requested that ORG be allowed to continue into peacetime at about 25% of its wartime size. Secretary Forrestal gave his approval shortly thereafter.

Both Admiral King and Secretary Forrestal concluded that much of ORG's unique value was due to its ability to provide an independent, scientific viewpoint to a broad range of Navy problems.

Consequently, in extending the service of ORG into peacetime, it was decided that its character could best be preserved by perpetuating the wartime arrangement through a contract with an academic institution. Such a contract was entered into with MIT in November 1945. At that time, ORG was renamed the Operations Evaluation Group (OEG), with Dr. Jacinto Steinhardt as its first director. OEG was to assist the Navy and its research laboratories in analyzing and evaluating new equipment, tactical doctrine and strategic warfare. OEG established a policy that all of its (male) analysts must spend time assigned to fleet operations, a practice that is partially maintained to this day by CNA.

After the war, OEG published several comprehensive reports on important naval operations, which included many new methodologies. Although some were originally classified secret, they later appeared in Morse and Kimball's *Methods of Operations Research*, Bernard Koopman's *Search and Screening*, and Charles Sternhell and Alan Thorndike's *Anti-submarine Warfare in World War II*. Taken together, these reports provided a record of vital lessons learned in World War II, as well as important operations research methods. With the Korean War and the intensification of the Cold War, the role of analysis in defense planning expanded in the 1950s. Once the Soviets had detonated their first thermonuclear device, the United States had to revise its thinking on many critical defense issues. As the consequences of nuclear war loomed and the cost of military preparedness escalated, the government, more than ever, needed reliable scientific information on which to base its strategic decision-making.

Before the Korean War, OEG began a slow but steady buildup. By 1950, the research staff had grown to about 40. As the war began, OEG received requests for analysts from combat commands. These analysts collected data, solved tactical problems and recommended improvements in procedures, improvements that were sometimes used immediately. OEG expended its major efforts on such specific tactical problems as: selection of weapons for naval air attack on tactical targets; scheduling of close air support; analysis of air-to-air combat; naval gunfire in shore bombardment; blockade tactics; and interdiction of land transportation. By the end of the war, OEG had 60 research staff members.

After the war, OEG continued to grow, albeit slowly. Analysts participated with naval forces in all post-Korean crises. The most important changes in the nature of the group's post-Korean activity were the results of major technological advances, particularly in the field of atomic energy and guided missiles. Issues were broadened to include the possible enemy use of nuclear weapons and the effect of U.S. policies and weapon system choices on the nature of wars the United States would have to be prepared to fight. During this period, the Navy also established the Long-Range Studies Project of MIT; it was later renamed the Institute for Naval Studies (INS).

Defense Management

By the 1960s, advances in weapons technology were causing defense costs to rise dramatically, and the increasing tempo of the Vietnam War later in the decade would cause the defense budget to balloon still further. The swearing in of Secretary of Defense Robert S. McNamara in 1961 marked the beginning of a new philosophy of defense management. Emphasis began to be placed on cost as well as effectiveness. McNamara believed that integrated systems analysis throughout the defense establishment was required to achieve a balanced, affordable military structure.

In 1961, MIT established an Economics Division within OEG because the cost of weapon systems was becoming a dominant factor in military decision-making. Until 1961, the Marine Corps had only one OEG analyst. By the early 1960s, however, Marine Corps requirements for operations research had increased substantially. The Marine Corps Section of OEG was established in December 1961.

By 1962, the Secretary of the Navy wanted to consolidate the study efforts of OEG and INS and began to look for a contractor. MIT, which had managed OEG since 1945, declined an invitation to manage this proposed new enterprise. The Navy then selected the Franklin Institute to administer the contract for the new organization. In August 1962, OEG and INS were brought under the common management of a new entity, the Center for Naval Analyses (CNA).

Center for Naval Analyses

Shortly after CNA was formed, OEG (now as a division) again became involved in an actual naval operation. In October 1962, it helped the Office of the Chief of Naval Operations (OPNAV) develop plans for the naval quarantine of Cuba and assessed the effectiveness of surveillance operations.

As combat escalated in Southeast Asia, so did the number of CNA field representatives providing direct support to the naval operating forces. CNA participated in the study of many operations, such as interdiction campaigns in North Vietnam and infiltration rates in South Vietnam. Also, a large data base on war-related activities was being developed and maintained in CNA's Washington office. In August 1967, management of the CNA contract transferred from the Franklin Institute to the University of Rochester.

Because the war in Vietnam was escalating, the Navy needed more combat analysis. As a result, the Southeast Asia Combat Analysis Group (SEACAG) was established within OPNAV. Shortly thereafter, the Southeast Asia Combat Analysis Division (SEA-CAD) was established within OEG. SEACAD's role was to support SEACAG and to increase the amount of war-related analysis that CNA was performing. CNA analyzed various operations of the Southeast Asian conflict, including combat aircraft losses, interdiction, strike warfare and carrier defense, surveillance and naval gunfire support.

In the 1970s, as the war in Vietnam wound down, military budgets, forces and equipment began to deteriorate. To maintain effectiveness in the face of reduced budgets, the Navy increased its emphasis on analysis. As new systems became available, the Navy needed to determine how best to exploit their capabilities. With old systems that were already deployed, the Navy needed to develop tactics that overcame technical shortcoming.

Military Buildup

The 1980s witnessed a major buildup of U.S. forces in response to the growth of Soviet military power during the 1970s. For the Navy, this meant not only more ships and aircraft but also more emphasis on a maritime strategy and on specific concepts of operations for employing the Fleet in a global war. These efforts matured by 1987, just as Gorbachev unleashed the forces that would lead to the razing of the Berlin Wall and, ultimately, the demise of the Soviet Union.

In 1982, CNA began a major study of concepts of operations for employing the Atlantic Fleet in a global war. This work involved issues ranging from Soviet objectives and intentions in a war to actions the Navy could take to counter Soviet strategy, as well as theater-level tactics that would be executable in the face of a concerted Soviet threat. The results of this work were put into practice in 1984 by Commander, Second Fleet, who also added important tactical innovations. The resulting interaction and cooperation of Washington and the Fleet (and of CNA-Washington and the field analysts) set the tone for similar efforts at other fleet commands.

By December 1982, differences concerning the management of CNA had arisen between the Department of the Navy and the University of Rochester. The Secretary of the Navy decided to open the CNA contract to competition, and several universities and nonprofit research organizations responded. In August 1983, the Navy announced that the Hudson Institute had been awarded the contract for the management of CNA, effective October 1983.

New World Order

The 1990s ushered in an entirely new security environment. In light of the collapse of the Soviet Union and the new emphasis on Third World threats, the Navy and Marine Corps are reevaluating their structure. Unlike the threat of the Cold War era, these new threats are smaller and more diffuse. They require smaller units that can operate jointly in distant areas where the United States often has a limited number of forces and restricted access to bases. Developing these types of forces and operations is a continuing theme for defense planning in the 1990s.

During the 1980s, some significant events had solidified CNA's stature in the analytical field. Demands for CNA's analytical assistance had grown, particularly from senior Navy and Marine Corps

leaders. CNA had become more involved in critical issues and issues of concern to top-level decision-makers, and CNA's staff had increased in size and quality to meet those growing demands.

Organizationally, CNA had changed often over the years to meet the demands of a changing world and a changing military environment. In the spring of 1990, CNA's management, the Board of Overseers, the Navy, and the Hudson Institute all agreed that CNA could function as an independent organization. On October 1, 1990, CNA became independent and began operating under a direct contract with the Department of the Navy, ready to help the Navy and Marine Corps cope with the impending changes in national security policy, defense strategy, defense budgets and defense management practices.

After Iraq annexed Kuwait in August 1990, the CNO asked CNA to track and document the events in the Middle East, to analyze activities, and to develop a lessons-learned data base. CNA had up to 20 field representatives providing support to various naval commands in the Middle East, including Commander, U.S. Naval Central Command.

After the Persian Gulf War, CNA was designated the Navy's lead agency for Desert Shield/Storm data collection and analysis. The Navy believed that future force composition, systems design and budget decisions would be shaped by events of the war and the subsequent analysis. CNA led the reconstruction of Desert Shield/Storm and provided the Navy with a 14-volume report. In addition, CNA is continuing its analysis of the war and is archiving all the fleet data for the National Archives.

During Desert Storm, the value of concepts that CNA had analyzed for the Navy and Marine Corps — the Tomahawk cruise missile, the air-cushioned landing craft (LCAC), the maritime prepositioning — became evident. The Tomahawk land-attack missile was one of the high-tech "stars" of the war; the LCAC played an important role in creating fear of an amphibious assault; and maritime prepositioning allowed two brigades of Marines to deploy to the Gulf in record time.

In the 1990s, CNA's most important task was to help the Navy and Marine Corps make the transition to a post-Cold War security environment. To do this, CNA's research program plan emphasized areas of immediate importance to this transition: the new security environment, littoral operations, communications, warfare area adjustments, training and education, investment alternatives, force structure, and economies and efficiencies.

Certainty Equivalence

Jeffery L. Guyse
University of California, Irvine, USA

The certainty equivalent of a gamble or lottery is the sum of money for which, in a choice between the money and the gamble, the decision maker is indifferent between the two. Certainty equivalents are used to determine decision makers' attitudes toward risk, which can then be reflected in the shape of their utility functions. Certainty equivalents can also be used to order a set of alternatives. Classic examples of operationalizations of certainty equivalents used in the literature are minimum selling price, maximum buying price, and cash equivalent. Buying and selling prices may be theoretically different though, due to income effects.

By definition, the utility of the certainty equivalent must be equal to the expected utility of the gamble. With this in mind, the relationship between the certainty equivalent (CE) and the expected value (EV) of a gamble can reveal the decision maker's attitude toward risk. If CE < EV, then the individual is said to exhibit a risk-averse attitude. In this case, the difference between the expected value and the certainty equivalent (EV − CE) is known as the "risk premium" that the decision maker is willing to pay in order to avoid the risk associated with the gamble. If CE > EV, a risk-prone (or risk-seeking) attitude is displayed. Finally, if the two values are equal (CE = EV), then the decision maker is risk-neutral. By assessing CEs, decision analysts can calibrate the utility function of the decision maker to reflect risk attitude in the decision process. For a formal discussion, see Keeney and Raiffa (1976).

Certainty equivalents are also used to elicit a preference order on a set of alternatives. It is assumed that the order induced by assigning certainty equivalents reveals the true preference order of the individual. If one alternative has a higher certainty equivalent than a second alternative, one would expect the individual to choose the former over the latter when asked to make a choice between the two. The method by which the certainty equivalents are elicited has been an area of ongoing research. It was once believed that subjects could simply state their certainty equivalent to a gamble, in which case their response is known as a judged certainty equivalent.

Recent empirical studies have provided evidence that the judged certainty equivalent may not necessarily equal the true certainty equivalent elicited through a choice mechanism. Such a violation of procedure invariance is examined in the stream of research on preference reversals. Subjects provide both judged certainty equivalents and then make choices between pairs of gambles. By carefully selecting the gambles, researchers have been able to elicit judged certainty equivalents that produce an ordering on the set, while the same subject's choices results in the reverse ordering (Grether and Plott 1979; Lichtenstein and Slovic 1971, 1973; Lindman 1971; Slovic and Lichtenstein 1983). Such a pair of gambles is:

A:	0.99 Win $4.00 0.01 Win $0	B:	0.25 Win $16.00 0.75 Win $0

The expected values of the two gambles are $3.96 and $4 respectively. A large proportion of people will indicate a preference for gamble A when asked to choose between the two, yet place a higher dollar value on B (Grether and Plott 1979, p. 623).

Work by Tversky, Slovic, and Kahneman (1990) as well as Bostic, Herrnstein, and Luce (1990) has shown that these preference reversals virtually disappear when the certainty equivalents are elicited through a choice mechanism, such as the Parameter Estimation by Sequential Testing (PEST) procedure. For a review of preference reversals, see Tversky and Thaler (1990).

► Stochastic Programming

Chance-Constrained Programming

A mathematical-programming problem in which the parameters of the problem are random variables and for which a solution must satisfy the constraints of the problem in a probabilistic sense. Here the usual linear-programming constraints are given as probability statements of the form $\Pr\{\sum_{j=1}^{n} a_{ij} x_j \leq b_i\} \geq \alpha_i$ for $i = 1, \ldots, m$, where the $\{\alpha_i\}$ are given constants between zero and one. Some forms of the chance-constrained programming problem can be transformed to an equivalent linear-programming problem.

Chaos

A mathematical term describing a situation in which arbitrarily small variations in independent variable values can produce large variations in the dependent variable. The term is most typically used to characterize the behavior of deterministic, nonlinear, differentiable dynamic systems. The term is sometimes used to describe situations in which true mathematical chaos is not present, but where the results are similarly disturbing. The disturbing effect in battle modeling, for example, is the apparent loss of deterministic behavior.

Chapman-Kolmogorov Equations

In a parameter-homogeneous Markov chain $\{X(t)\}$ with state space S, define $p_{ij}(t)$ as the probability that $X(t+s) = j$, given that $X(s) = i$ for $s, t \geq 0$. Then, for all states i, j and index parameters $s, t \geq 0$,

$$p_{ij}(t+s) = \sum_{k \in S} p_{ik}(t) p_{kj}(s)$$

are the Chapman-Kolmogorov equations. There is a comparable definition when the state space is instead continuous.

- ▶ Markov Chains
- ▶ Markov Processes

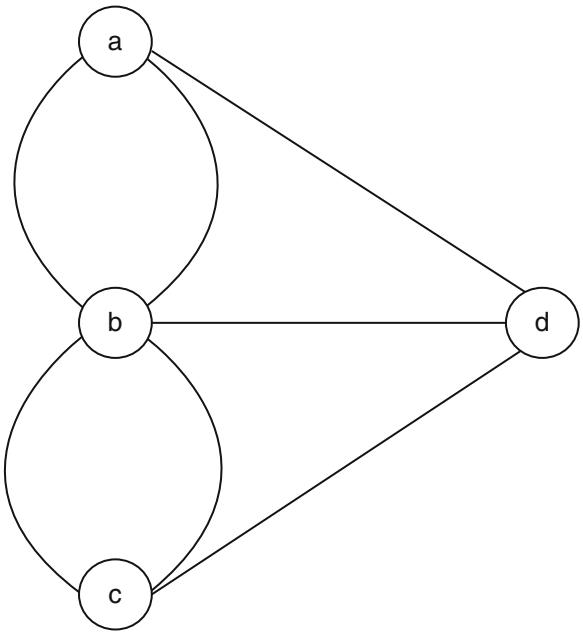
Characteristic Function

For a random variable X, the characteristic function is given by $\phi_X(t) = E[e^{itX}]$, where i denotes the imaginary number $\sqrt{-1}$.

Chinese Postman Problem

William R. Stewart Jr.
College of William and Mary, Williamsburg, VA, USA

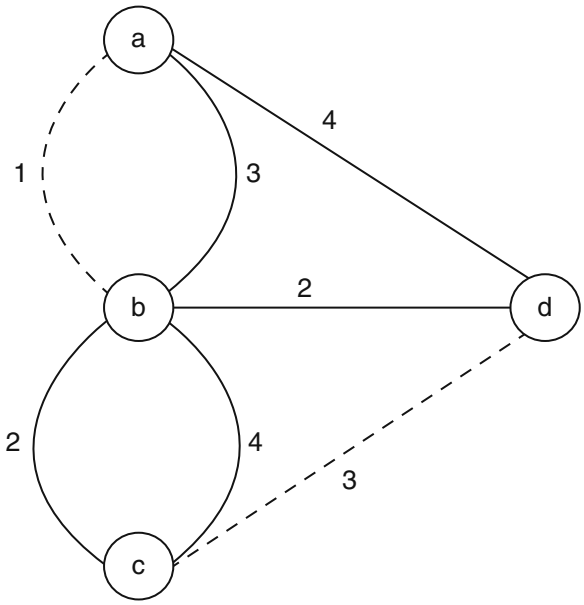
The Chinese Postman Problem acquired its name from the context in which it was first popularly presented. The Chinese mathematician Mei-Ko Kwan (1962) addressed the question of how, given a postal zone with a number of streets that must be served by a postal carrier (postman), does one develop a tour or route that covers every street in the zone and brings the postman back to his point of origin having traveled the minimum possible distance. Researchers who have followed on Kwan's initial work have since referred to this problem as the Chinese Postman Problem or CPP. In general, any problem that requires that all of the edges of a graph (streets, etc.) be traversed (served) at least once while traveling the shortest total distance overall is a CPP. Like its cousin, the traveling salesman problem, that seeks a route of minimum cost that visits every vertex of a graph exactly once before returning to the vertex of origin, the CPP has many real world manifestations, not the least of which is the scheduling of letter carriers. Such problems as street sweeping, snow plowing, garbage collection, meter reading and the inspection of pipes or cables can and have all been treated as CPPs.



Chinese Postman Problem, Fig. 1 A graph of Euler's Konigsberg bridge problem

In the following discussion, the terms tour and cycle will be used interchangeably to refer to a route on a graph that begins and ends at the same vertex and that traverses all of the edges of that graph at least once. Unless otherwise noted, the edges are assumed to be undirected (i.e., they may be traversed in either direction).

The CPP and its many variants have their roots in the origins of mathematical graph theory. The problem of finding a cycle (tour/route) on a graph which traverses all of the edges of that graph and returns to its starting point dates back to the mathematician Leonid Euler and his analysis in 1736 of a popular puzzle of that time, the Königsberg Bridge problem. Euler's problem of traversing all of the bridges of Königsberg and returning to his starting point without retracing his steps is equivalent to asking if there is a tour of the graph shown in Fig. 1 that traverses all of the edges exactly once. Euler showed that such a cycle exists in a graph if and only if each vertex in the graph has an even number of edges connecting to it or, in mathematical terms, each vertex is of even cardinality. This follows logically from the observation that, in a tour that traverses all of the edges exactly once, each vertex must be exited the same number of times it is entered. Tours that traverse each edge of a graph exactly



Chinese Postman Problem, Fig. 2 The Konigsberg bridge problem with edge costs

once are termed Euler cycles or tours, and graphs that contain an Euler cycle are appropriately called Eulerian. When costs are assigned to each of the edges, the problem of finding a minimum cost tour is a CPP.

When a graph is Eulerian, the cost of a tour is just the sum of the costs of all of the edges in the graph, and the solution to the CPP is any Eulerian tour, of which there are usually many. In general, an Eulerian tour can easily be found when one exists. When a graph has more than one odd cardinality vertex (exactly one such vertex is impossible), the CPP is the problem of finding which of the edges must be traversed more than once in order to produce a minimum cost tour. The graph shown in Fig. 1 has four vertices with odd cardinality, and a tour of this graph requires that one or more of the edges be crossed more than once. Figure 2 shows hypothetical costs on each edge, and the dashed lines indicate the edges that must be traversed twice in order to achieve a minimal cost tour. This tour will have a total cost of 23, the cost of crossing each edge once plus the cost of crossing edges (a, b) and (c, d) a second time each.

In mathematical terms, the CPP can be stated as follows: given a graph $G = \{V, E\}$, where V is a set of n vertices, E is a set of edges connecting these vertices, and each edge (i, j) connecting vertices i and j has a nonnegative cost, c_{ij}, find x_{ij}, the number of times that edge (i, j) is to be traversed from i to j so that the total cost of traversing all of the edges in E at least once is a minimum. The sum of x_{ij} and x_{ji} is the total times that the edge between vertices i and j must be traversed in an optimal tour.

$$\text{Minimize} \sum_i \sum_j c_{ij} x_{ij} \tag{1}$$

$$\text{Subject to} \sum_i x_{ik} - \sum_j x_{kj} = 0, \quad \text{for } k = 1, \ldots, n, \tag{2}$$

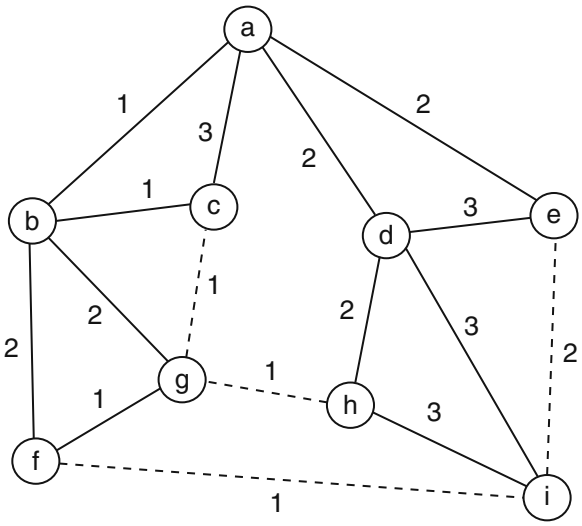
$$x_{ij} + x_{ji} \geq 1, \quad \text{for all } (i,j) \text{ and } (j,i) \in E, \tag{3}$$

$$x_{ij} \geq 0, \quad \text{and integer, for all } (i,j) \in E. \tag{4}$$

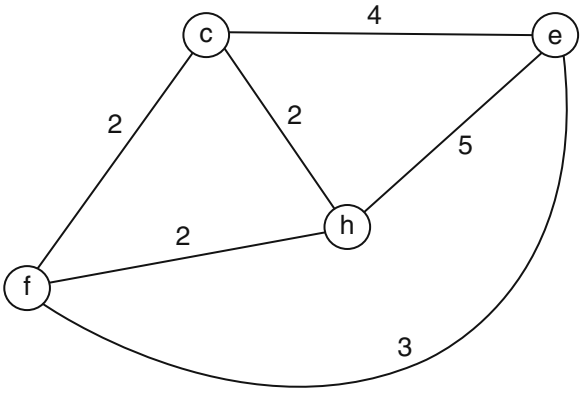
For ease of exposition, this formulation assumes that there is a maximum of one edge between any two vertices. As can be seen in the illustration in Figs. 1 and 2, this may not always be the case. However, cases where there are multiple edges between the same pair of vertices do not complicate the treatment, since those cases can easily be transformed into the form shown in (1)–(4).

As pointed out by Edmonds and Johnson (1973) and Christofides (1973), when there are odd cardinality vertices in the graph, the CPP reduces to the problem of finding a minimum cost matching among the odd cardinality vertices. A minimum cost matching on a graph is a pairing of the vertices on that graph such that each vertex is paired with exactly one other vertex and the total cost of the edges connecting the pairs is a minimum. When no edge exists between a pair of vertices, the cost of pairing them is the cost of the shortest path running between the pair. Replicating the edges that connect each pair of odd cardinality vertices in the minimum matching produces an Eulerian graph (i.e., all vertices now have even cardinality) where the total cost of all the edges, the edges in the original graph plus the edges that have been replicated as a result of the matching, is the cost of the optimal tour of the original graph.

To illustrate the general solution process, Figure 3 presents a graph with four odd cardinality vertices (c, e, f, h). None of the four vertices is directly connected to another of the four. To find the required minimum cost matching requires the construction of the graph G', shown in Fig. 4, which consists of the



Chinese Postman Problem, Fig. 3 The Graph G



Chinese Postman Problem, Fig. 4 The Graph G'

four odd cardinality vertices connected by edges whose costs are the cost of the shortest path between each pair on the original graph. The problem is then to find a minimum cost matching on the graph G'. This matching will determine which edges must be traversed twice to achieve a minimum cost tour on G. A quick inspection of G' shows that the edges (c, h) and (e, f) constitute a minimal matching on G'. The paths $(c\text{-}g\text{-}h)$ and $(e\text{-}i\text{-}f)$ on graph G in Fig. 3 correspond to this matching, and the edges along these paths will be traversed twice each in an optimal tour and are shown as dashed lines in Fig. 3.

Solving the CPP requires two operations, both of which can be performed in polynomial time. A matching of the odd cardinality vertices must be found and the corresponding edges replicated that results in an Eulerian graph. An Eulerian tour of this expanded graph must then be found. The complexity of the CPP is dominated by the complexity of solving the minimum cost matching problem, which can be solved in at most $O(n^3)$ time. Variations of the basic CPP, briefly described below, are generally not as tractable.

Variations of The Chinese Postman Problem

The CPP has many variations that can and do occur on a regular basis. In the CPP, the edges are undirected and they may be traversed in either direction. The most obvious variation of the CPP is the directed postman problem where each of the edges has a direction associated with it. This is often encountered when an edge represents a one way street in a routing problem, or an edge must be traversed twice, once in each direction, as might occur in routing a street sweeper. In this latter case, each street would be represented in the graph by two edges, one in each direction. Like the CPP, the directed postman problem can be solved in polynomial time. In a sense, it is even easier than the CPP since it requires a network flow algorithm rather than a matching algorithm.

When the graph contains a mixture of both directed and undirected edges, the problem of finding a minimum cost tour is called the mixed postman problem. The mixed postman problem has been shown to be NP-hard. The rural postman problem is a variation of the CPP where a subset of the edges in the graph must be traversed. The rural postman problem has been shown to be equivalent to a traveling salesman problem and, as such, it is also an NP-hard problem (see Lawler et al. 1985). Finally, the capacitated Chinese Postman Problem recognizes that each edge may have a nonzero demand for service and that the server (postman) may have a finite capacity for supplying service. In the general case, multiple servers must be assigned to routes such that the demands on all of the edges are met and no server is assigned a route that exceeds his capacity. This then is the problem of partitioning the edges of the graph into subsets and assigning a server (postman) to each subset in such a way that all capacity constraints are met and the total distance covered by all of the servers is a minimum. As with the directed and rural postman problems, the capacitated postman problem has been shown to be NP-hard.

Choice Theory

Leonard Adelman
George Mason University, Fairfax, VA, USA

Introduction

There is no one descriptive theory of human choice. Instead, there are different theoretically and empirically-based approaches for describing choice behavior. This article briefly overviews five approaches: bounded rationality, prospect theory, choice strategies, recognition-primed decision making, and image theory. These approaches are descriptive in the sense that they describe certain aspects of how people actually make choices. They contrast with prescriptive approaches, such as decision analysis or other economic-based theories (or models) of choice behavior, which prescribe how one should make decisions, but do not necessarily describe choice behavior.

Bounded Rationality

The concept of bounded rationality is attributed to Nobel laureate Herbert Simon (Simon 1955, 1979; Hogarth 1987), who argued that humans lack both the knowledge and computational skill required to make choices in a manner compatible with economic notions of rational behavior. The rational model's requirements are illustrated by the concept of a payoff matrix, an example of which is presented in Table 1.

The rows of the matrix represent all the different alternatives available to the decision maker for solving a choice problem. The columns represent all of the different states of the world, as defined by future events, that could affect the attractiveness of the alternatives. The $p_1,\ldots, p_k$ values represent the probabilities for each state of the world. The cell entries in the matrix indicate the value or utility of the outcome or payoff for each combination of alternatives and states of the world. Each outcome represents a cumulative payoff comprised of perceived advantages and disadvantages on multiple criteria of varying importance to the decision maker. Finally, the rational decision maker is required to select the alternative that maximizes expected utility, which is calculated for each alternative by multiplying the values for the outcomes by the probabilities for the future states, and then summing the products.

Numerous studies have shown that, unaided, people do not employ the above decision matrix due to the complex, dynamic nature of the environment and to basic human information acquisition and processing limitations. Therefore, how does unaided human choice remain purposeful and reasonable? Simon

Choice Theory, Table 1 The rational economic model's decision making requirements as represented in a payoff matrix

	States of the world			
Alternatives	S_1 (p_1)	S_2 (p_2)	. . .	S_k (p_k)
A	a_1	a_2	. . .	a_k
B	b_1	b_2	. . .	b_k
.	.	.	. . .	.
N	n_1	n_2	. . .	n_k

suggested that people employ three simplification strategies, which result in a bounded rationality. First, people simplify the problem by only considering a small number of alternatives and states of the world at a time. Second, people simplify the problem by setting aspiration (or acceptability) levels on the outcomes. And, third, people choose the first alternative that satisfies the aspiration levels. In other words, people do not optimize (i.e., choose the best of all possible alternatives), but satisfice (i.e., choose the first satisfactory alternative). In this way, people can reduce information acquisition and processing demands and act in a purposeful, reasonable manner.

Prospect Theory

Like Simon's bounded rationality, prospect theory is juxtaposed against expected utility theory. For example, this prospect (or choice) is taken from Kahneman and Tversky (1979):

$$\text{Choice } A: (\$4000 \text{ with } p = .8;\ \$0 \text{ with } p = .2), \text{ or}$$
$$\text{Choice } B: (\$3000 \text{ for sure; that is, } p = 1.0)$$

The majority of participants will select Choice B. Yet, Choice A has the greater expected value; that is, $\$4000 \times .8 = 3200$. Now, consider the following prospect:

$$\text{Choice } C: (-\$4000 \text{ with } p = .8;\ \$0 \text{ with } p = .2), \text{ or}$$
$$\text{Choice } D: (-\$3000 \text{ for sure; that is, } p = 1.0).$$

The only change in the second prospect is that the sign has been reversed so that one is now considering losses, not gains. In this case, however, the majority of the subjects picked Choice C. That is, they would now be willing to take a gamble of losing $4000 with a probability of.8, which has an expected value of losing $3200, instead of taking a sure loss of $3000. Again, they selected the choice with the lower expected value. In addition, they switched from the sure thing to preferring the gamble.

What Kahneman and Tversky (Tversky and Kahneman 1981) have shown is that the way the choice problem is presented (or framed) significantly affects how people evaluate it, such that information that should result in the same choice from the perspective of expected utility theory actually results in different choices. In particular, people perceive outcomes as gains or losses from a reference point rather than from final states (e.g., of wealth), as assumed by economic-based models of choice. The current position is usually considered as the reference point. However, the location of the reference point and, in turn, the coding of outcomes as either gains or losses, can be affected by how the choices are framed.

This framing is particularly important for choice because, as the example presented above indicates, people tend to be risk adverse when considering gains and risk seeking when considering losses, particularly if one of the prospects is certain. Moreover, the value function is steeper for losses than for gains, consistent with the observation that losses loom much larger than gains. For these reasons, many people are willing to gamble to avoid a sure loss, but unwilling to gamble when they have a sure gain, even when both choices have a lower expected value than another choice.

Choice Strategies

Substantial research has focused on describing the different strategies people use to combine information when facing a choice. In contrast to bounded rationality and prospect theory, these strategies are used when people (a) have information on a number of different dimensions (or attributes) describing the alternatives, and (b) do not consider probabilities, either in terms of different states of nature or the reliability (or accuracy) of the information. A representative type of problem is making a purchase decision, such as choosing a car.

The literature (Beach 1990; Hogarth 1987) makes a distinction between two classes of choice strategies: compensatory and noncompensatory. Compensatory

strategies are used when one trades-off (e.g., via relative importance weights) a low value on one attribute for a high value on another. For example, when choosing among cars, one may trade-off gas mileage for comfort. Non-compensatory strategies do not employ trade-offs but, rather, employ thresholds (or cut-offs) that need to be achieved for choice of an alternative. For example, one eliminates all cars that do not get at least 25 miles per gallon, regardless of comfort. Some of the strategies identified in the literature are defined below.

The literature cites three different types of compensatory models:

1. *Linear, additive strategy* — the value of an alternative is equal to the sum of the products, over all the dimensions, of the relative weight times the scale value for the dimension.
2. *Additive difference strategy* — the decision maker evaluates the differences between the alternatives on a dimension by dimension basis, and then sums the weighted differences in order to identify the alternative with the highest value overall.
3. *Ideal point strategy* — is similar to the additive difference model, except the decision maker compares the alternatives against an ideal alternative instead of each other.

The literature cites four different types of noncompensatory strategies:

4. *Dominance strategy* — select the alternative that is at least as attractive as the other alternatives on all the dimensions, but is better than them on at least one dimension. Although the dominance strategy is easier for an unaided decision maker to use, all three compensatory strategies will also identify the dominant alternative. Moreover, the compensatory strategies can be used if there is no dominant alternative; the dominance strategy cannot.
5. *Conjunctive strategy* — select the alternative that best passes some critical threshold on all dimensions. This is the satisficing strategy when one selects the first option that passes a threshold on all dimensions. The conjunctive strategy is often used to reduce the set of alternatives by eliminating all alternatives that fail to pass a threshold on all dimensions.
6. *Lexicographic strategy* — select the alternative that is best on the most important dimension. If two or more alternatives are tied, select among them by choosing the alternative that is best on the second most important dimension, and so on.
7. *Elimination by aspects* —sequentially identify different dimensions, either according to their importance or some more probabilistic scheme. Eliminate all alternatives that fail to pass the threshold or aspect for each dimension until only one alternative is left.

Research (Payne et al. 1993) has shown that people often use multiple strategies when considering choice alternatives. Typically, they use noncompensatory strategies to reduce the number of alternatives and dimensions under consideration. To use a job selection example, a person might first eliminate all alternatives that fail to pass a specific threshold on security, which may no longer be as important when considering the reduced set of alternatives. Then, after the set of alternatives and dimensions have been reduced to a smaller, more manageable set, people often employ a compensatory strategy where they weigh the strengths and weaknesses of the remaining alternatives in order to select the one which best satisfies their values.

Recognition-Primed Decision Making (RPD) and Image Theory

Some descriptive theories have been developed to explain the choice behavior of experts working in naturalistic settings (Zsambok and Klein 1997). These descriptive theories of choice behavior are farther removed from the basic rational economic man model than the three presented thus far. Two are presented here, RPD and image theory, for illustrative purposes.

The RPD model (Klein 1993) emphasizes four critical cognitive processes:

- *Situation recognition* — experienced decision makers know what cues (or indicators) to focus on and, often, simply recognize (or perceive) the situation they are facing through an automatic, feature (or pattern)-matching process, much like perceptual objects in our environment are recognized. People also are quite capable of using explanation-based reasoning to understand a situation when there uncertainties and anomalies in it. In fact, these stories are often, but not always, the causal explanations for the feature-matching process that appears to operate so automatically.

- *Decision option generation* — Once a situation is recognized, decision makers typically generate only one option for consideration, not multiple options.
- *Evaluation through mental simulation* — The initial option tends to be quite good for dealing with the (recognized) situation. Decision makers, however, may evaluate it by mentally simulating the consequences of implementing the option. Although the mental simulation will use intuitive and analytical thought processes, depending on the consequences being evaluated during the simulation, the option will seldom, if ever, be evaluated by a formal analysis on a set of attributes (e.g., by a decision matrix).
- *Use of a decision rule* (emphasizing acceptability, not optimality) — The mental simulation may result in modifications to the proposed option to address problems uncovered during the mental simulation, or even a new option, but the option will be accepted once it is deemed satisfactory; it does not have to be optimal. Thus, RPD explicitly incorporates Simon's (1955) satisficing concept.

Beach (1990, 1993) developed the concept of images to convey the notion that decision makers bring certain knowledge structures to bear on a problem that constrain (or frame) how they evaluate it. In particular, Beach discussed three images: value, trajectory, and strategic, as follows:

- *Value Image* — this is composed of the overriding principles that guide one's behavior or that of one's organization. They "serve as rigid criteria for the rightness or wrongness of any particular decision about a goal or plan" (Beach 1993, p. 151).
- *Trajectory Image* — this consists of previously adopted goals, the timetable for achieving them, and the ideal future once they are achieved.
- *Strategic Image* — this is composed of the plans for achieving the goals in the trajectory image. The plans consist of specific tactics (or actions) for implementing the more abstract plan, and forecasts of what will happen if specific tactics are implemented. These forecasts change in light of new information. "By monitoring these forecasts (or expectations) in relation to the goals on the trajectory image, the decision maker can evaluate his or her progress toward realization of the ideal agendum on the trajectory image" (Beach 1993, p. 152).

In many ways, Beach's image theory is another way for describing the cognitive processes emphasized in Klein's RPD model. Image theory also emphasizes: (a) monitoring behavior; (b) expectations and goals; (c) situation recognition through feature matching and explanation-based reasoning; (d) automatic generation of a decision option to deal with the recognized situation; (e) mental simulation to evaluate it; (f) satisficing; and (g) processes for monitoring and managing the decision process. It is different, however, in its emphasis of three things.

The first difference in emphasis is that the images strongly frame the interpretation of how well the situation is going or even what the problem is, as emphasized in Prospect Theory. (Keeney (1992) also emphasized framing in his approach, called value-focused thinking, but from more of a prescriptive than descriptive perspective.) Second, routine progress decisions are made to compare the current situation and future forecasts with the ideal future. And, third, adoption decisions are routinely made to modify plans, tactics, and expectancies (i.e., the elements of Strategic Image) — and, less frequently, goals, timetables, and ideal future (i.e., the elements of Trajectory Image) — in response to progress decisions. Depending on the situation and person, these adoption decisions are made using one or more of the choice strategies described above. Although frames, progress decisions, and adoption decisions may be concepts that are inherent in Klein's RPD model, they are strongly and explicitly emphasized in Beach's image theory. In addition, Beach's image theory explicitly incorporates the many descriptive choice strategies found in the literature. Thus, image theory integrates many of the concepts in the choice theory literature to describe how people choose to react to changing situations.

Concluding Remarks

In closing, there is a need to emphasize again that there is no one descriptive theory of human choice. Instead, there are different theoretically and empirically-based approaches for describing choice behavior. This article provided brief overviews of five of them: bounded rationality, prospect theory, choice strategies, recognition-primed decision making, and image

theory. These approaches were contrasted with prescriptive approaches, such as decision analysis or other economic-based theories of choice, which prescribe how one should make decisions, but do not necessarily describe choice behavior.

Closed-Loop Supply Chains

Gilvan C. Souza
Indiana University Bloomington, Bloomington, IN, USA

Introduction

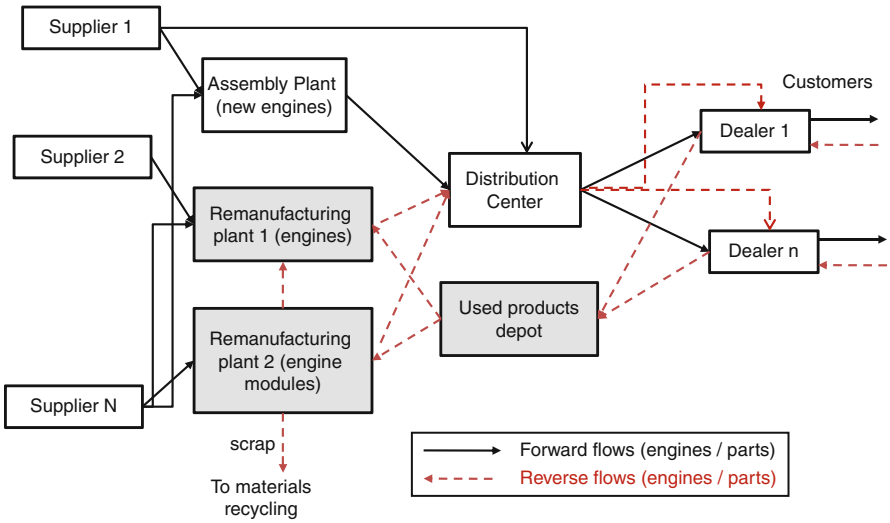
In a (regular) supply chain, there are physical flows of products, components or subassemblies from suppliers to subassembly manufacturers, from subassembly manufacturers to Original Equipment Manufacturers (OEMs), and from OEMs to customers through a distribution system. The distribution system could be comprised of a combination of distribution centers, central, and regional warehouses, and resellers. In the traditional supply chain literature, these physical flows are assumed to be unidirectional, from suppliers to customers. There are, however, bi-directional financial and information flows, for example, orders and payments placed from one tier in the supply chain (e.g., distributors) to its immediate upper tier (OEMs).

Closed-Loop Supply Chains (CLSC)

In a closed-loop supply chain (CLSC), there are, in addition to the forward physical flows described above, reverse physical flows of (used) products or components from customers to manufacturers (and possibly suppliers). As an example of closed-loop supply chain, consider the supply chain for diesel engines and parts for a major North American OEM (Fig. 1). Figure 1 depicts the main physical flows in this supply chain in a simplified manner; the flows are differentiated between forward and reverse flows. Forward flows consist of new parts and/or engines, and reverse flows consist of used parts and/or engines, and remanufactured parts or engines. Remanufacturing is the process of restoring a used product (post consumer use) to a common operating and aesthetic standard, sometimes with upgrades to the original product's functionality. For a diesel engine or module, remanufacturing consists of six different steps: (i) full disassembly to the part level, (ii) thorough cleaning of each part (often through multiple sequential techniques), (iii) making a disposition decision for each part (keep for remanufacturing or dispose the part for materials recycling), (iv) salvaging if necessary (value added work that restores functionality to that of a new part), (v) re-assembly, and (vi) testing. Other terms commonly used for remanufacturing include refurbishing, rebuilding, and overhauling, depending on the industry (no such distinctions are made in this article).

New engines are produced and assembled from new parts, some of which are manufactured and shipped by the OEM's many suppliers. Those suppliers also supply the firm's distribution center with spare parts. New engines are shipped to a (central) distribution center; they are then shipped from this (central) distribution center to several regional distribution centers (not depicted in Fig. 1), and from there to over 3,000 dealers in North America. Customers, say a trucking company, buy new (or remanufactured) diesel engines or engine modules, say a water pump or a turbocharger, from dealers due to replacement needs. They receive a dollar credit from returning the old engine or module upon purchasing a new (or remanufactured) engine or module; the dollar credit can be as high as 30% off the purchase price. Remanufactured engines or modules sell at a 35% discount relative to the corresponding new engine or module. Used modules or engines are shipped from dealers to one of 30 or so different consolidation points in North America (not depicted in Fig. 1), and from there to the OEM's main used products depot. At the depot, shipments are unpacked, customers are given the proper credit for returning the used module or engine; engines and modules are then shipped to one of two plants (or put into inventory for later shipment when needed): engine remanufacturing (plant 1), or part (or module) remanufacturing (plant 2). Remanufactured engines are shipped from plant 1 to the main distribution center, joining new engines or parts for distribution to the dealers. Remanufactured parts or modules are shipped from plant 2 to either the distribution center, or to the engine remanufacturing plant 1, depending on forecasts and current needs. Used parts not suited for remanufacturing are sold to recyclers. The flows depicted in Fig. 1 are simplified, but they convey the major flows in this CLSC. Used products are typically referred to as returns or cores.

The supply chain in Fig. 1 illustrates two major disposition decisions for cores: remanufacturing and recycling. Recycling means materials recovery, i.e., the



Closed-Loop Supply Chains, Fig. 1 CLSC for diesel engines and parts (simplified)

geometry of the used part or product is not preserved. Recycling occurs when remanufacturing is not possible or not economical, for example, the core is highly damaged (e.g., an engine block with a hole on it), there is significant wear and tear of the part (piston rings), or the part is technologically obsolete (this is common in consumer electronics and computers). In addition to these two disposition options, the firm can also disassemble a core, and use some of the resulting parts as spare parts for, say, fulfilling warranty claims or servicing products under service contracts; in these cases there may be no cleaning or salvage needed. Dismantling for spare parts is common in electronic goods industries, such as computers, and IT networking equipment (servers, routers, switches). Dismantling for spare parts can be an attractive alternative when it produces significant savings compared to procuring a new part from a supplier, when demand for remanufactured products is weak, or when the part supplier is no longer active. Other disposition decisions include incineration (which can recover energy, but there can be pollution concerns), and dumping in landfills (which is illegal for some materials known to contaminate water and soil). This article focuses on remanufacturing, as it presents significant operational challenges due to the natural mismatch between supply of cores, which for most firms is not certain, and demand for remanufactured products, which is also uncertain; as a result remanufacturing is a natural candidate for application of OR models.

In addition, Fig. 1 illustrates a CLSC where the main source of cores are end-of-use returns, where the product has undergone a full cycle of use with a customer, but the product still has significant value left for recovery. In addition to end-of-use returns, there are end-of-life returns, which are products that have reached the end of their useful life, mostly due to obsolescence, and whose main disposition decision is recycling; examples include very old computers, monitors, VCRs, and very old cars. Finally, there are consumer returns, which are products that have undergone little or no use by consumers—they are returned by consumers to retailers as a result of liberal returns policies by powerful retailers primarily in North America; most consumer returns are not defective. For example, about 80% of deskjet printers returned to retailers by consumers in the U.S. are not defective; reasons for return include remorse, and lack of product fit with consumer needs (Ferguson et al. 2006).

For the design and operation of a CLSC, the decision making is classified into three buckets, as is the case for regular supply chains: strategic, tactical, and operational. Examples of these three types of decisions are shown in Table 1. As Table 1 suggests, there are many different decisions in CLSC management that are amenable to the use of OR tools and techniques, including mathematical programming, Markov decision processes, and simulation.

Next, a brief description is given on how OR techniques are applied to two decisions: the decision to remanufacture or not by an OEM, and network design. A more complete review of the basic models and extensions for the other decisions is given in Souza (2008) and Ferguson and Souza (2010).

Closed-Loop Supply Chains, Table 1 Strategic, Tactical and Operational Decisions in CLSCs

Decision Type	Examples
Strategic	• **Remanufacturing or not:** Should an OEM remanufacture? • **Network design:** What is the location of remanufacturing plants, recycling plants, collection points, and consolidation points? Should used products be collected through retailers, or directly from consumers? Should forward and reverse flows be combined, or should the forward and reverse supply chain be separate? • **Leasing:** Should the firm lease or sell to customers? • **Strategic alliances:** Should the firm enter into partnerships with third-parties for remanufacturing or collection of its products? • **Design for recovery:** How should a firm design a product if there is remanufacturing at the end of use?
Tactical	• **Product acquisition:** How many used cores should the firm acquire, when, in which quality, and at what price? • **Remanufacturing planning and disposition:** Given a supply of cores, demand forecasts, relevant costs and revenues, what should a firm do with a core (remanufacture, recycle, dismantle for parts), and when?
Operational	• **Disassembly planning:** What is the sequence and depth of disassembly for a core? • **Shop floor scheduling and control**: What is the routing and scheduling priority for remanufacturing orders in the job shop?

Should an OEM Remanufacture?

On the surface, the decision to remanufacture or not by an OEM appears to be simple: if the price the firm can sell a remanufactured product far exceeds the variable cost to remanufacture a core, which includes collection and transportation of the core, disassembly, cleaning, salvaging, re-assembly, testing, and remarketing, then the firm should remanufacture, after properly accounting for any upfront fixed remanufacturing costs (e.g., building a facility and acquiring equipment). This simple revenue vs. cost accounting may not capture all of the facets of the problem, however. There are other factors that favor remanufacturing, such as: (i) extending the OEM's product line and offering a product, priced most likely lower than the corresponding new product, and therefore reaching a customer segment that would not otherwise be reached; (ii) allowing brand protection, given that many third party firms offer remanufactured products—if the OEM offers a certified remanufactured product, then it communicates to consumers that only its version of remanufactured product has the appropriate quality level; (iii) using as a deterrent to market entry of third-party remanufacturers; and (iv) value recovery for used products returned after leases, trade-in programs, or consumer returns. On the other hand, there are factors that do not favor remanufacturing; chiefly among them are: (a) the fear of cannibalization of sales of a (typically more expensive and more profitable) new product by a (typically less expensive and less profitable) remanufactured product; and (b) the ability to reliably collect an appropriate pipeline of cores to sustain a remanufacturing operation. Discussions with manufacturing managers indicate that factor (a) is of significant concern to firms in the IT equipment industry, while factor (b) is of significant concern to firms in automotive parts remanufacturing.

The following simple analytic model provides some insights into the answer to the critical strategic question, "Should an OEM remanufacture?" Consider an OEM selling a new product (say, a diesel engine model X), and considering the decision to offer its remanufactured counterpart (a remanufactured diesel engine model X). The firm has to decide whether to offer the remanufactured product, and if so, how to set the prices of remanufactured and new products, denoted by p_r and p_n respectively. First, consider a monopolist under a single period model (extensions are discussed below.) The model is based on some assumptions about consumer behavior. Specifically, assume that the consumer base is heterogeneous, so that consumers differ in their intrinsic valuation for the new product. A consumer such as a third-party logistics company, for example, with an extensive fleet of large trucks, has a high valuation for the new diesel engine; whereas an operator of small gasoline-powered delivery trucks has a low intrinsic valuation for a new diesel engine. This intrinsic valuation for the new product, which differs across the heterogeneous consumer base, is referred to as willingness-to-pay (the maximum amount a consumer is willing to pay), or w.t.p., for a new

product. Each consumer has an intrinsic w.t.p., a random variable that is denoted by θ. Thus, a consumer has a unique association with its w.t.p. θ and can be referred to simply as consumer θ. Further, it is assumed θ is uniformly distributed between a lower and an upper bound, where the bounds are normalized to be zero dollars and one dollar, respectively. Mathematically, $\theta \sim U[0,1]$. Thus, all consumers (potential customers) are distributed uniformly in the real line between \$0 and \$1. This assumption is common in the marketing and operations literature, because it results in linear demand curves, as shown below (it also allows analytical tractability). A consumer θ's w.t.p. for a remanufactured product is, however, $\delta\theta$, where $0 \leq \delta \leq 1$. If $\delta = 0$, then consumers do not consider the remanufactured product as a potential substitute for the new; this is a limiting case. An example that approaches this limit is retreaded passenger car tires in the U.S., where many consumers perceive them as unsafe, and there are many cheap imports that are priced quite low but are new. If $\delta = 1$, then consumers perceive remanufactured and new products as perfect substitutes. One example of this is retreaded truck tires used in commercial fleets in the U.S., where fleet owners have service contracts with certain dealers and pay them by each mile of service a tire provides to the fleet owner. These firms are insensitive as to whether the dealers use retreaded or new tires to keep the truck running. Most products fall in between, i.e., $0 < \delta < 1$; [see Hauser and Lund (2003), and Souza (2008) for a complete discussion]. For diesel engines, for example, $\delta \cong 0.65$; for power tools $\delta \cong 0.85$.

Suppose the firm only offers the new product at a price $p_n \leq 1$ (the firm would never offer a new product priced higher than \$1 because the maximum w.t.p. in the consumer base is \$1). Then, only those consumers with w.t.p θ higher than p_n buy the product, because they are the only ones with a non-negative net utility $(\theta - p_n)$ for the product. Because consumers' w.t.p. are distributed uniformly between 0 and 1, then the number of consumers that buy the new product (q_n) is $q_n = M \cdot \Pr\{\theta - p_n \geq 0\} = M \cdot \Pr\{\theta \geq p_n\}$, where M is the overall size of the consumer base (number of potential customers). Normalizing $M = 1$, and because $\theta \sim U[0,1]$, then $\Pr\{\theta \geq p_n\} = (1 - p_n)/1 = 1 - p_n$; as a result the firm sells $q_n = 1 - p_n$ new products. Now, suppose the firm offers both new and remanufactured products at prices p_n and p_r, respectively. A consumer θ's net utility for a new product is $\theta - p_n$, and for a remanufactured product is $\delta\theta - p_r$. Consumers whose net utilities are higher for a new than for a remanufactured product, i.e., $\theta - p_n > \delta\theta - p_r$, buy a new product; solving for θ yields $\theta > (p_n - p_r)/(1 - \delta)$. If $\theta < (p_n - p_r)/(1 - \delta)$, then consumers have a higher net utility for a remanufactured than a new product; they will buy remanufactured if their net utility is positive, that is, $\delta\theta - p_r > 0$, or $\theta > p_r/\delta$. Consumers with w.t.p. θ lower than p_r/δ will not buy anything. Given the uniform distribution for θ, the quantities of new and remanufactured products sold, given their prices, are $q_n = 1 - (p_n - p_r)/(1 - \delta)$, and $q_r = (p_n - p_r)/(1 - \delta) - p_r/\delta$, respectively. These two expressions constitute the demand curves for new and remanufactured products given respective prices; the demand curves are linear, assuming a uniform w.t.p. distribution (a different distribution results in a different demand curve shape). For a period with R cores available for remanufacturing, denote the remanufacturing yield—the percentage of cores that are found fit for remanufacturing—by μ. Further, assume that the remanufacturing cost per unit is constant at c_r, and the manufacturing cost per unit (new) is c_n. Then, the OEM's decision problem can be formulated as:

$$\max_{p_n, p_r} \Pi = q_n(p_n - c_n) + q_r(p_r - c_r), \tag{1}$$

$$\text{s.t. } q_r \leq \mu R, \tag{2}$$

$$q_n, q_r \geq 0, \tag{3}$$

Equation (1) is the OEM's per period profit; equation (2) is a constraint that limits the availability of cores for remanufacturing, and equation (3) is a logical constraint. Note that the decision variables are the prices p_n and p_r, thus, one needs to substitute the corresponding expressions for the quantities $q_n = 1 - (p_n - p_r)/(1 - \delta)$, and $q_r = (p_n - p_r)/(1 - \delta) - p_r/\delta$ in (1–3). This is a non-linear optimization problem, which can be solved analytically. The solution comprises several regions, depending on which constraints are binding or not. It can be shown that if $c_r < c\delta$ (and $R > 0$), then

the firm remanufactures, i.e., $q_r > 0$. Thus, the decision to remanufacture in this simple model is dependent upon the unit remanufacturing cost relative to new, the consumer's perception of remanufactured products relative to new (δ), and the availability of cores.

The model described above is very stylized, and does not include the following factors that are (typically) present in real life:

1. Competition: This transforms the decision problem into a game. There is a second decision maker with an objective function similar to the second term in (1). The demand functions now become significantly more complicated. See Atasu et al. (2008) for a way to incorporate competition.
2. Non-linear recovery costs: the model above assumes a constant marginal remanufacturing cost c_r. In practice, there is a cost of collection that is convex increasing in the quantity of cores collected, because it is increasingly more difficult to improve collection rates. Remanufacturing cost per se (i.e., disassembly, cleaning, salvage, testing) may also be convex increasing in the quantity remanufactured, because as remanufacturing quantity increases, the firm needs to dig deeper into the pile of cores, and remanufacture cores in worse quality condition, which demands more labor and materials. The combination of convex collection and remanufacturing costs implies that c_r in (1) is substituted with αq_r^2, where α is a positive constant. See Ferguson and Toktay (2006) for an analysis of this problem.
3. Availability of cores is dependent on sales in previous periods: simply put, the number of cores available for recovery are a function of sales in previous periods. To capture this dimension, one needs a multi-period model, so that all decision variables are defined for each period t: $p_{n,t}$, $p_{r,t}$, $q_{n,t}$, and $q_{r,t}$. If a product can only be remanufactured once (for example, if the product becomes technologically obsolete after the third generation is introduced), and L is the lag, in periods, between the sale of a new product, and its collection as a core post-consumer use, then (2) should be rewritten as $q_{r,t} \leq \mu q_{n,t-L}$, for each $t > L$. (See Ferrer and Swaminathan (2006), and Debo et al. (2005) for examples of models incorporating this dynamic aspect).

CLSC Network Design

As Table 1 indicates, designing a CLSC network requires deciding upon the locations of manufacturing and remanufacturing plants, warehouses (or distribution centers), points of sale, and consolidation centers for shipping cores from points of sale to remanufacturing plants, among other facilities. To help design such a network, a mixed-integer linear program (MILP) is described next based on the modeling framework by Fleischmann et al. (2001). For a review of CLSC network design, see Ammons et al. (2001) and Pochampally et al. (2008).

Assume an OEM that manufactures and remanufactures products, similar to the diesel engine CLSC shown in Fig. 1. The supply chain comprises four levels: (i) manufacturing and remanufacturing plants (a facility can do one or both), (ii) warehouses for distribution of manufactured and remanufactured products, (iii) consolidation centers for consolidating shipments of used products originating from resellers for shipment to plants, and (iv) resellers, who are independent entities that sell manufactured and/or remanufactured products to customers, in addition to collecting used products from customers.

Indexes

i Potential plant locations, $i \in I, I_0 = I \cup \{0\}$, where $i = 0$ is the disposal option.
j Potential warehouse locations, $j \in J$
k Fixed reseller locations, $k \in K$
l Potential consolidation center locations, $l \in L$

Variables

X_{ijk}^f Fraction of reseller k's demand served from plant i through warehouse j
X_{kli}^r Fraction of reseller k's returns returned to plant i through consolidation center l
U_k Unsatisfied fraction of reseller k's demand
W_k Uncollected fraction of reseller k's returns
Y_i^p Indicator variable for opening plant i ($= 1$ if plant is open; 0 otherwise); Y_j^w and Y_l^r are similarly defined

Costs

c_{ijk}^f Unit cost (transportation, production, handling) of serving k from i via j

c^r_{kli} Unit cost of returns (transportation, handling) from k to i via l

c^r_{kl0} Unit disposal cost (including collection, transportation, handling) for k via l

c^u_k Unit penalty cost for not serving reseller k's demand

c^w_k Unit penalty cost for not collecting reseller k's returns

f^p_i Fixed cost for opening plant i (f^w_j and f^r_l similarly defined)

Parameters

D_k Demand for reseller k

R_k Returns from reseller k

γ Minimal disposal fraction

Note that in this formulation, the continuous decision variables (e.g., X^f_{ijk} and X^r_{kli}) are defined in terms of *fractions* of demand and returns at each reseller, and as a result they are all bounded below by zero and above by one. An alternative formulation would have the continuous decision variables defined simply as quantities shipped. The firm's network design problem can be formulated mathematically as a MILP as follows:

$$TC = \min \sum_{i\in I} f^p_i Y^p_i + \sum_{j\in J} f^w_j Y^w_j + \sum_{l\in L} f^r_l Y^r_l + \sum_{i\in I}\sum_{j\in J}\sum_{k\in K} c^f_{ijk} D_k X^f_{ijk} + \sum_{k\in K}\sum_{l\in L}\sum_{i\in I_0} c^r_{kli} R_k X^r_{kli} + \sum_{k\in K}\left(c^u_k D_k U_k + c^w_k R_k W_k\right) \tag{4}$$

$$\text{s.t.} \sum_{i\in I}\sum_{j\in J} X^f_{ijk} + U_k = 1, \forall k \tag{5}$$

$$\sum_{l\in L}\sum_{i\in I_0} X^r_{kli} + W_k = 1, \forall k \tag{6}$$

$$\sum_{k\in K}\sum_{l\in L} R_k X^r_{kli} \le \sum_{j\in J}\sum_{k\in K} D_k X^f_{ijk}, \forall i \tag{7}$$

$$\gamma \sum_{i\in I_0} X^r_{kli} \le X^r_{kl0}, \forall k, \forall l \tag{8}$$

$$\sum_{j\in J} X^f_{ijk} \le Y^p_i, \forall i, \forall k \tag{9}$$

$$\sum_{i\in I} X^f_{ijk} \le Y^w_j, \forall j, \forall k \tag{10}$$

$$\sum_{i\in I_0} X^r_{kli} \le Y^r_l, \forall k, \forall l \tag{11}$$

$$Y^p_i, Y^w_j, Y^r_l \in \{0,1\}\ \forall i, \forall j, \forall l \tag{12}$$

$$0 \le X^f_{ijk}, X^r_{kli}, U_k, W_k \le 1, \forall i, \forall j, \forall k. \tag{13}$$

The objective function (4) minimizes total cost, comprised of fixed costs of opening and operating the facilities, and variable distribution costs. Constraints (5–6) represent basic flow constraints, which indicate that, for each reseller k, shipments plus unsatisfied demand are equal to total demand; similarly for reseller k's returns. Constraint (7) represents flow balancing at each plant, where the difference between incoming returns and outgoing shipments represent manufacturing of new products. Constraint (8) indicates that the number of disposed products should be larger than a given fraction of all returned products; in this model disposal is meant to represent material recycling or dismantling for spare parts. Thus, constraint (8) indicates the extent remanufacturing should take place (for example if $\gamma = 1$, then there is no remanufacturing, and all cores are recycled, or dismantled for spare parts). Constraints (9–11) are logical constraints—there is no shipment to/from a facility if that facility is not open. Constraint (12) states the binary decision variables for the problem, and constraint (13) represents the non-negativity constraints, and the fact that the continuous variables in this problem are defined as fractions of total demand or total returns at each reseller.

As described in Fleischmann et al. (2001), this formulation is very general and can accommodate many different scenarios. For example, if the firm has two separate networks for forward and reverse flows, then it can set R_k and D_k equal to zero, respectively. The values of c^f_{ijk} relative to c^r_{kli} and c^u_k can model different production scenarios for each plant, such as whether a plant only produces new products or it only produces remanufactured products, or both. In this model, demand can be met through remanufactured or new products. If there are separate demand streams for these products, then one can add another index, say t, to the decision variables and parameters of the problem to indicate the product type. For example, D_{kt} would be demand at customer k for product type t, where $t \in$ {remanufactured, new}. Finally, this

problem has been aggregated in that there is only one "aggregate" product being sold at the resellers. In the case of the CLSC for diesel engines, modules and parts remanufacturing are treated differently than engine remanufacturing; to accommodate this scenario one can again simply add another index to indicate product type (say, entire engines, or modules).

The discussion above was centered on remanufacturing as the key recovery activity taking place in the network. The same formulation can be used to design a network for recycling; an example is paper recycling, studied by Bloemhof-Ruwaard et al. (1996).

CLSC OR Applications

Closed-loop supply chain management provides numerous opportunities for application of OR methodology. The two applications discussed above are at the strategic level: an OEM's decision to engage in remanufacturing, and the design of a network of remanufacturing and manufacturing plants, distribution centers, and consolidation centers. The first model analyzes an OEM's decision to remanufacture—it is based on a model of consumer behavior that, in essence, implies linear demand curves for remanufactured and new products, and where they are partial substitutes for each other, so that each customer values a remanufactured product less than a corresponding new product. Based on these demand curves, and relevant costs, the firm chooses prices for remanufactured and new products that maximize its profit by solving a non-linear program. The second model is more of a decision support-type model—given relevant fixed costs of opening new facilities, relevant distribution costs, and demand and return points, the firm designs its CLSC network to minimize its fulfillment costs.

One significant area of application of OR models not covered in this article concerns the match between supply of cores and demand for remanufactured products and parts. The problem of product acquisition—acquiring the right amount of cores at the right price at the right quality at the right time, and its corresponding disposition decision—deciding what to do with a core: disassemble, remanufacture, recycle, or put it in inventory for future use, given relevant demand forecasts, and underlying costs is of significant importance to firms, at the tactical level. See Souza (2008) and Ferguson and Souza (2010) for more information on these models.

For the range of CLSC applications, especially from a policy maker's perspective, the design of environmental legislation is of significant concern. Specifically, the decision maker (say, the government) is interested in designing environmental legislation that sets appropriate collection and recycling levels to maximize society's welfare. This is comprised of total profits across all manufacturers impacted by legislation, consumer surplus, and environmental benefits of the legislation (e.g., lower pollution levels); notice that environmental benefits must be measured in dollar terms. Again, OR models can be used to help design such legislation (Ferguson and Souza 2010).

Cluster Analysis

Jay E. Aronson[1] and Lakshmi S. Iyer[2]
[1]The University of Georgia, Athens, USA
[2]The University of North Carolina at Greensboro, Greensboro, NC, USA

Introduction

Cluster analysis is a generic term for various procedures that are used objectively to group entities based on their similarities and differences. In applying these procedures, the objective is to group the entities (elements, items, objects, etc.) into mutually exclusive clusters so that elements within each cluster are relatively homogeneous in nature while the clusters themselves are distinct. The key purposes of cluster analysis are reduction of data, data exploration, determination of natural groups, prediction based on groups, classification, model fitting, generation and testing of hypotheses (Everitt 1993; Aldenderfer and Blashfield 1984; Lorr 1983).

Due to the importance of clustering in different disciplines such as psychology, zoology, botany, sociology, artificial intelligence and information retrieval, a variety of other names have been used to refer to such techniques: Q-analysis, typology, grouping, clumping, classification, numerical taxonomy, and unsupervised pattern recognition (Everitt 1993). In fact, as Jain and Dubes (1988) noted: "I.J. Good (1977) has suggested the new name botryology for the discipline of cluster analysis, from the Greek word for a cluster of grapes."

Though clustering techniques have existed for many years, profuse work in this area has been accomplished only in the past two decades. The primary stimuli for this were the founding of the Classification Society in 1970 and the publication of the *Principles of Numerical Taxonomy* by Sneath and Sokal (1973; also see, Lorr 1983). Other reasons for the rapid growth in cluster analysis literature are the basic importance of classification as a scientific procedure, prolific developments in high-speed computers, and the need to solve large, real-world problems efficiently. The complexity of clustering methods are known to increase tremendously with increase in problem sizes. With the availability of sophisticated computing power, the handling of large practical problems is of less concern now.

Applications of Cluster Analysis

Clustering methods are applied in a variety of fields including psychology, biology, medicine, economics, marketing research, pattern recognition, weather prediction, environmental science, linguistics, information systems design, electronic brainstorming and flexible manufacturing systems. Some interesting cluster analyses include analyzing large engineering records collections (Homayoun 1984), measuring welfare and quality of life across countries (Hirschberg et al. 1991), management of cutting tools in flexible manufacturing systems (DeSouza and Bell 1991), clustering as a quality management tool (Spisak 1992), identifying the structure and content of human decision making (Allison et al. 1992), mapping consumers' cognitive structures (Hodgkinson et al. 1991), information systems design (Aronson and Klein 1989; Karimi 1986; Klein and Aronson 1991), vehicle routing, production scheduling and sampling (Romesburg 1984), income tax bracket determination (Mulvey and Crowder 1979), management team construction, and idea grouping to handle information overload in electronic brainstorming. The maximum diversity problem forms clusters based on maximizing the differences (distances) among the items rather than the similarities. Applications include forming a single, diverse group from a larger set in which the objective function is imposed only on those items in the group (Kuo et al. 1993), and multiple diverse groups consisting of all items (Weitz and Lakshminarayanan 1997, 1998). Punj and Stewart (1983) provide a good description of the applications of cluster analysis,

including some details on the various clustering packages and programs that are available.

Clustering Techniques

Authors such as Everitt (1993), Cormack (1971), Aldenderfer and Blashfield (1984), Hartigan (1975), and Anderberg (1973) have provided good reviews on existing clustering methods. Nevertheless, there has been no unique classification of the various clustering methods. In fact, this is one of the pitfalls of cluster analysis. Due to work by Cormack (1971), Punj and Stewart (1983), and Everitt (1993), the following five categories have been accepted as a basis:

1. Hierarchical methods,
2. Optimization techniques,
3. Density search techniques,
4. Clumping methods, and
5. Other techniques.

Hierarchical methods: Hierarchical procedures are tree-like structures in which elements are first separated into broad classes. These classes are further subdivided into smaller classes and so on until the terminal classes are not further subdivisible. These methods are most frequently used in the biological sciences. The hierarchical methods are basically of two types — agglomerative and divisive.

The agglomerative methods begin by making each item its own cluster. In subsequent iterations two or more closest clusters are combined to form a new, aggregate cluster. Eventually, all items are grouped into one large cluster. Hence, these methods are some times referred to as build-up methods (Hair et al. 1987).

In contrast to agglomerative methods are the divisive methods that begin with one large cluster. Groups of items that are most dissimilar are removed and placed into smaller clusters. The process continues until each item becomes a one-element cluster. Cormack (1971), Everitt (1993), Aldenderfer and Blashfield (1984) and Hair et al. (1987) have provided comprehensive descriptions of the various agglomerative and divisive procedures.

Optimization techniques: These methods allow relocation of items during the clustering process, improving from an initial solution to optimality. The number of clusters must be decided a priori, although some methods allow for changes (manually or automatically) while solving. There are differences in optimization techniques due to the different methods used for obtaining an initial solution and different objective criteria (Everitt 1993).

Since most of the objective criteria of the optimization techniques are based on those of the well-established statistical concepts, very few mathematical programming approaches have been developed to solve these problems. The statistical methods have proved adequate for many situations, because (1) the solutions found are believed to be reasonably close to the optimum; (2) the solutions typically involve human analyst intervention to determine when an appropriate number of clusters have been identified; and (3) the combinatorial nature of clustering makes it difficult to solve a large problem to a guaranteed optimum. Mulvey and Crowder (1979) developed a subgradient method coupled with a simple search procedure for solving the clustering problem. However, their method did not yield an exact optimum. Though heuristics generally seem efficient, the need to obtain optima to problems such as effective information systems design (Klein et al. 1988) make heuristics less attractive. Klein and Aronson (1991) developed a mixed-integer programming model and method to obtain an optimal solution to clustering problems, where the objective function is the sum of pairwise interactions among all items in each cluster. No metric space nor median are used. Their method is based on the implicit enumeration method of Balas (1965). Extensions including precedence and group size limits are discussed by Aronson and Klein (1989). Earlier, Gower and Ross (1969) and Rohlf (1974) showed that there is a direct relationship between some common cluster formulations and certain types of well-known graph theoretic problems, primarily that of the minimum spanning tree. A further expansion on the use of graph theoretic techniques in cluster analysis may be found in Matula (1977).

Density search techniques: This concept, proposed by Gengerelli (1963), depicts the items as points in a metric space. Parts of the space where the distribution of points is very dense but separated by parts of low density suggest natural clusters. Everitt (1993) describes the different types of density search techniques.

Clumping techniques: These techniques are most popular in language studies where words that tend to have several meanings, when classified based on their

meaning, belong to several groups. Thus, in general, clumping techniques allows for overlapping clusters. This terminology was introduced by Jones, Needham, and co-workers at the Cambridge Language Research Unit (Everitt 1993). This method attempts to partition entities into two groups based on the similarity matrix from the original data. The Needham (1967) criterion is to minimize the cohesion function between the two groups. Other clumping procedures are also discussed in Rohlf (1974) and Everitt (1993).

Other techniques: This comprises all clustering techniques that do not fall in to the above four categories. For example, there is inverse "Q" factor analysis that is commonly used in behavioral sciences (Cattell 1952). The "R" factor analysis is a type of "Q" factor analysis that utilizes the correlations between variables. Gower (1966) provided a good review of the properties of various "Q" and "R" factor analysis techniques. Everitt (1993) and Aldenderfer and Blashfield (1984) included a good summary of various other clustering methods.

Issues of Concern

Though initially the concepts of cluster analysis seem to be intuitive, one can encounter a host of problems while performing an actual analysis. Some of the problems include selection of data units and variables, knowing exactly what to cluster, distance or similarity measures, transformation of measures, clustering criterion, the clustering method to use, the number of clusters and interpretation of the results (Anderberg 1973). Authors such as Aldenderfer and Blashfield (1984), Everitt (1993), Hair et al. (1987) and Anderberg (1973) have addressed some of the issues in great detail. A few of the more critical issues are discused next.

Measurement of distance or similarity matrix: The relationship between elements are represented by using either a similarity or distance measure. While similarity measures (indicating cohesion) take values between 0 and 1, distance measures can be any positive value. The output of any clustering method depends on the type of input measure used. One of the most commonly used measures is the Euclidean distance. This concept can be easily generalized for additional variables (Hair et al. 1987).

Another measure which allows for correlations between variables was originally proposed by Mahalanobis in 1936 (Everitt 1993). This is similar to Euclidean distance measure using standardized variables when the correlations are zero. The Mahalanobis distance measure has been used by McRae (1971). Everitt (1993), Hair Jr et al. (1987) and Hartigan (1975) have provided some discussions on other types of distance measurements. The clustering model for computer-assisted organization presented by Klein and Aronson (1991) accounts for total pairwise interactions independent of a metric. The need to consider all interactions among items in each cluster led to the formulation of a mixed-integer model for optimal clustering based on scaled, pairwise distance (Klein and Aronson 1991).

Which clustering method to use: The problem of choosing an appropriate clustering method generally arises after one has determined the variables, distance measure and criterion for clustering. A number of software packages and programs are available for clustering. Punj and Stewart (1983) and Anderberg (1973) identified some early programs for clustering; now, all major statistical packages contain one or more routines to do such analyses effectively. For selecting the best clustering method one should be aware of the performance characteristics of the various methods (Hair et al. 1987).

Appropriate number of clusters: One of the practical issues of concern in clustering is choosing the number of clusters. Some algorithms find the best fitting structure for a given number of clusters while others, like the hierarchical methods, provide configurations from the number of entities to one large cluster, that is, the entire data set as one cluster. However, if the number of clusters cannot be predetermined, a range of clusters can be selected, solving the problem for each of those cluster sizes, and then selecting the best alternative (Hair et al. 1987).

Column Generation

A technique that permits solution of very large linear-programming problems by generating the columns of the constraint matrix only when they are needed. It is typically employed when the constraint matrix is too large to be stored, or when it is only known implicitly. Column generation, as imbedded in the revised simplex method, has been used to solve the trim problem and other such problems in which the columns are formed from combinatorial considerations.

Combat Model

A model whose object is military combat or some aspect of some combat. Three associated terms are often used as synonyms, but are frequently used to differentiate three common aspects of combat modeling: combat model, combat simulation, and war game. When combat model is used as a discriminator it often is used to mean that the model in question is an analytic combat model.

See

► Analytic Combat Model
► Battle Modeling

Combat Simulation

A type of model whose object is military combat or some aspect of combat. Combat simulation is used as a discriminator to emphasize the time or process aspect of the model in question.

Combinatorial Auctions

Karla L. Hoffman
George Mason University, Fairfax, VA, USA

Introduction

The advent of the Internet has led to the creation of global marketplaces in which sales of everything from low-cost used merchandise to billion dollar government procurements are conducted through auctions. This article concentrates on designs where many items are auctioned simultaneously and where bidders have the flexibility to combine the goods into packages. The discussion (1) highlights alternative combinatorial auction designs and provides the reader with multiple references to resources that describe more fully the underlying theory of these designs., and (2) describes the mechanisms used to evaluate the efficacy of such approaches in terms of their efficiency, equity, and cognitive complexity, and presents some examples of the use of combinatorial auctions for high-value government lease rights, as well as the use of such auctions for supply-chain procurement. These auctions require knowledge of both game theory and combinatorial optimization.

General Concepts

Governments throughout the world use auctions to lease the right to explore and extract minerals, fuel, and lumber on government properties, to use the airwaves for mobile or broadcast communications, or to control emissions through cap and trade regulations. In addition, the use of business-to-business auctions (often called supply chain auctions) has become a billion-dollar industry. In each of these cases, the need to be able to bundle buys and sells has resulted in new auction theory and designs that enable the simultaneous selling or buying of items using mechanisms that allow participants to indicate their value for the entire package which may have a greater value than the sum of the items within that package. In addition, such auction designs allow users to specify quantity discounts, to indicate budget constraints on the total procurement, and to define other goals of the auction, e.g. social welfare goals in a government auction. These auction designs are computationally more complex for all participants and require languages that allow bidders to express their willingness to participate at a given price for a collection of objects. Such auctions have been termed combinatorial auctions. There are many books that describe the history of auctions, auction theory and its relationship to game theory, and others that are focused exclusively on combinatorial auction designs. For further reading on the subject, see: McMillan (2002) on the history of markets, Krishna (2002) on auction theory, Steiglitz (2007) on the success and pitfalls of EBAY auctions, Klemperer (2004) on auction theory and practice, and Milgrom (2004) and Cramton et al. (2005) on combinatorial auctions. In this review, only the major topics of the field are described, but multiple references are provided for further reading.

In what follows, one-sided auctions are considered and are restricted to the case where there is a single seller and multiple buyers (two-sided auctions are often referred to as exchanges, see Milgrom (2007), Parkes et al. (2001), and Hoffman and Menon (2010) on exchange designs). Since the multiple-sellers/single-buyer case and the multiple-buyers/single-seller case are symmetric, the discussion emphasizes the latter, but all results follow for either case. The concentration is on auction designs where that there are multiple items being sold. For at least some of the buyers, a collection of items must be procured to have a viable business plan; consideration is given only to auction designs that allow the packaging of collections of items. Such designs can provide greater efficiency, as well as greater revenue to the seller than the sequential selling of items individually. These designs are sufficiently general to allow bidders to express a value on a package where the collection of items may have a value greater than the individual items (i.e. the goods are complements), as well as on a package where a buyer can express a quantity discount for buying more of the good (i.e. the goods are substitutes).

Why are auctions such a popular mechanism for buying and selling valuable objects? With the advent of the Internet, auctions are capable of reaching many more possible participants. Here, the potential buyers wish to determine the minimum price that they must pay given that they must compete with others for the ownership of a good or collection of goods. From the

seller's perspective, submitting goods to an auction may increase the number of buyers, thereby increasing the potential for competitive bidding and higher selling prices. Thus, an auction is a mechanism to determine the market-based price, since the bidders set the price through the competition among the bids. This mechanism is dynamic and reacts to changes in market conditions. The determination of selling prices by an auction is perceived as fairer than if the price were set by bilateral negotiations because all buyers must adhere to the same set of rules. Most importantly, if the rules are well designed, the result will have the goods allocated to the entity that values them the most.

The two basic classes of auctions are described next: (1) sealed bid auctions whereby there is only a single opportunity to provide bids to the auction, and (2) multi-round auctions where bids are taken over a period of time and any high bid can be overtaken whenever a new bid is received that increases the overall revenue to the seller.

Sealed Bid Auctions

One common auction mechanism is the first-price (sealed bid) auction**.** In this design, all bidders submit their bids by a specified date. The bids are examined simultaneously and the auctioneer determines the set of bidders that maximizes the revenue to the seller. The optimization problem that determines a collection of package bids that do not often overlap and produce the maximum revenue is known as the Winner Determination Problem (WDP). Mathematically, the problem can be stated as follows:

$$WDP_{OR} : Max \sum_{b=1}^{\#Bids} BidAmount_b x_b \quad (1)$$

$$subject\ to:$$

$$Ax \leq 1$$

$$x \in \{0, 1\} \quad (2)$$

where x_b is a zero–one variable which indicates whether bid b loses or wins, respectively. A is an n x m matrix with m rows, one for each item being auctioned. Each of the n columns represents a bid where there is a one in a given row if the item is included in the bid and zero otherwise. Constraint set (1) specifies that each item can be assigned at most once. Set (1) constraints are equations when the seller chooses to put a minimum price on each item and is unwilling to sell any item below that price. In this case, there is a set of m bids each with only a single item in the package and a bid price at a price slightly below the minimum opening bid price. In this way, the seller will keep the item rather than allow it to be won by a bidder at less than the opening bid price.

In this formulation of the WDP, the bidder can win any combination of bids, as long as each item is awarded only once; this is referred to as the "OR" language. The problem with this language is that it creates a type of exposure problem, that of winning more than the bidder can afford. When multiple bids of a single bidder can be winning, it is incumbent on the software to highlight the maximum exposure to the bidder. This calculation requires that a combinatorial optimization problem be solved for each bidder that calculates the dollar exposure, creating new computational issues for the auctioneer and may result in packages that are not best for the bidder.

The most natural alternative to this "OR" language is the "XOR" language. In this case, the user supplies every possible combination of bids of interest along with a maximum bid price that she is willing to pay for that package. This language removes the dollar exposure problem, since the maximum number of bids that a bidder can possibly pay is the highest bid amount of any of its bids. The problem with the XOR language is that it places a new burden on the bidder: the bidder is forced to enumerate all possible combinations of packages of interest and their associated values. Clearly, as the number of items in an auction increase, the number of possible bids goes up exponentially. When the XOR bidding language is used the Winner Determination Problem (WDP_{XOR}) becomes:

$$WDP_{xor} : Max \sum_{b=1}^{\#Bids} BidAmount_b x_b \quad (3)$$

$$subject\ to:$$

$$x = 1$$

$$\sum_{b \in S_B} x_b \leq 1 \text{ for each bidder B} \quad (4)$$

$$x_b \in \{0, 1\} \quad (5)$$

Where S_B is the set of bids of bidder B, and constraint set (4) specifies that at most one of these bids can be in the winning set.

Fujishima et al. (1999) proposed a generalization of the OR language that does not require the enumeration of all possible combinations. They label this language OR*. Here, each bidder is supplied dummy items (these items have no intrinsic value to any of the participants). When a bidder places the same dummy item into multiple packages, it tells the auctioneer that the bidder wishes to win at most one of these collections of packages. This language is fully expressive, as long as bidders are supplied sufficient dummy items. This language is also relatively simple for bidders to understand and use, as was shown in a Sears Corporation supply-chain transportation auction. In that auction, all bids were treated as "OR" bids by the system. Some bidders cleverly chose a relatively cheap item to place in multiple bids thereby making these bids mutually exclusive, Ledyard et al. (2002). There have been a number of alternative bidding languages that have been proposed; see Fujishima et al. (1999), Nisan (2000), Boutilier and Hoos (2001), and Boutilier et al. (2001) for descriptions of alternative languages.

One serious flaw in a first-price sealed-bid design is that the bidder can experience what is referred to as the winner's curse, i.e., the winning bidder may pay more than was necessary to win since the second highest bid price was far less than the winning bid amount. For this reason, sealed-bid first price auctions encourage bidders to shave some amount off of the bid price. From a game-theoretic perspective, one wants an auction design that encourages straight-forward honest bidding.

An alternative that overcomes this problem is the second price (sealed bid) auction whereby the bidder that has submitted the highest bid is awarded the object (package), but the bidder pays only slightly more (or the same amount) as that bid by the second-highest bidder. In second price auctions with statistically independent private valuations, each bidder has a dominant strategy to bid exactly his valuation. The second price auction also is often called a Vickrey auction (1961).

In a second-price auction, one solves the same winner determination problem as one does for the first-price sealed-bid case, but the winners do not necessarily pay what they bid. Instead, one determines the marginal value to the seller of having this bidder participate in the auction. To do this, for each winning bidder, one calculates the revenue that the seller would receive when that bidder participates in the auction and when that bidder does not, i.e. when none of the bids of this bidder are in the winner determination problem. The difference in the two objective function values is known as the Vickrey-Clarke-Groves discount, named after the three authors, Vickrey (1961), Clarke (1971), and Groves (1973). Each of these authors wrote separate papers producing certain attributes that this auction design has as it relates to incentivizing bidders to reveal their truth value of the goods demanded, and the bidder pays the bid price minus the discount. When winners pay this amount, the auction is known as the Vickrey-Clarke-Groves (VCG) Mechanism.

Although it can be shown that the VCG mechanism encourages truthful bidding, it is almost never used in practice. For a complete list of reasons for it being impractical, see Ausubel and Milgrom (2006) and Rothkopf (2007). In essence, the prices provided by this mechanism may be very low. Worse yet, when items have complementary values, i.e. the package is worth more to the bidder than the sum of the values of the individual items, the outcome may price the items so low that there is a coalition of bidders that would prefer to renege on the auction and negotiate privately with the seller, and the seller may respond by reneging on the sale since both the seller and the coalition of buyers will be better off. Ausubel and Milgrom (2002) argue that prices should be set high enough so that no such coalitions exist. In game theoretic terms, the prices are set such that the outcome is in the core of a coalitional game. These authors introduced an auction design known as the ascending proxy auction in which the bidders provide all bids as if in a sealed-bid auction. Each bidder is provided with a proxy that bids for the bidder in a straightforward manner during an ascending auction. The proxy only announces bids to the auctioneer that maximize the bidder's profit, (i.e. bid price minus announced price) in any given round. The auction continues as an ascending package-bidding auction until, in some round, there are no new bids. Thus, the auction simulates, through proxy bidders, an ascending auction where the increment in each round is infinitesimally small and each bidder, through the use of its proxy, bids in a straight-forward manner.

This auction design is very similar to the iBundle design of Parkes and Ungar (2000).

Hoffman et al. (2005) provide a computational approach toward speeding up the calculations associated with this proxy auction design, and Day and Raghavan (2007) provide an elegant mechanism to obtain minimal core prices directly. The direct mechanism of Day and Raghavan sequentially solves winner determination problems to determine losing coalitions that could supply more revenue to the seller at the current prices. When the solution to this optimization problem yields revenue greater than what the VCG mechanism would provide, the prices of the winning bid set are raised so that the total price paid by winning bidders is equal to this new revenue. To determine these new prices, one must be sure that any winning bidder that forms part of this blocking coalition does not have its price raised from its prior price since it would not be willing to join a coalition if it were to lose revenue relative to its prior offer by the seller. The algorithm is an iterative cutting plane algorithm that forces the prices higher at each iteration until one can find no coalition that can increase revenue to the seller. Therefore, the algorithm finds prices for each winning bidder that are in the core. Since there may be many such minimum core prices, Day and Milgrom (2008) suggest that, in order to encourage sincere bidding, one choose the minimum core prices that are closest in Euclidean distance from the VCG prices. Alternatively, Erdil et al. (2009) argue for a different set of minimum core prices that are based "on a class of 'reference rules' in which bidders' payments are, roughly speaking, determined independently of their own bids as far as possible."

These core-selecting second-price sealed-bid mechanisms have the following properties: They are in the core, they eliminate the exposure problem, and they encourage bidders to bid sincerely. As with all sealed-bid auctions, they make collusion and punishment for not adhering to tacit agreements extremely difficult.

There are, however, negatives associated with this auction, as well as for all sealed-bid auction designs, in that it puts a significant burden on the bidders. Each bidder needs to assess, for every possible combination of items, whether it is a package of interest and then, for all such packages, determine the maximum it is willing to pay. In addition, such mechanisms do not provide any information about how the packages submitted might fit with packages submitted by other bidders. To overcome these problems, a number of authors have suggested simultaneous ascending combinatorial auction designs that allow users price information during the auction.

Multi-round Auctions

Often the value of the good or package of goods being auctioned is not completely known and/or private. Instead, there is a common component to the bid value, that is, the value of the item is not independent of the other bidders, but rather there is a common underlying value as well. In such situations, each agent has partial information about the value. Many high-stakes auctions, such as government auctions for spectrum, oil exploration, and land use, fall into this class. In the case of package-bidding auctions, when there is a common component and bidders want to assess how much others are willing to pay for that item or package of items, the auction is usually an ascending auction with multiple rounds. A round consists of a given time period where bidders have the opportunity to submit new bids. When the round ends, all bids are collected and the winner determination problem is solved. This optimization problem determines the packages that provide the seller with the maximum revenue. The bids that are in the winning set are labeled "provisionally winning," i.e. they would be winning if the auction ended in this round. Thus, in an ascending combinatorial auction, all items are sold simultaneously and a bidder can bid on any collection of items in a given round. To overcome the current set of provisionally winning bids, a bidder must submit a bid that increases the total revenue to the seller.

There are a number of design question that must be answered to have a complete combinatorial auction design:

1. How does the auction end?
2. Must bidders participate in every round?
3. Are bids from previous rounds part of the bids considered by the winner determination problem?
4. How are the prices set in each round?
5. What do bidders know about the bids of other bidders?
6. What other rules might be necessary to ensure that collusion is avoided, to make reneging costly, and to encourage bidders to act truthfully?

Of importance is how to assure that the auction ends in a reasonable period of time and that price discovery (the main reason for a multi-round auction) is accomplished. Most package-bidding auctions have discrete time periods, called rounds, and in each round, the auctioneer provides a price to the user that is the minimum price that the bidder must supply in order to place a new bid. One can choose either a fixed stopping rule or a stopping rule that is determined dynamically. A fixed time stopping rule specifies that the auction will end at a given time. With a fixed stopping time, bidders are encouraged to not provide any bids until the very last seconds of the auction, called sniping. The purpose of sniping is to give other bidders no chance of responding to an offer. In this way, a bidder can acquire price information from other bidders but does not reciprocate, since throughout most of the auction, the bidder is silent. If all bidders chose to snipe and provide no bids until the end of the auction, the auction essentially becomes a first-price sealed-bid auction. To overcome the problem of sniping and to encourage price discovery, most package bidding auctions use an alternative stopping criteria whereby the auction ends when no new bids are presented within a round.

Often, for high-stakes multi-round auctions, there are also activity rules that require a bidder to bid in a consistent way throughout the auction. Activity rules force bidders to maintain a minimum level of bidding activity to preserve their eligibility to bid in the future. Thus, a bidder desiring a large quantity at the end of the auction (when prices are high) must bid for a large quantity early in the auction (when prices are low). If the bidder cannot afford to bid on a sufficient number of items to maintain current eligibility, then eligibility will be reduced so that it is consistent with current bidding. Once eligibility is decreased, it can never be increased. As the auction progresses, the activity requirement increases, reducing a bidder's flexibility. The lower activity requirement early in the auction gives the bidder greater flexibility in shifting among packages early on when there is the most uncertainty about what will be obtainable. Precisely how the activity and eligibility rules are set matters and must be depend upon the type of auction – the value of the items being auctioned, the projected length of the auction, the number of participants, etc. In many high-stakes auctions, such as spectrum or electricity, these activity rules have proven highly successful, Klemperer (2002), McMillan (2002), and Milgrom (2004).

In an ascending multi-round auction design, the auctioneer must provide information about the current value of each package. This information is used for two related purposes: (1) to specify the minimum bid for each item or package in the next round and (2) to provide valuation information to bidders so that they can determine what might be required for a bid to be winning in a subsequent round. While pricing information is easy to ascertain in single item auctions or in simultaneous multi-round auctions without package bidding, (i.e. where bids can be placed on only single items), pricing information for combinatorial auctions is not well defined. Bidders provide only aggregate package prices without providing the information about how each of the individual components that made up the bundle contributes to the overall price. Attempting to disaggregate these bundles into single item prices unambiguously is not possible. Also, since there are many ways that some bundle might partner with other packages to create a winning set, determining the minimal cost partnering for a given package by a given bidder is a complex problem.

To further complicate the pricing issue, bidders may view certain items as substitutes and other items as complements. In the case where items are substitutes, bidders are likely to express sub-additive values for their packages. That is, the value of a package of items is less than or equal to the sum of the values of the items that make up the package. In the complementary case, bidders are likely to express super-additive values for packages. In this case, the value of a package of items is greater than or equal to the sum of the values of the items that make up the package. When items can be both substitutes and complements for bidders, providing unambiguous, complete and accurate price information is an unsolved problem. The non-convex nature of the problem means that the linear prices (i.e. the sum of a package is equal to the sum of the individual items that make up the package) that can be obtained from dual prices from the linear relaxation of the WDP problem will overestimate the true values of the items. In most auctions, one adjusts the dual prices so that the prices are modified so that when one sums the items in each of the winning packages, the prices on those packages exactly equal the prices bid by the provisionally winning bidders (i.e. the winners at the end of the current round). Rassenti et al. (1982) terms these prices pseudo-dual prices.

(For theoretical issues with duals associated with non-convex problems see Wolsey(1981), and for non-anonymous non-linear prices see deVries and Vohra (2003) and Bikhchandani and Ostroy (2002).

Although linear pricing cannot accommodate all aspects of the pricing associated with the non-linear, non-convex, winner determination problem, there are still good reasons for considering its use for determining future bid requirements. First, even perfect pricing is only correct when all other aspects of the problem remain fixed, i.e. when bid amounts remain the same on all other bids and when no new bids are submitted. Second, a dual price associated with a given constraint is only correct when one changes this single restriction (the right-hand-side of the associated constraint) by a very small amount. In the case of combinatorial auctions, the item is either won or it is not. Changes to a constraint would either remove the item entirely from consideration or create a second identical item. Thus, even non-linear, non-anonymous pricing has serious limitations in the context of the winner determination problem since the removal of a single item from the auction (e.g. the removal of the New York City market from consideration in a nationwide spectrum auction) may change the willingness of bidders to participate.

Finally, in an ascending bid auction, bidders need pricing information that is easy to use and understand, and is perceived to be fair. In this situation, easy to use means that bidders can quickly compute the price of any package, whether or not it had been previously bid. Often, bidders want to know what it would take for such a bid to be competitive, i.e. have some possibility of winning in the next round. Bidders may also perceive such prices to be fair since all bidders must act on the same information. Linear prices are likely to move the auction along and deter such gaming strategies as parking (parking is an approach whereby the bidder bids on packages that currently have very low prices knowing that these packages have a very low probability of winning). Bidding on such low-priced packages allows a bidder to maintain eligibility (by maintaining activity), while hiding interest in the packages that are really desired until later in the auction). Thus, virtually all ascending combinatorial auctions use pseudo-dual pricing. For more on alternative pricing within this general framework and the testing thereof, see (Dunford et al. (2003), Bichler et al. (2009) and Brunner et al. (2011).

In 1999, DeMartini et al. proposed an auction design labeled The Resource Allocation Design or RAD where the WDP is solved each round and all losing bidders can only bid on packages where the package price is the sum of the pseudo-dual prices plus some increment (as announced by the auctioneer). There is no activity rule for this auction design. In 2002, the Federal Communications Commission (FCC) announced a similar package bidding design but proposed refinements to the pseudo-price calculations that attempts to limit fluctuations (both positive and negative) in prices. A related design was proposed by Bichler et al. (2009) and is called the Approximate Linear Pricing Scheme (ALPS). It also uses similar rules but chooses the ask price to better balance prices across items. Note that all of these pricing procedures allow prices to both increase and decrease depending upon the packages that are in the winning set. In virtually all of these designs, any bid submitted in any round is considered active throughout the auction. This rule works well with the XOR language since only one bid of a bidder can be in an optimal set and bidders should be willing to win bids placed in early rounds of the auction, when prices were low. This rule forces bidders to provide sincere bids throughout the auction.

A very different ascending package bidding design was proposed by Porter et al. (2003). It is called the combinatorial clock auction. In this design, the auctioneer provides prices for each unique good (if there are multiple identical items, then the bidder indicates that number of units of that item they desire) based solely on whether there is more demand for the item than for supply; no WDP problem is solved. There is no concept of a provisionally winning bidder. Instead, prices increase whenever demand for a given item is greater than supply. Bidders indicate the single package bid that is best given the per-unit prices announced by the auctioneer. All bidders must rebid on any item that they wish to procure in each round. The only information provided to bidders at the end of each round is the quantity demanded for each item and the price for the next round. As long as demand exceeds supply for at least one item, the price is increased for those items with excess demand. If there are no new bids in a round and supply equals demand, then the auction ends. However, it may happen that when there are no new bids, demand has been reduced to below supply. If this occurs, a WDP is solved using all bids from all rounds. If the computed

prices do not displace any bids from the last round, then the auction ends. Otherwise, the auction resumes with the prices determined by using the pseudo-prices calculated from the WDP. Thus, for most rounds, the computation has been drastically reduced to merely increasing prices by a given increment. Only, when demand has dropped below supply is the WDP solved.

Other approaches are the auction designs that simplify the problem by only allowing a few pre-defined packages (Harstad et al. 1998) for which the WDP is polynomially solvable. This idea of only allowing a certain pre-determined set of packages (called hierarchical packages, Goeree and Holt 2010) was used in the 2009 FCC auction for broadband spectrum that brought over $19B into the U.S. Treasury. In that design, all bids were additive (the OR language applied) and the WDP was solved in linear time. When it is possible, in advance, to understand the needs of the bidders and when the packages most desired can be represented in a hierarchical fashion, then one obtains an auction design that is both simpler and quite efficient. However, if the demand for packages does not take on this hierarchical structure, then imposing such structure on the problem for the sake of computability will likely lead to less efficient outcomes.

Hybrid Designs

Ausubel et al. (2005) have argued for a hybrid design that reduces the computational burden on both the bidder and the auctioneer. Here, one first uses a combinatorial clock design followed by a last round second-price sealed-bid approach. The combinatorial clock is similar to that proposed by Porter et al. (2003) with the further enhancement that bidders who find the increment too high are able to place a bid at a price between the old price and the new price that indicates the maximum amount the bidder is willing to pay for that combination of items. In this way, the efficiency loss due to increment size is lessened. This phase of the auction ends when demand is less than or equal to supply or when demand on most items has trailed off. When demand does not exactly equal supply on all items, a sealed-bid phase is initiated. Here, the ascending proxy auction of Ausubel and Milgrom (2002) is imposed. When these two auction designs are merged, one must be careful that the activity rules work well for both phases of the auction. One wants tight activity rules in the ascending phase of the auction to ensure that the bidders are forced to bid sincerely. However, these rules may need to be relaxed or altered during the final sealed-bid phase or a straightforward bidder may be precluded from providing all of the packages that bidder values during the sealed-bid round. Also, theory dictates that in order to guaranteed an efficient outcome, losing bidders (i.e. bidders who dropped out prior to the final phase) must also provide all of the bids that they value in the final phase. Thus, although this hybrid auction is promising in that it is likely to speed up combinatorial auctions, research is still necessary to better understand how the rules of these two disparate auctions should be set so that they mesh well. For more on testing of this design, see Bichler et al. (2011).

Complexity of Combinatorial Auctions

As the previous discussion illustrates, most combinatorial auction designs requires considerable computation and most of the computational burden falls to the auctioneer. This seems appropriate since the auctioneer wants an auction that allows much participation; bidders should not be required to understand combinatorial optimization in order to participate. In terms of these computations, commercial software, such as CPLEX, GUROBI, or XPRESS have shown their ability to solve such problems in reasonable times (less than 30 minutes). Thus, although there is much in the literature that argues against combinatorial auctions because of the computational burden, the optimization software has proven up to be capable of handling the problems that are currently being considered applicable for this type of auction. For more on the computational issues in computing winner determination problems, see Leyton-Brown et al. (2005) and Bichler et al. (2009).

Since multi-item auctions are complex and require bidders to consider multiple alternative bid options, it is important that the computer software used for communication between the bidder and the auctioneer be easy to use and understand. Good graphical user interfaces help bidders to feel comfortable that they understand the current state of the auction (they have been able to find the current

price information, the items they are winning, the amount of bidding necessary to remain eligible, their dollar exposure based on what they have bid, etc.). The system must also provide easy ways for bidders to input their next moves and confirm that they have provided the system with the correct information. As the use of auctions is spreading, computer interfaces for such processes continue to improve and to provide better ways of displaying information to the users through charts, graphs and pictures. There is likely to be continued improvement in this area.

These tools do not, however, help the bidder determine the optimal combination of items to bundle as a package and the optimal number of packages to supply to the system. Since bidders face the serious problem of determining which bids are most likely to win at prices that are within the their budgets, tools that assist bidders in understanding the state of the auction is important. In both supply-chain auctions and in high-stakes government auctions (such as spectrum auctions), bidder-aided tools are often developed to assist the bidder in determining the package or packages to submit in any given round. In the case of supply-chain auctions, the auctioneer often suggests packages to the suppliers that will fit well with other bidder's bids (e.g. by either adding or removing a single item from the package, or by considering a quantity discount for supplying more of an item). Such tools have been found to be very useful and also computationally tractable; see An et al. (2005), Dunford et al. (2003), and Boutilier et al. (2004). Day and Raghavan (2005) and Parkes (2005) provide alternative ways for bidders to express preferences that do not require that the bidder specify particular packages to the auctioneer.

Applications of Combinatorial Auctions

There are many examples of governments' using auctions for the allocation of valuable assets. In most of these auctions, the government is allocating a good and uses auctions to determine both the price and the allocation. Since 1994, governments throughout the world have been using simultaneous multi-round auctions for the allocation of spectrum. For spectrum, a government has the goal of allocating the good to the entities that value it the most with the hope that the bid cost will encourage the build-out of the services. To assure that there is sufficient competition in the telecommunications industry, the U.S. government has, in the past, set spectrum caps for each region. These auctions have been copied globally and are now the standard way that spectrum is allocated. Recently, a number of different package-bidding designs are being tried including the hierarchical ascending auction, the combinatorial clock auction, or the clock-proxy design. As of 2005, these auctions have resulted in revenues in excess of $200 billion dollars worldwide (Cramton 2005).

Within the power industry, there has also been an evolutionary movement toward auctions for the determination of who can supply power to the electricity grid and at what price. Most of the allocation is determined one day ahead of the demand. The auction reflects the unique characteristics (both physical and structural) of the industry. The allocation is determined by a complicated optimization that evaluates the demands at various nodes of the networks and prices power generation at each such node. The spot market corrects this allocation for any last minute changes due to weather, plant outages, etc. Long term contracts make this process work.

Similarly, auctions have been used to bring market-based forces to control air pollution. Here, a government entity (either nationally run or regionally administered) establishes a fixed number of tradable allowances each of which represents the legal right for its owners to emit a fixed quantity of pollution. A firm holding an allowance can emit the fixed quantity and surrender the allowance to the government, or if the firm can abate its emissions, it can profit by selling the allowance to another polluter than cannot so inexpensively abate emissions. The establishment of the fixed quantity is the cap. The exchange of allowances (credits) between polluters is the trade. See Ellerman et al. (2003) and Tietenberg (2006) for a general overview of cap and trade ideas.

The use of combinatorial auctions for the procurement of goods in services has also been growing. Some of these auctions are sealed-bid auctions, while most are moving toward multi-round auction designs. In such auctions, the providers of the goods and services are pre-screened and are then allowed to provide bids for collections of good and/or services as all or nothing packages. For a general

survey of supply-chain auctions, see Bichler et al. (2006). The three applications described next highlight a few examples to show how such auctions differ from government auctions.

1. The first use of a combinatorial auction within the transportation industry was an auction conducted by Sears. Here, suppliers of freight delivery were allowed to bundle multiple lanes together into a single bid thereby allowing carriers to coordinate multiple businesses and reduce empty or low value backhaul movements. It also provided a means to incorporate surge demand contingencies into the longer (3-year) contracts, thereby lessening the need to renegotiate contracts whenever demands changed; Ledyard et al. (2002).
2. Mars Incorporated used a combinatorial auction mechanism to procure the necessary goods from multiple suppliers allowing bidders to specify complex bid structures that indicated quantity discounts, minimum supply, and multiple goods collected within a single bid. No bidder was allowed to supply more than a certain percentage of the overall quantity needed and newer suppliers were limited more severely than their suppliers they had used over a number of years. The algorithm also assured that there were multiple suppliers in the solution for each critical entity. These auctions are not simple, but work to match the needs of the procurer, Mars, with the capabilities of the suppliers (often farmers). The allocation considers geographic, volume and quality factors. The suppliers liked the auction mechanism because of its transparency, shorter negotiation time and fairness; Honer et al. (2003).
3. Motorola Corporation used auctions for the procurement of the multitude of parts needed for cellular devices. Motorola needed to reduce both the time and the effort required to prepare for and conduct negotiations with its suppliers, simplify their coordination, and optimize contract awards across sectors, in order to save costs; Metty et al. (2005).

Governments are moving toward procuring their goods and services in a similar fashion. One such example is the use of auctions to determine the suppliers of lunches in a large school system. Chile spends around US$180 million a year to feed 1,300,000 students from low income families. To improve the quality of the goods and services being provided to the school system and to save money, the government chose to assign catering contracts in a single-round sealed-bid combinational auction. This auction resulted in a transparent and objective allocation approach, thereby generating competition among firms. It also allowed the companies to build flexible territorial bids to include their scale of economies, leading to more efficient resource allocation. This new methodology improved the price-quality ratio of the meals with yearly savings of around US$40 million, equivalent to the cost of feeding 300,000 children during one year; Epstein et al. (2002).

In supply-chain auctions, rules are designed to assure a certain diversification in suppliers and to assure the reliability of the supply chain. In each case, are goals other than revenue maximization or efficiency that drove the auction design. In addition, the auction design must consider the nature of the investment. For spectrum, where there was both uncertainty in the long-term use of the technologies and where the cost of build-out are high, long-term leases were chosen. For energy, auctions are used for a much shorter decision problem. The U. S. Treasury uses multiple auctions for short, medium and long-term debt allocation. Oil and gas exploration must have a relatively long-term horizon where payments for wildcatting are based on the bid price and a yearly rent, whereas payments for extraction are based on bid price and royalties.

Thus, one must consider carefully the application when designing the allocation mechanism and the payment scheme. Auction theory and its use is growing because of its proven value. It provides price discovery and signals where more capacity is needed. It is often a fairer and more transparent process for the allocation of goods and services.

Concluding Remarks

Combinatorial auctions are appropriate for problems where the bidders need to procure a collection of items that contribute to their having a viable business plan. When evaluating alternative designs, one is likely to want to satisfy the following goals:

1. The property rights are well-defined.
2. Bidders are able to, through their bids, announce the entire collection of objects that they need for a given business plan.

3. The auction results in maximum revenue to the seller.
4. The auction results in an efficient outcome i.e. all items are collectively allocated to the bidders that value these items the most.
5. The auction is perceived as fair to all bidders.
6. The auction ends in a reasonable amount of time.
7. The auction has limited transaction costs, i.e. the rules are not so difficult or the bidding so complicated that a straightforward bidder finds it difficult to participate.
8. The auction cannot be gamed, i.e. truthful bidding is an optimal strategy for all bidders.
9. The auction allows price discovery.
10. The auction is computationally feasible and scalable.

It is not possible to have all such attributes obtain simultaneously. For each applications, some of these goals will be more important than others. One should, however, keep all of these goals in mind when evaluating a mechanism.

In addition, the auction mechanism should consider any application-specific issues that might arise. For example, in government auctions one might want to consider how market power impacts the outcome, whether there will be sufficient participation, and whether the outcome will limit future competition in the industry. In certain situations, there may need to be a transition period that allows the market to adjust to a change in the way rights are allocated; One may have to consider the associated rights that a bidder would need to be able to use the right being sold or leased in the auction; The seller needs to determine if the rights are paid for over time or at the end of the auction; The money obtained may need to be designated for a specific use in order for the government to obtain the approval of all constituents. The auction design may also need to satisfy other social goals specific to the application (e.g. reducing emissions, increasing competition, incentivizing innovation, improving multi-modal transportation). Similarly, in supply chain auctions, a variety of goals need to be considered– quality of the goods, price, historical dependability of the supplier, among others.

Combinatorics

Eugene L. Lawler

Combinatorics is the branch of mathematics that deals with arrangements of objects, usually finite in number. The term arrangement encompasses, among other possibilities, selection, grouping, combination, ordering or placement, subject to various constraints.

Elementary combinatorial theory concerns permutations and combinations. For example, the number of permutations or orderings of n objects is $n! = n(n-1) \ldots (2)(1)$, and the number of combinations of n objects taken k at a time is given by the binomial coefficient $\binom{n}{k} = n!/[k!(n-k)!]$. In order to compute the probability of throwing a seven with two dice, or of drawing an inside straight at poker, one must be able to count permutations and combinations, as well as other types of arrangements. Indeed, combinatorics is said to have originated with investigations of games of chance. Combinatorial counting theory is the foundation of discrete probability theory as is exists today.

Experimental design provides the motivation for another classic area of combinatorial theory. Suppose five products are to be tested by five experimental subjects over a period of 5 days, with each subject testing one product per day. Labeling the subjects A, B, C, D, E, the products 1,2,3,4,5, and the days M, Tu, W, Th, F, one way to schedule the tests is as follows:

	M	*Tu*	*W*	*Th*	*F*
1	A	B	C	D	E
2	B	C	D	E	A
3	C	D	E	A	B
4	D	E	A	B	C
5	E	A	B	C	D

A square array of symbols, with each symbol occurring in each row exactly once and in each column exactly once, is called a Latin square.

Now suppose each of the tests is to be performed by a subject in the presence of an observer. In order to reduce the effects of bias due to subject-observer interactions, the Latin square should represent the

schedule for the subjects to be combinatorially orthogonal to the Latin square for the observers. This means that when the two Latin squares are superimposed, each of the 25 possible subject-observer pairs appears exactly once in the resulting array, called a Graeco-Latin square. Labeling the observers a, b, c, d, e, a 5 × 5 Graeco-Latin for our experiment is as follows:

Aa	Bb	Cc	Dd	Ee
Bc	Cd	De	Ea	Ab
Ce	Da	Eb	Ac	Bd
Db	Ec	Ad	Be	Ca
Ed	Ae	Ba	Cb	Dc

Leonhard Euler observed that no 2 × 2 Graeco-Latin square exists and found he was able to construct examples of $n \times n$ Graeco-Latin squares for n up to five, but had trouble with six. In 1782 Euler conjectured the nonexistence of such an arrangement for any $n = 4k + 2$, where k is an integer. About 1900, Euler's conjecture was confirmed, by systematic examination of cases, for $n = 6$. However, his more general conjecture remained unsettled until 1959 when Bose, Shirkhande and Parker exhibited a 22 × 22 Graeco-Latin square. Shortly after, these same investigators (Euler's Spoilers) demolished what remained of Euler's conjecture by establishing that Graeco-Latin squares do exist for all n other than two and six. Their work made use of results of number theory, a branch of mathematics with which combinatorics exists in happy symbiosis.

Another investigation of Euler turned out to have considerable importance for combinatorial mathematics. In the old city of Königsberg in Eastern Prussia the River Pregel divided into two branches surrounding an island. The river was spanned by seven bridges. It is said that the people of Königsberg entertained themselves by trying to find a route around the city that would cross each of the bridges exactly once. In 1736, Euler provided a definitive answer to the Königsberg bridge problem, and any related instances: "If there are no more than two areas to which an odd number of bridges lead, then such a journey is not possible. If, however, the number of bridges is odd for exactly two areas, then the journey is possible if it starts in either of these areas. If, finally, there are no areas to which an odd number of bridges leads, then the required journey can be accomplished from any area." This result has been viewed as the oldest theorem of what is now known as graph theory.

With the advent of digital computers and operations research, the emphasis of combinatorics shifted from problems of counting and existence of arrangements to problems of optimization. Modern combinatorics may be said to have come of age with the development of network flow theory by Lester Ford and Ray Fulkerson in the 1950s. This remarkable theory enables a great variety of practical optimization problems to be solved by efficient algorithms. A number of elegant duality results follow directly from Ford and Fulkerson's Max-Flow Min-Cut Theorem. For example, consider the König-Egervary Theorem, which can be stated as follows: Let us call a subset of elements of a matrix independent if no two of the elements lie in the same row or the same column. Let all elements be 0 or 1. Then the maximum size of an independent set of 1 s is equal to the minimum number or rows and columns containing all the 1 s in the matrix.

In the 1960s Jack Edmonds generalized many of the results of Ford and Fulkerson by exploiting the concept of a matroid, a combinatorial structure abstracting the notion of linear independence. Edmonds also developed a general theory of matching in graphs, where a matching is a subset of edges, no two of which are incident to the same vertex. He also proved a generalization of the König-Egervary Theorem, which may be viewed as a duality theorem for matchings in the special case of bipartite graphs.

Edmonds (1965) further observed that the running time of his general matching algorithm was bounded by a polynomial in the size of the graph it is applied to, and made an eloquent argument for the goodness of polynomial-time bounded algorithms. The significance of polynomial time bounds came to be more fully appreciated with the development of NP-completeness theory by Stephen Cook, Richard Karp and Leonid Levin in 1973. The theory of NP-completeness has been an essential tool for researchers in combinatorial optimization ever since.

Algorithms arising from network flow theory, matroid optimization theory, matching theory, or similar theories, may all be viewed as special-purpose linear programming algorithms. Combinatorial duality results, including the Max-Flow Min-Cut Theorem and the König-Egervary Theorem, are most often special cases of linear programming duality. The term applied

to the general paradigm of formulating and solving combinatorial problems by linear programming techniques is polyhedral combinatorics.

More often than not, combinatorial optimization problems that arise in the real world are too idiosyncratic and complicated to be fully tamed by polyhedral techniques alone. For these problems, it is usually necessary to engage in some form of enumeration of cases if one seeks to find a provably optimal solution. The Traveling Salesman Problem (TSP) is prototypical of a difficult (NP-complete) problem with a real-world flavor. In this problem, one is asked to find a shortest closed tour of n cities (visiting each city exactly once, and ending at the starting point), given an $n \times n$ matrix of intercity distances. The number of possible tours is, of course, finite: $(n-1)!$. But for any interesting value of n, say 100 or 1,000, the number of tours is so astronomically large as to be effectively infinite. An exhaustive enumeration of even a tiny fraction of the tours is out of the question. Hence if the TSP is to be solved by enumeration, the enumeration must be very artfully limited.

The TSP has served as a testbed for algorithmic research. Indeed, the approaches that have been applied to the TSP are representative of the full range of techniques of combinatorial optimization. These include polyhedral and integer linear programming, Lagrangian relaxation, nondifferentiable optimization, heuristic and approximation algorithms, branch-and-bound, dynamic programming, neighborhood search, and simulated annealing. With much effort by many investigators, it is today possible to find optimal, or provably near-optimal, solutions to instances of the TSP with hundreds, even thousands of cities.

Combinatorial optimization has assumed great practical importance, in such diverse problem areas as machine scheduling and production planning, vehicle routing, plant location, network design, VLSI design, among many others. The practical and theoretical importance of this field can only be expected to grow in the future.

Common Value Bidding Model

A bidding model in which the value of what is being auctioned, while unknown at the time of the auction, is known to be the same for all bidders. In such a model, bidders must correct for the selection bias, often called

the winner's curse, caused by the fact that winning bidder is likely to have been the one who most overestimated the value.

Communications Networks

Edward A. Sykes
Make Systems, Inc., Carey, NC, USA

Introduction

Communications networks are systems of electronic and optical devices that support information exchange among their subscribers. Examples of communications networks are abundant in everyday life: telephone networks, broadcast and cable television networks, and computer communications networks such as the Internet. The impacts of communications networking on the individual, society and the planet are staggering, rivaling that of the tall ship and the automobile. In just under two centuries, humanity has been transformed from myriad villages and towns isolated in obscure corners of the continents to one global information village. This transformation is no more evident than in the fact that the very boundaries between information transfer and information processing are increasingly hard to define. The integration of communications networks, computing technology, and end-user devices (e.g., the telephone, television, personal computer) is increasingly being referred to simply as the information infrastructure. This global transformation of the world community is no more evident than in the Internet, which some analysts predict will be the predominate mechanism for conducting business (both consumer and business-to-business) within 5 years.

OR and MS have been major players in the development, deployment and management of information technologies and infrastructure. Applications of OR/MS in modeling, analysis and design of communications networks are among the oldest of the fields, dating from the late nineteenth and early twentieth century. Among the most notable of all work in OR/MS history is queueing modeling of telephony by A.K. Erlang. Modeling, analysis and design of communications networks, moreover, is an area rich in applications of more generic OR/MS work. Communications networks are, fundamentally, networks and thus, almost all generic discussion of networks applies. Analogous remarks are appropriate: in communications network modeling and analysis for topics such as queueing and queueing networks, simulation, and network reliability; and in communications network design for topics such as facility location, topological design and optimization, capacity optimization and allocation. Finally, communications networking problems have a great deal of commonality with problems arising in other domains, for example, modeling, analysis and design of transportation systems, water resource distribution systems, etc.

A discussion of the wealth of communications networking issues arising in the application of OR/MS techniques would be quite extensive. Here the focus is on several classes of modeling, analysis, and design problems arising in a variety of modern communications technologies.

Basic Structure and Concepts

A typical communications network comprises a set of subscribers that offer subscriber-to-subscriber traffic requirements to be supported on the given network architecture. For example, a typical household (subscriber) makes telephone calls (traffic requirements) to be supported on a voice network switching fabric (architecture). In most communications architectures, a hierarchy of communications devices exist to support traffic, but the most basic of these are customer premises equipment, local access equipment, and switching equipment. Customer premises equipment is associated directly or indirectly with the generation of traffic requirements. Local access equipment provides a means of connecting the subscriber to the network, that is, the interface between the subscriber and the network necessary for traffic to enter the network and be routed over it. Switching equipment routes the traffic from its source subscriber to its destination subscriber.

All three types of equipment are determined by the nature of the traffic requirements and their associated technology and architecture. In a voice (i.e., telephone) network, the customer premises equipment is generally just a telephone – in this case, the subscriber is the household whose aggregate traffic (telephone calls) enters and leaves the network at the telephone. The local access equipment in this case is owned and provided by the local telephone company. Although there typically is switching in the local access in this case (for local calls), for purposes of the discussion here, the long haul switching equipment is owned and provided by a common carrier such as AT&T. Analogous examples can be provided for data communications networks, video teleconferencing networks, etc.

Communications networks differ on the manner in which they carry traffic requirements. Considerable attention has been paid to quality-of-service (QoS) issues in communications networks, with major trends in standards and implementations increasingly focused on assuring that different applications receive the QoS they require across the technologies they traverse. Most voice networks set-up calls from source to destination in a circuit switched manner, that is, dedicating capacity along the entire path of the call. Most data networks segment information into streams of packets or cells which are routed independent from one another from source to destination and reassembled into the original information at the destination. Data networks can operate with or without functions that route traffic according to QoS needs and with or without reservation or dedication of capacity along the path. Many variations and hybrids of these basic approaches exist and the evolution of technology is becoming increasingly toward supporting traffic sources with differing traffic characteristics and differing service requirements differently. For example, voice traffic is error tolerant (one can tolerate a little static on the line) but delay sensitive (one cannot tolerate long delays between the time a word is spoken and the time it is received at the destination). Some data traffic (e.g, file transfer) is typically error intolerant but delay insensitive. Consideration of these kinds of issues is addressed in network modeling and simulation.

A common thread among most network modeling, analysis and design conceptualizations is the view of a network as a graph comprising nodes and links. A node is used to abstractly represent a device location (e.g., a subscriber location or a switching location). A link is used to represent connections between subscribers and switches and between switches. A link typically has a capacity for supporting traffic. One can view a link as analogous to a pipe and the capacity of the link as analogous to the diameter of the pipe, but with one caveat. A communications link of a given capacity typically supports traffic at that capacity in both directions, that is, it is more properly viewed as two pipes of equal capacity in parallel, each flowing in a direction opposite the other. In addition, a single link can support many "logical" entities as well – for example, it can have its bandwidth dedicated in some proportions to support different service classes or priorities for purposes of providing differential QoS to traffic applications. Design of communications networks typically addresses selecting the number of and the placement of backbone (central) nodes, selecting and sizing the links between subscribers and backbone nodes, selecting and sizing the links between pairs of backbone nodes, and configuring logical constructs (virtual links sharing physical links, bandwidth allocations among service classes, etc.).

Modeling

Communications networks are large scale systems with enormous complexity. As with most such systems, modeling relies heavily on computer-based techniques and the nature of the models developed depends strongly on the questions the model is intended to answer. For example, a simulation may be used to answer detailed questions regarding the interaction of communications devices or protocols. Often these studies address questions as to the feasibility of a given device or protocol to support certain types of traffic requirements with acceptable performance. Such models can be used to design the devices or protocols as well. Simulation of communications systems typically models the generation, transfer, and disposition of each unit of information (e.g., call, packet, cell), the protocol decisions as the system operates and the physical behavior of the devices that make up the network. As with any simulation, various

aspects of the system may be ignored or aggregated to improve the computational speed of the simulation.

An alternative to simulation approaches is analytical modeling (a classic reference is Kleinrock 1976), which typically implicitly aggregates traffic units into flows whose characteristics are captured using statistical or probabilistic models. The advantage of analytical modeling is that the behavior of a network can be predicted by a system of equations more quickly computed than the operation of the network can be simulated. The disadvantage is in the aggregation and averaging of detail, effectively capturing the behavior of the network on average rather than accurately depicting a realization of performance over time. Most analytical models of communications systems employ individual and network queueing models. Information units (calls, packets, cells) are the customers in these queueing systems and communications devices (switches, links, etc.) are the servers.

Hybrid simulation/analytical modeling is a third and increasingly popular approach to communications network modeling (Sage and Sykes 1994). The tenets of this approach are to use simulation techniques in capturing key protocol decisions in traffic admission, routing, congestion control, and resource allocation, but to use analytical techniques for modeling the behavior of the traffic itself, thus avoiding the computational complexity incurred if each packet or cell were to be simulated individually. Hybrid simulation/analytical models of communications networks also have been described as "flow-based simulations," in which the paths that traffic flows take are simulated while the flows themselves are modeled analytically.

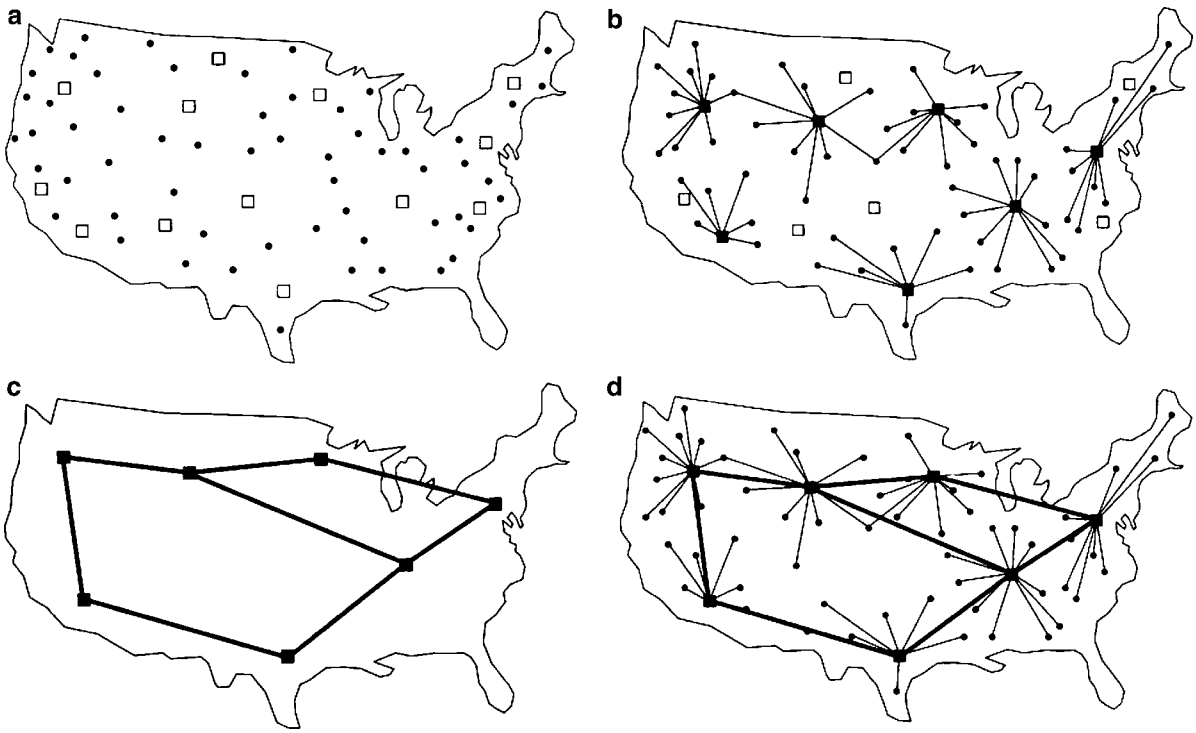
Selection of modeling approach depends strongly on the purpose to which the model is applied. For purposes of protocol or device design, where many replications of realizations of performance are required to observe the entity under a wide variety of operational conditions and circumstances, simulation approaches dominate. For analysis and design purposes, where often the intent is to assess the quality of the design or to compare alternative designs, models which provide average behavior over many potential realizations of performance are useful. Performance can be computed over multiple simulation replications, but analytical tools or simulation analytical hybrids which compute those aver-ages directly and more efficiently are dominant.

Analysis

Network analysis is the application of one or more network models to characterize a communications network. In many communications network design contexts, the central step of the design process is to characterize a design on a number of categories of measures: cost, topological properties, performance, behavior under failures (survivability) being the major ones. For each of these categories of measures, models which compute specific measures of interest can be applied, with the aggregate network analysis being produced in summary from the results of the individual models. Cost measures can include one-time (e.g., device purchase) and recurring costs (e.g., link leasing), often commensurate to the same units. Topological measures are generally technology independent characterizations of the network structure along gross lines (e.g., measures summarizing path availability and diversity, path lengths in number of links or hops from source to destination, etc.). Performance measures are generally technology dependent characterizations of the ability of the network to support the offered traffic and the quality of that support. Survivability measures are indications of what traffic can be supported under various failure scenarios and what the performance of the network will be in those scenarios.

Design

A common paradigm for design of communications networks is one in which the design process is broken down into two phases: *access area design* and *backbone design* (Boorstyn and Frank 1977). Access area design determines the number and location of backbone nodes and homes (i.e., provides a link from) each subscriber to a backbone node. Backbone design determines the interconnections among (links between) backbone nodes. The process is depicted in Fig. 1. Figure 1(a) represents the starting point, where the subscriber locations (black circles) and candidate backbone node locations (squares) are given.



Communications Networks, Fig. 1 (**a**) Network design – starting point. (**b**) Network design – access area design. (**c**) Network design – backbone design. (**d**) Network design – integrated solution

Figure 1(b) represents the completion of the access area design phase, where the black squares are the selected backbone nodes and the lines from the subscribers to the backbone nodes are the homings (implicit in the homings is the assumption that the communications links from each subscriber to its switch is of type and capacity to support the subscriber's offered traffic requirements). The output of the access area design phase is the input to the backbone design phase: the number and location of backbone nodes and the aggregate traffic requirements among the backbone nodes. The aggregate traffic is computed based on the homings. In the backbone phase, the interconnections among backbone nodes are designed to support the backbone traffic with adequate performance, to meet other constraints and typically to minimize cost. Figure 1(c) depicts a backbone design and Fig. 1(d) depicts the final overall solution.

It is notable that solution of the global design problem (including all access and backbone components) is precluded by the computational complexity of the design problem for all but a few special cases which will be ignored here. It also is notable that the structure of the decomposition of the global problem into access area and backbone design phases can lead to gross suboptimalities in the overall solution. To illustrate this assertion, consider a global design problem in which the total cost of the network includes three components:

- homing link costs, the sum of the costs of links homing subscribers to nodes, which can vary for each subscriber-node pair;
- backbone node costs, typically the cost associated with purchasing each node selected as part of the backbone, which typically is uniform over all candidate nodes; and
- backbone link costs, the sum of the costs of links between backbone nodes, which can vary for each subscriber-node pair.

Under fairly general assumptions, the following relationships hold as the number of nodes selected for the backbone increases:

- the access area homing costs tend to decrease (because the access links tend to decrease in length and hence cost);

- the node activation costs increase linearly (directly with the number of nodes selected); and
- the backbone link costs tend to increase (as the number of backbone nodes increases, more backbone links are required).

Thus, if the access area design phase optimizes solely on the basis of homing and node activation costs, it tends to select too many nodes. Two remedies to this pathology are commonly employed: (i) using some estimate of the backbone cost in the access area design problem; or (ii) iterating on the number of backbone nodes selected (i.e., fixing the number of activated nodes to given number, solving the access area and backbone problems in sequence for that number, and computing the total solution cost, but doing so over a wide range of numbers of nodes and selecting the best total cost solution obtained). Neither remedy guarantees global optimality, but both approaches can improve solution costs substantially.

Access area design problems often are formulated as 0-1 integer-programming problems (Fischer et al. 1993) that are strongly related to discrete location problems and/or facility location problems generally (Mirchandani and Francis 1990). In many cases, these integer programs are too large to be solved directly, so a variety of solution approaches are used; for example, linear-programming relaxation methods, Lagrangian relaxation methods, cutting plane and column generation methods, etc. (Ahuja et al. 1993). Alternatively, heuristic algorithms can be used to solve the access problem, and perhaps, more generally, clustering techniques can be used as a solution approach. The basic access area design problem can be stated as follows:

Given:	Subscriber-to-subscriber traffic requirements; Candidate node locations.
Minimize:	Sum of costs of homing each subscriber to a backbone node + Sum of node activation costs.
Over:	Node activations; Subscriber homings.
Subject to:	Node port constraints (limit on the number of subscribers than can be homed to a node); Node traffic constraints (limit on the total amount of subscriber traffic that can be homed to a node); Each subscriber must be homed to a node (occasionally subscribers must be homed to more than one node); (Optionally, a constraint fixing the number of node activations).

Backbone design problems can be formulated as 0-1 or general integer-programming problems (Gavish 1986), however, it is difficult if not impossible to accurately capture or predict network performance in that context. Moreover, many of the critical aspects of the backbone problem that can be captured in the integer-programming formulation (e.g., topological constraints) can also cause a combinatorial explosion in its solution time. Nonetheless, OR/ MS literature is replete with many IP backbone design formulations. In these cases, the solution techniques again typically rely on LP relaxation or Lagrangian relaxation approaches.

An alternative to the mathematical-programming approach to backbone design is commonly employed in interactive software based tools for solving design problems (Stiffler and Sykes 1990; Monma and Shallcross 1989). This iterative approach:

- starts the design process with an initial design;
- analyzes the design using a series of models assessing measures of various aspects of cost, topological properties, performance, and physical constraints on feasibility;
- makes an assessment as to whether the design is satisfactory, stopping if so; and if not
- improves one or more design deficiencies and returns to the analysis step.

This iterative paradigm for backbone design has been used extensively and successfully for design of communications networks with a wide range of architectures (e.g., voice, packet data, multiplexer, asynchronous transfer mode). It also can capture directly a broader set of design objectives and constraints than mathematical-programming methods, as well as be implemented in ways which more accurately predict network performance. All of this is possible through the embedding of the comprehensive network analysis at the core of the process, along with the decomposition of the optimization process into smaller steps aimed at initial design generation and design improvement. Unlike mathematical-programming approaches, which often can be solved to optimality or at least provide bounds from optimality for the solutions they produce, iterative approaches typically cannot guarantee nor bound optimality.

A typical backbone design problem can be stated as follows:

Given:	Backbone node-to-node traffic requirements; Node locations; Link availability and costing.
Minimize:	Sum of link costs.
Over:	Link Placement.

(*continued*)

Subject to:	Topological Constraints, such as – Node connectivity (lower bound on the number of node-disjoint paths available between each node pair); Diameter (upper bound on the minimum number of links a node pair must traverse in order to communicate); and Node port degree (upper bound/physical limit on the number of links that can be incident to each node). Performance Constraints, such as – Constraints on throughput, utilization, delay, blocking, etc., as appropriate for a given network architecture; and Constraints on achieving the QoS requirements of individual traffic demands or, on the achievement of service level agreements computed as a function of QoS of individual traffic demands.

Concluding Remarks

For an overview of telecommunications systems and their operations, see Bertsekas and Gallager (1987); Schwartz (1987); Tanenbaum (2010). For an introduction to network design problems and optimization approaches, see Cahn (1998) or Kershenbaum (1993). For a classical introduction to data communications networking, see Kleinrock (1976), that contains extensive basic modeling and optimization discussions. Also see Pattavina (1998); Ross (1995) or Woodward (1994) for modeling work, and Schmidt and Minoli (1998) or Partridge (1994) for technologies of communications networking. Of a general interest are the books by Ball et al. (1995); León-Garcia and Widjaja (2004), Koster and Muñoz (2010).

Community OR

Rebecca Herron
University of Lincoln, Lincoln, UK

Introduction

Community OR is perhaps best understood as a subdiscipline of OR that focuses on communities

as alternative clients for (and users of) OR and related activity.

One defining characteristic of this has been the explicit consideration of two key questions:

1. How can communities benefit from OR approaches, i.e., what can OR offer?
2. Who are the clients/beneficiaries?

These questions have also prompted the subsidiary methodological question: "How should OR practice and theory change in light of this?" These are non-trivial questions which can radically change the view that OR (or management science) as a discipline, only serves traditional managerial interests.

Community OR analysts, or facilitators, as they more frequently refer to themselves, aim to develop engagements within community groups, not-for-profit organizations and/or local multi-agency partnerships so as to provide them analytical support that build capacity and resilience within these communities. Such engagements are frequently related to improving awareness of options and choices available to individuals and groups, and the likely outcomes of various courses of action, e.g. planning and decision-making. They also often involve exploring issues that directly affect people's lives and the strengthening of discourse, dialogue, and local/global agency in relation to these (dialogue, critical awareness, and encouraging self-organization).

The idea of a wider client group for OR and an interdisciplinary approach is not a new idea or pursuit – indeed it has its origins deep in OR's early history – nor is it a concept that has developed identically with different Community OR contributors since. Despite these important differences, common themes have emerged between researchers and practitioners alike that unite the endeavor under the term Community OR.

The practice of Community OR has been organized in many different ways. Much work has been carried out by individuals acting in a voluntary capacity within their own communities, often as a natural extension/application of their personal OR background. Other work has been generated through formalized units and research centers. Both provide contrasting experiences and insights, with different roles and practical and ethical considerations for the Operational Researcher concerned.

Much debate has taken place within the Community OR community about what approaches and methods are appropriate. Given the broad nature of community issues, problems, and choices to be considered, it should not be surprising to find a wide variety of OR/Management Science tools being put to use. While some authors have reported the importance of developing the capacity for quantitative analysis within community groups, a large proportion of the Community OR work has involved softer OR methods that help structure issues: Problem Structuring Methods, understanding inter-related issues and exploring choices; Strategic Choice Approach and decision making/planning, and helping communities reflect on current and future situations and to organize themselves in light of these reflections; and workshops, organizational learning, or creative methods.

Links to systems research are a particularly strong feature of many Community OR studies, but this is not a universal precondition for Community OR. In particular, ideas of socio-technical systems, viable systems modeling (cybernetics), soft systems methodology, boundary critique, and critical systems have played key roles in the development of Community OR.

There is a strong U.K. tradition of Community OR, encouraged by the U.K. OR Society, but global perspectives have been just as important in shaping the development of the subject, including work in Venezuela, Columbia, Ghana, Kenya, New Zealand and Mexico. Many links can also be found in the writings of Community OR researchers and practitioners with Social Justice, Community Development, and Participatory Methods in research and evaluation.

The emphasis of Community OR is often on trying to build meaningful engagements with groups of people in the community and creating increased capacity within the groups. Community OR, therefore, pays great attention to issues of engagement, facilitation, group work, ethical interactions, and sustainability. These are not issues unique to Community OR, but they are in sharp focus in this field.

Another consideration is the question of motivating factors for involvement in Community OR. One factor has already been introduced – a volunteer applying OR skills within his/her own personal communities. Others, however, are motivated to work within new communities, usually ones where there is felt to be some kind of social

inequality or collective issue to address. Community OR researchers tend not to see themselves as the expert in these situations; rather, authors write about bringing another viewpoint/set of skills to a community who are already expert in their own situations. As such, there are some very interesting issues about knowledge and power to unpick in Community OR, and political, religious or ethical beliefs to reflect upon. These have often shaped the way Community OR has been developed by individuals or groups of researchers; seen particularly in the theoretical foundations of the approaches developed and, indeed, in the choices of community issues that are addressed in practice.

History

The desire that OR should be put to use for societal aims is not a new one. As early as the 1930s, Patrick Blackett (often referred to as "the father of OR"), John Bernal and others were calling for science to be put to use for wider social benefit (Blackett 1935; Bernal 1939). In the post-war years in the U.K., OR departments were set up across governmental and nationalized industries.

By the 1970s, some of the initial social objectives of OR seemed to have been somewhat forgotten. There were, however, several key figures who campaigned for redressing this balance and restoring the interdisciplinary, action-focused aspects of the OR enterprise.

In the U.S., Russell Ackoff and colleagues at the University of Philadelphia pioneered work with local residents. In the title of his 1970 paper, "*A black ghetto's research on a university,*" Ackoff made an important distinction that was picked up later by Community OR researchers (Ackoff 1970). It was not the University's research on the ghetto, but the research participants' research on a University. Ackoff continued developing his program and calling for a systems approach to societal problems (Ackoff 1974). Other researchers of the same era famously also called for new perspectives (Churchman 1979) and the recognition and appropriate handling of wicked, i.e. messy & complex, social problems (Rittel and Webber 1973).

In the U.K. there were also calls within the OR community to turn attention again to the social application of OR. The Institute of OR had been established in 1963, later to become attached to the Tavistock Institute of Human Relations, both with an interest in understanding social and public affairs and to work to improve planning processes; Friend and Hickling (2005) discuss some of the long term legacies from this work. Other researchers continued to argue strongly that OR should be used to benefit society and lead to improved well-being (Cook 1973; Thunhurst 1973).

By the 1980s, the movement pressing for OR to move beyond its now well-established scope and client-base to encompass community beneficiaries had gathered considerable momentum. In 1985, under the presidency of Jonathon Rosenhead, the U.K. OR Society wanted to challenge perceived views about who the clients of OR were and to find a significant social role for OR:

> The idea behind the Unit is that is should give extensive experience of how formal problem-structuring approaches can assist non-hierarchical organizations, disposing of few resources, but attempting to represent the interests of their members … we see the unit as extending the range of OR's potential clients … we shall be expanding the domain of rational argument, tackling a new and exciting range of unstructured problems, and contributing to making our society a better one to live in. (Rosenhead 1987, quoted in Parry and Mingers 1991).

The OR Society set up the original Community Operational Research Unit at Barnsley College, Yorkshire (Ritchie et al. 1994, discuss case studies from this period). A new Community OR Network was created the following year by the Society, and a Centre for Community OR was also set up at Hull University, building on the work of Jackson and Keys (Jackson 1987, gives an overview of these 3 initiatives).

Other work in this era also fed into the discussion of the newly emerging concept of Community OR. This included the work of Jones and Eden (1981) and parallel, but related systemic researches such as Ulrich's Critical Heuristics (Ulrich 1983).

By the 1990s, sufficient examples of Community OR were appearing in the literature (Thunhurst 1987; Mar Molinero 1993; Taket and White 1994; Ritchie et al. 1994, and others) to enable the community to reflect on Community OR as an entity and approach in its own right (Jackson 1987;

Mar Molinero 1992; Midgley and Ochoa-Arias 1999; Ochoa-Arias 1994; Parry and Mingers 1991; White and Taket 1993; Wong and Mingers 1994). These papers demonstrate a breadth of OR activity drawn from a range of OR techniques (hard and soft OR methods), drawing on different intellectual traditions (e.g. different forms of systems modeling or political theory), but sharing common aims and interests, such as participation, social justice, and community empowerment.

The following decade saw a period of consolidation for Community OR with the publication of three core OR texts that in different ways document and shape the record of Community OR theory and practice. *Planning under Pressure* (Friend and Hickling 2005) shares the authors' and 21 other contributors' experiences of using the Strategic Choice Approach. *Rational Analysis for a Problematic World Revisited* (Rosenhead and Mingers 2001) brings together the work of several authors associated with the development of Community OR and illustrates their approaches to Problem Structuring in a range of decision contexts. *Community Operational Research, OR and Systems Thinking for Community Development* (Midgley and Ochoa-Arias 2004) focuses specifically on Community OR and brings together several key papers as well as setting the scene for some future development, e.g. in environmental OR (Midgley and Reynolds 2004).

At the end of the 1990's the Community Operational Research Unit (CORU) moved to the University of Lincolnshire and Humberside (soon to become the University of Lincoln). During the subsequent decade researchers from CORU developed citizen learning networks and participatory evaluations - exploring issues for social justice, well-being, community self-organization and social action research (Herron (2006) and Herron & Mendiwelso Bendek (2007) introduce examples in two Special Editions of *OR Insight*, vol. 19 issue 2 and vol. 20 issue 2).

The expansion possibilities of the scope of Community OR, in terms of geographical spread of activity and the issues under consideration, are extensive. There are important global issues that call for the continued and renewed attention: poverty alleviation, social justice, community well-being, environmental responsibility, fair trade, community organization and resilience, as well as local, national, and international calls for greater community participation in local decision making and planning.

Emerging Themes for Community OR

There has been much interesting debate about the variety within Community OR that reflects the range of different professional contexts of researchers and practitioners and different contributing areas of expertise within OR/Systems/Action Research. Accounts of different engagements provide a rich source of case studies of using different OR methods and approaches with different communities (Ritchie et al. 1994; Midgley and Ochoa-Arias 2004).

The nature of the community situations encountered has also clearly had a large impact in what has been done under the banner of Community OR, and creating engagements that are meaningful and have value for those taking part may mean the selection, and modification, customization of different OR methods. It does not seem very practicable to attempt to define Community OR by the choice of methods or tools used, although a familiarity with Soft OR/Problem Structuring Methods is useful for understanding much of the existing literature or to develop skills likely to be of use within a number of community contexts (Rosenhead and Mingers 2001; Friend and Hickling 2005).

Community OR could also be defined as the resulting body of work of a community of practice (the socially constructed definition). But, to define the subject this way provides little insight for the initial enquirer, as it requires a familiarity and further knowledge of the outputs of the community of practice concerned.

Importantly, all this does not mean that it is not possible to identify Community OR themes that have emerged over the past decades. Rather than discussing a single unified methodology for Community OR, it seems productive to describe similarities of approach that transcend discussion of which methods have been developed or applied, and focuses instead on some of the general characteristics and values emergent in Community OR. An introduction would not be complete without at least starting to draw out a few of these themes that recur in many, if not necessarily all, Community OR activities. Alongside the other elements presented above, these will help to provide a fuller introduction to the subject.

Engaging with Communities

Interventions and Interactions with Local Groups

Community OR is generally understood as a form of action research. In this sense, it returns to some of the original intentions and conceptions of OR where interdisciplinary teams work together to support solutions to problematic situations and/or work with problem-owners to explore improvements in how they operate (Jackson 1987). In Community OR this usually always involves some form of engagement with community groups, not-for-profit organizations, or multi-agency partnerships working toward a social/community aim.

To work in meaningful ways with community groups, regardless of the type of method used, requires the establishment of good working relations with the relevant parties and the identification of key stakeholders, particularly those made vulnerable or marginalized by the current situation. Many Community OR approaches start with some form of stakeholder analysis and the scoping of different perspectives and points of view, along with other forms of collective sense-making or mess-structuring activity (Rittel and Webber 1973; Rosenhead and Mingers 2001).

Encouraging the full participation of all the stakeholders identified can be very challenging and requires the building of trust and the careful consideration of issues of access and appropriate delivery. Flexibility and creativity of approach is likely to be valuable – and many Community OR engagements include the need to adapt methods and delivery styles for the particular group concerned. Thus, in addition to content discussions, much Community OR literature also explores these softer issues of group facilitation, interacting with communities and sense-making activities that handle multiple perspectives and conflict of opinion and objective.

Analytical Process Support

A common motivation for undertaking Community OR work is the desire to support a community or communities. Often this support is in terms of providing some structured intervention such as workshop, training, or participant research that helps strengthen the groups' ability to think through and analyze a situation, identify or create new resources, build robust arguments and narratives (sometimes even models), or create improved dialogue and awareness of a situation amongst stakeholders.

Much of the work done in this respect has links to, and has implications for, planning and decision making, awareness of options, and choice of action. Community OR interventions are very often workshop-based or use other forms of community-based learning. Community OR facilitators usually provide process-facilitation and spaces for reflection and dialogue: the aim being to support increased capacity within communities to understand and be more resilient to changes in their external environment.

Emphasizing once again that Community OR is not defined by the application of any particular method, approaches applied in community contexts have included:

- Cognitive Mapping
- Community Visioning
- Critical Systems Heuristics (CSH)
- Drama Theory
- Strategic Choice Approach (SCA)
- Strategic Options Development and Analysis (SODA)
- Soft Systems Methodology (SSM)
- Viable Systems Modeling (VSM)

The exact form of analytical support provided by each Community OR researcher/practitioner will, of course, be context dependent—specific to the exact needs of a particular group and the issue concerned at a certain time—and it will also be bounded by the choice of method or approach chosen. Certain themes, however, emerge in terms of what Community OR may be said to support, including:

- Processes and structures (exploring, building, and rethinking)
- Dialogue and supporting groups to build stronger arguments (logical argumentation)
- Information and enabling groups to make more informed choices (handling information)
- Reasoning about local issues, including exploring links to global issues
- Negotiation and creating rules of engagement
- Engaging relevant others; exploring and extending stakeholders
- Sweeping-in new elements to the model such as individuals, issues, values, ethics

- Critical awareness of learning processes, political impact on decision making, changing environments, and the possible impacts and side effects of choices and actions

Reasons for doing this include:

- Organizational learning – facilitating community-learning processes
- Knowledge transfer – co-creating knowledge and analysis
- Addressing inequalities – providing access to analytical resources
- Increasing choice and resilience for communities - managing uncertainty
- Increasing community knowledge and confidence to act in changing environments

Emancipation and Social Justice

The U.K. OR Society has described OR as "The Science of Better." For Community OR, this highlights the key issues of improvement, i.e., improvement for whom, and how?

Community OR, as much as any subdiscipline of OR, has highlighted the complexity of working for improvement in contexts where there are multiple goals and perspectives. It has provided many examples and ways of proceeding in situations where there are multiple world-views, value systems, and objectives interacting to build up a complex collective logic. In this, Community OR has often been seen as working in the way suggested by Rittel and Webber (1973): continually solving and resolving tricky, messy, and complex situations and providing ongoing support for situations that continue to evolve.

Community OR practice seems to generate several key themes related to making the notion of a Science of Better meaningful for work with communities:

- Ethical dimensions: considering the likely impact on multiple stakeholders
- Locus of control: who has ownership of the goals? processes? outcomes?
- Surfacing issues: creating models participants find authentic and provide insight
- Increasing understanding and fairer dialogue
- Collective improvement: critical reflection from different perspectives
- Consideration of likely side-effects and issues of robustness and sustainability
- Increasing individual and collective control and agency
- Supporting vulnerable people, readdressing inequalities, and rethinking the client
- Exit strategies: building community capacity for learning, analysis, and reflection

Different Community OR facilitators have approached many of these issues in different styles and by using different methodologies, especially SSM, VSM, CSH, SCA, the choice of which depends very much on their experiences, cultural and intellectual traditions, and personal beliefs. However some common emergent themes are worth noting:

- Inclusion of vulnerable groups in decision making and new forms of participation
- Empowerment of communities, emancipation, and addressing social inequality
- Democratic decision making: dialogue, interaction, and community learning
- Handling plurality: multiple realities and objectives
- Self-organization and local control: strengthening civil society
- Feedback, communication, and the interlinking of issues
- Linking local issues to global concerns

Community OR also continues a long tradition in OR of valuing the co-creation of knowledge. The Community OR facilitator will usually have certain process knowledge to contribute (e.g., problem structuring, mess-handling, restructuring, drama theory, game theory), but other participants in the group will have been involved because of their local context knowledge and experience, or other specific knowledge bases. Community OR practice usually explicitly values these other knowledge forms and encourages groups to take ownership of the process of exploration, and idea and solution generation. This is also consistent with the emancipatory interests of many researchers and practitioners, often underpinned by distinct philosophical positions including those shaped by the works of Habermas and Foucault.

Core to any discussion about any Science of Better must also be a critical reflection of who has the power to determine decisions – and the directions chosen for improvement. More critically still, those who do not have any say in these decisions are excluded from the dialogue for any number of reasons, or only able to have a very small voice in the decision-making

processes that affect their lives? Thus, while much of OR strives to remain firmly outside political discourse, Community OR practitioners work in situations where strengthening collective critical awareness of the rules of engagement, and the fairness of these, is seen as an important aspect of the work of the analyst.

Complementarity Applications

Steven A. Gabriel
University of Maryland, College Park, MD, USA

Introduction

This article emphasizes complementarity applications found in the infrastructure industries. A number of

such industries in the U.S. and overseas have been restructured with the goals of making them more competitive and transparent. Examples of these industries in the U.S. include: energy (production, transmission, and distribution), air transportation, and telecommunications. The business model for these industries dramatically changed with a greater emphasis on the microeconomic, game theory effects of individual market players seeking to maximize their own profits or utilities rather than just having a central facility optimizing a stream of regulated profits. Along with these changes came the rise of data-gathering culminating in the present-day Internet which in some cases is nearly real-time. These two sources of change (no doubt with other contributing factors) have led to the rise of complementarity models in the operations research community.

This broad class of mathematical programs includes many optimization problems (via their Karush-Kuhn-Tucker conditions), n-person Nash games, solving nonlinear equations, and many other interesting problems in a variety of engineering and economic settings (Cottle et al. 1992; Facchinei and Pang 2003). A related class of problems, variational inequalities, also benefitted from these contributing factors (see Facchinei and Pang (2003) for a discussion of the relationship between these two problem classes). Collectively, complementarity or variational inequality problems are sometimes called equilibrium problems in that they both seek to arrive at a solution so that the system under study is balanced or has no incentive to change.

One advantage of complementarity problems over traditional optimization is the ability to simultaneously manipulate both primal variables as well as shadow prices for resources, usually expressed as Lagrange multipliers for constraints. This ability, coupled with the complicated picture of restructured industries which often are composed of both regulated and deregulated portions, can usually be approached from the complementarity perspective resulting in richer, more realistic models.

As complementarity models have become more mainstream like linear programs that preceded them, other more complicated and potentially more realistic problem classes have been studied. These extensions of complementarity problems include: mathematical programs with equilibrium constraints (MPECs) which are optimization problems having two or more levels with the bottom ones potentially complementarity problems (Luo et al. 1996), quasi-variational inqualities corresponding to Generalized Nash games (Harker 1991), (Facchinei and Pang 2003), and equilibrium problems with equilibrium constraints (EPECs), problems with two or more levels with an equilibrium at multiple levels, which are some of the hardest problems to solve (Facchinei and Pang 2003).

There are several forms for the complementarity problem, the most common of which is the mixed one abbreviated as MCP (mixed complementarity problem). Note that the term mixed refers to the presence of both equations and inequalities. Having a function $F : R^n \to R^n$, MCP(F) is to find vectors $x \in R^{n_1}, y \in R^{n_2}$ such that the following conditions hold:

$$F_x(x, y) \geq 0, x \geq 0, x^T F_x(x, y) = 0 \tag{1a}$$

$$F_y(x, y) = 0, y \quad \text{free} \tag{1b}$$

where the notation $F_x(x, y), F_y(x, y)$ refers, respectively, to those components of F that match up with the vectors x and y. Equivalently, the first set of conditions (1a) can be stated as $F_i(x, y) \geq 0, x_i \geq 0, x_i \cdot F_i(x, y) = 0$, for $i = 1, \ldots, n$ with the last set referred to as "complementary conditions" (either x_i or $F_i(x, y)$ or both must equal zero). A more compact representation of this first set of conditions is often stated as $0 \leq F_x(x, y) \perp x \geq 0$ with the perpendicular operator $\perp$ denoting the inner product of two vectors equal to zero. The statement of MCP(F) is deceptively simple– just a set of inequalities and complementarity conditions, as well as equations that must simultaneously be satisfied. This very general form, however, includes many problems in optimization, game theory, as well as a host of other areas some of which are described below; additional examples and/or related theory can be found in Cottle et al. (1992), Harker and Pang (1990), Harker (1993), Ferris and Pang (1997), Ferris et al. (2001), Facchinei and Pang (2003), Gabriel et al. (2013).

Discussion

To demonstrate the generality and flexibility of (1), a few representative examples are next shown.

A Simple Complementarity Example

Let $n_1 = 2$, $n_2 = 1$ and $F : R^3 \to R^3$ be defined as:

$$F(x_1, x_2, y_1) = \begin{pmatrix} F_1(x_1, x_2, y_1) \\ F_2(x_1, x_2, y_1) \\ F_3(x_1, x_2, y_1) \end{pmatrix} = \begin{pmatrix} x_1 - x_2 \\ x_1 + y_1 \\ x_1 - y_1 + 1 \end{pmatrix}. \quad (2)$$

The corresponding MCP is to find x_1, x_2, y_1 that simultaneously solve the following conditions:

$$\begin{aligned} F_1(x_1, x_2, y_1) = x_1 - x_2 \geq 0, \\ x_1 \geq 0, (x_1 - x_2) \cdot x_1 = 0; \\ F_2(x_1, x_2, y_1) = x_1 + y_1 \geq 0, \\ x_2 \geq 0, (x_1 + y_1) \cdot x_2 = 0; \\ F_3(x_1, x_2, y_1) = x_1 - y_1 + 1 = 0, \\ y_1 \text{ free}. \end{aligned} \quad (3)$$

The first question with any mathematical programming problem is to try to find the solution set. For small problems like (3), the set of solutions can often be determined by enumeration of several cases and then by some algebra. Doing so additionally provides some insight into the structure of complementarity problems.

The first step is to eliminate the free variable y_1 by using the equation $x_1 - y_1 + 1 = 0 \Leftrightarrow y_1 = x_1 + 1$ and then making the substitution in the remaining two sets of conditions to obtain an equivalent set of conditions:

$$\begin{array}{lll} x_1 - x_2 \geq 0, & x_1 \geq 0, & (x_1 - x_2) \cdot x_1 = 0, \\ 2x_1 + 1 \geq 0, & x_2 \geq 0, & (2x_1 + 1) \cdot x_2 = 0. \end{array} \quad (4)$$

Next, the following four cases can be analyzed to determine the solution set:

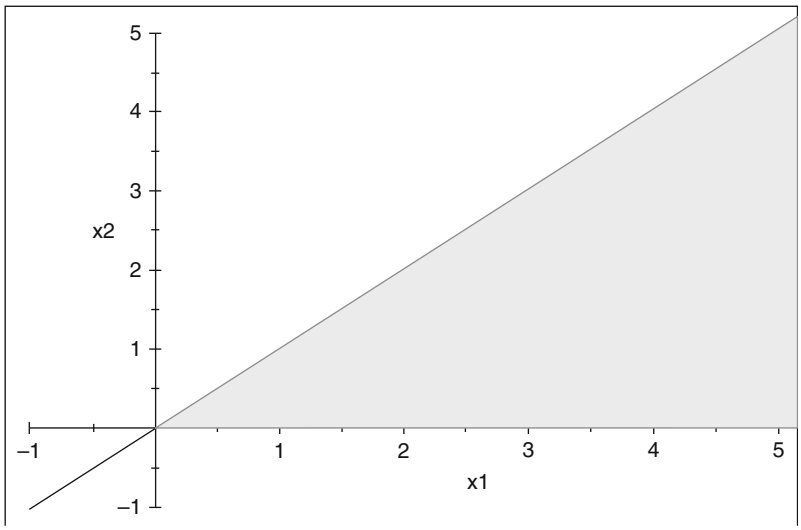
1. $x_1 > 0, x_2 > 0$
2. $x_1 = 0, x_2 > 0$
3. $x_1 > 0, x_2 = 0$
4. $x_1 = 0, x_2 = 0$

Using the complementary conditions, the first case implies that

$$(x_1 - x_2) = 0, (2x_1 + 1) = 0,$$

or that $x_1 = x_2 = -\frac{1}{2}$, which is not possible since both these variables must be positive. Case 2 also is not possible since by complementarity it would imply that $x_1 = -\frac{1}{2} \not\geq 0$. Analyzing Case 3 shows that by complementarity, $x_1 - x_2 = 0$ or that both values must be the same. This is not possible under this case as $x_1 > 0, x_2 = 0$. Lastly, if both values are equal to zero, then all the inequalities as well as complementarity conditions hold. Thus, $(x_1, x_2, y_1) = (0, 0, 1)$ is the unique solution to this linear MCP. This simple, three-variable linear MCP can also be viewed from a geometric point of view in $x_1 - x_2$ space as shown in Fig. 1. The conditions: $x_1 - x_2 \geq 0, x_1 \geq 0, x_2 \geq 0$ represent a polyhedron a sample of which is shown by the shaded region. The condition $2x_1 + 1 \geq 0 \Leftrightarrow x_1 \geq -\frac{1}{2}$ is superfluous given that x_1 must be nonnegative. The first complementarity condition $(x_1 - x_2) \cdot x_1 = 0$ can be interpreted as: if $x_1 > 0$ then the potential solution must be on the line $x_1 = x_2$ which in turn would make $x_2 > 0$. The second complementarity condition would then force $x_1 = -\frac{1}{2}$ which is not in the shaded region. Thus, the only other choice it to have $x_1 = 0$ (satisfying the first complementarity condition) but forcing $x_2 = 0$ by the second one in (4). Hence, the only point in the shaded region that satisfies all the six conditions of (4) is the origin.

While this simple example had a unique solution, in general this will not be the case for MCPs. Indeed, there can be no solutions, one solution, any finite number of solutions or an infinite number since MCPs generalize solving nonlinear (or linear) equations, optimization problems (one or more), or combinations thereof. To see that (1) includes solving equations, consider the case when there are no inequalities, i.e., just $F_y(x, y) = 0, y$ free. In the next sections, the connection with optimization problems and extensions is explored.



Complementarity Applications, Fig. 1 Geometric Depiction of Simple Example

Connection between Optimization and Complementarity Problems

Consider the following standard (primal) linear program and its corresponding dual problem:

$$\min_{x} \boldsymbol{c}^{\boldsymbol{T}}\boldsymbol{x} \tag{5a}$$

$$s.t.\ \boldsymbol{A}\boldsymbol{x} \geq \boldsymbol{b} \tag{5b}$$

$$\boldsymbol{x} \geq 0 \tag{5c}$$

$$\max_{y} \boldsymbol{b}^{\boldsymbol{T}}\boldsymbol{y} \tag{6a}$$

$$s.t.\ \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y} \leq \boldsymbol{c} \tag{6b}$$

$$\boldsymbol{y} \geq 0 \tag{6c}$$

where $\boldsymbol{A}$ is a real-valued $m \times n$ matrix, $\boldsymbol{c} \in R^n, \boldsymbol{b} \in R^m$. The m primal constraints $\boldsymbol{A}\boldsymbol{x} \geq \boldsymbol{b}$ are associated with the dual vector $\boldsymbol{y} \in R^m$ and likewise the n dual constraints match up with the primal variables $\boldsymbol{x} \in R^n$. The Complementarity Slackness Theorem (Luenberger 1984) states that if:

1. x is feasible to the primal problem (5)
2. y is feasible to the dual problem (6)

then a necessary and sufficient condition for (x, y) to be optimal solutions to their respective problems is that complementary slackness is satisfied, namely: $(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})_j \cdot y_j = 0, j = 1, \ldots, m$ and $\left(\boldsymbol{c} - \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y}\right)_i \cdot x_i = 0, i = 1, \ldots, n.$

However, the feasibility and complementary conditions amount to:

1. $\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} \geq 0, \boldsymbol{x} \geq 0$
2. $\boldsymbol{c} - \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y} \geq 0, \boldsymbol{y} \geq 0$
3. $(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})_j \cdot y_j = 0, j = 1, \ldots, m$ and $\left(\boldsymbol{c} - \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y}\right)_i \cdot x_i = 0, \quad i = 1, \ldots, n.$

After realizing that complementarity slackness can be re-expressed as $(\boldsymbol{A}\boldsymbol{x} - \boldsymbol{b})^T \boldsymbol{y} = 0$ and $\left(\boldsymbol{c} - \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y}\right)^T \boldsymbol{x} = 0$ given the nonnegativity of the quantities involved, these three sets of optimality conditions can be expressed succinctly as the linear complementarity problem with only inequalities (i.e., "pure complementarity problem") with $F : R^{n+m} \rightarrow R^{n+m}$ given as follows:

$$F(\boldsymbol{x}, \boldsymbol{y}) = \begin{pmatrix} \boldsymbol{c} - \boldsymbol{A}^{\boldsymbol{T}}\boldsymbol{y} \\ \boldsymbol{A}\boldsymbol{x} - \boldsymbol{b} \end{pmatrix} = \begin{pmatrix} 0 & -\boldsymbol{A}^{\boldsymbol{T}} \\ \boldsymbol{A} & 0 \end{pmatrix} \begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{y} \end{pmatrix} + \begin{pmatrix} \boldsymbol{c} \\ -\boldsymbol{b} \end{pmatrix}$$

Moreover, if the original primal LP had equalities, via a similar line of reasoning, the result would be a mixed (as opposed to pure) complementarity problem. This shows that every linear program is an instance of an MCP. A key distinction to be made here between optimization and complementarity problems is that the latter's formulation involves both primal and dual variables whereas the former's formulation is only in terms of primal (or just dual) variables. As will be shown in some of the examples below, the complementarity approach can lead to richer models that manipulate the dual variables (i.e., prices) while

also considering the primal (usually physical) variables in many infrastructure applications. First, the next section shows that any nonlinear program via its Karush-Kuhn-Tucker (KKT) conditions is also an instance of an MCP generalizing the results for linear programs.

Consider a standard nonlinear program as follows:

$$\min_{\boldsymbol{x}} f(\boldsymbol{x}) \tag{7a}$$

$$s.t.\ g_i(\boldsymbol{x}) \leq 0, i = 1, \ldots, m \tag{7b}$$

$$h_j(\boldsymbol{x}) = 0, j = 1, \ldots, p \tag{7c}$$

where $f, g_i(\boldsymbol{x}), h_j(\boldsymbol{x}) : R^n \rightarrow R$ are respectively, the objective function and the constraint functions. The KKT conditions (Bazaraa et al. 1993) are to find $\boldsymbol{x} \in R^n$, Lagrange multipliers $\boldsymbol{\lambda} \in R^m$ (for the inequality constraints) and $\boldsymbol{\gamma} \in R^p$ (for the equality constraints) such that the following conditions hold:

$$\nabla f(\boldsymbol{x}) + \sum_{i=1}^{m} \lambda_i \cdot \nabla g_i(\boldsymbol{x}) + \sum_{j=1}^{p} \gamma_j \cdot \nabla h_j(\boldsymbol{x}) = 0, \boldsymbol{x} \text{ free} \tag{8a}$$

$$-g_i(\boldsymbol{x}) \geq 0, \lambda_i \geq 0, g_i(\boldsymbol{x}) \cdot \lambda_i = 0, i = 1, \ldots, m \tag{8b}$$

$$h_j(\boldsymbol{x}) = 0, \gamma_j \text{ free}, j = 1, \ldots, p. \tag{8c}$$

Clearly the KKT conditions are just a set of equations with corresponding free variables and inequalities with associated nonnegative variables and complementarity conditions. As such, the KKT conditions are also an instance of an MCP (Gabriel 2008; Gabriel et al. (2013)) with $F : R^{n+m+p} \rightarrow R^{n+m+p}$ given as:

$$F\begin{pmatrix} \boldsymbol{x} \\ \boldsymbol{\lambda} \\ \boldsymbol{\gamma} \end{pmatrix} = \begin{pmatrix} \nabla f(x) + \sum_{i=1}^{m} \lambda_i \cdot \nabla g_i(\boldsymbol{x}) + \sum_{j=1}^{p} \gamma_j \cdot \nabla h_j(\boldsymbol{x}) \\ -g_i(\boldsymbol{x}), i = 1, \ldots, m \\ h_j(\boldsymbol{x}), j = 1, \ldots, p \end{pmatrix}$$

with the first and third sets of constraints being equations and the second set inequalities (≥ 0). Optimization problems that do not have valid KKT conditions are not directly special cases of MCPs.

Since KKT conditions for integer programs (IPs) are not generally valid, there is not a direct connection between MCPs and IPs. However, there is an indirect association between these two classes of problems. In particular, consider the following mixed, linear complementarity problem as an example. This problem in general form, is to find vectors $\boldsymbol{x}, \boldsymbol{y}$ such that:

$$0 \leq \boldsymbol{q}_1 + (\boldsymbol{M}_{11}\boldsymbol{x} + \boldsymbol{M}_{12}\boldsymbol{y}) \perp \boldsymbol{x} \geq 0 \tag{9a}$$

$$0 = \boldsymbol{q}_2 + (\boldsymbol{M}_{21}\boldsymbol{x} + \boldsymbol{M}_{22}\boldsymbol{y}), \boldsymbol{y} \text{ free} \tag{9b}$$

where the matrices $\boldsymbol{M}_{11}, \boldsymbol{M}_{12}, \boldsymbol{M}_{21}, \boldsymbol{M}_{22}$ are of order $r_1 \times n_1, r_1 \times n_2, r_2 \times n_1, r_2 \times n_2$, respectively, coinciding with $\boldsymbol{x} \in R^{n_1}, \boldsymbol{y} \in R^{n_2}$. Also, the constant vectors $\boldsymbol{q}_1, \boldsymbol{q}_2$ are of size r_1 and r_2, respectively. This system can be re-expressed as the following set of polyhedral constraints with additional binary variables $b \in \{0, 1\}^{r_1}$:

$$0 \leq \boldsymbol{q}_1 + (\boldsymbol{M}_{11}\boldsymbol{x} + \boldsymbol{M}_{12}\boldsymbol{y}) \leq K\boldsymbol{b} \tag{10a}$$

$$0 \leq \boldsymbol{x} \leq K(1 - \boldsymbol{b}) \tag{10b}$$

$$0 = \boldsymbol{q}_2 + (\boldsymbol{M}_{21}\boldsymbol{x} + \boldsymbol{M}_{22}\boldsymbol{y}), \boldsymbol{y} \text{ free} \tag{10c}$$

with K a suitably chosen positive constant (could vary for each of the r_1 constraints). To see why this works it suffices to realize that complementarity conditions are either-or type restrictions. Either one term equals zero or the other does (or both). This disjunction is equivalently expressed in (10) via the binary variables $\boldsymbol{b}$ and the constant K (Fortuny-Amat and McCarl 1981). In principle then, one could replace a linear complementarity problem's conditions by a set of linear conditions with binary variables as shown above. The problem arises in determining an appropriate constant K. Too small a value will unnecessarily restrict the problem and result in (3) being infeasible. Too large a value may result in numerical ill-conditioning that could make the problem hard to solve. See Gabriel and Leuthold (2010) for an example of disjunctive constraints and some guidance on computing the constant K relative to energy modeling in the context of a two-level optimization problem of which the bottom level is an MCP.

Nash-Cournot Production Game

The next example concerns a classical Nash-Cournot production game (Shy 1995) with two producers. Such a model is applicable in a variety of areas such as energy, manufacturing, as well as many others. Also, the model can easily be extended to more than two producers with additional producer-level constraints included or marketing-clearing conditions as depicted in the network example shown below. The particular instance of this duopoly is from Gabriel (2008); Gabriel et al. (2013).

Unlike a perfectly competitive production environment, in the current setting each producer can affect market prices by adjusting its own production level. This market power feature is encoded in the objective function of each of the players $i = 1, 2$. More specifically, each player must decide on their own production level $q_i, i = 1, 2$ given that they have knowledge of the (inverse) market demand function $p(q_1 + q_2) = \alpha - \beta(q_1 + q_2)$ where $\alpha, \beta > 0$. This function gives the price of the produced good but takes into account both producers' production levels. If only one player decided to increase production, the total price for the market would go down (since $\beta > 0$) but that producer's profit might go up due to a more favorable market share. If both producers are considering production levels under these circumstances, it is not immediately clear what might be an equilibrium solution (i.e., one in which neither player has an incentive to deviate). The Nash concept is to have each player optimally solve for their production level which maximizes net profit (or other suitable function), given that the other player's level is fixed at its own optimal level.

Assuming for ease of presentation that both players have a linear production cost function given by $c_i(q_i) = \delta_i q_i$ for $\delta_i > 0, i = 1, 2$, then the resulting profit-maximization problem that player i solves is:

$$\max_{q_i} p(q_1 + q_2) \cdot q_i - c_i(q_i) \tag{11a}$$

$$s.t.\ q_i \geq 0 \tag{11b}$$

or

$$\max_{q_i} (\alpha - \beta(q_1 + q_2)) \cdot q_i - \delta_i q_i \tag{12a}$$

$$s.t.\ q_i \geq 0 \tag{12b}$$

The KKT conditions are both necessary and sufficient for this problem. Necessity follows by the linearity of the constraints and sufficiency is because the objective function is a (strictly) concave function of q_i (in addition to the linear constraints). To see the concavity result, note that the second derivative of the objective function relative to q_i is just $-2\beta < 0$ (Bazaraa et al. 1993). The resulting KKT conditions for each player taken together form a Nash-Cournot equilibrium and are given as:

$$0 \leq 2\beta q_1 + \beta q_2 - \alpha + \delta_1, q_1 \geq 0,$$

$$(2\beta q_1 + \beta q_2 - \alpha + \delta_1) \cdot q_1 = 0 \text{ (producer 1)} \tag{13a}$$

$$0 \leq \beta q_1 + 2\beta q_2 - \alpha + \delta_2, q_2 \geq 0,$$

$$(\beta q_1 + 2\beta q_2 - \alpha + \delta_2) \cdot q_2 = 0 \text{ (producer 2)} \tag{13b}$$

These conditions taken together constitute the following pure linear complementarity problem with function F:

$$F\begin{pmatrix} q_1 \\ q_2 \end{pmatrix} = \begin{pmatrix} 2\beta q_1 + \beta q_2 - \alpha + \delta_1 \\ \beta q_1 + 2\beta q_2 - \alpha + \delta_2 \end{pmatrix} = \begin{pmatrix} 2\beta & \beta \\ \beta & 2\beta \end{pmatrix}\begin{pmatrix} q_1 \\ q_2 \end{pmatrix} + \begin{pmatrix} -\alpha + \delta_1 \\ -\alpha + \delta_2 \end{pmatrix}.$$

If one can assume that both quantities $q_i > 0$ in an equilibrium solution, then the above conditions become a set of two unknowns (production) in two equations, namely:

$$0 = 2\beta q_1 + \beta q_2 - \alpha + \delta_1, \text{ (producer 1)} \tag{14a}$$

$$0 = \beta q_1 + 2\beta q_2 - \alpha + \delta_2, \text{ (producer 2)} \tag{14b}$$

Solving for the positive production levels in these two equations amounts to using a best reaction or best response function (Osborne and Rubinstein 1994), essentially closed-form expressions for q_i as a function of the other production quantity. Due to limitations on assuming positive production for all producers, or for example, the need for considering more challenging constraints (apart from nonnegativity), it is much more efficient to use the complementarity approach. Indeed, for more realistic models, it is not always possible to use this best response approach. Some MCP examples with

realism that have been presented (in energy markets) include Hobbs (2001), Gabriel et al. (2005a), Gabriel et al. (2005b), Hobbs et al. (2008).

PIES Energy Equilibrium

While the above models have considered either one or more optimization problems or nonlinear equations as instances of MCPs, the PIES (Project Independence Evaluation System) energy planning model is an important example that combines both these two approaches into a complementarity problem (Hogan 1975; Josephy 1979; Ahn 1979; Ahn and Hogan 1982). A stylized version of a much later and more complicated generation of PIES is the National Energy Modeling Systems (NEMS). NEMS has also been shown to be an instance of an MCP (Gabriel et al. 2001) and is currently used by the U.S. Department of Energy for a variety of energy market studies and reports.

The PIES model considers the supply and demand sides of the energy market separately with x denoting the vector of decision variables in energy production. The supply side is modeled as a production cost minimization given as follows with $\boldsymbol{c}$ a vector of costs conformal with $\boldsymbol{x}$:

$$\min_{\boldsymbol{x}} \boldsymbol{c}^T\boldsymbol{x} \tag{15a}$$

$$s.t.\ \boldsymbol{A}\boldsymbol{x} \geq \boldsymbol{q} \qquad (\pi) \tag{15b}$$

$$\boldsymbol{B}\boldsymbol{x} \geq \boldsymbol{b} \qquad (\gamma) \tag{15c}$$

$$\boldsymbol{x} \geq 0 \tag{15d}$$

In this linear-programming problem, besides the nonnegativity restrictions, there are two sets of constraints: meeting demand q by a combination of energy production types Ax (15b) and other, non-demand related conditions to be met (15c). The dual prices are π and γ in (15b) and (15c), respectively. As opposed to a straightforward linear program, these two prices will enter directly into another part of the MCP formulation for this problem. In particular, the demand side of the energy market is given by econometric equations of the following form where p is price:

$$q_i(p) = q_i^0 \prod \left(\frac{p_i}{p_i^0}\right)^{e_{ij}} \tag{16}$$

Here q_i^0, p_i^0 are, respectively, reference demands and prices for energy product i, and e_{ij} is an elasticity between energy products i and j. The supply and demand sides of the energy market are combined by the equilibration condition:

$$\pi = p \tag{17}$$

In a nutshell, this condition states that the price used in the demand equation (16) should reflect the value of the resources involved, i.e., be the dual price to the demand equation from (15b).

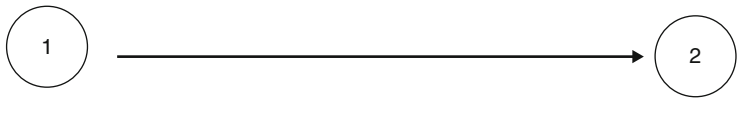
One way to join these two parts of the energy market is to substitute $\pi = p$ into (16) and then restrict π to be the dual vector to (15b). This can be done by considering the (necessary and sufficient) optimality conditions to (15) taking q as a fixed quantity. Then, the formula for q from (16) is used. The resulting MCP function for PIES (Cottle et al. 1992) is thus the following:

$$F\begin{pmatrix} x \\ \pi \\ \gamma \end{pmatrix} = \begin{pmatrix} c - A^T\pi - B^T\gamma \\ Ax - q(\pi) \\ Bx - b \end{pmatrix}$$

To try to directly incorporate both sides of the market as described above with just an optimization problem is not possible. In particular, to compute the vector of dual prices π, the LP (15) must first be solved. But to solve it, the optimal demand quantity $q = q(\pi)$ is required which in turn depends on the optimal π via (16) and (17). The MCP formulation gets around this computational issue by simultaneously determining both primal and dual variables. This feature is a strength of complementarity problems and thus easily allows combining both equations and optimization problems in one formulation.

Market Equilibrium with Underlying Network

The Nash-Cournot model described above as well as it's n-player counterpart assumes that each player has some ability to manipulate market prices by adjusting their own production levels. In fact, it is only in the objective functions of the players' problems that their separate decision variables interact. Two interesting variations on this paradigm are: Generalized Nash



Complementarity Applications, Fig. 2 Sample Two-Node Network

equilibrium problems (Facchinei and Pang 2003) and network equilibria. Generalized Nash problems allow for other players' variables to enter into the constraint set of a player. Using the two-player example shown above, in a Generalized Nash version, there might be a common constraint for each player of the form:

$$q_1 + q_2 + Inv \geq Dem \tag{18}$$

where *Inv* is the amount of inventory (for a region) and *Dem* its demand level. This common constraint would then say that the total supply (production + inventory) must at least meet the demand level. These sorts of problems belong to a class of mathematical programs that are generally harder to solve than MCPs but under certain conditions on these common constraints are expressable as complementarity problems or the related variational inequality problem. See Harker (1991) for a discussion of this result, as well as Facchinei and Pang (2003) for a theoretical treatment of variational inequalities and extensions that relate to Generalized Nash problems.

Another variation on the previous Nash equilibrium is to have multiple players each optimizing their objectives but without the ability to directly influence prices, i.e., they are price-takers. Rather, there is a market-clearing equation (or equations) whose dual variables are the associated market prices. Since the decision variables for each player contribute to the market-clearing conditions, these players have some indirect influence on the prices. As compared to the Generalized Nash model, these conditions do not appear in the constraint set of the players though. Often such problems have an underlying infrastructure network related perhaps to distribution of energy, water, or other products to transport.

Consider the following sample network equilibrium problem from Gabriel et al. (2013). There are two nodes in the network as depicted in Fig. 2. These nodes can represent cities, countries, regions, or just a market for a particular product. Production can occur at either node but only node 2 can receive additional product from the other node as indicated by the uni-directional arc. The product in question could be energy (e.g., electricity), fuels (natural gas, oil, coal), treated water, manufactured goods (e.g., televisions) or raw materials to name a few choices. There are a number of key questions that such an equilibrium model should answer.

For example, in meeting the demand at node 2, how much should be locally produced at node 2 and how much should be imported from the other node? What will be the equilibrium prices at each node if all players are acting in their own interests to maximize profits?

The production aspects can be modeled by the following optimization problem (shown here for producer A) in which net profit is to be maximized subject to production, balance, and nonnegativity constraints:

$$\max_{s_1^A, q_1^A, f_{12}^A} \pi_1 s_1^A + \pi_2 f_{12}^A - c_1^A\left(q_1^A\right) - \left(\tau_{12}^{\text{Reg}} + \tau_{12}\right) f_{12}^A \tag{19a}$$

$$s.t.\ q_1^A \leq \overline{q}_1^A \ \left(\lambda_1^A\right) \tag{19b}$$

$$s_1^A = q_1^A - f_{12}^A \ \left(\delta_1^A\right) \tag{19c}$$

$$s_1^A, q_1^A, f_{12}^A \geq 0 \tag{19d}$$

where

- $p \in \{A, B, C, D\}$ is the index for the producers
- $i \in \{1, 2\}$ is the index for the nodes
- q_n^p is the production quantity for producer p at node n
- $\overline{q}_n^p$ is the maximum production capacity for producer p at node n
- s_n^p is the amount sold by producer p at node n
- f_{12}^A, f_{12}^B are respectively, the amount of exports from node 1 to 2 by producers A and B (the other two producers do not have that option)
- π_n is the price at node n determined by market-clearing conditions
- $\tau_{12}^{Reg}, \tau_{12}$ are respectively, the exogenous, regulated export tariff when sending product from node 1 to 2 and the endogenously-determined congestion tariff between the two nodes (but exogenous from the perspective of the producer's optimization problem)

- $c_n^p\left(q_n^p\right)$ is the (marginal) production cost function for producer p at node n. For simplicity, this function is assumed linear and of the form $c_n^p\left(q_n^p\right) = \gamma_n^p q_n^p$ with $\gamma_n^p > 0$
- λ_n^p, δ_n^p are Lagrange multipliers (e.g., dual variables) for the associated constraints

Producer B's problem is similar to the one for A but the other two producers do not have any export-related terms. Since each producer is solving a linear program, the KKT conditions are both necessary and sufficient (Bazaraa et al. 1993). These KKT conditions for each of the four producers are as follows.

Producer A, node 1

$$0 \le -\pi_1 + \delta_1^A \perp s_1^A \ge 0 \tag{20a}$$

$$0 \le \gamma_1^A + \lambda_1^A - \delta_1^A \perp q_1^A \ge 0 \tag{20b}$$

$$0 \le -\pi_2 + \left(\tau_{12}^{Reg} + \tau_{12}\right) + \delta_1^A \perp f_{12}^A \ge 0 \tag{20c}$$

$$0 \le \overline{q}_1^A - q_1^A \perp \lambda_1^A \ge 0 \tag{20d}$$

$$0 = s_1^A - q_1^A + f_{12}^A, \delta_1^A \text{ free} \tag{20e}$$

Producer B, node 1

$$0 \le -\pi_1 + \delta_1^B \perp s_1^B \ge 0 \tag{21a}$$

$$0 \le \gamma_1^B + \lambda_1^B - \delta_1^B \perp q_1^B \ge 0 \tag{21b}$$

$$0 \le -\pi_2 + \left(\tau_{12}^{Reg} + \tau_{12}\right) + \delta_1^B \perp f_{12}^B \ge 0 \tag{21c}$$

$$0 \le \overline{q}_1^B - q_1^B \perp \lambda_1^B \ge 0 \tag{21d}$$

$$0 = s_1^B - q_1^B + f_{12}^B, \delta_1^B \text{ free} \tag{21e}$$

Producer C, node 2

$$0 \le -\pi_2 + \delta_2^C \perp s_2^C \ge 0 \tag{22a}$$

$$0 \le \gamma_2^C + \lambda_2^C - \delta_2^C \perp q_2^C \ge 0 \tag{22b}$$

$$0 \le \overline{q}_2^C - q_2^C \perp \lambda_2^C \ge 0 \tag{22c}$$

$$0 = s_2^C - q_2^C, \delta_2^C \text{ free} \tag{22d}$$

Producer D, node 2

$$0 \le -\pi_2 + \delta_2^D \perp s_2^D \ge 0 \tag{23a}$$

$$0 \le \gamma_2^D + \lambda_2^D - \delta_2^D \perp q_2^D \ge 0 \tag{23b}$$

$$0 \le \overline{q}_2^D - q_2^D \perp \lambda_2^D \ge 0 \tag{23c}$$

$$0 = s_2^D - q_2^D, \delta_2^D \text{ free} \tag{23d}$$

The market-clearing conditions forcing supply to equal demand are:

$$0 = \left[s_1^A + s_1^B\right] - D_1(\pi_1),\ \pi_1 \text{ free} \tag{24a}$$

$$0 = \left[s_2^C + s_2^D + f_{12}^A + f_{12}^B\right] - D_2(\pi_2),\ \pi_2 \text{ free} \tag{24b}$$

where $\left[s_1^A + s_1^B\right]$, $\left[s_2^C + s_2^D + f_{12}^A + f_{12}^B\right]$ are the supply amounts for nodes 1 and 2, respectively and $D_n(\pi_n), n = 1, 2$ are the demands at each node taking into account the nodal price π_n.

Besides production and market-clearing, in some applications (e.g., energy, water) there is a player that makes sure the network is running smoothly. This network system operator (NSO) also solves an optimization problem which can take on a variety of forms maximizing for example, social welfare or net profit to name two. Using net profit, a stylized network operator problem is as follows:

$$\max_{g_{12}} \left(\tau_{12}^{\text{Reg}} + \tau_{12}\right) g_{12} - c^{NSO}(g_{12}) \tag{25a}$$

$$s.t.\ \ g_{12} \le \overline{g}_{12}\ (\varepsilon_{12}) \tag{25b}$$

$$g_{12} \ge 0 \tag{25c}$$

where g_{12} represents the flow from node 1 to node 2 that the NSO manages, $c^{NSO}(g_{12})$ is a network operations cost function (assume linear for simplicity, i.e., $c^{NSO}(g_{12}) = \gamma^{NSO} g_{12}$ where $\gamma^{NSO} > 0$) and ε_{12} is the dual variable associated with the capacity constraint involving the flow upper bound $\overline{g}_{12}$. Like the producers' problems, this is a linear program so that the KKT conditions are both necessary and sufficient and are the following:

$$0 \le -\tau_{12}^{\text{Reg}} - \tau_{12} + \gamma^{NSO} + \varepsilon_{12} \perp g_{12} \ge 0 \tag{26a}$$

$$0 \le \overline{g}_{12} - g_{12} \perp \varepsilon_{12} \ge 0 \tag{26b}$$

To determine the congestion tariff τ_{12}, the following market-clearing conditions can be used:

$$0 = g_{12} - \left[f_{12}^A + f_{12}^B\right],\ \tau_{12} \text{ free} \tag{27}$$

The overall market equilibrium on this network can be expressed as an MCP by collecting the KKT conditions of the producers: (20)–(23) the supply–demand market-clearing conditions (24), the KKT conditions of the NSO (26) and the market-clearing conditions of the network flows (27).

As discussed in Gabriel et al. (2013), suppose the following input data are used.

$$\begin{aligned}
\tau_{12}^{\text{Reg}} &= 0.5 \\
\gamma_1^A = 10, \gamma_1^B &= 12, \gamma_2^C = 15, \gamma_2^D = 18 \\
a_1 = 20, b_1 &= 1, a_2 = 40, b_2 = 2 \\
\overline{q}_1^A = 10, \overline{q}_1^B &= 10, \overline{q}_2^C = 5, \overline{q}_2^D = 5 \\
\overline{g}_{12} &= 5 \\
\gamma^{NSO} &= 1 \\
D_1(\pi_i) &= a_i - b_i \pi_i
\end{aligned}$$

Then, an MCP solution in terms of production quantities, flows, prices, and tariffs is as follows:

$$\begin{aligned}
&q_1^A = 10, q_1^B = 3, q_2^C = 5, q_2^D = 0 \\
&f_{12}^A = 2.561, f_{12}^B = 2.439 \\
&\quad (\text{the sum is } 5 = \text{the capacity of the link}) \\
&\pi_1 = 12, \pi_2 = 15 \\
&\tau_{12} = 2.5 \\
&\quad (\tau_{12}^{\text{Reg}} + \tau_{12} = 3, \text{ the difference in the nodal prices})
\end{aligned}$$

Traffic Equilibrium

One of the classical problems in complementarity modeling is that of predicting steady state flows of cars (or other vehicles) along a congested road. Consider as a simple example, an origin (node 1) and two destinations (nodes 4 and 5) as well as intermediate nodes 2 and 3 as shown in Fig. 3 Wardrop 1952; Aashtiani and Magnanti 1981; Magnanti 1984; Florian 1986, 1989). These nodes can relate to intersection points, cities, regions, etc. The idea is to try to predict how many drivers will be using the individual paths in the network if for example, the price (e.g., time, disutility) of a particular path is taken into account in the decision-making process. That is, if the flow is price-based.

In this simple example, there are two origin–destination (OD) pairs: (1, 4) and (1, 5) which represent where drivers begin and end their trip. In going from node 1 to node 4, drivers can choose either to travel along path 1-2-4 or 1-3-4; for the OD pair (1, 5) there is only one path: 1-2-5. Wardrop (1952) stated an equilibrium where no driver had an incentive to deviate from a particular chosen path resulting in:

- Paths with positive flow serving the same OD pair all having equal costs (otherwise drivers would deviate to the less costly ones)
- Paths with costs higher than the minimum having no flow

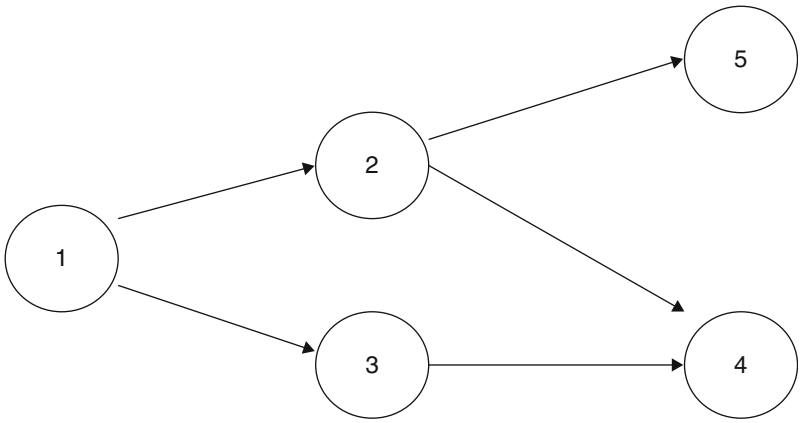
Essentially, such an equilibrium needs to take into account that all drivers are doing what is in their own best interests but that there should be no incentive for any one driver to deviate from a path they pick on their own. As compared to the previous examples of MCPs, in this case there is no explicit optimization problem(s), just an indirect acknowledgement that drivers want to minimize the time or cost of the path chosen.

To present the associated complementarity problem, it is necessary to define some related terms. First, path flows on a path p will be denoted by h_p, e.g., the flow on path 1-2-4 is h_{1-2-4}. The vector of all path flows is given by h which for this example is lexicographically given as:

$$h = \begin{pmatrix} h_{1-2-4} \\ h_{1-2-5} \\ h_{1-3-4} \end{pmatrix}.$$

Flows on an arc a are given by f_a with the vector of all such flows denoted as f. For the sample network shown above:

$$f = \begin{pmatrix} f_{1,2} \\ f_{1,3} \\ f_{2,4} \\ f_{2,5} \\ f_{3,4} \end{pmatrix}.$$



Complementarity Applications, Fig. 3 Sample Network for Traffic Equilibrium Problem

Both h and f are related by the equation:

$$f = \Delta h \tag{28}$$

where $\Delta = \left[\delta_{ap}\right]$ is the arc-path incidence matrix with $\delta_{ap} = 1$ if arc a is on path p and is equal to zero otherwise. Thus, for the network shown above:

$$\Delta = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

Parallel to the flow vectors h and f are the cost vectors for paths and arcs, given respectively as $C(h)$ and $c(f)$ which for the sample network are as follows:

$$C(h) = \begin{pmatrix} C_{1-2-4}(h) \\ C_{1-2-5}(h) \\ C_{1-3-4}(h) \end{pmatrix}, c(f) = \begin{pmatrix} c_{1,2}(f) \\ c_{1,3}(f) \\ c_{2,4}(f) \\ c_{2,5}(f) \\ c_{3,4}(f) \end{pmatrix}.$$

The relationship between these two vectors is:

$$C(h) = \Delta^T c(f) \tag{29}$$

indicating that the paths costs are the sum of the arc costs for those arcs on the path. This is the standard additive model which is well-studied but not always realistic when one considers for example tolls. In that case, nonadditive approaches such as those given in Gabriel and Bernstein (1997) and Bernstein and Gabriel (1997) may be more appropriate. An important point to note is that the path costs for a particular path are a function of all the path flows in the network. Likewise, the arc costs for a given arc are a function of all the arc flows. This is a very realistic representation of the network indicating the interaction effects. A more restrictive version is to assume that path p (arc a) only affects the costs for that path (arc) in essence a separability argument. This was an initial assumption used early on in part because it led to solving an equivalent optimization problem (Magnanti 1984; Florian 1989) which was easier to solve before the large growth in complementarity problem algorithms in the 1990s.

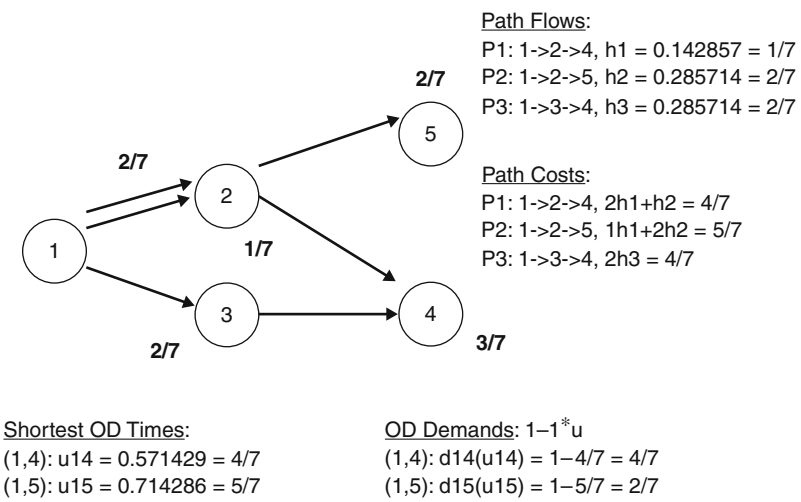
Besides the flow, the complementarity problem associated with a traffic equilibrium also needs to account for meeting the OD demand. For each OD pair i, such demand is denoted by D_i which itself is a function of the shortest time u_i (or least disutility) between the origin and destination i. In the network from Fig. 3, the vector versions of these quantities are thus:

$$D(u) = \begin{pmatrix} D_{(1,4)}(u) \\ D_{(1,5)}(u) \end{pmatrix}, \text{ with } u = \begin{pmatrix} u_{(1,4)} \\ u_{(1,5)} \end{pmatrix}.$$

There is one last notational element to define: the path-OD pair incidence matrix $\Gamma = \left[\gamma_{pi}\right]$ where $\gamma_{pi} = 1$ if path p serves OD pair i and is equal to zero otherwise. For the example above,

$$\Gamma = \begin{pmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \end{pmatrix}$$

for paths 1-2-4, 1-2-5, 1-3-4, and OD pairs, (1,4) and (1,5), respectively.



Complementarity Applications, Fig. 4 Solution to Sample Traffic Equilibrium Problem

The formal statement of the (additive) traffic equilibrium problem is thus to find path flows h and shortest times u such that:

$$0 \leq C_p(h) - u_i \text{ for all } p \in P_i, i \in I, \; h \geq 0 \tag{30a}$$

$$0 = \left(C_p(h) - u_i\right) \cdot h_p \text{ for all } p \in P_i, i \in I \tag{30b}$$

$$0 = \sum_{p \in P_i} h_p - D_i(u) \text{ for all } i \in I, u \geq 0 \tag{30c}$$

where P_i is the set of paths that serve OD pair i and I is the set of OD pairs. Equation (30a) simply states that the path cost $C_p(h)$ must be by definition greater than or equal to the shortest time u_i for all paths serving that OD pair i; also only nonnegative path flows are allowed. Equation (30b) is a translation of the Wardrop statement that appeared above. Namely, if the path p has any positive flow then the path cost must be equal to the shortest time and this must be true for all paths serving that OD pair. Also, if the path cost is strictly greater than the shortest time, there should be no flow along that path. Lastly, (30c) indicates that the total path flow across all paths that serve OD pair i must equal the demand; also, only nonnegative shortest times u_i are allowed. As stated, (30) is not an MCP since the equations in (3) do not match up with free variables u. As shown in Aashtiani and Magnanti (1981), (30c) can be relaxed to $0 \leq \sum_{p \in P_i} h_p - D_i(u)$ for all $i \in I, u \geq 0$ as long as some mild conditions on the path cost and demand functions hold and the corresponding MCP will have a solution that matches up with (30). Another important result is that if the demand function is invertible (or just fixed demand), an arc formulation instead of the more cumbersome path version can be used (Magnanti 1984; Florian 1989). In that case, taking into account (28) and (29), the resulting MCP is as follows:

$$0 \leq \left(\Delta^T c(\Delta h) - \Gamma u\right) \perp h \geq 0 \tag{31a}$$

$$0 \leq \Gamma^T h - D(u) \perp u \geq 0 \tag{31b}$$

assuming the mild restrictions on C and D are also in effect.

To make this formulation (31) concrete, consider the following specific choice for costs and demand functions for the sample network shown above:

$$c_a(f) = f_a \tag{32a}$$

$$D_i(u) = 1 - 1u_i \tag{32b}$$

The resulting solution is shown in Fig. 4. Note that both paths 1-2-4 and 1-3-4 serve OD pair (1,4) and since they both have positive flow ($h_{1-2-4} = \frac{1}{7}$, $h_{1-3-4} = \frac{2}{7}$), by Wardrop's principle they should both

have the same costs and equal to the lowest cost (shortest time) $u_{(1,4)}$ as is shown below. But from (28):

$$f = \begin{pmatrix} f_{1,2} \\ f_{1,3} \\ f_{2,4} \\ f_{2,5} \\ f_{3,4} \end{pmatrix} = \Delta h = \begin{pmatrix} 1 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} 1/7 \\ 2/7 \\ 2/7 \end{pmatrix} = \begin{pmatrix} 3/7 \\ 2/7 \\ 1/7 \\ 2/7 \\ 2/7 \end{pmatrix}$$

$$C_{1-2-4}(h) = \frac{3}{7} + \frac{1}{7} = \frac{4}{7}$$
$$C_{1-3-4}(h) = \frac{2}{7} + \frac{2}{7} = \frac{4}{7}$$
$$u_{(1,4)} = \frac{4}{7}$$
$$C_{1-2-5} = \frac{3}{7} + \frac{2}{7} = \frac{5}{7}$$
$$u_{(1,4)} = \frac{5}{7}$$

Concluding Remarks

In this article, complementary problems have been defined and their relevance to certain infrastructure models has been emphasized. Complementarity problems generalize optimization, game theory, and a host of other interesting problems in engineering and economics. As such, this flexible class of mathematical programs has great relevance to many important operations research problems.

Complementarity Condition

A relation between two nonnegative vectors in which, whenever a given component of one of the vectors is positive, the corresponding component of the other vector must be zero. For example, two nonnegative n-dimensional vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ satisfy a complementarity condition if their ith components are such that $x_i\, y_i = 0$, $i = 1, \ldots, n$.

Complementarity Problems

Richard W. Cottle
Stanford University, Stanford, CA, USA

Introduction

In its most elementary form, a complementarity problem CP($\boldsymbol{f}$) is an inequality system stated in terms of a mapping $\boldsymbol{f} : R^n \to R^n$. Given $\boldsymbol{f}$, one seeks a vector $\boldsymbol{x} \in R^n$ such that

$$\boldsymbol{x}_i \geq 0, \quad f_i(\boldsymbol{x}) \geq 0, \quad \text{and} \quad x_i f_i(\boldsymbol{x}) = 0 \quad i = 1, \ldots, n. \tag{1}$$

When the mapping $\boldsymbol{f}$ is affine, say of the form $\boldsymbol{f}(\boldsymbol{x}) = \boldsymbol{q} + \boldsymbol{M}\boldsymbol{x}$, problem (1) is called a linear complementarity problem, denoted LCP$(\boldsymbol{q}, \boldsymbol{M})$ or sometimes just $(\boldsymbol{q}, \boldsymbol{M})$. Otherwise, it is called a nonlinear complementarity problem and is denoted NCP($\boldsymbol{f}$).

If $\bar{\boldsymbol{x}}$ is a solution to (1) satisfying the additional nondegeneracy condition $\bar{x}_i + f_i(\bar{\boldsymbol{x}}) > 0, i = 1, \ldots, n$, the indices i for which $\bar{x}_i > 0$ or $f_i(\bar{\boldsymbol{x}}) > 0$ form complementary subsets of $\{1, \ldots, n\}$. This is believed to be the origin of the term complementary slackness as used in linear and nonlinear programming. It was this terminology that inspired the name complementarity problem.

Sources of Complementarity Problems

The complementarity problem is intimately linked to the Karush-Kuhn-Tucker necessary conditions of local optimality found in mathematical programming

theory. This connection was brought out in Cottle (1964, 1966) and again in Cottle and Dantzig (1968). Finding solutions to such systems was one of the original motivations for studying the subject. Another was the finding of equilibrium points in bimatrix and polymatrix games. This kind of application was emphasized by Howson (1963) and Lemke and Howson (1964). These early contributions also included essentially the first algorithms for these types of problems. There are numerous applications of the linear and nonlinear complementarity problems in computer science, economics, various engineering disciplines, finance, game theory, statistics, and mathematics. Descriptions of—and references to—these applications can be found in the books by Murty (1988), Cottle et al. (1992, 2009), Isac (1992), Isac et al. (2002), and Facchinei and Pang (2003). The survey article by Ferris and Pang (1997) is the richest compendium yet published on engineering and economic applications of complementarity problems.

Equivalent Formulations

The problem CP($\boldsymbol{f}$) can be formulated in several equivalent ways. An obvious one calls for a solution $(\boldsymbol{x}, \boldsymbol{y})$ to the system

$$\boldsymbol{y} - \boldsymbol{f}(\boldsymbol{x}) = 0, \quad \boldsymbol{x} \geq 0, \quad \boldsymbol{y} \geq 0, \quad \boldsymbol{x}^{\mathrm{T}}\boldsymbol{y} = 0. \tag{2}$$

Another is to find a zero $\boldsymbol{x}$ of the mapping

$$\boldsymbol{g}(\boldsymbol{x}) = \min\{\boldsymbol{x}, \boldsymbol{f}(\boldsymbol{x})\} \tag{3}$$

where the symbol $\min\{\boldsymbol{a}, \boldsymbol{b}\}$ denotes the componentwise minimum of the two n-vectors $\boldsymbol{a}$ and $\boldsymbol{b}$. Yet another equivalent formulation asks for a fixed point of the mapping

$$\boldsymbol{h}(\boldsymbol{x}) = \boldsymbol{x} - \boldsymbol{g}(\boldsymbol{x}),$$

i.e., a vector $\boldsymbol{x} \in R^n$ such that $\boldsymbol{x} = \boldsymbol{h}(\boldsymbol{x})$.

The formulation of CP($\boldsymbol{f}$) given in (3) is related to the (often nonconvex) optimization problem:

$$\begin{aligned} &\text{minimize } \boldsymbol{x}^{\mathrm{T}} f(\boldsymbol{x}) \\ &\text{subject to } \boldsymbol{f}(\boldsymbol{x}) \geq 0 \\ &\qquad \boldsymbol{x} \geq 0 \end{aligned} \tag{4}$$

In such a problem, the objective is bounded below by zero, thus any feasible solution of (4) for which the objective function $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{f}(\boldsymbol{x}) = 0$ must be a global minimum as well as a solution of CP($\boldsymbol{f}$). As it happens, there are circumstances (for instance, the monotonicity of the mapping $\boldsymbol{f}$) under which all the local minima for the mathematical programming problem (4) must in fact be solutions of (3).

Also noteworthy is a result of Eaves and Lemke (1981) showing that the LCP is equivalent to solving a system of equations $\boldsymbol{y} = \varphi(\boldsymbol{x})$ where the mapping $\varphi : R^n \to R^n$ is piecewise linear. In particular, LCP($\boldsymbol{q}$, $\boldsymbol{M}$) is equivalent to finding a vector $\boldsymbol{u}$ such that

$$\boldsymbol{q} + \boldsymbol{M}\boldsymbol{u}^{+} - \boldsymbol{u}^{-} = \boldsymbol{0}$$

where (for $i = 1, \ldots, n$) $u_i^{+} = \max\{0, u_i\}$ and $u_i^{-} = -\min\{0, u_i\}$.

The Linear Complementarity Problem

The LCP has quite an extensive literature, far more so than the NCP. This is most likely attributable to the LCP's relatively greater accessibility. Within this field of study, there are several main directions: the existence and uniqueness (or number of) solutions, mathematical properties of the problem, generalizations of the problem, algorithms, applications, and implementations.

Much of the theory of the linear complementarity problem is strongly linked in various ways to matrix classes. For instance, one of the earliest theorems on the existence of solutions is due to Samelson et al. (1958). Motivated by a problem in structural mechanics, they showed that the LCP($\boldsymbol{q}$, $\boldsymbol{M}$) has a unique solution for every $\boldsymbol{q} \in R^n$ if and only if the matrix $\boldsymbol{M}$ has positive principal minors. (That is, the determinant of every principal submatrix of $\boldsymbol{M}$ is positive.) The class of such matrices has come to be known as **P**, and its members are called **P**-matrices. (It is significant that the Samelson-Thrall-Wesler theorem characterizes a class of matrices in terms of the LCP.) The class **P** includes all positive definite (**PD**) matrices, i.e., those square matrices $\boldsymbol{M}$ for which $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{x} > 0$ for all $\boldsymbol{x} \neq 0$. In the context of the LCP, the term "positive definite" does not

require symmetry. An analogous definition (and usage) holds for positive semi-definite (**PSD**) matrices, namely, $\boldsymbol{M}$ is **PSD** if $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{M}\boldsymbol{x} > 0$ for all $\boldsymbol{x}$. Some authors refer to such matrices as monotone because of their connection with monotone mappings. **PSD**-matrices have the property that the associated LCPs ($\boldsymbol{q}$, $\boldsymbol{M}$) are solvable whenever they are feasible, whereas LCPs ($\boldsymbol{q}$, $\boldsymbol{M}$) in which $\mathbf{M} \in \mathbf{PD}$ are always feasible and (since $\mathbf{PD} \subset \mathbf{PSD}$) are always solvable. Murty (1968, 1972) gave this distinction a more general matrix form. He defined $\mathbf{Q}$ as the class of all square matrices for which LCP($\boldsymbol{q}$, $\boldsymbol{M}$) has a solution for all $\boldsymbol{q}$ and $\mathbf{Q}_0$ as the class of all square matrices for which LCP($\boldsymbol{q}$, $\boldsymbol{M}$) has a solution whenever it is feasible. Although the goal of usefully characterizing the classes $\mathbf{Q}$ and $\mathbf{Q}_0$ has not yet been realized, much is known about some of their special subclasses. Indeed, there are now literally dozens of matrix classes for which LCP existence theorems have been established. See Murty (1988), Cottle et al. (1992, 2009), Cottle (2010) and Isac (1992) for an abundance of information on this subject.

Algorithms for Solving LCPs

The algorithms for solving linear complementarity problems are of two major types: pivoting (or, direct) and iterative (or, indirect). Algorithms of the former type are finite procedures that attempt to transform the problem ($\boldsymbol{q}$, $\boldsymbol{M}$) to an equivalent system of the form $(\boldsymbol{q}', \boldsymbol{M}')$ in which $\boldsymbol{q}' \geq 0$. Doing this is not always possible; it depends on the problem data, usually on the matrix class (such as **P**, **PSD**, etc.) to which $\boldsymbol{M}$ belongs. When this approach works, it amounts to carrying out a principal pivotal transformation on the system of equations

$$\boldsymbol{y} = \boldsymbol{q} + \boldsymbol{M}\boldsymbol{x}.$$

To such a transformation there corresponds an index set α (with complementary index set $\bar{\alpha} = \{1, \ldots, n\} \backslash \alpha$) such that the principal submatrix $\boldsymbol{M}_{\alpha\alpha}$ is nonsingular. When this (block pivot) operation is carried out, the system

$$\begin{aligned} \boldsymbol{y}_\alpha &= \boldsymbol{q}_\alpha + \boldsymbol{M}_{\alpha\alpha}\boldsymbol{x}_\alpha + \boldsymbol{M}_{\alpha\bar{\alpha}}\boldsymbol{x}_{\bar{\alpha}} \\ \boldsymbol{y}_{\bar{\alpha}} &= \boldsymbol{q}_{\bar{\alpha}} + \boldsymbol{M}_{\bar{\alpha}\alpha}\boldsymbol{x}_\alpha + \boldsymbol{M}_{\bar{\alpha}\bar{\alpha}}\boldsymbol{x}_{\bar{\alpha}} \end{aligned}$$

becomes

$$\begin{aligned} \boldsymbol{x}_\alpha &= \boldsymbol{q}'_\alpha + \boldsymbol{M}'_{\alpha\alpha}\boldsymbol{y}_\alpha + \boldsymbol{M}'_{\alpha\bar{\alpha}}\boldsymbol{x}_{\bar{\alpha}} \\ \boldsymbol{y}_{\bar{\alpha}} &= \boldsymbol{q}'_{\bar{\alpha}} + \boldsymbol{M}'_{\bar{\alpha}\alpha}\boldsymbol{y}_\alpha + \boldsymbol{M}'_{\bar{\alpha}\bar{\alpha}}\boldsymbol{x}_{\bar{\alpha}} \end{aligned}$$

where

$$\begin{aligned} \boldsymbol{q}'_\alpha &= -\boldsymbol{M}_{\alpha\alpha}^{-1}\boldsymbol{q}_\alpha \\ \boldsymbol{M}'_{\alpha\bar{\alpha}} &= -\boldsymbol{M}_{\alpha\alpha}^{-1} \\ \boldsymbol{M}'_{\alpha\bar{\alpha}} &= -\boldsymbol{M}_{\alpha\alpha}^{-1}\boldsymbol{M}_{\alpha\bar{\alpha}} \\ \boldsymbol{q}'_{\bar{\alpha}} &= \boldsymbol{q}_{\bar{\alpha}} - \boldsymbol{M}_{\bar{\alpha}\alpha}\boldsymbol{M}_{\alpha\alpha}^{-1}\boldsymbol{q}_\alpha \\ \boldsymbol{M}'_{\bar{\alpha}\alpha} &= \boldsymbol{M}_{\bar{\alpha}\alpha}\boldsymbol{M}_{\alpha\alpha}^{-1} \\ \boldsymbol{M}'_{\bar{\alpha}\bar{\alpha}} &= \boldsymbol{M}_{\bar{\alpha}\bar{\alpha}} - \boldsymbol{M}_{\bar{\alpha}\alpha}\boldsymbol{M}_{\alpha\alpha}^{-1}\boldsymbol{M}_{\alpha\bar{\alpha}}. \end{aligned}$$

There are two main pivoting algorithms used in processing LCPs. The more robust of the two is due to Lemke (1965). Lemke's method embeds the LCP($\boldsymbol{q}$, $\boldsymbol{M}$) in a problem having an extra "artificial" nonbasic (independent) variable x_0 with coefficients specially chosen so that when x_0 is sufficiently large, all the basic variables become nonnegative. At the least positive value of x_0 for which this is so, there will (in the nondegenerate case) be (exactly) one basic variable whose value is zero. That variable is exchanged with x_0. Thereafter the method executes a sequence of (almost complementary) simple pivots. In each case, the variable becoming basic is the complement of the variable that became nonbasic in the previous exchange. The method terminates if either x_0 decreases to zero—in which case the problem is solved—or else there is no basic variable whose value decreases as the incoming nonbasic variable is increased. The latter outcome is called termination on a secondary ray. For certain matrix classes, termination on a secondary ray is an indication that the given LCP has no solution. Eaves (1971) was among the first to study Lemke's method from this point of view.

The other pivoting algorithm for the LCP is called the Principal Pivoting Method (see Cottle and Dantzig (1968)). The algorithm has two versions: symmetric and asymmetric. The former executes a sequence of principal (block) pivots or order 1 or 2, whereas the latter does sequences of almost complementary pivots, each of which results in a block principal pivot or order potentially larger than 2. The class of problems to

which the Principal Pivoting Method applies is more restrictive. (See Cottle et al. (1992, 2009) for a treatment of this algorithm.)

Iterative methods are often favored for the solution of very large linear complementarity problems. In such problems, the matrix $\boldsymbol{M}$ tends to be sparse (i.e., to have a small percentage of nonzero elements) and frequently structured. Since iterative methods do not modify the problem data, these features of large-scale problems can be used to advantage. Ordinarily, however, an iterative method does not terminate finitely; instead, it generates a convergent sequence of trial solutions. As is to be expected, the applicability of algorithms in this family depends on the matrix class to which $\boldsymbol{M}$ belongs. Details on several algorithms of this type are presented in the books by Kojima et al. (1991) as well as the one by Cottle et al. (1992, 2009).

Some Generalizations

The linear and nonlinear complementarity problems have been generalized in numerous ways. One of the earliest generalizations was given by Habetler and Price (1971) and Karamardian (1971) who defined the problem $\mathrm{CP}(K, \boldsymbol{f})$ as that of finding a vector $\boldsymbol{x}$ in the closed convex cone K such that $\boldsymbol{f}(x) \in K^*$ (the dual cone) and $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{f}(\boldsymbol{x}) = 0$. Through this formulation, a connection can be made between complementarity problems and variational inequality problems, that is, problems $\mathrm{VI}(X, \boldsymbol{f})$ wherein one seeks a vector $\boldsymbol{x}^* \in X$ (a nonempty subset of R^n) such that

$$\boldsymbol{f}(\boldsymbol{x}^*)^{\mathrm{T}}(\boldsymbol{y} - \boldsymbol{x}^*) \geq 0 \quad \text{for all } \boldsymbol{y} \in X.$$

Karamardian (1971) established that when X is a closed convex cone, say K, with dual cone K^*, then $\mathrm{CP}(K, \boldsymbol{f})$ and $\mathrm{VI}(X, \boldsymbol{f})$ have exactly the same solutions (if any).

Robinson (1979) has considered the generalized complementarity problem $\mathrm{CP}(K, \boldsymbol{f})$ defined above as an instance of a generalized equation, namely to find a vector $\boldsymbol{x} \in R^n$ such that

$$0 \in \boldsymbol{f}(\boldsymbol{x}) + \partial\psi_K(\boldsymbol{x})$$

where ψ_K is the indicator function of the closed convex cone K and ∂ denotes the subdifferential operator as used in convex analysis.

Among the diverse generalizations of the linear complementarity problem, the earliest appears in Samelson et al. (1958). There—for given $n \times n$ matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ and n-vector $\boldsymbol{c}$—the authors considered the problem of the finding n-vectors $\boldsymbol{x}$ and $\boldsymbol{y}$ such that

$$\boldsymbol{A}\boldsymbol{x} + \boldsymbol{B}\boldsymbol{y} = \boldsymbol{c}, \quad \boldsymbol{x} \geq 0, \quad \boldsymbol{y} \geq 0 \quad \text{and} \quad \boldsymbol{x}^{\mathrm{T}}\boldsymbol{y} = 0.$$

A different generalization was introduced by Cottle and Dantzig (1970). In this sort of problem, one has an affine mapping $\boldsymbol{f}(\boldsymbol{x}) = \boldsymbol{q} + \boldsymbol{N}\boldsymbol{x}$ where $\boldsymbol{N}$ is of order $\sum_{j=1}^{k} p_j \times n$ partitioned into k blocks; the vectors $\boldsymbol{q}$ and $\boldsymbol{y} = \boldsymbol{f}(\boldsymbol{x})$ are partitioned conformably. Thus,

$$\boldsymbol{y}^j = \boldsymbol{q}^j + \boldsymbol{N}^j\,\boldsymbol{x} \text{ for } j = 1, \ldots, k.$$

The problem is to find a solution of the system

$$\boldsymbol{y} = \boldsymbol{q} + \boldsymbol{N}\boldsymbol{x}, \quad \boldsymbol{x} \geq 0, \quad \boldsymbol{y} \geq 0, \quad \text{and} \quad x_j \prod_{i=1}^{p_j} y_i^j = 0$$

$$(j = 1, \ldots, k).$$

Several authors have further investigated this vertical generalization while others have studied some analogous horizontal generalizations. For representative papers on the vertical LCP, see Ebiefung (1995) and Mohan and Neogy (1997). For the horizontal generalization, Tütüncü and Todd (1995) and Zhang (1994). A further generalization called extended linear complementarity problem (ELCP) was introduced by Mangasarian and Pang (1995) and subsequently developed in Gowda (1995, 1996) and Sznajder and Gowda (1995). Also called the extended linear complementarity problem is another variant expounded by De Schutter and De Moor (1996) that captures the previously mentioned HLCP, VLCP and ELCP.

The Nonlinear Complementarity Problem

The NCP($\boldsymbol{f}$) as an identified problem first appeared in Cottle (1964, 1966). There—under very strong assumptions on f—an existence theorem and an

analogue of the principal pivoting method for the LCP were presented. As described in Pang (1995), contemporary iterative NCP algorithms tend to fall into three categories: (i) the basic Newton method, (ii) nonsmooth-equations approaches, and (iii) interior-point methods. Some algorithms are inspired by the equivalence between the NCP(f) and the variational inequality problem $\mathrm{VI}(X, f)$ in the case where $X = R^n_+$. Some seek zeros of a function such as g defined in (3) whereas others attack the nonlinear program (4) or a variant thereof. Despite the existence of several fine collections of research articles on nonlinear complementarity problems, the authoritative surveys of Harker and Pang (1990) and Pang (1995) came as close as anything then available to a monograph on this topic. The field now benefits from the publication of the masterful two-volume work on variational inequalities and complementarity problems by Facchinei and Pang (2003).

Software for Complementarity Problems

Complementary Pivot Algorithm

► Quadratic Programming

Complementary Slackness Theorem

For the symmetric form of the primal and dual problems the following theorem holds: For optimal feasible solutions of the primal and dual (symmetric) systems, whenever inequality occurs in the *k*th relation of either system (the corresponding slack variable is positive), then the *k*th variable of its dual is zero; if the *k*th variable is positive in either system, the *k*th relation of its dual is equality (the corresponding slack variable is zero). Feasible solutions to the primal and dual problems that satisfy the complementary slackness conditions are also optimal solutions. A similar theorem holds for the unsymmetric primal-dual problems: For optimal feasible solutions of the primal and dual (unsymmetric) systems, whenever the *k*th relation of the dual is an inequality, then the *k*th variable of the primal is zero; if the *k*th variable of the primal is positive, then the *k*th relation of the dual is equality. This theorem just states the optimality conditions of the simplex method.

Complex Problem Analyzing Method (Compram)

Dorien J. DeTombe
International Research Society on Methodology of Societal Complexity, Amsterdam, The Netherlands

Complex societal problems are worldwide natural problems caused by viruses such as the flu pandemic, fowl plague, and HIV/AIDS; local natural disasters especially earthquakes, hurricanes, avalanches and floods; technical dangers caused by industry including pollution (CO2), traffic, and nuclear power plants; climate change and agricultural activities; man-made threats such as wars, terrorism, internet vulnerability, stock exchange manipulation, credit crises, and identity theft. The concept of societal complexity and an approach to their resolution, the Complex Problem Analyzing Method (Compram),

are discussed by DeTombe (2001). Compram is based on the idea that societal problems must be handled in a multi-disciplinary and cooperative manner by experts, stakeholders, and policy makers. Compram combines aspects of different methods into a structured interactive approach for policy making to find possible transitions of the situation that can be mutually accepted and implemented (DeTombe 1994).

The related difficult and complicated group processes are guided and structured by a facilitator. Those involved discuss the content and possible solutions based on a cooperative (simulation) model of the problem. The methodology emphasizes facilitating the exchange of knowledge, and understanding and communication between the participants. Compram has been used on a theoretical basis for handling over sixty real-life cases in the field of societal policymaking. The Organisation for Economic Cooperation and Development (OECD) suggests that the analysis of a complex societal problem be supported by the application of Compram (OECD 2006). (Further information on Compram and Societal Complexity can be found on Web sites maintained by the author).

Computational Biology

Harvey J. Greenberg[1] and Allen G. Holder[2]
[1]University of Colorado-Denver, Denver, CO, USA
[2]Rose-Hulman Institute of Technology, Terre Haute, IN, USA

Computational biology is an interdisciplinary field that applies the techniques of computer science, applied mathematics, and statistics to address biological questions. OR is also interdisciplinary and applies the same mathematical and computational sciences, but to decision-making problems. Both focus on developing mathematical models and designing algorithms to solve them. Models in computational biology vary in their biological domain and can range from the interactions of genes and proteins to the relationships among organisms and species.

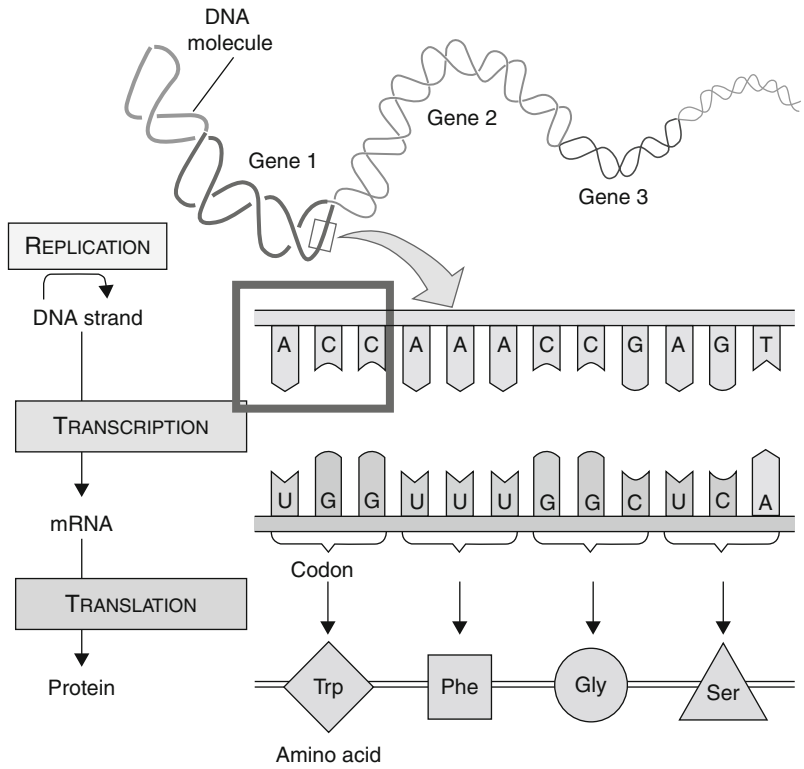
Genes are stretches of deoxyribonucleic acid (DNA), which is sometimes called the user manual for life and is a double-stranded helix of nucleic acids bonded by base-pairs of complements (`a-t`, `c-g`). The central dogma of molecular biology asserts that information in a cell flows from DNA to ribonucleic acid (RNA) to protein (note, Francis Crick used dogma when he introduced this in 1958 to mean without foundation because there was no experimental evidence at that time). Proteins are the workers of the cell, and there is much focus on recognizing, predicting, and comparing their properties (Fig. 1).

Proteins interact either directly by modifying each other's properties through direct contact or indirectly by participating in the production and modification of cellular metabolites. Collectively, the biochemical reactions and the possible intermediates that produce a metabolite comprise a metabolic pathway, and a metabolic network is a collection of these pathways. The study of complex networks like that of the metabolism is called systems biology.

Linear Programming: A linear program (LP) is an optimization problem in which the variables are in $\mathbb{R}^N$, and the constraints and the objective are linear.

Flux Balance Analysis (FBA) – A biochemical process is defined by n reactions that convert m compounds:

$$a_{1j}x_1 + \cdots + a_{mj}x_m \underset{k_-^j}{\overset{k_+^j}{\rightleftharpoons}} b_{1j}x_1 + \cdots + b_{mj}x_m,$$



Computational Biology, Fig. 1 Central dogma of molecular biology

where x_i is the concentration of the ith compound, and $k_{\pm}^{j}$ is the jth reaction rate (for a 2-way reaction the reverse rate need not equal the forward rate). The corresponding ODE is:

$$\frac{\mathrm{d}x_i(t)}{\mathrm{d}t} = \sum_{j=1}^{n} (b_{ij} - a_{ij}) \left(k_{+}^{j} x_1^{a_{1j}} \cdots x_m^{a_{mj}} - k_{-}^{j} x_1^{a_{1j}} \cdots x_m^{a_{mj}} \right)$$
$$= \sum_{j=1}^{n} S_{ij} v_j(x),$$

where v is the flux (production or consumption of mass per unit area per unit time), and S_{ij} is defined as a stoichiometric (pronounced `stoy-kee-uh-me'-trik`) coefficient. These coefficients are interpreted as:

$S_{ij} > 0 \Rightarrow$ rate of compound i produced in reaction j;
$S_{ij} < 0 \Rightarrow$ rate of compound i consumed in reaction j.

The following holds asymptotically provided that the system approaches a steady state toward equilibrium concentrations $\bar{x}$:

$$\lim_{t \to \infty} \frac{\mathrm{d}x(t)}{\mathrm{d}t} = Sv(\bar{x}) = 0. \tag{1}$$

Dropping the dependence of the flux on $\bar{x}$, the flux cone is defined by this homogeneous system plus non-negativity for one-way reactions, indexed by J:

$$\mathcal{F} = \{v : Sv = 0, \;\; v_J \geq 0\}. \tag{2}$$

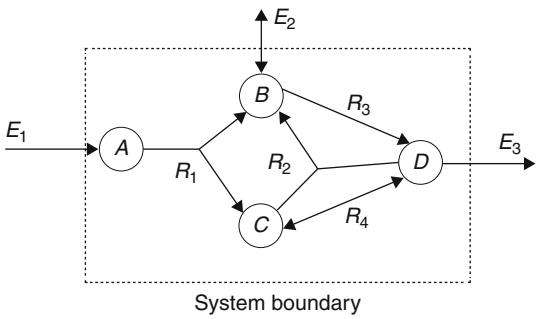
In a metabolic network, reactions are distinguished between external and internal. The flux associated with an external reaction is an exchange between the network of interest and the cell's environment (Fig. 2).

The stoichiometric matrix for the internal reactions is extended to include external reactions, each being a singleton column with ± 1:

$$S = \begin{array}{c} \\ A \\ B \\ C \\ D \end{array} \begin{array}{c} \begin{array}{cccc|ccc} R_1 & R_2 & R_3 & R_4 & E_1 & E_2 & E_3 \end{array} \\ \left[\begin{array}{cccc|ccc} -1 & 0 & 0 & 0 & 1 & 0 & 0 \\ 1 & 1 & -2 & 0 & 0 & -1 & 0 \\ 2 & -1 & 0 & -2 & 0 & 0 & 0 \\ 0 & -2 & 1 & 3 & 0 & 0 & -1 \end{array} \right] \end{array}$$

Computational Biology, Fig. 2 Example metabolic network with four internal and three external reactions

$R_1 : A \rightharpoonup B + 2C$ (multiple output)
$R_2 : C + 2D \rightharpoonup B$ (multiple input)
$R_3 : 2B \rightharpoonup D$ (simple)
$R_4 : 2C \leftrightharpoons 3D$ (simple, 2-way)
$E_1 : \rightharpoonup A$ (supply)
$E_2 : B \leftrightharpoons$ (2-way exchange)
$E_3 : D \rightharpoonup$ (demand)



All reactions are one-way reactions, except R_4 and E_2, so $J = \{1, 2, 3, 5, 7\}$, leaving v_4 and v_6 without sign restriction in the flux cone.

Strictly speaking, a metabolic network is usually not a network in the OR sense because some internal reactions have multiple inputs or outputs (sometimes called a process network in chemical engineering). Hence, LP is used, rather than specialized network algorithms, to find fluxes. The FBA LP model has the form:

$$\max \quad c^T v : \quad v \in \mathcal{F} \cap \mathcal{B}, \tag{3}$$

where $\mathcal{B}$ is a bounding set so that the linear program has an optimal solution if it is feasible. A common objective is to maximize the rate of growth defined in terms of metabolites, where the objective coefficients (c) depend on the organism. Other objectives include maximizing some metabolite production, minimizing by-product production, minimizing substrate requirements, and minimizing mass nutrient uptake (Palsson 2006).

An optimal basis depends on the definition of $\mathcal{B}$. Three possibilities, which may be combined, are:

$$\begin{aligned} &\text{simple bound :} && L_K \le v_K \le U_K \\ &\text{fixing inputs and/or outputs :} && v_K = \bar{v}_K \\ &\text{normalization :} && \textstyle\sum_{j \in K} v_j = b, \end{aligned}$$

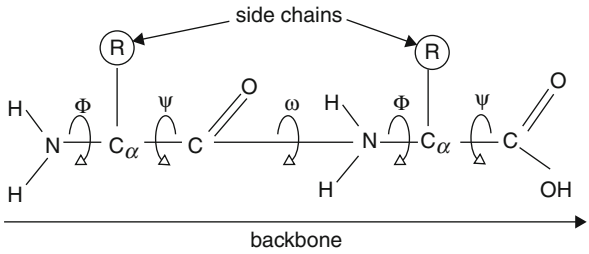
where K is a subset of reactions. Inputs and outputs are generally a subset of the exchanges. Normalization applies to one-way reactions – i.e., $K \subseteq J$. Each extreme ray of the flux cone corresponds to an extreme point of the polytope. The converse is generally not true – viz., fixing the flux of a reaction that transports metabolites in or out of the cell can introduce extreme points with no extreme ray of the flux cone passing through them.

Pathways are subnetworks with a single biological effect. In an ordinary network, where each internal reaction has a single input and output, this is a path. A cut set is defined as a set of reactions whose removal renders the stoichiometric (1) infeasible for a specified output. For an ordinary network, the OR terminology is a disconnecting set. A minimal cut set for a specified output is, in OR terminology, simply a cut set. For the example, a cut set that separates D from the rest of the network is $\{R_1, R_3, R_4, E_1\}$. Finding a (minimal) cut set in the general case becomes an IP, using binary variables to block pathways to some specified output.

Nonlinear Programming: A nonlinear program (NLP) is defined by having the objective or some constraint function be nonlinear in the decision variables.

Protein Folding – Most proteins go through a process that twists and turns the molecules from their primary state of a linear progression of amino acids to a native three-dimensional state in which it remains. That process is called folding, and it is theoretically possible to predict a protein's native state, or structure, by knowing its primary state. This determines a protein's function, and some diseases (e.g., Alzheimer's, Huntington's, and cystic fibrosis) are associated with protein misfolding.

Predictive models became possible following the work of Christian B. Anfinsen, who in 1961 published experimental results supporting the Thermodynamic Hypothesis: A protein's native state is uniquely determined by its primary sequence; it transitions to a state of minimum free energy. This leads to a nonlinear program with the decision space defined as the spatial coordinates of atoms, constrained by the biochemistry of a protein's defining amino acid sequence. The objective function is a free energy determined by potential energies from atomic bonds and non-bond interactions.



Computational Biology, Fig. 3 Covalent bonds along the backbone result in a residue for each of the amino acids. The torsion angles are denoted by Ψ and Φ; ω is the dihedral angle

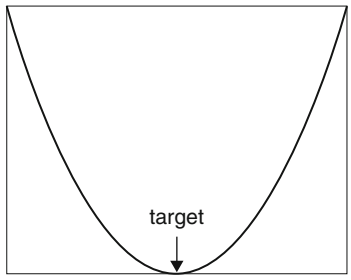
The bonds for the sequence of amino acids shown in Fig. 3 are covalent, meaning that they share electrons, and these strong bonds hold the backbone together. Objective terms for the ith covalent bond include the energies required to stretch, bend, and twist the bond.

Action	Energy	
Stretching	E^{stretch}	$= \sum_i K_i^L \left(L_i - L_i^0\right)^2$
Bending	E^{bend}	$= \sum_i K_i^\theta \left(\theta_i - \theta_i^0\right)^2$
Twisting	E^{twist}	$= \sum_i K_i^\phi (1 - \cos(\omega_i))$

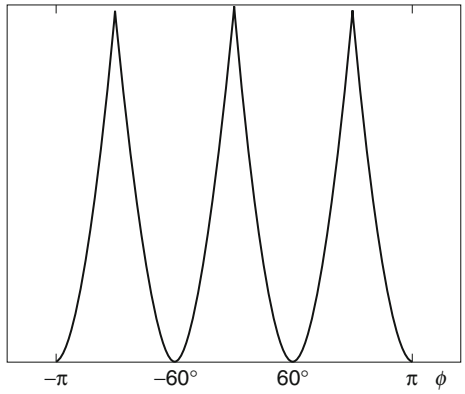
The variables are the bond length (L) and the bond angles, ω and $\theta = (\Psi, \Phi)$, which are determined by atomic coordinates. Parameters include target values (L^0, θ^0). Weight parameters (K) are scale factors that put the energy terms in the same unit; those values can be measured or derived. For example, if it requires 100 kcal/mole to break a bond, and two positive charges within 3.3 Å (Angstrom) have at least 100 kcal/mole, then the total energy is reduced by breaking a bond to keep positive charges distant. Estimating these values to determine weight parameters is not an exact science, so even these basic energy functions are inexact, and there are other energy functions for non-covalent bonds and among non-bonding atoms.

Two common energy functions estimate the electrostatic and Van der Waals interactions:

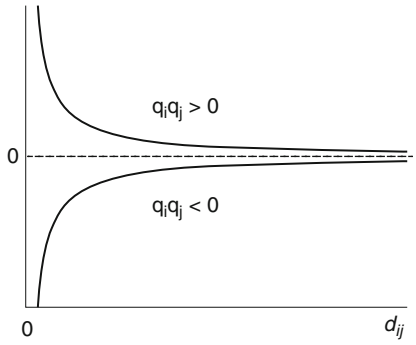
Action	Energy	
Electrostatic	E^{elec}	$= \sum_{i<j} K_{ij}^{\text{elec}} \frac{q_i q_j}{d_{ij}}$
Van der Waals	E^{vdw}	$= \sum_{i<j} K_{ij}^{\text{vdw}} \left(\left(\frac{d_{ij}^*}{d_{ij}}\right)^{12} - \alpha_{ij} \left(\frac{d_{ij}^*}{d_{ij}}\right)^{6} \right)$



Computational Biology, Fig. 4 The squared deviation of E^{stretch} and E^{bend} is convex



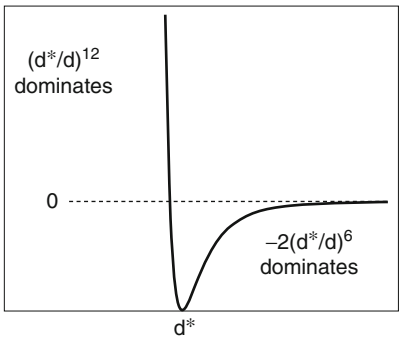
Computational Biology, Fig. 5 E^{twist} with $\omega = 3/2(\phi - \pi)$



Computational Biology, Fig. 6 E^{elec} depends on the sign of $q_i q_j$. Oppositely signed atoms attract, so the energy is negative and favors them being close

The variables are the pairwise distances (d), which are determined by the atomic coordinates. Parameters are the atomic charges (q) and equilibrium distances (d^*) (Figs. 4–7).

The NLP approach (Floudas and Pardalos 2000) uses energy principles that underlie molecular



Computational Biology, Fig. 7 Lennard-Jones approximation of E^{vdw} for $\alpha = 2$

dynamics, and these methods attempt to find the native state and a pathway to it. In practice, not all parameters are grounded in some physical law. An energy function could include contributions from non-bonded and uncharged pairs, based on their distance and radii. Alternatively, known structures can be used to predict an unknown structure, based on their evolutionary similarity. This is called homology, and it is focused on determining the native state and not on discerning the dynamic pathways to reach it.

The multi-modal shape of the energy landscape leads to the Levinthal Paradox: Many proteins reach their native state within milliseconds, yet the number of stable conformations grows exponentially in the number of amino acids. One explanation is that proteins fold into a nearby local minimum of the free energy instead of the global minimum. Global optimization methods based on this principle are called funneling methods. Another explanation is that the dimension of the problem is not the length of the amino acid sequence but is instead the number of chains that obey patterns not fully understood. Combinatorial optimization methods based on this principle are called chain growth and zipping and assembly algorithms.

Comparing Protein Function – A protein's function is determined by its 3D native state, of which many confirmations are known. Comparing protein structures relates protein function and collects proteins into functionally similar families that help identify a protein's functions.

Proteins typically have multiple functional domains, each of which would act as an independent protein if its amino acid subsequence had folded independently. Two proteins are considered to be functionally similar if they share a (nearly) common domain. Each domain is composed of secondary structures, notably α-helices and β-sheets, illustrated in Fig. 8. In structure alignment the goal is to best align the secondary structures between two proteins' domains. The input to the alignment problem is a set of coordinates for the C_α atoms for each domain – i.e., the spatial coordinates for the carbon atoms linked to the side chains (c.f., Fig. 3).

To remove a dependency on rigid body motion, structures are often aligned with respect to pairwise distances, d_{ij}, which is a measure between the ith and jth C_α atoms. Let d'_{ij} and d''_{kr} be the intra-distance measures for the two domains, and consider the binary variable:

$$x_{ik} = \begin{cases} 1 & \text{if the } i^{th}\ C_\alpha \text{ atom of the first domain is paired with} \\ & \text{the } k^{th}\ C_\alpha \text{ atom of the second domain;} \\ 0 & \text{otherwise.} \end{cases}$$

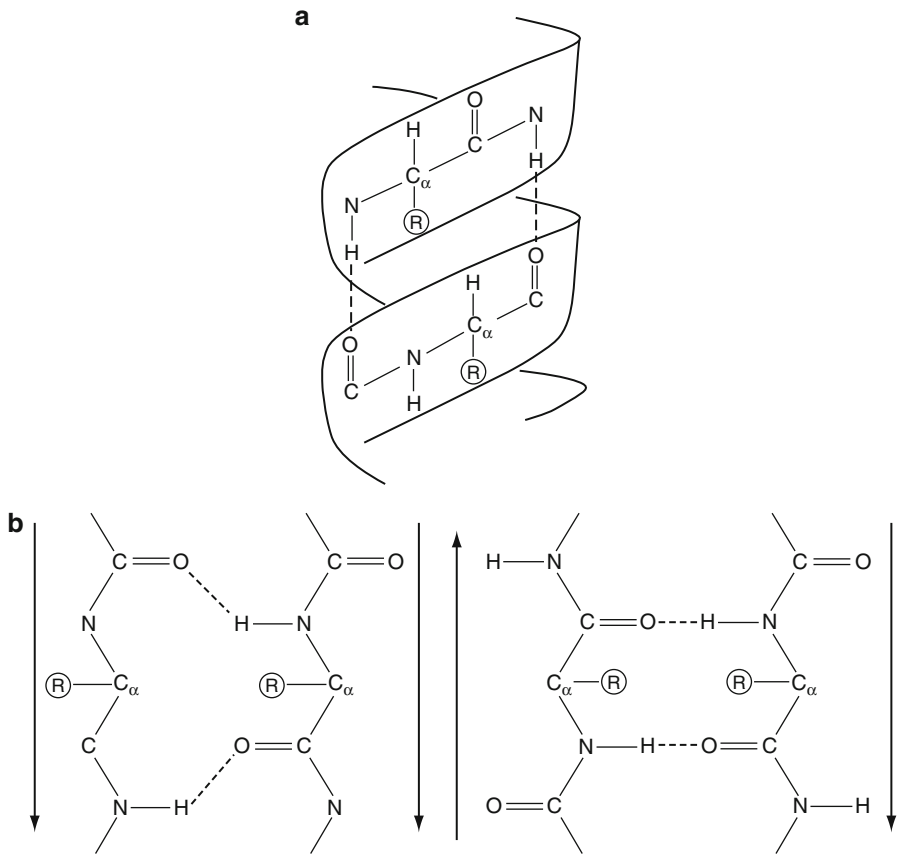
An optimal pairing between the two domains can be calculated by solving a quadratic integer program:

$$\max \sum_{i,k,j,r} x_{ik} x_{jr} d'_{ij} d'_{kr} : \sum_k x_{ik} \le 1,$$
$$\sum_i x_{ik} \le 1,\ x_{ik} = 0,\ (i,k) \in \mathcal{S},$$

where $(i, k) \in \mathcal{S}$ if the ith and kth C_α atoms are in different types of secondary structures.

Besides the choice of metric, a variation is to allow pairings between C_α atoms whose secondary structures are different. This is accommodated by removing the restriction that $x_{ik} = 0$ for $(i, k) \in \mathcal{S}$ and adding penalty terms in the objective: $-\sum_{(i,k)\in\mathcal{S}} p_{ik} x_{ik}$. The problem as stated includes the possibility of a non-sequential alignment, i.e., one in which the C_α atoms can be paired independent of the amino acid sequence. A combinatorial optimization model of alignments that requires the same ordering of the amino acid residues is called contact map optimization (Burkowski 2009; Glodzik and Skolnick 1994; Goldman et al. 1999).

Integer Programming: An integer program (IP) is an optimization problem in which some or all of the variables are restricted to be integer valued. For combinatorial optimization, the integer values are simply $\{0, 1\}$.



Computational Biology, Fig. 8 Secondary structures formed along the backbone define a protein's shape. *Dotted lines* represent hydrogen bonds; ® represents a side chain. (**a**) α-Helix, most closely packed arrangement of residues, defined by three parameters: pitch, rise, and turn. (**b**) *β*-Sheets form if the backbone is loosely packed, almost fully extended; they can be parallel (*left*), antiparallel (*right*), or a mixture

Pathway Analysis – Consider the FBA model (3) with added binary variables associated with each process with finite bounds (given or derived), $L_j \le v_j \le U_j$:

$$y_j = \begin{cases} 1 & \text{if } v_j \neq 0; \\ 0 & \text{otherwise.} \end{cases}$$

Replacing the bound constraints with $L_j y_j \le v_j \le U_j y_j$ forces $v_j = 0$ if $y_j = 0$. This corresponds to excluding reaction j, which is called a knock-out. Drug side effects are caused by unintended knock-outs, which, if cannot be avoided, can at least be identified and minimized. In drug design, one may want to block all pathways to some final output. If P is a pathway leading to the targeted output, then adding the constraint

$$\sum_{j \in P} y_j \le |P| - 1$$

removes the pathway, where $j \in P$ if pathway P contains reaction j.

A cut set can be computed with successive pathway-generation for a specified output and adding its pathway-elimination constraint. For the example in Fig. 2, pathways to produce D can be generated by fixing $v_7 = 1$ (and not have y_7). The first basic optimal solution uses reactions R_1, R_3, R_4, E_1, E_3. This leads to the addition of the constraint:

$$y_1 + y_3 + y_4 + y_5 \le 3.$$

The next pathway generated is R_3, E_1, and $y_3 = 0$ satisfies both pathway constraints. After eliminating R_3, the solution is R_1, R_4, E_1, E_3.

Other logical constraints include process conflict, $y_j + y_{j'} \le 1$ (i.e., inclusion of j requires exclusion of j'), and process dependence, $y_j \ge y_{j'}$ (i.e., exclusion of j requires exclusion of j'), for $j \neq j'$.

Rotamer Assignment – Part of the protein folding problem is knowing the side-chain conformations – i.e., knowing the torsion angles of the bonds (c.f., Fig. 3). The rotation about a bond is called a rotamer, and there are libraries that give configuration likelihoods, for each amino acid (from which energy values can be derived). The rotamer

assignment (RoA) problem is to find an assignment of rotamers to sites that minimizes the total energy of the molecule. For the protein folding problem, the amino acid at each site is known. There are about 10–50 rotamers per amino acid, depending on what else is known (such as knowing that the amino acid is located in a helix), so there are about 10^n to 50^n rotamer assignments for a protein of length n.

Let r be in the set of rotamers that can be assigned to site i, denoted by $\mathcal{R}_i$, and let

$$x_{ir} = \begin{cases} 1 & \text{if rotamer } r \text{ is assigned to site } i; \\ 0 & \text{otherwise.} \end{cases}$$

An optimal assignment is a solution to the quadratic semi-assignment problem:

$$\min \sum_i \sum_{r \in R_i} \left(\mathcal{E}_{ir} x_{ir} + \sum_{j>i} \sum_{t \in R_j} E_{irjt} x_{ir} x_{jt} \right): \\ \sum\nolimits_{r \in R_j} x_{ir} = 1 \, \forall i, \quad x \in \{0, 1\}.$$

The objective function includes two types of energy: (1) within a site, E_{ir}, and (2) between rotamers of two different sites, $\mathcal{E}_{irjt}$ for $i \neq j$. The summation condition $j > i$ avoids double counting, where $E_{irjt} = E_{jtir}$.

Besides its role in determining a protein's structure, the RoA problem is useful in drug design. Specifically, the RoA problem can be used to determine a minimum-energy docking site for a ligand, which is a small molecule such as a hormone or neurotransmitter that binds to a protein and modifies its function. The ligand-protein docking problem is characterized by only a few sites, and if the protein is known, the dimensions are small enough that the RoA problem can be solved exactly. However, if the protein is to be engineered, then there can be about 500 rotamers per site (20 acids @ 25 rotamers each), in which case solutions are computed with metaheuristics or approximation algorithms. There are other bioengineering problems associated with the RoA problem, such as determining protein-protein interactions. While the mathematical structure is the same, the applications have different energy data, which can affect algorithm performance (Forrester and Greenberg 2008).

Also see Clote and Backofen (2000), Jones and Pevzner (2004), and Lancia (2006).

Dynamic Programming: This is a computational approach to sequential decision making. Two fundamental biological sequences are taken from the alphabet of nucleic acids, {a, c, g, t}, and from the alphabet of amino acids, {A, R, N, D, C, Q, E, G, H, I, L, K, M, F, P, S, T, W, Y, V}. The former is a segment of DNA (or RNA if u replaces t – i.e., uracil instead of thymine); the latter is a protein segment.

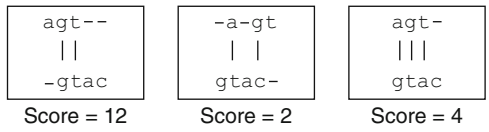
Sequence Alignment – Two sequences can be optimally aligned by dynamic programming, where optimal is one that maximizes an objective that has two parts:

1. A *scoring function*, given in the form of an $m \times m$ matrix S, where m is the size of the alphabet. The value of S_{ij} measures a propensity for the i^{th} alphabet-character in one sequence to align with the j^{th} alphabet-character in some position of the other sequence.
   Example: Let $s =$ agt and $t =$ gtac. If the first character of s is aligned with the first character of t, then the score is S_{ag}, which is the propensity for a to be aligned with g.
2. A *gap penalty function*, expressed in two parts: a fixed cost of beginning a gap, denoted G_{open}, and a cost to extend the gap, denoted G_{ext}.
   Example: Let $s =$ agt and $t =$ gtac. One alignment is $\begin{matrix} \mathtt{agt-} \\ \mathtt{gtac} \end{matrix}$, which puts a gap at the end of the first sequence.

A gap is called an indel because it can be either an insertion into one sequence or a deletion from the other sequence: insert $\downarrow$ $\begin{bmatrix} - \\ \mathtt{a} \end{bmatrix}$ delete $\uparrow$ If one sequence evolved directly from the other, the evolutionary operation is determined by their time-order. If they have a common ancestor, they evolved along different paths, resulting in the indel when comparing them. The evolutionary biology explains why sequences can be more similar than a simple alignment (without gaps) may suggest.

Figure 9 shows three different alignments for the two nucleic acid sequences, agt and gtac. Scores are shown for the following scoring matrix and do not account for gapping:

$$S = \begin{matrix} \mathtt{a} & \mathtt{c} & \mathtt{g} & \mathtt{t} \end{matrix} \\ \begin{bmatrix} 6 & 1 & 2 & 1 \\ 1 & 6 & 1 & 2 \\ 2 & 1 & 6 & 1 \\ 1 & 2 & 1 & 6 \end{bmatrix} \begin{matrix} \mathtt{a} \\ \mathtt{c} \\ \mathtt{g} \\ \mathtt{t} \end{matrix}$$



Computational Biology, Fig. 9 Three alignments for two sequences

If the objective is a linear affine function of gap lengths, the total objective function for the 2-sequence alignment problem is:

$$\sum_{i,j} S_{s_i t_j} - G_{\text{open}}(N_s + N_t) - G_{\text{ext}}(M_s + M_t),$$

where the sum is over aligned characters, s_i from sequence s with t_j from sequence t. The number of gaps opened is N_s in sequence s and N_t in sequence t; the number of gap characters (–) is M_s in sequence s and M_t in sequence t. In the examples of Fig. 9, if $G_{\text{open}} = 2$ and $G_{\text{ext}} = 1$, the gap penalties are 7, 9, and 3, respectively.

The alphabet is extended to include the gap character, with S extended to include gap extension, as $S_{a-} = S_{-a} = G_{\text{ext}}$ for all a in the alphabet. (So, G_{ext} includes the penalty for the first alignment with -.) Let s^i denote the subsequence $(s_1, \ldots, s_i)$, with $s^0 = \varnothing$. Here is the DP recursion for $G_{\text{open}} = 0$:

$$F(s^i, t^j) = \max \begin{cases} F(s^{i-1}, t^{j-1}) + S_{s_i t_j} & \text{match;} \\ F(s^{i-1}, t^j) + S_{s_i -} & \text{insert} - \text{into } t; \\ F(s^i, t^{j-1}) + S_{-t_j} & \text{insert} - \text{into } s. \end{cases} \tag{4}$$

The initial conditions are:

$$\begin{aligned} &F(\emptyset, \emptyset) = 0; \\ &F(s^i, \emptyset) = F(s^{i-1}, \emptyset) + S_{s_i -}, \quad i = 1, \cdots |s|; \\ &F(\emptyset, t^j) = F(\emptyset, t^{j-1}) + S_{-t_j}, \quad j = 1, \cdots |t|. \end{aligned}$$

The DP recursion (4) is for global alignment, and it has been extended to allow $G_{\text{open}} > 0$ and to not penalize leading or trailing gaps (allowing a short sequence to be aligned with a large one meaningfully). Local alignment is finding maximal substrings (contiguous subsequences) with an optimal global alignment having maximum score (Gusfield 1997; Waterman 1995).

Sequences from many species can be compared simultaneously in a Multiple Sequence Alignment (MSA). One way to evaluate an MSA is by summing pairwise scores. Figure 10 shows an example. The sum-of-pairs score, based on the scoring matrix S, is shown for each column. For example, column 1 has $3S_{\texttt{aa}} + 3S_{\texttt{ac}} = 3$. The sum-of-pairwise scores for column 2 is zero because gap scores are not shown by columns; they are penalized for each sequence (rows of alignment) with $G_{\text{open}} = 2$ and $G_{\text{ext}} = 1$. The total objective value is $152 - 37 = 115$.

MSA is a computational challenge to exact DP due to the combinatorial explosion of the state space, but one could use approximate DP or formulate MSA as an IP.

Phylogenetic Tree Construction – Phylogeny is the evolutionary history of some biological entity. A phylogenetic tree (PT) is a graphical presentation of a phylogeny. A leaf represents an Operational Taxonomic Unit (OTU), which can be various levels – e.g., species, genes, pathways, and enzymes. Each edge, or branch, is a relation between a pair of OTUs. Each internal node is constructed so that the resulting PT is consistent with the OTU data, and the root represents a common ancestor of the OTUs.

Example. Consider five OTUs and an MSA of DNA sites with six base-pairs (Fig. 11):

	site					
OTU	1	2	3	4	5	6
A	c	a	g	a	c	a
B	c	a	g	g	t	a
C	c	g	g	g	t	a
D	t	g	c	g	t	a
E	t	g	c	a	c	t

If the number of mutations is the distance between two sequences, then the distance between OTUs is the length of the unique path between them in the PT. The example has the distance matrix:

$$D = \begin{array}{c} \begin{matrix} A & B & C & D & E \end{matrix} \\ \begin{bmatrix} 0 & & & & \\ 2 & 0 & & & \\ 3 & 1 & 0 & & \\ 5 & 3 & 2 & 0 & \\ 8 & 6 & 5 & 3 & 0 \end{bmatrix} \end{array} \begin{matrix} A \\ B \\ C \\ D \\ E \end{matrix}$$

Computational Biology, Fig. 10 A multiple alignment of four sequences

													Gap penalty

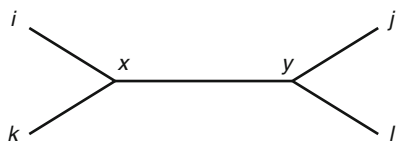
Computational Biology, Fig. 11 The example maximum-parsimony PT has eight mutations, shown on the branches. (All other PTs have more than 8.)

This is not the same as the MSA distance. For example, $D(A, E) = 8$ in the PT but is only 4 in the MSA.

Regardless of how the distance matrix is derived (MSA or not), there may not exist a PT that satisfies specified distances. For that to be true, it is necessary and sufficient that the metric be additive – i.e., for any four leaves, there exist labels i, j, k, ℓ such that

$$D(i,j) + D(k,\ell) = D(i,\ell) + D(j,k) \geq D(i,k) + D(j,\ell).$$

The reason for this is that there must be some splitting i, k from j, ℓ with an internal branch:



Additivity does not usually hold, so the problem is to construct a PT whose associated leaf-distance matrix, D, minimizes some function of nearness to the given D^0, such as $\|D - D^0\|$. This problem is NP-hard. Heuristics include sequential clustering: Un-weighted/Weighted Pair Group Method with Arithmetic Mean (UPGMA/WPGMA) and neighbor-joining algorithms.

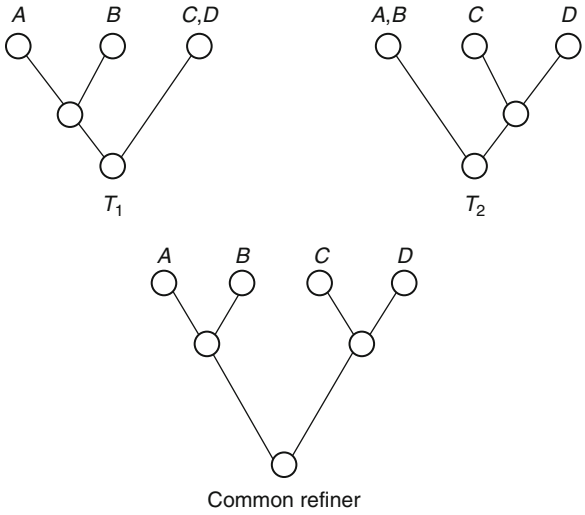
There may be multiple PTs, which generally come from different data – e.g., one from an MSA of a DNA segment, another from the maximum likelihood of some property. If a series of edge-contractions is applied to a PT, the resulting PT is called a refinement and the original is called a refiner. Two trees are compatible if they have a common refiner. One problem is to determine whether two PTs are compatible, and if so, what is their common refiner? If incompatible, how is a PT constructed that has some agreement with the given PTs?

A Matrix Representation with Parsimony (MRP) of a PT with k internal nodes is a binary matrix defined as:

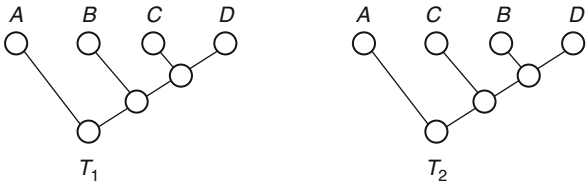
$$M_{ij} = \begin{cases} 1 & \text{if internal node } j \text{ is in the (unique) path} \\ & \text{from the root to OTU } i; \\ 0 & \text{otherwise.} \end{cases}$$

Conversely, given a binary matrix, if it has an associated PT, it is called a perfect phylogeny.

Given two PTs for the same OTUs with MRPs, M^1, M^2, their column-union is $[M^1\ M^2]$.



Computational Biology, Fig. 12 PTs T_1, T_2 are compatible



Computational Biology, Fig. 13 PTs T_1, T_2 are incompatible

Theorem. Two PTs are compatible if, and only if, their MRP column-union represents a perfect phylogeny.

The trees in Fig. 12 have the MRP column-union:

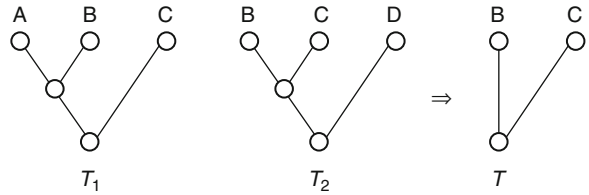
$$M = \begin{array}{c} M^1M^2 \\ \left[\begin{array}{c|c} 1 & 0 \\ 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{array}\right] \end{array} \begin{array}{l} A \\ B \\ C \\ D \end{array}$$

This is the MRP of the common refiner in Fig. 12 and represents a perfect phylogeny.

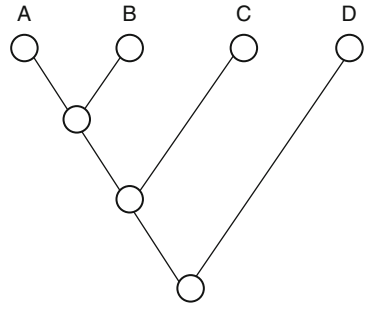
The MRP column-union of the PTs in Fig. 13 is:

$$M = \begin{array}{c} \quad M^1 \quad\quad M^2 \\ \left[\begin{array}{cc|cc} 0 & 0 & 0 & 0 \\ 1 & 0 & 1 & 1 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \end{array}\right] \end{array} \begin{array}{l} A \\ B \\ C \\ D \end{array}$$

M does not correspond to any PT. (After drawing A, C, D with four internal nodes as the path to D, OTU B cannot be drawn with the path 0-1-3-4 without introducing the cycle, 1-2-3-1.)



Computational Biology, Fig. 14 A maximum agreement subtree with 2 of the 4 OTUs



Computational Biology, Fig. 15 An agreement supertree of the trees in Fig. 14

Suppose the trees are incompatible. A Maximum Agreement Subtree (MAST) is a refined subtree with the greatest number of leaves (Fig. 14).

The DP recursion for two subtrees (Steel and Warnow 1993) is nontrivial. The state is a pair of subtrees with specified roots, $\left(T_1^r, T_2^s\right)$. Each tree has an inclusion-ordered sequence of such subtrees, which is computed during the recursion. The decision space to compute $MAST\left(T_1^r, T_2^s\right)$, given $MAST\left(T_1^{r'}, T_2^{s'}\right)$ for $\left(T_1^{r'}, T_2^{s'}\right) \prec \left(T_1^r, T_2^s\right)$, requires the computation of a maximum weighted-matching on the complete r-s bipartite graph, weighted with $\{MAST(r', s')\}$.

Whereas MAST uses an intersection of PT information, a supertree uses their union. Construction methods vary, and some of the criteria address common order preservation. An agreement supertree, T, is a minimal tree such that each T_i is a refined subtree of T (Fig. 15).

Markov Chains and Processes: A stochastic process has the Markov property if the transition from one state to the next depends on only the current state. Classical models include the evolution of some biological states over time (Allen 2003; Wilkinson 2006). Molecular applications of Markov models also

consider ordered sequences of nucleotides (viz., DNA and RNA) and amino acids (viz., proteins).

CpG Island Recognition – In the human genome the appearance of the dinucleotide CG is rare because it causes the cytosine (C) to be chemically modified by methylation, which causes it to mutate into thymine (T). Methylation is suppressed around the promoters, or start regions, of many genes, and there are more CG dinucleotides than elsewhere. Such regions are called CpG islands, and they are typically a few hundred bases long. (CpG is used instead of CG to avoid confusion with a C–G base pair; the p is silent.) The recognition problem is: Given a short segment of a genomic sequence, decide if it is part of a CpG island.

Two Markov chains are defined: P^+ is the state-transition matrix within a CpG island; P^- is the state-transition matrix outside a CpG island. Each is applied to the given sequence and the log-odds ratio determines which is more likely.

Example. Consider a first-order Markov chain model with transition matrices determined by the frequencies in a database having more than 60,000 human DNA sequences:

$$P^+ = \begin{array}{c} \\ \mathtt{A} \\ \mathtt{C} \\ \mathtt{G} \\ \mathtt{T} \end{array} \begin{array}{c} \begin{array}{cccc} \mathtt{A} & \mathtt{C} & \mathtt{G} & \mathtt{T} \end{array} \\ \begin{bmatrix} 0.18 & 0.27 & 0.43 & 0.12 \\ 0.17 & 0.37 & 0.27 & 0.19 \\ 0.16 & 0.34 & 0.38 & 0.12 \\ 0.08 & 0.36 & 0.38 & 0.18 \end{bmatrix} \end{array}$$

$$P^- = \begin{array}{c} \\ \mathtt{A} \\ \mathtt{C} \\ \mathtt{G} \\ \mathtt{T} \end{array} \begin{array}{c} \begin{array}{cccc} \mathtt{A} & \mathtt{C} & \mathtt{G} & \mathtt{T} \end{array} \\ \begin{bmatrix} 0.30 & 0.20 & 0.29 & 0.21 \\ 0.32 & 0.30 & 0.08 & 0.30 \\ 0.25 & 0.25 & 0.30 & 0.20 \\ 0.18 & 0.24 & 0.29 & 0.29 \end{bmatrix} \end{array}$$

Given the sequence AACTTCG, its total log-odds ratio is

$$\sum_{i=1}^{6} \log_2\left(P^+_{s_i s_{i+1}} / P^-_{s_i s_{i+1}}\right) = -0.737 + 0.433 - 0.659 - 0.688 + 0.585 + 1.755 = 0.6888.$$

The conclusion is that the DNA segment is in a CpG island.

There is enough data to support the use of the more accurate 5th-order Markov chain, whose six-tuples correspond to two coding regions. At least 4^5 six-tuples are required in the database to estimate the conditional probabilities, $\Pr(x_6|x_1x_2x_3x_4x_5)$, which directly yield the state-transition probabilities:

$$\Pr(y_1y_2y_3y_4y_5|x_1x_2x_3x_4x_5) = \begin{cases} \Pr(x_6|x_1x_2x_3x_4x_5) & \text{if } y = (x_2x_3x_4x_5x_6); \\ 0 & \text{otherwise.} \end{cases}$$

For the particular example, there are only two state transitions, and the same database gives the transition probabilities:

$$P^+(\mathtt{C}|\mathtt{AACTT}) = 0.4 \qquad P^-(\mathtt{C}|\mathtt{AACTT}) = 0.2$$
$$P^+(\mathtt{G}|\mathtt{ACTTC}) = 0.1 \qquad P^-(\mathtt{G}|\mathtt{ACTTC}) = 0.3$$

In this case, the more accurate 5th-order chain yields the log-odds ratio $\log_2 0.4/0.2 + \log_2 0.1/0.3 = -0.585$, and the conclusion is that the DNA segment is not in a CpG island.

A host of related problems use the same Markov model. For example, transcription splices the DNA into coding regions, called exons, removing the remainder, called introns (misnamed junk DNA). A structure recognition problem is to identify exons versus introns.

Many of the structure recognition, comparison, and prediction problems have hidden states, but emissions are observed according to a known probability. These are Hidden Markov Models (HMMs) and are central in modern biology (Durbin et al. 1998).

Queueing Theory: A queue in a system is any set of objects awaiting service, and service is some process (es) involving the object.

T-Cell Signaling – A T-cell is a type of white blood cell distinguished by having a receptor – i.e., an ability to bind to other molecules. The receptor interacts with intracellular pathway components, starting a cascade of protein interactions called signal transduction. A way to view this process is that a T-cell receptor (TCR) enters a queue upon activation and goes through a series of processes, such as phosphorylation (Wedagedera and Burroughs 2006). Service completion is defined by the deactivation of the TCR, returning it to the inactive pool; however, it is possible that the T-cell's service is aborted before it completes service. Of interest is the probability of activation – i.e., in service for some threshold of

time. If it completes service and detects infection, the T-cell signals cell death (called apoptosis; the second p is silent).

Other queueing models apply to genetic networks, allowing signals that affect the population to enter and leave the system (Arazi et al. 2004; Jamalyaria et al. 2005). This applies queueing to a broad range of self-assembly systems – i.e., form an arrangement without external guidance.

Simulation: Dynamical state evolution is fundamental in both classical mathematical biology and modern systems biology. Evolution and biochemical pathways are prime examples; the underlying state-transition structure and the sheer size are sufficient to need simulation.

The kinetic laws of a biosystem depend upon the objects, particularly their scale (viz., molecules vs. cells). The deterministic rate equations have the form:

$$\frac{\mathrm{d}x_i}{\mathrm{d}t} = f_i(x;k) \qquad \text{for } i = 1,\ldots,m,$$

where x is the system state (e.g., concentrations of m metabolites) and k is a vector of parameters, called rate constants.

Sources of randomness can be intrinsic – e.g., errors in parameter estimation, or extrinsic – e.g., protein production in random pulses (Meng et al. 2004). To deal with reaction uncertainty, Gillespie (2008, 1977) introduced the probability equation:

$$\Pr(x;t+\mathrm{d}t) = \sum\nolimits_r \Pr(x-v_r;t)a_r(x-v_r)\,\mathrm{d}t + \Pr(x;t) \times \left(1 - \sum\nolimits_r a_r(x)\mathrm{d}t\right),$$

where $a_r(x)\,\mathrm{d}t$ is the probability that reaction r occurs in the time interval $(t, t+\mathrm{d}t)$, changing the state from x to $x + v_r$. The first summation represents being one reaction removed from the state x; the last term represents having no reaction during the interval.

Auto-regulatory Network – Puchalka and Kierzek (2004) consider a metabolic network with regulatory processes and random fluctuations in gene expression. Using Gillespie's equation, given the state x at time t, the probability that the next reaction, r, occurs during $(t+\tau, t+\tau+\mathrm{d}t)$ is given by:

$$\Pr(\tau, r|x,t) = a_r(x)\; e^{-\sum_j a_j(x)\tau}.$$

The simulation is run by generating (τ, r) using this joint density function. The simulation also allows for pulse production – a receptor site may be on or off to regulate gene expression (restricting the choice of r).

Other models use rare-event simulation, such as for tumor development (Abbott 2002). Simulation is used in systems biology to understand how non-dominant pathways affect assembly kinetics (Zhang and Schwartz 2006).

Game Theory: The central idea of game theory is that each player has its own objective to optimize. Historically, evolutionary biologists used game theory to model natural selection (Maynard Smith 1982; Perc and Szolnoki 2010). In OR, game theory is used to model competition for economic resources, and this extends to modeling species-invasion into an existing ecosystem. The same game model applies to the propagation of tumor cells that can mutate to create a cancer population that overwhelms normal cells (Tomlinson 1997). New applications are at the molecular scale, such as the following example.

Protein Binding – There are two sets of players: protein classes (including drugs) and DNA binding sites. Their joint strategies result in allocation of proteins to sites. Sites seek to maximize their occupancy; proteins seek to minimize excess binding. Sites compete for nearby proteins; proteins choose target sites to which they transport. (Mechanisms to achieve these choices are not well understood.) The affinity for protein i to bind to site j is denoted by the constant K_{ij}, but this applies only if the protein is in the proximity of the site.

Let $i = 1,\ldots, N_p$ index proteins and $j = 1,\ldots, N_s$ index sites, and consider the parameters:

$$\begin{aligned} v_i &= \text{nuclear concentration},\\ E_{ij} &= \text{transport affinity},\\ K_{ij} &= \text{binding affinity}. \end{aligned}$$

A protein's decision variable is its fractional transported amounts, $p^i = \left(p^i_0,\ldots,p^i_{N_s}\right)$, where $p^i_0 = 1 - \sum_{j=1}^{N_s} p^i_j$ is the portion of protein i not allocated to a site. A site's decision variable is its choice of binding frequency, $s^j = \left(s^j_0,\ldots,s^j_{N_p}\right)$, where $s^j_0 = 1 - \sum_{i=1}^{N_p} s^i_j$ is the portion of time that site j is unoccupied. There are resource constraints on joint strategies, notably $s^j_i \le p^i_j v_i$ for $i > 0$ – i.e., binding cannot exceed allocated concentration.

A solution is a joint strategy $(\bar{p}, \bar{s})$ that satisfies the optimality criteria:

$$\bar{p}^i \in \underset{p^i \in P(\bar{s})}{\operatorname{argmax}} \left\{ f_p^i(p^i, \bar{s}) \right\} \quad \bar{s}^j \in \underset{s^j \in S(\bar{p})}{\operatorname{argmin}} \left\{ f_s^j(\bar{p}, s^j) \right\},$$

where f_p, f_s denote objective functions for each protein and site, and $P \subseteq \mathbb{R}_+^{N_s+1}$, $S \subseteq \mathbb{R}_+^{N_p+1}$ denote feasible regions, each dependent on the other decisions. An example of objective functions are maximizing total binding affinity and minimizing the amount of protein not assigned:

$$f_p^i(p^i, s) = \sum_{j=1}^{N_s} E_{ij} p_j^i \left(1 - s_0^j\right)$$

$$f_s^j(s^j, p) = s_0^j \sum_{i=1}^{N_p} K_{ij} \left(p_j^i v_i - s_i^j\right).$$

With mild modifications, a solution exists and there is a simple algorithm to find it (Pérez-Breva et al. 2006).

This game model is a simplification of a broader biology, where sites can coordinate, not just compete, and proteins can form complexes to bind to the same site. There are also promoters that bind to a protein in order to send it to another site. Although current thinking is that proteins roam randomly until they bump into an unoccupied site for which they have affinity, the game model attributes a purposeful behavior to proteins, suggesting that they choose to transport to some site. While this rational behavior is not due to intelligence, it could be due to an environmental context that is not yet understood and whose net effect makes proteins behave as if they are rational players.

Computational Complexity

Leslie Hall
The Johns Hopkins University, Baltimore, MD, USA

Introduction

The term computational complexity has two usages which must be distinguished. On the one hand, it refers to an algorithm for solving instances of a problem: broadly stated, the computational complexity of an algorithm is a measure of how many steps the algorithm will require in the worst case for an instance or input of a given size. The number of steps is measured as a function of that size.

The term's second, more important use is in reference to a problem itself. The theory of computational complexity involves classifying problems according to their inherent tractability or intractability — that is, whether they are easy or hard to solve. This classification scheme includes the well-known classes *P* and *NP*; the terms *NP*-complete and *NP*-hard are related to the class *NP*.

Algorithms and Complexity

To understand what is meant by the complexity of an algorithm, algorithms, problems, and problem instances must be defined. Moreover, one must understand how one measures the size of a problem instance and what constitutes a step in an algorithm. A problem is an abstract description coupled with a question requiring an answer; for example, the Traveling Salesman Problem (TSP) is: "Given a graph with nodes and edges and costs associated with the edges, what is a least-cost closed walk (or *tour*) containing each of the nodes exactly once?" An instance of a problem, on the other hand, includes an exact specification of the data: for example, "The graph contains nodes 1, 2, 3, 4, 5, and 6, and edges (1, 2) with cost 10, (1, 3) with cost 14, . . ." and so on. Stated more mathematically, a problem can be thought of as a function p that maps an instance x to an output $p(x)$ (an answer).

An algorithm for a problem is a set of instructions guaranteed to find the correct solution to any instance in a finite number of steps. In other words, for a problem p, an algorithm is a finite procedure for computing $p(x)$ for any given input x. Computer scientists model algorithms by a mathematical construct called a Turing machine, but a more concrete model will be considered here. In a simple model of a computing device, a "step" consists of one of the following operations: addition, subtraction, multiplication, finite-precision division, and comparison of two numbers. Thus if an algorithm requires one hundred additions and 220 comparisons for some instance, then the algorithm requires 320 steps on that instance. In order to make this number meaningful, it should be expressed as a function of the size of the corresponding instance, but determining the exact function would be impractical. Instead, since the main concern is how long the algorithm takes (in the worst case) asymptotically as the size of an instance gets large, one formulates a simple function of the input size that is a reasonably tight upper bound on the actual number of steps. Such a function is called the complexity or running time of the algorithm.

Technically, the *size* of an instance is the number of bits required to encode it. It is measured in terms of the inherent dimensions of the instance (such as the number of nodes and edges in a graph), plus the number of bits required to encode the numerical information in the instance (such as the edge costs). Since numerical data are encoded in binary, an integer C requires about $\log_2 |C|$ bits to encode and so contributes logarithmically to the size of the instance. The running time of the algorithm is then expressed as a function of these parameters, rather than the precise input size. For example, for the TSP, an algorithm's running time might be expressed as a function of the number of nodes, the number of edges, and the maximum number of bits required to encode any edge cost. As was seen, the complexity of an algorithm is only a rough estimate of the number of steps that will be required on an instance. In general — and particularly in analyzing the inherent tractability of a problem — an asymptotic analysis is the main interest: how does the running time grow as the size of the instance gets very large? For these reasons, it is useful to introduce Big-O notation. For two functions $f(t)$ and $g(t)$ of a nonnegative parameter t, $f(t) = O(g(t))$ if there is a constant $c > 0$ such that, for all sufficiently large t, $f(t) \leq cg(t)$. The function $cg(t)$ is thus an asymptotic upper bound on f. For example, $100(t^2 + t) = O(t^2)$, since by taking $c = 101$ the relation follows for $t \geq 100$; however, $0.0001\ t^3$ is not $O(t^2)$. Notice that it is possible for $f(t) = O(g(t))$ and $g(t) = O(f(t))$ simultaneously.

An algorithm is said to run in polynomial time (is a polynomial-time algorithm) if the running time $f(t) = O(P(t))$, where $P(t)$ is a polynomial function of the input size. Polynomial-time algorithms are generally (and formally) considered efficient, and problems for which polynomial time algorithms exist are considered easy. For the remainder of this article, the term polynomial will mean as a function of the input size.

The Classes P and NP

In order to establish a formal setting for discussing the relative tractability of problems, computer scientists first define a large class of problems called recognition (or decision) problems. This class comprises precisely those problems whose associated question requires the answer yes or no. For example, consider the problem of determining whether an undirected graph is connected (that is, whether there a path between every pair of nodes in the graph). This problem's input is a graph G consisting of nodes and edges, and its question is, "Is G connected?" Notice that most optimization problems are not recognition problems, but most have recognition counterparts. For example, a recognition version of the TSP has as input both a graph G, with costs on the edges, *and* a number K. The associated question is, "Does G contain a traveling salesman tour of length less than or equal to K?" In general, an optimization problem is not much harder to solve than its recognition counterpart. One can usually embed the recognition algorithm in a binary search over the possible objective function values to solve the optimization problem with a polynomial number of calls to the embedded algorithm.

The class P is defined as the set of recognition problems for which there exists a polynomial-time algorithm, where P stands for polynomial time. Thus, P comprises those problems that are formally considered easy. The larger problem class NP contains the class P. The term NP stands for nondeterministic polynomial and refers to a different, hypothetical model of computation, which can solve the problems in NP in polynomial time (for further explanation, see references).

The class NP consists of all recognition problems with the following property: for any yes-instance of the problem there exists a polynomial-length certificate or proof of this fact that can be verified in polynomial time. The easiest way to understand this idea is by considering the position of an omniscient being (say, the wizard Merlin) who is trying to convince a mere mortal that some instance is a yes-instance. Suppose the problem is the recognition version of the TSP, and the instance is a graph G and the number $K = 100$. Merlin knows that the instance does contain a tour with length at most 100. To convince the mortal of this fact, he simply hands her a list of the edges of this tour. This list is the certificate: it is polynomial in length, and the mortal can easily verify, in polynomial time, that the edges do in fact form a tour with length at most 100.

There is an inherent asymmetry between yes and no in the definition of NP. For example, there is no obvious, succinct way for Merlin to convince

a mortal that a particular instance does NOT contain a tour with length at most 100. In fact, by reversing the roles played by yes and no leads to a problem class known as *Co-NP*. In particular, for every recognition problem in *NP* there is an associated recognition problem in *Co-NP* obtained by framing the *NP* question in the negative (e.g., "Do *all* traveling salesman tours in *G* have length *greater* than *K*?"). Many recognition problems are believed to lie outside both of the classes *NP* and *Co-NP*, because they seem to possess no appropriate certificate. An example would be the problem consisting of a graph *G* and two numbers *K* and *L*, with the question, "Is the number of distinct traveling salesman tours in *G* with length at most *K* exactly equal to *L*?"

NP-Complete Problems

To date, no one has found a polynomial-time algorithm for the TSP. On the other hand, no one has been able to prove that no polynomial-time algorithm exists for the TSP. How, then, can one argue persuasively that the TSP and many problems in *NP* are intractable? Instead, an argument is presented that is slightly weaker but also compelling. It is shown that the recognition version of the TSP, and scores of other *NP* problems, are the *hardest* problems in the class *NP* in the following sense: if there is a polynomial-time algorithm for any one of these problems, then there is a polynomial-time algorithm for every problem in *NP*. Observe that this is a very strong statement, since *NP* includes a large number of problems (such as integer programming) that appear to be extremely difficult to solve, both in theory and in practice! Problems in *NP* with this property are called *NP*-complete. Otherwise stated, it seems highly unlikely that a polynomial algorithm will be found for any *NP*-complete problem, since such an algorithm would actually provide polynomial time algorithms for *every* problem in *NP*!

The class *NP* and the notion of complete problems for *NP* were first introduced by Cook (1971). In that paper, he demonstrated that a particular recognition problem from logic, SATISFIABILITY, was *NP*-complete, by showing directly how every other problem in *NP* could be encoded as an appropriate special case of SATISFIABILITY. Once the first *NP*-complete problem had been established, however, it became easy to show that others were *NP*-complete. To do so requires simply providing a polynomial transformation from a known *NP*-complete problem to the candidate problem. Essentially, one needs to show that the known hard problem, such as SATISFIABILITY, is a special case of the new problem. Thus, if the new problem has a polynomial-time algorithm, then the known hard problem has one as well.

Related Terms

The term *NP*-hard refers to any problem that is at least as hard as any problem in *NP*. Thus, the *NP*-complete problems are precisely the intersection of the class of *NP*-hard problems with the class *NP*. In particular, optimization problems whose recognition versions are *NP*-complete (such as the TSP) are *NP*-hard, since solving the optimization version is at least as hard as solving the recognition version.

The polynomial hierarchy refers to a vast array of problem classes both beyond *NP* and *Co-NP* and within. There is an analogous set of definitions which focuses on the space required by an algorithm rather than the time, and these time and space definitions roughly correspond in a natural way. There are complexity classes for parallel processing, based on allowing a polynomial number of processors. There are classes corresponding to randomized algorithms, those that allow certain decisions in the algorithm to be made based on the outcome of a coin toss. There are also complexity classes that capture the notions of optimization and approximability. The most famous open question concerning the polynomial hierarchy is whether the classes *P* and *NP* are the same, i.e., $P \stackrel{?}{=} NP$. If a polynomial algorithm were discovered for any *NP*-complete problem, then all of *NP* would collapse to *P*; indeed, most of the polynomial hierarchy would disappear.

In algorithmic complexity, two other terms are heard frequently: strongly polynomial and pseudo-polynomial. A strongly polynomial-time algorithm is one whose running time is bounded polynomially by a function *only* of the inherent dimensions of the problem and independent of the sizes of the numerical data. For example, most sorting algorithms are strongly polynomial, since they normally require a number of comparisons polynomial in the number of entries and do not depend on the actual values being

sorted; an algorithm for a network problem would be strongly polynomial if its running time depended only on the numbers of nodes and arcs in the network, and not on the sizes of the costs or capacities.

A pseudo-polynomial-time algorithm is one that runs in time polynomial in the dimension of the problem and the magnitudes of the data involved (provided these are given as integers), rather than the base-two logarithms of their magnitudes. Such algorithms are technically exponential functions of their input size and are therefore not considered polynomial. Indeed, some *NP*-complete and *NP*-hard problems are pseudo-polynomially solvable (sometimes these are called weakly *NP*-hard or-complete, or *NP*-complete in the ordinary sense). For example, the *NP*-hard knapsack problem can be solved by a dynamic programming algorithm requiring a number of steps polynomial in the size of the knapsack and the number of items (assuming that all data are scaled to be integers). This algorithm is exponential-time since the input sizes of the objects and knapsack are logarithmic in their magnitudes. However, as Garey and Johnson (1979) observe, "A pseudo-polynomial-time algorithm. . .will display 'exponential behavior' only when confronted with instances containing 'exponentially large' numbers, [which] might be rare for the application we are interested in. If so, this type of algorithm might serve our purposes almost as well as a polynomial time algorithm." The related term strongly *NP*-complete (or unary *NP*-complete) refers to those problems that remain *NP*-complete even if the data are encoded in unary (that is, if the data are small relative to the overall input size). Consequently, if a problem is strongly *NP*-complete then it cannot have a pseudo-polynomial-time algorithm unless $P = NP$.

For textbook introductions to the subject, see Papadimitriou (1993) and Sipser (1997). The most important reference on the subject, Garey and Johnson (1979), contains an outstanding, relatively compact introduction to complexity. Introduction

Computational geometry is the discipline of exploring algorithms and data structures for computing geometric objects and their often extremal attributes. The objects are predominantly finite collections

of points, flats, hyperplanes, arrangements, or polyhedra, all in finite dimensions. The algorithms are typically finite, their complexity playing a central role. Emphasis is on problems in low dimensions, exploiting special properties of the plane and 3-space.

A relatively young field; its name coined in the early 1970s. It has since witnessed explosive growth, stimulated in part by the largely parallel development of computer graphics, pattern recognition, cluster analysis, and modern industry's reliance on computer-aided design (CAD) and robotics (Forrest 1971; Graham and Yao 1990; Lee and Preparata 1984). It plays a key role in the emerging fields of automated cartography and computational metrology.

The *Handbook of Discrete and Computational Geometry*, edited by Goodman and O'Rourke (1997), provides overviews of key topics. For general texts, see Preparata and Shamos (1985), O'Rourke (1987), Edelsbrunner (1987), and, de Berg et al. (2008). Pertinent concepts of discrete geometry are presented in Grünbaum (1967).

There are strong connections to operations research, whose classical problems such as finding a minimum spanning tree, a maximum-length matching, or a Steiner tree become problems in computational geometry when posed in Euclidean or related normed linear spaces. The Euclidean traveling salesman problem remains *NP*-complete (Papadimitriou 1977). Facility location, and shortest paths in the presence of obstacles, are other examples. Polyhedra and their extremal properties, typical topics of computational geometry, also lie at the foundation of linear programming. Its complexity, particularly in lower dimensions, attracted early computational geometric research, heralding the achievement of linear complexity for arbitrary fixed dimension (Megiddo 1982, 1984; Clarkson 1986).

Problems

A fundamental problem is to determine the convex hull conv(S) of a set S of n points in d-dimensional Cartesian space $\mathfrak{R}^d$. This problem has a weak and a strong formulation. Its weak formulation requires only the identification of the extreme points of conv(S). In operations research terms, that problem is well known as (the dual of) identifying redundant constraints in a system of linear inequalities. The strong formulation requires, in addition, characterization of the facets of the polytope conv(S). For dimension $d > 3$, the optimal complexity of the strong convex hull problem in $\mathfrak{R}^d$ is $O(n^{\lceil d/2 \rfloor})$ (Chazelle 1991).

Early $O(n \log n)$ methods for delineating convex hulls in the plane — vertices and edges of the convex hull of a simple polygon can be found in linear time — were based on divide-and-conquer (Graham and Yao 1983) and (Preparata and Hong 1977). In this widely used recursive strategy, a problem is divided into subproblems whose solutions, having been obtained by further subdivision, are then combined to yield the solution to the original problem. Divide-and-conquer heuristics find applications in Euclidean optimization problems such as optimum-length matching (Reingold and Supowit 1983).

The following bridge problem is, in fact, a linear program: given two sets S_1 and S_2 of planar points separated by a line, find two points $p_1 \varepsilon S_1$ and $p_2 \varepsilon S_2$ such that the line segment $[p_1, p_2]$ is an upper edge of the convex hull conv($S_1 \cup S_2$), bridging the gap between the two sets. Or, through which edge does a given directed line leave the — not yet delineated — convex hull of n points in the plane? As a linear program of fixed dimension 2, the bridge problem can be solved in linear time. Kirkpatrick and Seidel (1986) have used it along with a divide-and-conquer paradigm to devise an $O(n \log m)$ algorithm for the planar convex hull of n points, m of which are extreme.

When implementing a divide-and-conquer strategy, one typically wishes to divide a set of points $S \subset \mathfrak{R}^d$ by a straight line into two parts of essentially equal cardinality, that is, to execute a ham-sandwich cut. This can be achieved by finding the median of, say, the first coordinates of the points in S. It is a fundamental result of the theory of algorithms that the median of a finite set of numbers can be found in linear time. The bridge problem is equivalent to a double ham-sandwich cut of a planar set: given a first cut, find a second line quartering the set. Threeway cuts in three dimensions and results about higher dimensions were reported in Dobkin and Edelsbrunner (1984).

The Euclidean post office problem is a prototype for a class of proximity search problems encountered, for instance, in the implementation of expert systems. Sites p_i of n post offices in $\mathfrak{R}^d$ are given, and the task is

to provide suitable preprocessing for efficiently identifying a post office closest to any client location.

Associated with this problem is the division of space into postal regions, that is, sets of locations $V_i \subset \Re^d$ closer to postal site p_i than to any other site p_j. Each such region V_i around site p_i is a convex polyhedron, whose facets are determined by perpendicular bisectors, that is, (hyper)planes or lines of equal distance from two distinct sites. Those polyhedra form a polyhedral complex covering $\Re^d$ known as a Voronoi diagram. The Voronoi diagram and its dual, the Delaunay triangulation, are important related concepts in computational geometry.

Once a Delaunay triangulation of a planar set of n sites has been established, an $O(n \log n)$ procedure, a pair of nearest points among these sites can be found in linear time. The use of Delaunay triangulations for computational geometric problems was pioneered by Shamos and Hoey (1975).

The problem of efficiently finding a Voronoi cell V_i for an arbitrary query point p is an example of point location in subdivisions. Practical algorithms for locating a given point in a subdivision of the plane generated by n line segments in time $O(\log n)$ requiring preprocessing of order $O(n \log n)$ and storage of size $O(n \log n)$ or $O(n)$, respectively, have been proposed (Preparata 1990). For point location in planar Voronoi diagrams, Edelsbrunner and Maurer (1985) utilized acyclic graphs and packing. A probabilistic approach to the post office problem is given in Clarkson (1985).

Whether a given point lies in a certain simple polygon can be decided by an $O(n)$ process of examining the boundary intersections of an arbitrary ray emanating from the point in question. For convex polygons, an $O(n)$ preprocessing procedure permits subsequent point inclusion queries to be answered in $O(\log n)$ time (Bentley and Carruthers 1980).

An important concept with operations research implications is the medial axis of a polygon (Lee 1982), the locus of interior points with equal distance from the boundary; more precisely, those interior points with more than one closest boundary point. Such medial axes may be obtained in $O(n)$ time (Chin et al. 1995).

Let $h_e(x)$ be the truth function expressing point inclusion in the half plane to the left of a directed line segment e. Muhidinov and Nazirov (1978) have shown that a polygonal set can be characterized by a Boolean expression of n such functions, one for each edge e of the polygonal set, where each such function occurs only once in the expression. This Boolean expression transforms readily to an algebraic expression for the characteristic function of the polygon. For 3-dimensional polyhedral bodies, Dobkin, Guibas, Hershberger, and Snoeyink (1988) investigated the existence and determination of analogous constructive solid geometry (CSG) representations (they may require repeats of half space truth functions). In general, CSG representations use Boolean operations to combine primitive shapes, and are at the root of some commercial CAD/CAM and display systems. For a survey of methods for representing solid objects see Requicha (1980).

Given a family of polygons, a natural generalization of point inclusion is to ask how many of those polygons include a query point. This and similar intersection-related problems are subsumed under the term stabbing. The classical 1-dimensional stabbing problem involves n intervals. Here the stabbing number can be found in $O(\log n)$ time and $O(n)$ space after suitable preprocessing. Similar results hold for special classes of polygons such as rectangles (Edelsbrunner 1983).

Sweep-techniques rival divide-and-conquer in popularity. Plane-sweep or line-sweep, for instance, conceptually moves a vertical line from left to right over the plane, registering objects as it passes them. Plane-sweep permits one to decide in $O(n \log n)$ time (optimal complexity) whether n line segments in the plane have at least one intersection (Shamos and Hoey 1976).

Important special cases of the above intersection problem are testing for (self-)intersection of paths and polygons. Polygon simplicity can be tested for in linear time by trying to triangulate the polygon.

Polygon triangulation, more precisely, decomposing the interior of a simple polygon into triangles whose vertices are also vertices of the polygon, is a celebrated problem of computational geometry. In a seminal paper, Garey, Johnson, Preparata, and Tarjan (1978) proposed an $O(n \log n)$ algorithm for triangulating a simple polygon of n vertices. They used a plane sweep approach for decomposing the polygon into monotone polygons, which can each be triangulated in linear time. A related idea is to provide a trapezoidization of the polygon, from which a triangulation can be obtained in linear time. Chazelle (1990) introduced the concept of

a visibility map, a tree structure which might be considered a local trapezoidization of the polygon, and based on it an $O(n)$ triangulation algorithm for simple polygons. In 3-space, an analogous tetrahedralization (without additional Steiner points for vertices) for nonconvex polyhedral bodies may not exist. Moreover, the problem of deciding such existence is *NP*-complete (Ruppert and Seidel 1989).

For algorithms that depend on sequential examination of objects, bucketing or binning may improve performance by providing advantageous sequencing (Devroye 1986). The idea is to partition an area into a regular pattern of simple shapes such as rectangles to be traversed in a specified sequence. The problem at hand is then addressed locally within buckets or bins followed by adjustments between subsequent or neighboring buckets. Bucketing-based algorithms have provided practical solutions to Euclidean optimization problems, such as shortest paths, optimum-length matching, and a Euclidean version of the Chinese Postman Problem: minimizing the pen movement of a plotter (Asano et al. 1985). The techniques of quadtrees and octrees might be considered as hierarchical approaches to bucketing, and are often the methods of choice for image processing and spatial data analysis including surface representation (Samet 1990a, b).

The position of bodies and parts of bodies, relative to each other in space, determines visibility from given vantage points, shadows cast upon each other, and impediments to motion. Hidden line and hidden surface algorithms are essential in computer graphics, as are procedures for shadow generation and shading (Sutherland et al. 1974; Atherton et al. 1978). Franklin (1980) used bucketing techniques for an exact hidden surface algorithm.

Lozano-Pérez and Wesley (1979) used the concept of a visibility graph for planning collision-free paths: given a collection of mutually disjoint polyhedral objects, the node set of the above graph is the set of all vertices of those polyhedral objects, and two such nodes are connected if the two corresponding vertices are visible from each other.

The piano movers problem captures the essence of motion planning (Schwartz and Sharir 1983, 1989). Here a 2-dimensional polygonal figure, or a line segment (ladder), is to be moved, both translating and rotating, amidst polygonal barriers.

Geometric objects encountered in many areas such as Computer-Aided Design (CAD) are fundamentally nonlinear (Dobkin and Souvaine 1990). The major thrust is generation of classes of curves and surfaces with which to interpolate, approximate, or generally speaking, represent data sets and object boundaries (Barnhill 1977; Bartels et al. 1987; Farin 1988). A classical approach, building on the concepts of splines and finite elements, has been to use piecewise polynomial functions over polyhedral tilings such as triangulations. Examples are the TIN (triangulated irregular network) approach popular in terrain modeling, C^1 functions over triangulations, and the arduous solution of the corresponding C^2 problem (Heller 1990; Lawson 1977; Alfeld and Barnhill 1984).

Bézier curves and surfaces involve an elegant concept: the use of control points to define elements of curves and surfaces, permitting intuition-guided manipulation important in CAD (Forrest 1972). In general, polynomials are increasingly supplanted by rational functions, which suffer fewer oscillations per numbers of coefficients (Tiller 1983). All these techniques culminate in NURBS (non-uniform rational B-splines) which are recommended for curve and surface representation in most industrial applications.

In geometric calculations, round-off errors due to floating-point arithmetic may cause major problems (Fortune and Milenkovic 1991). When testing, for instance, whether given points are collinear, a tolerance level, eps, is often specified, below which deviations from a collinearity criterion are ignored. Points p_1, p_2, p_3 and p_2, p_3, p_4, but not p_1, p_2, p_4 may thus be found collinear. Such and similar inconsistencies may cause a computation to abort. Robust algorithms are constructed so as to avoid breakdown due to inconsistencies caused by round-off (Guibas et al. 1989; Beichl and Sullivan 1990). Alternatively, various forms of exact arithmetic are increasingly employed (Fortune and Van Wyck 1993; Yap 1993). Inconsistencies occur typically whenever an inequality criterion is satisfied as an equality. An example is the degeneracy behavior of the simplex method of linear programming. Lexicographic perturbation methods can be employed to make consistent selections of subsequent feasible bases and thus assure convergence. Similar consistent tie breaking, coupled with exact arithmetic, is the aim of the simulation of simplicity approach proposed by Edelsbrunner and Mücke (1988) in a more general computational context.

Introduction

As inexpensive and massive amounts of computing power have rapidly become more widely available, the operational aspects of computational-based organizational research have become a reality. Today, the concepts of Computational Organization Theory (COT) can be easily implemented and practiced by an ever-increasingly larger group of researchers. Some foresee such computer-science related computational thinking (Wing 2006), as the future of all scholarly research, and COT is part of this broader trend.

COT involves the theorizing about, describing, understanding, and predicting the behavior of organizations and the process of organizing, using

quantitative-based and structured approaches (computational, mathematical and logical models). This involves computational abstractions that are incorporated into organizational research and practice through COT tools, procedures, measures and knowledge.

The notion of an organization, as used here, spans the wide range of human-conceived collections of people, i.e., groups, teams, societies, corporations, industries, and governments, see Carley and Prietula, (1994); Prietula, Carley, and Gasser, (1998); and Gilbert and Doran, (1994). COT practitioners use computational models and analysis to develop a better understanding of fundamental principles for organizing and behaviors within an organization. Organizational members, i.e., people, are considered information-processing actors. They can interact with and adapt to their environment. They can learn, and they can communicate. While their behavior is certainly complex, this behavior and the underlying determinate of the behaviors can be reduced to basic mathematical equations and algorithms. With this formalization, researchers can develop complete computerized models of an organization, which enables the use of computer simulation to create virtual worlds for non-obtrusive experimentation. After running these simulations the collective outcome of these virtual interactions and behaviors can be quantified and collected for extensive analysis. Typically, the results from these experiments are then incorporated into a formalized and thoughtful comparison against findings from controlled lab experiments and real-world empirical cases studies. The history of COT is rich with academic insight, with its research and application proving fruitful to organization researchers and practitioners alike.

History

The field of COT has benefitted from several decades of research. One of the earliest works is Cyert and March's *The Behavioral Theory of the Firm*, (1963), in which a simple information-processing model of an organization is used to address issues of organization design and performance. During the past decade an explosion of interest has occurred for theory development and testing in the organizational and social sciences (Carley 1995). The use is expanding for a number of reasons: (a) there is growing recognition that social and organizational processes are complex, dynamic, adaptive, and nonlinear, and, thus, are hard to study in the real-world; (b) researchers and practitioners have come to realize that organizational and social behavior emerges from interactions within and between ecologies of entities (people, groups, technologies, agents, etc.), which is hard to reproduce and control in the laboratory and real-world; and (c) the relationships among these entities are critical constraints on individual and organizational action, which is hard to control with direct human-based research. Researchers now recognize that organizations are inherently computational since they have a need to scan and observe their environment, store facts and programs, communicate among members and with their environment, and transform information by human or automated decision making (Burton and Obel 1996).

COT has a fundamentally interdisciplinary intellectual history with contributions from social network theory, distributed artificial intelligence and the organizational information processing tradition. Within COT, researchers draw heavily on work in the information/resource processing tradition (Simon 1947; March and Simon 1958; Thompson 1967; Galbraith 1973; Cyert and March 1963; Pfeffer and Salancik 1978) and social information processing (Salancik and Pfeffer 1978), as modified by work in cognitive science (Carley and Newell 1994), institutionalism (Powell and DiMaggio 1991), population ecology (Hannan and Freeman 1977, 1989), and the contemporary contingency theory (Baligh et al. 1990). Within social network and communication/coordination theory, there has been important work done on measures of organizational design and communication (Wasserman and Faust 1994; Malone 1986), cognitive social structures (Krackhardt 1987), network effects on performance, influence, and power (Wasserman and Galaskiewicz 1994; Kaufer and Carley 1993; Granovetter 1985; Burt 1992), and research on inter-organizational networks (Baum and Oliver 1991; Stuart and Podolny 1996). Within the area of distributed artificial intelligence, researchers draw on findings regarding representation (Lesser and Corkill 1988); teams (Decker 1996); coordination (Durfee and Montgomery 1991); and strategy (Gasser and Majchrzak 1994).

Methodological Approaches

Models are both integral and integrating components of theory building in COT. No matter what their disciplinary home, researchers in this area assume that meaningful and predictive models of organizations can be built. Computational organizational theorists use models to (1) describe organizational phenomena observed in the world, including structuring real or hypothetical experiences as described or postulated by individuals or groups, (2) formalize and integrate theoretical principles from science that are relevant to organizational activities, and (3) simulate the dynamics of temporal changes in a particular organizational process, action, or policy.

Models are abstractions of reality, and modeling is the process of creating these abstractions. Because reality is near infinitely complex and all empirical data are processed with reference to that complexity, model building involves the simplification of reality as data are transformed into knowledge. The models created are, essentially, forms of codified knowledge and used to represent the reality of things not known from things that are known (Waisel et al. 1998). Modeling is the sine qua non of science. Virtually all-scientific activities require modeling in some sense, and any scientific theory requires this kind of representational system (Nersessian 1992). Models are usually thought of as being quantitative, and able to be represented mathematically. However, qualitative models are no less and arguably more common, particularly in the context of COT.

Employing a variety of methodologies has made advances in computational organization theory. To illustrate this variety, five of the most significant approaches to modeling will be discussed: (1) general intellective models, (2) distributed artificial intelligence and multi-agent models, (3) organizational engineering models, (4) social network models, and (5) mathematical and/or logic based models.

Organizational theorists are most familiar with the general intellective models. These models often represent the organization or various processes as a set of nonlinear equations and/or a set of interacting agents. In these models, the focus is on explaining and theorizing about a particular aspect of organizational behavior. Consequently, the models often abstract many of the factors in actual organizations, laying bear only the entities and relations essential to the theory. Models embody theory about how the team, group, or organization will behave. Given these models, a series of virtual experiments are run to test the effect of a change in a particular process, action, policy, etc. These models are used to illustrate the theory's story about how the organization will behave under various conditions. These models enable cumulative theory building as multiple researchers rebuild, augment, and develop variations of earlier models.

Many researchers are building organizational models using multi-agent techniques. Multi-agent techniques have grown out of the work in distributed artificial intelligence. Distributed artificial intelligence intended to perform highly specific but stylized tasks such as soccer, navigation or surveillance (Bond and Gasser 1988; Gasser and Huhns 1989; Cohen 1986). Strength of this approach is the focus on representation and knowledge. For example attention is often focused on how to represent the task and knowledge about how to do the task via the agent. Another strength of this approach is a focus on decision making as search. Models are often developed to address issues of communication, coordination, planning, or problem solving, often with the intent of using these models as the brains in artificial agents. These models can explain many organizational phenomena and test the adequacy and efficiency of various definitions or representation schemes. Today, much of this work goes under the rubric of multi-agent modeling. Work in this area is beginning to focus on the role of emotions, the development of team mental models, and coordination of large numbers of agents. From an organizational theory perspective two issues stand out. First, how scalable are these models and representation schemes? That is, do the results from systems of two to five agents performing a highly stylized task generalize to larger more complex organizations? Second, when are these cognitively simple agents adequate or valid representations of human behavior?

Organizational engineering models are characterized by the extensive detail with which they represent the formal sides of organizations or tasks (organizational chart, workflow, communication paths, and rework routines) and the attention to the specific features of particular organization. These models generally focus on predicting overall

organizational or group response rather than the actions and behaviors of individual agents. These models are sufficiently detailed that they can be used to analyze potential policy changes and address what-if questions for the particular organization for which the model has been tuned (Levitt et al. 1994; Gasser and Majchrzak 1994). Model adequacy is often demonstrated by determining whether the parameters can be adjusted so that one or more important team or organizational behaviors is described at least at a qualitative level. Importantly, simply having managers work with the research team to elicit the data on the organization needed to model it often leads the manager to gain important insights into organizational problems. As such, these models are a valuable decision aid. The same is true of system models.

Social network models are characterized by representations of teams, groups, organizations, and markets in terms of the relationships among individuals or organizations. These models emphasize the structural or relational aspect of the organization and demonstrate when and how they can affect individual or organizational behaviors. Work in this field has focused on developing models of network adaptation, evolution, and change, and on developing a better understanding of how agent knowledge affects and is affected by an agent's position in the network. Network models have successfully been used to examine issues such as power and performance, information diffusion, innovation, and turnover. The adequacy of these models is determined using techniques from non-parametric statistics.

Logic models are characterized by representations of organizations and organizational processes using the techniques and formalisms of formal logic. Such models enable researchers to focus on the generative aspects of organizational form given a specific grammar (See Salanick and Leblebici 1998) and to test the consistency of extant verbal theories. These models tend to be among the most limited in their realism and the least likely to capture dynamic aspects of organizational behavior. However, these models are the only ones from which complete proofs and an exhaustive understanding of behavior can be generated. These models provide, independent of a specific machine implementation, a way of assessing the internal validity of extant theories and generating proofs about organizing behavior.

This brief review of these methodological approaches just begins to describe the vast array of modeling techniques and tools that have been used to examine organizations. These and other approaches address a variety of questions about organizations ranging from questions of design, to questions of learning, to questions of culture. As work continues in this field, researchers are beginning to employ models, which contain intellective and emulative elements. These models, for example, draw on the work in cognitive science and contribute to the work on multi-agent systems, use network representations and measures, and use logic in developing formalizations.

Models and Applications

COT models extend from simple intellective principles of general decision-making behavior (Cohen et al. 1972; Carley 1992) to representations of the decision processes and information flow within specific real-world organizations (Levitt et al. 1994; Zweben and Fox 1994). Models may even operationally specific management-decisions, or practices and polices (Gasser and Majchrzak 1992, 1994; Majchrzak and Gasser 1991, 1992). These COT models enable the researcher to examine the potential impact of general management strategies (Gasser and Majchrzak 1994; Carley and Svoboda 1996), or enable the manager to examine the organizational implications of specific management decisions (Levitt et al. 1994).

Several multipurpose computational-models of organization have been developed including well-known models such as the Garbage Can Model (Cohen et al. 1972), Plural-Soar (Carley et al. 1992), Team-Soar (Kang et al. 1998), and ORGAHEAD (Lee and Carley 2004). In a review of the state of computational modeling (Ashworth and Carley 2004, 2007), 29 specific organization theory computer simulations were found to have been introduced between 1989 and 2003; the authors also made a point that the richness of the models has also increased over those years. More recently, the CONSTRUCT model has been used extensively for theory generation and testing, notably in realms looking at the impact of communications occurring through diverse mEdia. CONSTRUCT provides a vigorous model of organization that has its

roots in symbolic interactionism (Blumer 1969), structural interactionism (Stryker 1980), and structural differentiation theory (Blau 1970). These core-theories are combined into a computational theory called constructuralism (Carley 1991), which is embodied in the CONSTRUCT model. The model recognizes that people interact within a dynamic social-based organizational network and are characteristically information-seeking agents. They interact to exchange information and purposefully may seek out others who have information that they do not yet hold. Others seeking their information, or knowledge are also seeking them out. This interaction dynamic is played out innumerable times in any organization. When this dynamic is coupled with the organization-membership changes (hiring and firing) in an organization, this emerging micro-interaction dynamic is manifested in complex organization-level dynamics and outcomes.

Computational organizational theorists often address issues of organizational design, organizational learning, and organizational adaptation. Consider the design question: organizations, through their design, are expected to be able to overcome the cognitive, physical, temporal, and institutional limitations of individual agency. Research has shown that there is no single organizational design that yields the optimal performance under all conditions, yet it has shown, that for a particular task and under particular conditions, there is a set of optimal designs. Organizational performance itself is dynamic, even under the same design (Cohen 1986). Thus, the determination of which organizational design is best depends on a plethora of factors, which interact in complex nonlinear ways to effect performance. Such factors include the task(s) being performed; intelligence, cognitive capabilities, skills, or training; available resources; quality and quantity of information; volatility of the environment; legal or political constraints on organizational design; the type of outcome desired (e.g., efficiency, effectiveness, accuracy, or minimal costs). The organization's design is considered to be capable of being intentionally changed in order to improve its performance. Consequently, computational models focused on design should be an invaluable decision aid to managers who are interested in comparing and contrasting different types of organizations. Researchers are thus providing guidelines for when to use which design, and developing computational tools for enabling managers to do just-in-time design.

Organizational learning, adaptation and change are one of the areas where COT continues to provide invaluable knowledge and understandable promise. In most organizations, multiple types of learning appear to co-exist and interact in complex ways. Organizational learning has been characterized in terms of the search for knowledge (Levinthal and March 1981), constraint based optimization (Carley and Svoboda 1996), and aggregation of individual learning (Carley 1992). In organizational learning, one major challenge is to link multiple models of organizational learning together and to see how they inform each other. It is necessary to understand how organizational networks evolve and how an evolved organizational design can be characterized as being statistically different from an initial design. Such issues of measurement are subjects of continued research within the field of COT.

Research Opportunities

The focus of COT is evolving. Past research has focused on representations of natural or human organizations. Increasingly, researchers are using COT methods to study organizations that are also composed of artificial agents, or combinations of both human and artificial agents. Human organizations, and artificial systems in general, often show intelligence and a set of capabilities that are distinct from the intelligence and capabilities of the membership within them. These systems can exhibit organization, intentional adaptation, and can display non-random and repeated patterns and processes of action, communication, knowledge, and memory regardless of whether or not the agents are human. By improving our understanding of the behavior of artificial worlds in general, researchers may discover whether there are general principles of organizing that transcend the type of agent in the organization. Artificial or virtual organizations are appearing and being used to do certain tasks such as scheduling or robotic control. One of the issues is how to structure inter-agent coordination and communications. Should organizations of humans and artificial agents be designed in the same way? Do artificial agents need to communicate the same type of information, as do

humans to be effective? Modeling the interactivity of humans and artificial agents should enable us to answer these questions.

COT will move theories of organizations beyond empirical description to predictive modeling. By focusing on the components (such as agent, structure, task, and resources), the networks of connections among these components (such as the communication structure or the resource access structure), and the processes by which they are altered (such as routines, learning, adaptation), a more dynamic and coherent view of the organization as an embedded, complex, adaptive system of human and automated agents with greater predictive ability will emerge (Carley and Prietula 1994). Attending to these factors will necessarily increase the complexity and veridicality of the models, as well as increasing the difficulty in building and validating the models. The resulting models, however, will be capable of addressing the concerns of both the theoretician and the practitioner, and yield greater predictive ability and practical guidance. COT thus has the potential to generate a better theoretical understanding of organizations, better tools for designing and reengineering organizations in real-time, and better tools for teaching people how teams, groups, and organizations function.

Computational Probability

Broadly defined, computational probability is the computer-based analysis of stochastic models with a special focus on algorithmic development and computational efficacy. The computer and information revolution has made it easy for stochastic modelers to build more realistic models even if they are large and seemingly complex. Computational probability is not just concerned with questions raised by the numerical computation of existing analytic solutions and the exploitation of standard probabilistic properties. It is the additional concern of the probabilist, however, to ensure that the solutions

obtained are in the best and most natural form for numerical computation. Before the advent of modern computing, much effort was directed at obtaining insight into the behavior of formal models, while avoiding computation. On the other hand, the early difficulty of computation has allowed the development of a large number of formal solutions from which limited qualitative conclusions may be drawn, and whose appropriateness for algorithmic implementation has not been seriously considered. Ease of computation has now made it feasible to have the best of all worlds: computation is now possible for classical models heretofore not completely solved, while complex algorithms can be developed for providing often needed insights on stochastic behavior.

Computer Science and Operations Research Interfaces

John W. Chinneck[1] and Ramesh Sharda[2]
[1]Carleton University, Ottawa, Ontario, Canada
[2]Oklahoma State University, Stillwater, OK, USA

Introduction

Operations research (OR) and computer science (CS) grew up together. George Dantzig relates how his early work on linear programming (LP), the archetypal OR method, led to the funding of the development of the first electronic computers during the 1940s (Dantzig 1988, 2002). In the early years of commercial computing, a large fraction of all computing effort was devoted to linear programming. Rapid development of applications for linear programming and then for the many other OR methods followed quickly thereafter, and such developments still continue. From that same starting point, CS and computer engineering developed on parallel tracks, with the disciplines continuing to interact while developing their own separate traditions and foci of study. There has been a renewed exploration of the many areas of overlap, with the development of much improved hybrid methods for solving difficult problems.

Evidence of ongoing interest in the OR/CS interface is easy to find. There are a number of academic journals devoted to the interface, including *The INFORMS Journal on Computing, Computers and Operations Research, Computers and Industrial Engineering, Computational Optimization and Applications*, and *Mathematical Programming Computation*. The INFORMS Computing Society, a subgroup of INFORMS, the largest OR professional group, is devoted to the study of the interfaces between OR and CS.

OR can be viewed as a collection of methodologies for solving common problems related to operating organizations and designing systems. Computers are essential in using these techniques to solve problems of industrial scale. Computers carry out the numerous calculations involved in most OR methods and provide database functions to manage the very large volumes of data that are input and output. There are several important interfaces between OR and the discipline of CS; some of the main interfaces are reviewed below.

Computer Hardware

The essential interface of OR with CS and computer engineering is the computer itself. Computer hardware has seen numerous changes since the 1940s: mainframes, supercomputers, inexpensive personal computers, with additional major changes that include grids, clouds, and inexpensive multi-core machines. This has affected OR in terms of the methods used and the scale of the problems solved. OR methods have been adapted to solve extremely challenging problems of

very large scale by taking advantage of inexpensive and massively parallel computer architectures. Capabilities such as pipelining, vectorization, and superscalar computations have been employed in implementations of the simplex method, as well as interior point methods for LP. Algorithms have also been developed to exploit multiple as well as massively parallel processors: see the summaries by Zenios (1989) and Eckstein (1993). Thain et al. (2005) address distributed computing, which makes use of massively parallel computing resources that are heterogeneous and physically distributed, and subject to interruption by other uses that have higher priority. The CONDOR software used for this purpose is primarily directed toward high-throughput computing. As described in a special cluster of papers in the *INFORMS Journal on Computing* (*Volume 21, Issue 3, 2009*) on high-throughput optimization, the CONDOR software is a major enabler of large-scale optimization because it facilitates flexible access to a large pool of computers. A second major theme in the special cluster is the parallelization of tree search of various kinds.

Computers themselves, especially computer chips composed of Very Large Scale Integrated (VLSI) circuits, are extremely complex to design. There are many difficult optimization problems to solve during the design process. Some examples: What is the best way to arrange the devices on the chip to pack the maximum number of devices into the smallest area? How should the connecting wires be routed to minimize the total length of wiring? Which technologies should be employed for each of the devices? Here, not surprisingly, OR optimization techniques find many applications. The OR techniques of queueing analysis and simulation are also widely used to investigate the behavior of the chips prior to their production and the behavior of the entire computer system. For example, buffering delays related to queueing for memory or CPU access can be estimated. The survey by Chinneck et al. (2005) describes the many applications of OR in Computer-Aided Design (CAD) of VLSI chips.

Other useful developments in computer hardware that generally contribute to speedier computations also improve the speed of OR-related computations. These developments include cache memory and superscalar computation. Since the LP matrix computations involve working with sparse matrices, use of cache memory allows faster access and manipulation of matrix elements. Similarly, superscalar architectures, as well as vectorization facilities of the new computer, allow vectored calculations. LP codes such as Gurobi and IBM's CPLEX are examples of codes that have exploited the recent developments in computer architecture quite well.

OR has benefitted greatly from advances in computer design that originate in CS and computer engineering. Larger and more complex problems can now be solved. At the same time, the advances in computer hardware would likely not have been possible without the use of OR techniques in generating the designs. The fields are mutually reinforcing.

Software: Algorithms

Perhaps the widest area of overlap between OR with CS is software, particularly algorithms. While CS has a general interest in all algorithms, OR constitutes a particularly important subset of algorithms that have immediate practical applications. Interestingly, the two disciplines have often approached problems of mutual interest in completely different ways. This is particularly apparent in the field of combinatorial optimization where OR has traditionally taken a more mathematical approach while CS has taken a purely algorithmic approach as in constraint programming. The two approaches have begun to merge into a stronger hybrid. For example, concepts from constraint programming have been incorporated into branch-and-bound-based implementations of mixed-integer linear programming solvers. Hooker (2007) presents an excellent exposition of this theme.

The OR repertoire has been considerably expanded through the adoption of optimization techniques that arise from the CS algorithmic tradition, instead of the traditional OR mathematical tradition. Many of these are interesting heuristics that may not provide solution guarantees, but which can be effective in practice for certain classes of very difficult problems. Examples include Genetic Algorithms (Goldberg 1989), ant colonies, particle swarms, and other evolutionary algorithms. Partly as a consequence of exposure to these CS-originated methods, OR now develops CS-flavored methods, for example, scatter search and path relinking (Glover et al. 2000). Powell (2010) merges AI and OR to solve high-dimensional

stochastic optimization problems. Both OR and CS are keenly interested in artificial intelligence, knowledge and data management, and machine learning. Here the mixing of the two traditions is common. For example, an AI technique for robot route planning may use the solution of a number of standard OR problems as steps in a larger planning algorithm.

Software: User Interfaces

Both OR and CS face issues related to user interaction with complex objects. In OR, the objects are typically mathematical models, which may consist of functions representing the objective and the constraints in an optimization application, or the relationships representing interacting objects and their governing probability distributions in the case of simulation. This sort of modeling is a particular strength of OR because it allows the power of various algorithms and analysis techniques to be brought to bear. The problem is making a large amount of complex information and data comprehensible to the user. New graphical user interfaces (drop-down menus, hierarchically expandable-contractable structures, buttons, etc.) have been rapidly adopted in commercial OR implementations. Many graphical user interfaces are being developed to aid in formulation (Chari and Sen 1997; Androulakis and Vrahatis 1996). Jones (1998) provides an excellent overview of the use of graphics and visualization technologies in modeling and solutions.

In addition, spreadsheets have become a ubiquitous paradigm for managing models and associated data, as well as tools for delivery and presentation of results. Many spreadsheets include linear and nonlinear programming algorithms as a part of the standard function set. The spreadsheets are changing the way OR analysts prepare, manage, and deliver the models. Lijima (1996) discusses an automatic model building approach.

Software: Data Structures and Databases

New data structures developed in CS are routinely used in OR algorithms. As any serious OR algorithm developer knows very well, learning about sparse matrix approaches such as linked lists, arrays, orthogonal lists, etc. is key in implementing an algorithm. As an example, Adler et al. (1989) focus on the data structures employed in their implementation of interior point methods.

The developments in data structures and databases have helped OR in modeling and algorithmics. But OR has been a key player in designing distributed databases. OR models and their solutions are important in designs of such databases. Information storage and retrieval research has also been the beneficiary of OR algorithms for query optimization. Kraft (1985) provides a good survey of this interface between OR and CS. OR approaches (e.g., mixed-integer programming) are also used in artificial intelligence. Specific examples include the use of mixed-integer programming (MIP) in automated theorem proving. A similar example is a graph theory–based approach for partitioning knowledge bases (Srikanth 1995).

Areas of Mutual Interest

Combinatorial optimization is an area of great mutual interest for both OR and CS. Here the many algorithmic tools in both communities are brought to bear. For example, the iconic traveling salesman problem (TSP), so easy to state but so difficult to solve, has been the subject of much research in both communities. OR has used approaches such as branch-and-bound and heuristics, while CS has attempted solutions using heuristics and tree search algorithms similar to branch-and-bound. The artificial intelligence and neural network communities have also focused on solving the TSP. Other heuristics approaches, such as genetic algorithms, simulated annealing, and tabu search, are being employed by both OR and CS specialists to solve combinatorial optimization problems. Computer scientists are using logic programming to solve routing and scheduling problems. These combinatorial problems have also been the focus of much research in the OR community. The TSP belongs to the larger class of routing problems, which continue to be of great interest to both communities. Potvin (2009) outlines the many methods and combinations thereof that have been applied to routing problems by both communities.

As noted above, computer design is the subject of research in both communities. This includes hardware

design, database design, and operating system design. An example given by Greenberg (1988) includes the use of random walk theory to analyze various storage allocation approaches, an important issue in operating systems. Telecommunications systems are also vital to modern information processing and the timely delivery of OR models and solutions. Real-time data access is a key in successful implementation of many models and that is possible only because of advances in telecommunications. As complex systems in their own right, telecommunications problems are the targets of much OR research: network design and routing, location analysis, etc. Decisions in telecommunications networks are based on OR approaches using queueing theory, Markov analysis, simulations, and MIP models.

Of course, the tremendous growth of the Internet has resulted in a complete transformation of OR/MS model development, solution, and delivery. It has also profoundly impacted the OR/MS profession in terms of education and professional communication through conferences and journals. Bhargava and Krishnan (1998) discuss this important interface.

Another example of the impact of CS on OR is the field of computational probability. Researchers continue to work on developing improved numerical techniques for solving large systems of equations appearing in stochastic models (Albin and Harris 1987). Simulation research and practice has also been a beneficiary of CS advances. One example is the use of artificial intelligence techniques in design and interpretation of simulations. Advances in parallel processing have led to active research in parallel simulation to speed up the computations (Fujimoto 1993).

Concluding Remarks

The objective was to illustrate the vibrancy of the symbiosis between OR and CS. As a final example, consider these areas covered in the *INFORMS Journal on Computing*: Computational Probability and Analysis, Constraint Programming and Optimization, Design and Analysis of Algorithms, Heuristic Search and Learning, Knowledge and Data Management, Modeling: Methods and Analysis, Simulation, Telecommunications, and Electronic Commerce. These areas are also covered in CS journals. As an article in *Computer World* (Betts 1993) noted, OR/MS needs corporate data for its algorithms and needs the algorithms used in strategic information systems to make a real impact. On the other hand, information systems (IS) groups need OR to build smart applications. Betts calls the individuals with significant OR/MS and CS/IS skills the new Efficiency Einsteins, a term that indeed appropriately describes the individuals trained in this interface.

Concave Function

A function that is never below its linear interpolation. Mathematically, a function $f(x)$ is concave over a convex set S, if for any two points, x_1 and x_2 in S and for any $0 \leq \alpha \leq 1$, $f[\alpha x_1 + (1 - \alpha)x_2] \geq \alpha f(x_1) + (1 - \alpha) f(x_2)$.

Conclusion

A portion of a rule composed of series of one or more actions that the inference engine can carry out if a rule's premise can be established to be true.

Conditional Value-at-Risk (CVaR)

Gaia Serraino[1] and Stanislav Uryasev[2]
[1]American Optimal Decisions, Gainesville, FL, USA
[2]University of Florida, Gainesville, FL, USA

Introduction

Conditional Value-at-Risk (CVaR), introduced by Rockafellar and Uryasev (2000), is a popular tool for managing risk. CVaR approximately (or exactly, under certain conditions) equals the average of some percentage of the worst case loss scenarios. CVaR risk measure is similar to the Value-at-Risk (VaR) risk measure which is a percentile of a loss distribution. VaR is heavily used in various engineering applications, including financial ones. VaR risk constraints are equivalent to the so called chance constraints on probabilities of losses. Some risk communities prefer VaR, others prefer chance (or probabilistic) functions. There is a close correspondence between CVaR and VaR: with the same confidence level, VaR is a lower bound for CVaR. Rockafellar and Uryasev (2000, 2002) showed that CVaR is superior to VaR in optimization applications. The problem of choice between VaR and CVaR, especially in financial risk management, has been quite popular in academic literature. Reasons affecting the choice between VaR and CVaR are based on the differences in mathematical properties, stability of statistical estimation, simplicity of optimization procedures, acceptance by regulators, etc.

Definition of VaR and CVaR

Let X be a random variable with the cumulative distribution function $F_X(z) = P\{X \le z\}$. X may have meaning of loss or gain. In what follows, X has meaning of loss and this impacts the sign of functions in the definition of VaR and CVaR. Figure 1 presents the graphical representation of VaR and CVaR.

Definition 1: Value-at-Risk. Value-at-Risk (VaR) of X with confidence level $\alpha \in]0,1[$ is

$$\mathrm{VaR}_\alpha(X) = \min\{z | \boldsymbol{F_X}(z) \ge \alpha\}. \tag{1}$$

By definition, $\mathrm{VaR}_\alpha(X)$ is a lower α-percentile of the random variable X. Value-at-Risk is commonly used in many engineering areas involving uncertainties, such as military, nuclear, material, air and space, finance, etc. For instance, finance regulations like Basel I and Basel II, use VaR-deviation measuring the width of daily loss distribution of a portfolio.

For normally distributed random variables, VaR is proportional to the standard deviation. If $X \sim N(\mu, \sigma^2)$ and $F_X(z)$ is the cumulative distribution function of X, then (see Rockafellar and Uryasev 2000),

$$\mathrm{VaR}_\alpha(X) = F_X^{-1}(\alpha) = \mu + k(\alpha)\sigma, \tag{2}$$

where $k(\alpha) = \sqrt{2}\mathrm{erf}^{-1}(2\alpha - 1)$ and $\mathrm{erf}(\boldsymbol{z}) = \frac{2}{\sqrt{\pi}}\int_0^z \boldsymbol{e}^{-t^2}\boldsymbol{dt}$.

Ease and intuitiveness of VaR is counterbalanced by its mathematical properties. As a function of the confidence level, for discrete distributions $\mathrm{VaR}_\alpha(X)$ is a non-convex, discontinuous function. For discussion of numerical difficulties of VaR optimization see, for example, Rockafellar (2007), and Rockafellar and Uryasev (2000).

Definition 2: Conditional Value-at-Risk. An alternative percentile measure of risk is the Conditional Value-at-Risk (CVaR). For random variables with continuous distribution functions, $\mathrm{CVaR}_\alpha(X)$ equals the conditional expectation of X subject to $X \ge \mathrm{VaR}_\alpha(X)$. This definition is the basis for the name of Conditional Value-at-Risk. The term Conditional Value-at-Risk has been introduced by Rockafellar and Uryasev (2000). The general definition of CVaR for random variables with possibly discontinuous distribution function is as follows (see Rockafellar and Uryasev 2002).

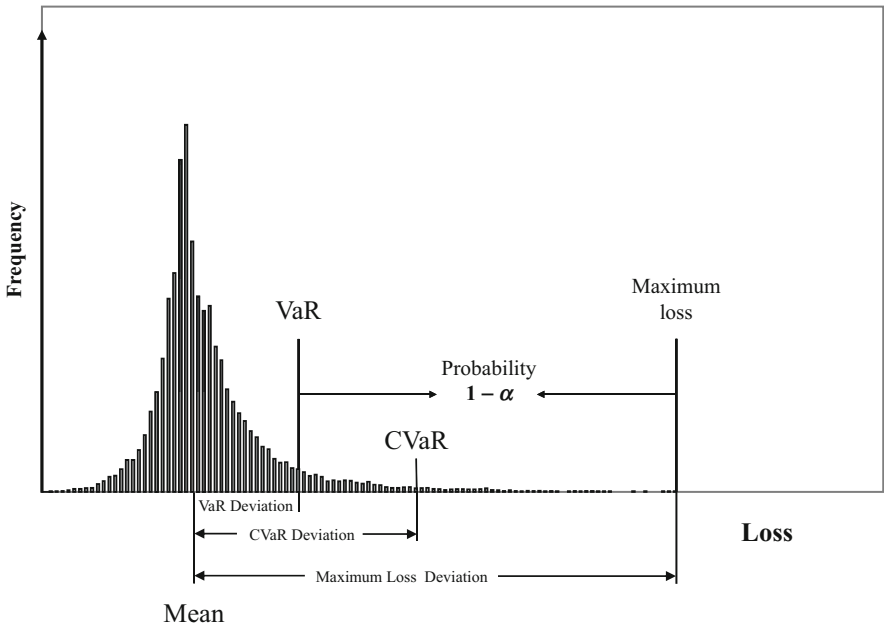
Conditional Value-at-Risk (CVaR) of X with confidence level $\alpha \in]0,1[$ is the mean of the generalized α-tail distribution:

$$\mathrm{CVaR}_\alpha(X) = \int_{-\infty}^{\infty} z dF_X^\alpha(z), \tag{3}$$

where

$$F_X^\alpha(z) = \begin{cases} 0, & \text{when } z < \mathrm{VaR}_\alpha(X), \\ \frac{F_X(z)-\alpha}{1-\alpha}, & \text{when } z \ge \mathrm{VaR}_\alpha(X). \end{cases}$$

Contrary to popular belief, in the general case, $\mathrm{CVaR}_\alpha(X)$ is not equal to an average of outcomes



Conditional Value-at-Risk (CVaR), Fig. 1 Risk Functions. Graphical Representation of VaR, VaR Deviation, CVaR, CVaR Deviation, Max Loss, Max Loss Deviation

greater than $\mathrm{VaR}_\alpha(X)$. For general distributions, one may need to split a probability atom. For example, when the distribution is modeled by scenarios, CVaR may be obtained by averaging a fractional number of scenarios. To explain this idea in more detail, alternative definitions of CVaR are presented in the following. Let $\mathrm{CVaR}^+_\alpha(X)$, called upper CVaR, be the conditional expectation of X subject to $X > \mathrm{VaR}_\alpha(X)$.

$$\mathrm{CVaR}^+_\alpha(X) = E[X \,|\, X > \mathrm{VaR}_\alpha(X)].$$

$\mathrm{CVaR}_\alpha(X)$ can be alternatively defined as the weighted average of $\mathrm{VaR}_\alpha(X)$ and $\mathrm{CVaR}^+_\alpha(X)$, as follows. If $F_X(\mathrm{VaR}_\alpha(X))<1$, so there is a chance of a loss greater than $\mathrm{VaR}_\alpha(X)$, then

$$\mathrm{CVaR}_\alpha(X) = \lambda_\alpha(X)\,\mathrm{VaR}_\alpha(X) + (1-\lambda_\alpha(X))\,\mathrm{CVaR}^+_\alpha(X), \tag{4}$$

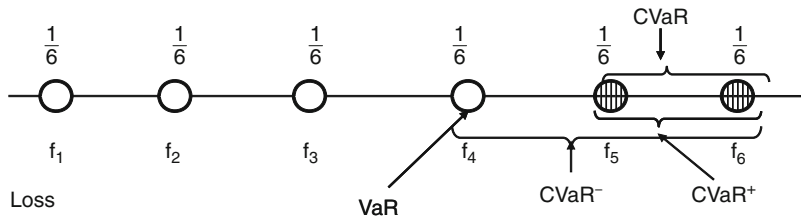
$$\text{where } \lambda_\alpha(X) = \frac{F_X(\mathrm{VaR}_\alpha(X)) - \alpha}{1-\alpha}, \tag{5}$$

whereas if $F_X(\mathrm{VaR}_\alpha(X)) = 1$, so that $\mathrm{VaR}_\alpha(X)$ is the highest loss that can occur, then

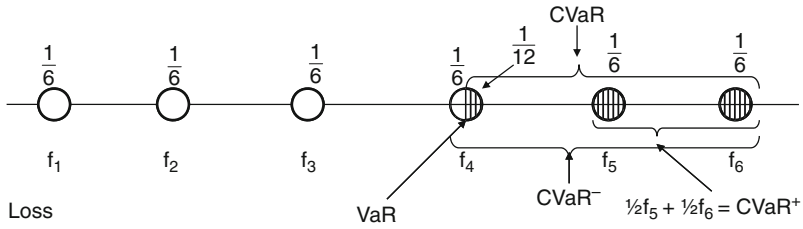
$$\mathrm{CVaR}_\alpha(x) = \mathrm{VaR}_\alpha(x)\ . \tag{6}$$

Definition (4) demonstrates that CVaR is not defined as a conditional expectation. The function $\mathrm{CVaR}^-_\alpha(X) = E[X \,|\, X \geq \mathrm{VaR}_\alpha(X)]$, called "lower CVaR", coincides with $\mathrm{CVaR}_\alpha(X)$ for continuous distributions; however, for general distributions it is discontinuous with respect to α and not convex. The construction of CVaR_α as a weighted average of VaR_α and $\mathrm{CVaR}^+_\alpha(X)$ is a major innovation. Neither VaR nor $\mathrm{CVaR}^+_\alpha(X)$ behaves well as a measure of risk for general loss distributions (both are discontinuous functions), but CVaR is a very attractive function. It is continuous with respect to α and jointly convex in (X, α). The unusual feature in the definition of CVaR is that VaR atom can be split. If $F_X(x)$ has a vertical discontinuity gap, then there is an interval of confidence level α having the same VaR. The lower and upper endpoints of that interval are $\alpha^- = F_X(\mathrm{VaR}^-_\alpha(X))$ and $\alpha^+ = F_X(\mathrm{VaR}_\alpha(X))$ where $F_X(\mathrm{VaR}^-_\alpha(X)) = P\{X < \mathrm{VaR}_\alpha(X)\}$. When $F_X(\mathrm{VaR}^-_\alpha(X)) < \alpha < F_X(\mathrm{VaR}_\alpha(X)) < 1$ the atom $\mathrm{VaR}_\alpha(X)$ having total probability $\alpha^+ - \alpha^-$ is split by the confidence level α in two pieces with probabilities $\alpha^+ - \alpha$ and $\alpha - \alpha^-$. Equation 4 highlights this splitting.

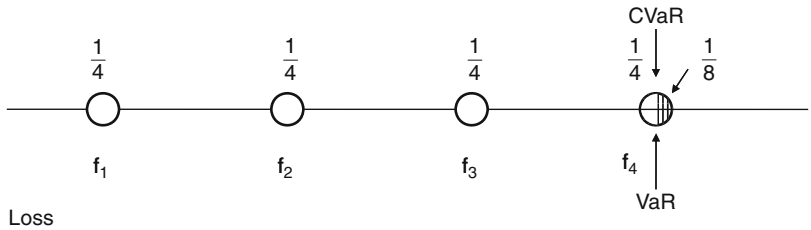
CVaR definition is illustrated further with the following examples, in which 6 equally likely scenarios have losses $f_1 \ldots f_6$. Let $\alpha = \frac{2}{3}$, see Fig. 2.



Conditional Value-at-Risk (CVaR), Fig. 2 CVaR Example 1. Computation of CVaR when α does not spilt the atom



Conditional Value-at-Risk (CVaR), Fig. 3 CVaR Example 2. Computation of CVaR when α splits the atom



Conditional Value-at-Risk (CVaR), Fig. 4 CVaR Example 3. Computation of CVaR when α splits the last atom

In this case α does not split any probability atom. Then $\mathrm{VaR}_\alpha(X) < \mathrm{CVaR}_\alpha^-(X) < \mathrm{CVaR}_\alpha(X) = \mathrm{CVaR}_\alpha^+(X)$, $\lambda_\alpha(X) = \frac{F_X(\mathrm{VaR}_\alpha(X)) - \alpha}{1-\alpha} = 0$ and $\mathrm{CVaR}_\alpha(X) = \mathrm{CVaR}_\alpha^+(X) = \frac{1}{2}f_5 + \frac{1}{2}f_6$, where f_5, f_6 are losses number five and six.

Let now $\alpha = \frac{7}{12}$, see Fig. 3. In this case α does split the $\mathrm{VaR}_\alpha(X)$ atom, $\lambda_\alpha(X) = \frac{F_X(\mathrm{VaR}_\alpha(X)) - \alpha}{1-\alpha} > 0$ and $\mathrm{CVaR}_\alpha(X)$ is given by:

$$\begin{aligned}\mathrm{CVaR}_\alpha(X) &= \frac{1}{5}\mathrm{VaR}_\alpha(X) + \frac{4}{5}\mathrm{CVaR}_\alpha^+(X) \\ &= \frac{1}{5}f_4 + \frac{2}{5}f_5 + \frac{2}{5}f_6 \ .\end{aligned}$$

In the last case, there are four equally likely scenarios and $\alpha = \frac{7}{8}$ splits the last atom; see Fig. 4. Now $\mathrm{VaR}_\alpha(X) = \mathrm{CVaR}_\alpha^-(X) = \mathrm{CVaR}_\alpha(X)$, upper CVaR, $\mathrm{CVaR}_\alpha^+(X)$ is not defined, $\lambda_\alpha(X) = \frac{F_X(\mathrm{VaR}_\alpha(X)) - \alpha}{1-\alpha} > 0$ and $\mathrm{CVaR}_\alpha(X) = \mathrm{VaR}(X) = f_4$. Portfolio Safeguard package (see American Optimal Decisions 2009), defines CVaR function for discrete distributions equivalently to (4) through the lower CVaR and upper CVaR. Suppose that $\mathrm{VaR}_\alpha(X)$ atom having total probability $\alpha^+ - \alpha^-$ is split by the confidence level α in two pieces with probabilities $\alpha^+ - \alpha$ and $\alpha - \alpha^-$. Then,

$$\begin{aligned}\mathrm{CVaR}_\alpha(X) = &\frac{\alpha^+ - \alpha}{\alpha^+ - \alpha^-}\,\frac{1-\alpha^-}{1-\alpha}\,\mathrm{CVaR}_\alpha^-(X) \\ &+ \frac{\alpha - \alpha^-}{\alpha^+ - \alpha^-}\,\frac{1-\alpha^+}{1-\alpha}\,\mathrm{CVaR}_\alpha^+(X),\end{aligned} \tag{7}$$

$$\begin{aligned}\text{where } \mathrm{CVaR}_\alpha^-(X) &= E[X \,|\, X \geq \mathrm{VaR}_\alpha(X)], \\ \mathrm{CVaR}_\alpha^+(X) &= E[X \,|\, X > \mathrm{VaR}_\alpha(X)]\,.\end{aligned} \tag{8}$$

Pflug (2000) followed a different approach and suggested to define CVaR via an optimization problem which he borrowed from Rockafellar and Uryasev (2000)

$$\begin{aligned}\mathrm{CVaR}_\alpha(X) = &\\ &\min_C \left\{ C + \frac{1}{1-\alpha}\,E[X - C]^+ \right\}, \\ &\text{where } [t]^+ = \max\{0, t\}.\end{aligned} \tag{9}$$

One more equivalent representation of CVaR was given by Acerbi (2002), who showed that CVaR is equal to "expected shortfall" defined by

$$\mathrm{CVaR}_{\alpha}(X) = \frac{1}{\alpha}\int_0^{\alpha} \mathrm{VaR}_{\beta}(X)d\beta\,.$$

For normally distributed random variables, CVaR deviation is proportional to the standard deviation. If $X \sim N(\mu, \sigma^2)$, then (see Rockafellar and Uryasev 2000),

$$\begin{aligned}\mathrm{CVaR}_{\alpha}(X) &= E[X \mid X \geq \mathrm{VaR}_{\alpha}(X)] \\ &= \mu + k_1(\alpha)\sigma,\end{aligned} \tag{10}$$

where

$$k_1(\alpha) = \left(\sqrt{2\pi} exp\left(\mathrm{erf}^{-1}(2\alpha - 1)\right)^2 (1-\alpha)\right)^{-1}$$

and $\mathrm{erf}(z) = \frac{2}{\sqrt{\pi}}\int_0^z e^{-t^2}dt$.

CVaR Optimization

CVaR optimization has been researched in Rockafellar and Uryasev (2000) and Uryasev (2000). Nowadays VaR has achieved the high status of being written into industry regulations (for instance, in regulations for financial companies). It is difficult to optimize VaR numerically when losses are not normally distributed. Only recently VaR optimization was included in commercial packages such as Portfolio Safeguard (see American Optimal Decisions 2009). As a tool in optimization modeling, CVaR has superior properties in many respects. CVaR optimization is consistent with VaR optimization and yield the same results for normal or elliptical distributions (see definition of elliptical distribution in (see definition of elliptical distribution in Embrechts et al. (2001)); for models with such distributions, working with VaR, CVaR or minimum variance (Markowitz 1952) is equivalent (see Rockafellar and Uryasev 2000). Most importantly, CVaR can be expressed by a minimization formula suggested by Rockafellar and Uryasev (2000). This formula can be incorporated into the optimization problem with respect to decision variables $x \in X \in \Re^n$ that are designed to minimize risk or shape it within bounds. Significant shortcuts are thereby achieved while preserving the crucial problem features like convexity. Let the random loss function $f(x, y)$ depends upon the decision vector x and a random vector y of risk factors. For instance, $f(x, y) = -(y_1x_1 + y_2x_2)$ is the negative return of a portfolio involving two instruments. Here x_1, x_2 are positions and y_1, y_2 are rates of returns of two instruments in the portfolio. The main idea in Rockafellar and Uryasev (2000) is to define a function that can be used instead of CVaR:

$$F_{\alpha}(x, \zeta) = \zeta + \frac{1}{1-\alpha}E\{[f(x, y) - \zeta]^+\}\,. \tag{11}$$

The authors proved that:

1. $F_{\alpha}(x, \zeta)$ is convex w.r.t. α,
2. $\mathrm{VaR}_{\alpha}(x)$ is a minimum point of function $F_{\alpha}(x, \zeta)$ w.r.t. ζ,
3. Minimizing $F_{\alpha}(x, \zeta)$ w.r.t. ζ gives $\mathrm{CVaR}_{\alpha}(x)$:

$$\mathrm{CVaR}_{\alpha}(x) = \min_{\alpha} F_{\alpha}(x, \zeta)\,. \tag{12}$$

In optimization problems, CVaR can enter into the objective or constraints or both. A big advantage of CVaR over VaR in that context is the preservation of convexity, i.e., if $f(x, y)$ is convex in x than $\mathrm{CVaR}_{\alpha}(x)$ is convex in x. Moreover, if $f(x, y)$ is convex in x then the function $F_{\alpha}(x, \zeta)$ is convex in both x and ζ. This convexity is very valuable because minimizing $F_{\alpha}(x, \zeta)$ over $(x, \zeta) \in X \times \Re$, results in minimizing $\mathrm{CVaR}_{\alpha}(x)$

$$\min_{x \in X} \mathrm{CVaR}_{\alpha}(x) = \min_{(x,\zeta) \in X \times \Re} F_{\alpha}(x, \zeta)\,. \tag{13}$$

In addition, if (x^*, ζ^*) minimizes F_{α} over $X \times \Re$, then not only does x^* minimize $\mathrm{CVaR}_{\alpha}(x)$ over X but also

$$\mathrm{CVaR}_{\alpha}(x^*) = F_{\alpha}(x^*, \zeta^*)\,.$$

In risk management CVaR can be utilized to "shape" the risk in an optimization model. For that purpose several confidence levels can be specified. Rockafellar and Uryasev (2000) showed that for any selection of confidence levels α_i and loss tolerances ω_i, $i = 1, \ldots, l$, the problem:

$$\begin{aligned} &\min_{x \in X} \; g(x) \\ s.\,t. \quad &\mathrm{CVaR}_{\alpha_i}(x) \leq \omega_i, \quad i = 1, \ldots, l \end{aligned} \tag{14}$$

is equivalent to the problem:

$$\min_{x,\zeta_1,..,\zeta_l,\in X\times\Re\times...\Re} g(x) \quad s.\,t. \quad F_{\alpha_i}(x,\zeta_i) \le \omega_i, \quad i=1,\ldots,l. \tag{15}$$

When X and g are convex and $f(x,y)$ is convex in x, the optimization problems (13) and (14) are ones of convex programming and thus especially favorable for computation. When Y is a discrete probability space with elements y_k, $k=1,..,N$ having probabilities p_k, $k=1,..,N$:

$$F_{\alpha_i}(x,\zeta_i) = \zeta_i + \frac{1}{1-\alpha_i} \times \sum_{k=1}^{N} p_k[\,f(x,y_k)-\zeta_i]^+ \,. \tag{16}$$

The constraint $F_\alpha(x,\zeta)\le\omega$ can be replaced by a system of inequalities by introducing additional variables η_k :

$$\eta_k \ge 0, \quad f(x,y_k)-\zeta-\eta_k \le 0, \quad k=1,..,N, \tag{17}$$

$$\zeta + \frac{1}{1-\alpha}\sum_{k=1}^{N} p_k\eta_k \le \omega \,.$$

The minimization problem in (14) can be converted into the minimization of $g(x)$ with the constraints $F_{\alpha_i}(x,\zeta_i)\le\omega_i$ being replaced as presented in (17). When f is linear in x, constraints (17) are linear.

Risk Measures

Axiomatic investigation of risk measures was suggested by Artzner et al. (1999). Rockafellar (2007) defined a functional $\mathcal{R}:\mathcal{L}^2\to]-\infty,\infty]$ as a coherent risk measure in the extended sense if:

R1: $\mathcal{R}(\mathrm{C})=\mathrm{C}$ for all constant C,

R2: $\mathcal{R}((1-\lambda)X+\lambda X')\le(1-\lambda)\mathcal{R}(X)+\lambda R(X')$ for $\lambda\in]0,1[$ (convexity),

R3: $\mathcal{R}(X)\le\mathcal{R}(X')$ when $X\le X'$ (monotonicity),

R4: $\mathcal{R}(X)\le 0$ when $||X^k-X||_2\to 0$ with $\mathcal{R}(X^k)\le 0$ (closedness).

A functional $\mathcal{R}:\mathcal{L}^2\to]-\infty,\infty]$ is called a *coherent risk measure in the basic sense* if it satisfies axioms R1, R2, R3, R4 and additionally the axiom 4

R5: $\mathcal{R}(\lambda X)=\lambda\mathcal{R}(X)$ for $\lambda>0$ (positive homogeneity).

A functional $\mathcal{R}:\mathcal{L}^2\to]-\infty,\infty]$ is called an averse risk measure in the extended sense if it satisfies axioms R1, R2, R4 and

R6: $\mathcal{R}(X)>EX$ for all nonconstant X (aversity).

Aversity has the interpretation that the risk of loss in a nonconstant random variable X cannot be acceptable, i.e. $\mathcal{R}(X)<0$, unless $EX<0$.

A functional $\mathcal{R}:\mathcal{L}^2\to]-\infty,\infty]$ is called an averse risk measure in the basic sense if it satisfies R1, R2, R4, R6 and also R5.

Examples of coherent measures of risk are $\mathcal{R}(X)=\mu X=E[X]$ or $\mathcal{R}(X)=\sup X$. However, $R(X)=\mu(X)+\lambda\sigma(X)$ for some $\lambda>0$ is not a coherent measure of risk since it does not satisfies the monotonicity axiom R3.

$R(X)=\mathrm{VaR}_\alpha(X)$ is not a coherent nor an averse risk measure. The problem lies in the convexity axiom $R2$, which is equivalent to the combination of positive homogeneity and subadditivity, this last defined as $\mathcal{R}(X+X')\le\mathcal{R}(X)+\mathcal{R}(X')$. Although positive homogeneity is obeyed, the subadditivity is violated. The lack of coherency can destroy convexity; this can still be present if the distribution of the random variable X belongs to the log-concave class, but even then there are technical hurdles because the convexity of R is missing relative to the entire space $\mathcal{L}^2$. It has been proved, for example in Acerbi and Tasche (2002), Pug (2000), Rockafellar and Uryasev (2002), that for any probability level $\alpha\in]0,1[$, $\mathcal{R}(X)=\mathrm{CVaR}_\alpha(X)$ is a coherent measure of risk in the basic sense. $\mathrm{CVaR}_\alpha(X)$ is also an averse measure of risk for $\alpha\in]0,1]$ An averse measure of risk might not be coherent; a coherent measure might not be averse.

Deviation Measures

This section refers to Rockafellar (2007) and Rockafellar et al. (2006). A functional $\mathcal{D}:\mathcal{L}^2\to[0,\infty]$ is called a deviation measure in the extended sense if it satisfies

D1: $\mathcal{D}(C)=0$ for constant C, but $D(X)>0$ for nonconstant X,

D2: $\mathcal{D}((1-\lambda)X+\lambda X')\le(1-\lambda)\mathcal{D}(X)+\lambda D(X')$ for $\lambda\in]0,1[$ (convexity),

D3: $\mathcal{D}(X) \leq d$ when $||X^k - X||_2 \to 0$ with $\mathcal{D}(X^k) \leq$ d (closedness).

A functional is called a deviation measure in the basic sense when it satisfies axioms D1, D2, D3, and furthermore

D4: $\mathcal{D}(\lambda X) = \lambda \mathcal{D}(X)$ for $\lambda > 0$ (positive homogeneity).

A deviation measure in extended or basic sense is called a coherent measure in extended or basic sense if it additionally satisfies

D5: $\mathcal{D}(X) \leq \sup X - E[X]$ for all X (upper range boundedness).

An immediate example of a deviation measure in the basic sense is the standard deviation:

$$\sigma(X) = \left(E[X - EX]^2\right)^{1/2},$$

which satisfies axioms D1, D2, D3, D4, but not D5. I.e., standard deviation is not a coherent deviation measure. Here are more examples of deviation measures in the basic sense:

Standard semideviations

$$\sigma_+(X) = \left(E[\max\{X - EX, 0\}]^2\right)^{1/2},$$

$$\sigma_-(X) = \left(E[\max\{EX - X, 0\}]^2\right)^{1/2},$$

Mean Absolute Deviation

$$MAD(X) = E[|X - EX|].$$

Moreover it is possible to define the α-Value-at-Risk deviation measure and the α-Conditional Value-at-Risk deviation measure as:

$$\mathrm{VaR}_\alpha^\Delta(X) = \mathrm{VaR}_\alpha(X - EX) \tag{18}$$

and

$$\mathrm{CVaR}_\alpha^\Delta(X) = \mathrm{CVaR}_\alpha(X - EX)\ . \tag{19}$$

VaR deviation measure $\mathrm{VaR}_\alpha^\Delta(X)$ is not a deviation measure in the general or basic sense because the convexity axiom D2 is not satisfied. CVaR deviation measure $\mathrm{CVaR}_\alpha^\Delta(X)$ is a coherent deviation measure in the basic sense.

Risk Measures Versus Deviation Measures

Rockafellar et al. originally in Rockafellar et al. (2006), and then in Rockafellar (2007) obtained the following result:

Theorem 1. *A one-to-one correspondence between deviation measures D in the extended sense and averse risk measures $\mathcal{R}$ in the extended sense is expressed by the relations*

$$\mathcal{R}(X) = \mathcal{D}(X) + EX,$$

$$\mathcal{D}(X) = \mathcal{R}(X - EX),$$

additionally,

$$\mathcal{R}\ \textit{is coherent}\ \leftrightarrow\ \mathcal{D}\ \textit{is coherent}\ .$$

Moreover the positive homogeneity is preserved:

$$\mathcal{R}\ \textit{is positively homogeneous} \leftrightarrow\ \mathcal{D}\ \textit{is positively homogeneous}\ .$$

i.e., for an averse risk measures $\mathcal{R}$ in the basic sense and a deviation measures $\mathcal{D}$ in the basic sense the one-to-one correspondence is valid, and additionally, coherent $\mathcal{R}$ $\leftrightarrow$ coherent $\mathcal{D}$.

With this theorem it is obtained that for the standard deviation, $\sigma(X)$, which is a deviation measure in the basic sense, the counterpart is the standard risk $EX + \sigma(X)$, which is a risk averse measure in the basic sense. For CVaR deviation, $\mathrm{CVaR}_\alpha^\Delta(X)$, which is a coherent deviation measure in the basic sense, the counterpart is CVaR risk, $\mathrm{CVaR}_\alpha(X)$, which is a risk averse coherent measure in the basic sense.

Another coherent deviation measure in the basic sense is the so-called Mixed Deviation CVaR, quite promising for risk management purposes. Mixed Deviation CVaR is defined as:

$$Mixed - \mathrm{CVaR}_\alpha^\Delta(X) = \sum_{k=1}^{K} \lambda_k \mathrm{CVaR}_{\alpha_k}^\Delta(X)$$

for $\lambda_k \geq 0$, $\sum_{k=1}^K \lambda_k = 1$ and α_k in $]0, 1[$. The counterpart to the Mixed Deviation CVaR is the

Mixed CVaR, which is the coherent averse risk measure in the basic sense, defined by

$$Mixed - \mathrm{CVaR}_{\alpha}(X) = \sum_{k=1}^{K} \lambda_k \mathrm{CVaR}_{\alpha_k}(X) \ .$$

Generalized Regression Problem

In linear regression a random variable Y is approximated in terms of random variables $X_1, X_2, \ldots, X_n$ by an expression $c_0 + c_1X_1 + \ldots + c_nX_n$. The coefficients are chosen by minimizing mean square error:

$$\min_{c_0, c_1, .., c_n} E(Y - [c_0 + c_1X_1 + \ldots + c_nX_n])^2 \ . \qquad (20)$$

Mean square error minimization is equivalent to minimizing standard deviation with the unbiasedness constraint (see Rockafellar et al. 2002, 2008):

$$\begin{array}{ll} \min & \sigma(Y - [c_0 + c_1X_1 + \ldots + c_nX_n]) \\ s.\,t. & E[c_0 + c_1X_1 + \ldots + c_nX_n] = EY \ . \end{array} \qquad (21)$$

Rockafellar et al. (2002, 2008) considered a general axiomatic setting for error measures and corresponding deviation measures. They defined an error measure as a functional $\mathcal{E} : \mathcal{L}^2(\Omega) \to [0, \infty]$ satisfying the axioms

E1: $\mathcal{E}(0) = 0$, $\mathcal{E}(X) > 0$ for $X \neq 0$, $\mathcal{E}(C) < \infty$ for constant C

E2: $\mathcal{E}(\lambda X) = \lambda \mathcal{E}(X)$ for $\lambda > 0$ (positive homogeneity)

E3: $\mathcal{E}(X + X') \leq \mathcal{E}(X) + \mathcal{E}(X')$ for all X and X' (subadditivity)

E4: $\{X \in \mathcal{L}^2(\Omega) | \mathcal{E}, (X) \leq c\}$ is closed for all $c < \infty$ (lower semicontinuity)

For an error measure $\mathcal{E}$ the projected deviation measure $\mathcal{D}$ is defined by the equation, $\mathcal{D}(X) = \min_C \mathcal{E}(X - C)$, and the statistic, $S(X)$, is defined by $\mathcal{S}(X) = \arg\min_C \mathcal{E}(X - C)$. Their main finding is that the general regression problem:

$$\min_{c_0, c_1, .., c_n} \mathcal{E}(Y - [c_0 + c_1X_1 + \ldots + c_nX_n]) \qquad (22)$$

is equivalent to:

$$\min_{c_1, .., c_n} \mathcal{D}(Y - [c_1X_1 + \ldots + c_nX_n])$$
$$c_0 \in \mathcal{S}(Y - [c_1X_1 + \ldots + c_nX_n]) \ .$$

The equivalence of optimization problems (20) and (21) is a special case of this theorem This leads to the identification of a link between statistical work on percentile regression (see Koenker and Bassett 1978) and CVaR deviation measure: minimization of the Koenker and Bassett error measure is equivalent to minimization of CVaR deviation. Rockafellar et al. (2008) show that when the error measure is the Koenker and Basset function: $\mathcal{E}^{\alpha}_{KB}(X) = E[\max\{0, X\} + (\alpha^{-1} - 1)\max\{0, -X\}]$ the projected measure of deviation is: $\mathcal{D}(X) = \mathrm{CVaR}^{\Delta}_{\alpha}(X) = \mathrm{CVaR}_{\alpha}(X - EX)$ with the corresponding averse measure of risk and associated statistic given by

$$\mathcal{R}(X) = \mathrm{CVaR}_{\alpha}(X),$$

$$\mathcal{S}(X) = \mathrm{VaR}_{\alpha}(X) \ .$$

Then:

$$\min_{C \in \Re} (E[X - C]_+ + (\alpha^{-1} - 1)E[X - C]_-)$$
$$= \mathrm{CVaR}^{\Delta}_{\alpha}(X),$$

$$\arg\min_{C \in \Re} (E[X - C]_+ + (\alpha^{-1} - 1)E[X - C]_-)$$
$$= \mathrm{VaR}_{\alpha}(X) \ .$$

Similar result is available for the "mixed Koenker and Bassett error measure" and the corresponding mixed deviation CVaR (see Rockafellar et al. 2008).

Comparative Analysis of VaR and CVaR

VaR is a relatively simple risk management notion. Intuition behind α-percentile of a distributions is easily understood and VaR has a clear interpretation: how much it is possible to lose with certain confidence level. VaR is a single number measuring risk, defined by some specified confidence level, e.g., $\alpha = 0.95$.

Two distributions can be ranked by comparing their VaR's for the same confidence level. Specifying VaR for all confidence levels completely defines the distribution. In this sense, VaR is superior to the standard deviation. Unlike the standard deviation, VaR focuses on a specific part of the distribution specified by the confidence level. This is what is often needed, which made VaR popular in risk management, including finance, nuclear, air and space, material science, and various military applications. One of important properties of VaR is stability of estimation procedures. Since VaR disregards the tail, it is not affected by very high tail losses, which are usually difficult to measure. VaR is estimated with parametric models, for instance Covariance-VaR based on the normal distribution assumption is very well known in finance, with simulation models such as historical or Monte Carlo or by using approximations based on second order Taylor expansion.

VaR does not account for properties of the distribution beyond the confidence level. This implies that $\mathrm{VaR}_\alpha(X)$ may increase dramatically with a small increase in α. In order to adequately estimate risk in the tail, one may need to calculate several VaRs with different confidence levels. The fact that VaR disregards the tail of the distribution may lead to unintentional bearing of high risks. In financial setting, for instance, the strategy of "naked" shorting deep out-of-the-money options will result most of the time in receiving an option premium without any loss at expiration. However, there is a chance of a big adverse market movement leading to an extremely high loss. VaR cannot capture this risk. Risk control using VaR may lead to undesirable results for skewed distributions. VaR is a non-convex and discontinuous function for discrete distributions. For instance, in financial setting, VaR is a non-convex and discontinuous function w.r.t. portfolio positions when returns have discrete distributions. This makes VaR optimization a challenging computational problem. There are codes, such as Portfolio Safeguard (PSG), that can work with VaR functions very efficiently. Portfolio Safeguard can optimize VaR performance function and also shape distributions with multiple VaR constraints. For instance, in portfolio optimization it is possible to maximize expected return with several VaR constraints at different confidence levels.

CVaR has a clear engineering interpretation. It measures outcomes which hurt the most. For example, if L is a loss then the constraint $\mathrm{CVaR}_\alpha(L) \le \bar{L}$ ensures that the average of $(1-\alpha)\%$ highest losses does not exceed $\bar{L}$. Defining $\mathrm{CVaR}_\alpha(X)$ for all confidence levels α in $(0,1)$ completely specifies the distribution of X. In this sense it is superior to standard deviation. Conditional Value-at-Risk has several attractive mathematical properties. CVaR is a coherent risk measure. $\mathrm{CVaR}_\alpha(X)$ is continuous with respect to α. CVaR of a convex combination of random variables $\mathrm{CVaR}_\alpha(w_1X_1 + \ldots + w_nX_n)$ is a convex function with respect to $(w_1, \ldots, w_n)$. In financial settings, CVaR of a portfolio is a convex function of portfolio positions. CVaR optimization can be reduced to convex programming, in some cases to linear programming (i.e. for discrete distributions).

CVaR is more sensitive than VaR to estimation errors. If there is no good model for the tail of the distribution, CVaR value may be quite misleading; accuracy of CVaR estimation is heavily affected by accuracy of tail modelling. For instance, historical scenarios often do not provide enough information about tails, hence it is necessary to assume a certain model for the tail to be calibrated on historical data. In the absence of a good tail model, one should not count on CVaR. In financial settings, equally weighted portfolios may outperform CVaR-optimal portfolios out of sample when historical data have mean reverting characteristics. VaR and CVaR measure different parts of the distribution. Depending on what is needed, one may be preferred over the other. This topic can be illustrated with financial applications of VaR and CVaR, to examine which one of these measures is better for portfolio optimization. A trader may prefer VaR to CVaR, as he may like high uncontrolled risks; VaR is not as restrictive as CVaR with the same confidence level. Nothing dramatic happens to a trader in case of high losses. He will not pay losses from his pocket; if fired, he may move to some other company. A company owner will probably prefer CVaR; he has to cover large losses if they occur, hence he "really" needs to control tail events. A board of directors of a company may prefer to provide VaR based reports to shareholders and regulators since it is less than CVaR with the same confidence level. However,

CVaR may be used internally, thus creating asymmetry of information between different parties.

In financial optimization, VaR may be better for optimizing portfolios when good models for tails are not available. VaR disregards the hardest to measure events. CVaR may not perform well out of sample when portfolio optimization is run with poorly constructed set of scenarios. Historical data may not give right predictions of future tail events because of mean-reverting characteristics of assets. High returns typically are followed by low returns, hence CVaR based on history may be quite misleading in risk estimation. If a good model of tail is available, then CVaR can be accurately estimated and CVaR should be used. CVaR has superior mathematical properties and can be easily handled in optimization and statistics. When comparing stability of estimation of VaR and CVaR, appropriate confidence levels for VaR and CVaR must be chosen, avoiding comparison of VaR and CVaR for the same level of α, as they refer to different parts of the distribution (Sarykalin et al. 2008).

Cone

A set which contains the ray generated by any of its points. Mathematically, a set S is a cone if the point x in S implies that αx is in S for all $\alpha \geq 0$.

Congestion System

Often used to be synonymous with queueing system because congestion refers to the inability of arriving customers to get immediate service, which is the reason behind doing queueing analyses.

See

► Queueing Theory

Conjoint Analysis

Situations are presented to subjects, with the features of the situations varied by experimental design. The subjects are asked to state their preferences among the situations, and the importance of each feature is assessed by statistical analysis.

See

► Forecasting

Conjugate Gradient Method

► Quadratic Programming

Connected Graph

A graph (or network) in which any two distinct nodes are connected by a path.

Conservation of Flow

(1) A set of flow-balance equations governing the flow of a commodity in a network that state that the difference between the amount of flow entering and leaving a node equals the supply or demand of the commodity at the node. (2) A set of equations that state that the limiting rates that units enter and leave a state or entity of a queueing system or related random process must be equal. The entities may be service facilities (stages), where the limiting number of units coming in must equal the limiting departing; balance at a state might mean, for example, that the rate at which a queueing system goes up to n customers equals the rate at which it goes down to n from above.

Constrained Optimization Problem

A problem in which a function $f(X)$ is to be optimized (minimized or maximized), where the possible solutions X lie in a defined solution subspace S, which is usually determined by a set of linear and/or nonlinear constraints.

Constraint

An equation or inequality relating the variables in an optimization problem; a restriction on the permissible values of the decision variables of a given problem.

Constraint Programming

Irvin Lustig[1] and Jean-Francois Puget[2]

Introduction

Arising from research in the computer science community, constraint programming is a technique for solving optimization problems. It often is applied to difficult combinatorial optimization problems arising in configuration, sequencing, and scheduling. To apply constraint programming, users must write software that includes both a model of an optimization problem plus an algorithmic search procedure that indicates how to search for a solution.

Background

Constraint programming is often called constraint logic programming and originates in the artificial intelligence literature in the computer science community. Here, the word programming refers to computer programming. Knuth (1968) defines a computer program as "an expression of a computational method in a computer language." A computer program can be viewed as a plan of action of operations of the computer, and, hence, the common concept of a plan is shared with the origins of linear programming. With respect to constraint programming, it is a computer programming technique, with a name that is in the spirit of other programming techniques such as object-oriented programming, functional programming, and structured programming. Van Hentenryck (1999) wrote:

> The essence of constraint programming is a two-level architecture integrating a constraint and a programming component. The constraint component provides the basic

operations of the architecture and consists of a system reasoning about fundamental properties of constraint systems such as satisfiability and entailment. The constraint component is often called the constraint store, by analogy to the memory store of traditional programming languages. Operating around the constraint store is a programming-language component that specifies how to combine the basic operations, often in non-deterministic ways.

Hence, a constraint program is not a statement of a problem as in mathematical programming, but is rather a computer program that indicates a method for solving a particular problem. It is important to emphasize the two-level architecture of a constraint programming system. Because it is first and foremost a computer programming system, the system contains representations of programming variables, which are representations of memory cells in a computer that can be manipulated within the system. The first level of the constraint programming architecture allows users to state constraints over these programming variables. The second level of this architecture allows users to write a computer program that indicates how the variables should be modified so as to find values of the variables that satisfy the constraints.

The roots of constraint programming can be traced back to the work on constraint satisfaction problems in the 1970s, with the advent of arc consistency techniques (Mackworth 1977) on the one hand, and the language ALICE (Lauriere 1978) that was designed for stating and solving combinatorial problem on the other hand. In the 1980s, work in the logic programming community showed that the PROLOG language could be extended by replacing the fundamental logic programming algorithms with more powerful constraint solving algorithms. For instance, in 1980, PROLOG II used a constraint solver to solve equations and disequations on terms. This idea was further generalized in the constraint logic programming scheme and implemented in several languages (Colmerauer 1990; Jaffar and Lassez 1987; Van Hentenryck 1989). Van Hentenryck (1989) used the arc-consistency techniques developed in the constraint satisfaction problem (CSP) framework as the algorithm for the basic constraint solving. This was termed finite domain constraints.

In the 1990s, a rich area of research in constraint programming was the development of special purpose programming languages to allow people to apply the techniques of constraint programming to different classes of problems. Constraint logic programming was first proposed in the context of the programming language PROLOG, and there are many other specialized languages that have been developed that offer extended functionalities compared to traditional constraint logic programming systems. Some of these are implemented as libraries in mainstream languages, such as ILOG Solver C++ (Puget 1994) or Lisp (Puget 1992). Some others are special purpose languages, such as Oz (Smolka 1995) and Claire (Caseau and Laburthe 1995).

In the design of such languages, an axiom of their development is that they provide completeness with respect to being languages for doing computer programming. A recent innovative approach with respect to languages for constraint programming is in the design of the Optimization Programming Language (OPL) (Van Hentenryck 1999), where the language was designed with the purpose of making it easy to solve optimization problems by supporting constraint programming and mathematical programming techniques. Here, the completeness of the language for computer programming is not important. Instead, the language is designed to support the representation of optimization problems and includes the facilities to use an underlying constraint programming engine, with the ability to program a search strategy to find solutions to problems. The OPL language is not a complete programming language, but rather a language that is designed to solve optimization problems using either constraint programming or mathematical programming techniques. An advantage of OPL is that the same language is used to unify the representations of decision variables from traditional mathematical programming with programming variables from traditional constraint programming.

Constraint Satisfaction Problems

To understand the constraint programming framework, a formal definition of a constraint satisfaction problem is given next using the terminology of mathematical programming. Given a set of n decision variables $x_1, x_2, \ldots, x_n$, the set D_j of allowable values for each decision variable x_j, $j = 1, \ldots, n$, is called the

domain of the variable x_j. The domain of a decision variable can be any possible set, operating over any possible set of symbols. For example, the domain of a variable could be the even integers between 0 and 100, or the set of real numbers in the interval [1,100], or a set of people {Tom, John, Jim, Jack}. There is no restriction on the type of each decision variable, and, thus, decision variables can take on integer values, real values, set elements, or even subsets of sets.

Formally, a constraint $c(x_1, x_2,\ldots, x_n)$ is a mathematical relation, that is, a subset S of the set $D_1 \times D_2 \times \ldots \times D_n$, such that if $(x_1, x_2,\ldots,x_n) \varepsilon S$, then the constraint is said to be satisfied. Alternatively, a constraint can be defined as a mathematical function f: $D_1 \times D_2 \times \ldots D_n \rightarrow \{0,1\}$ such that $f(x_1, x_2,\ldots, x_n) = 1$ if and only if $c(x_1, x_2,\ldots, x_n)$ is satisfied. Using this functional notation, a constraint satisfaction problem (CSP) can be defined as follows:

Given n domains $D_1, D_2,\ldots, D_n$ and m constraints $f_1, f_2,\ldots, f_m$, find $x_1, x_2,\ldots, x_n$ such that

$$f_k(x_1, x_2, \ldots, x_n) = 1, \quad 1 \le k \le m$$
$$x_j \varepsilon D_j, \quad 1 \le j \le n$$

Note that this problem is only a feasibility problem, and that no objective function is defined. It is important to note here that the functions f_k do not necessarily have closed mathematical forms and can simply be defined by providing the set S described above. A solution to a CSP is simply a set of values of the variables such that the values are in the domains of the variables, and all of the constraints are satisfied.

Algorithms for Constraint Satisfaction

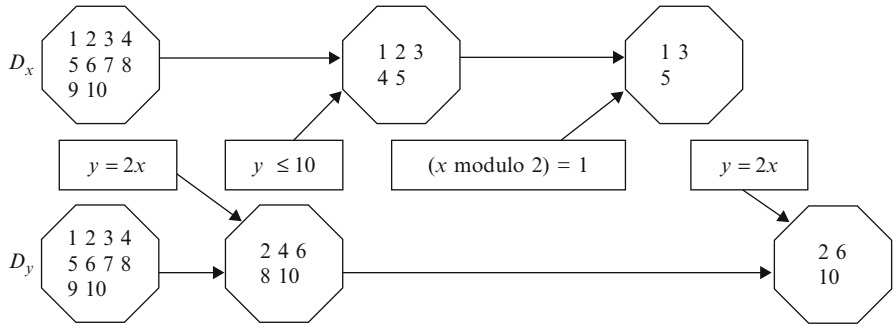
Up to now, there has been no discussion about the algorithm that a constraint programming system uses to determine solutions to constraint satisfaction problems. As mentioned earlier, a constraint programming system requires that the user programs a search strategy that indicates how the values of the variables should change so as to find values that satisfy the constraints. In OPL, there is a default search strategy that is used if the user does not program a search strategy. Most constraint programming systems require the user to program a search strategy. The first fundamental algorithm underlying a constraint programming system is given next, followed by a discussion of the methodologies used to program search.

Constraint Propagation and Domain Reduction

A constraint is defined as a mathematical function $f(x_1, x_2,\ldots, x_n)$ of the variables. Because constraint programming has its roots in computer programming, the variables can be viewed as programming language variables within a computer programming environment. Within this environment, assume there is an underlying mechanism that allows the domains of the variables to be maintained and updated. When a variable's domain is modified, the effects of this modification are then propagated to any constraint that interacts with that variable. For each constraint, a domain reduction algorithm is then programmed that modifies the domains of all the variables in that constraint, given the modification of one of the variables in that constraint. The domain reduction algorithm for a particular kind of constraint discovers inconsistencies among the domains of the variables in that constraint by removing values from the domains of the variables. If a particular variable's domain becomes empty, then it can be determined that the constraint cannot be satisfied, and an earlier choice can be undone.

This is best illustrated by the example in Fig. 1. Consider two variables x and y, where the domains of each variable are given as $D_x = \{1, 2, 3, 4, \ldots, 10\}$ and $D_y = \{1, 2, 3, 4, \ldots, 10\}$, and the single constraint $y = 2x$. For the variable y and this constraint, it is clear that y must be even and the domain of y can be changed to $D_y = \{2, 4, 6, 8, 10\}$. Now, considering the variable x, since $y \le 10$, it then follows that $x \le 5$, and the domain of x can be changed to $D_x = \{1, 2, 3, 4, 5\}$. Suppose that now a constraint is added of the form x (modulo 2) = 1. This is equivalent to the statement that x is odd. This reduces the domain of x to be $D_x = \{1, 3, 5\}$. Now, reconsidering the original constraint $y = 2x$, the values of 4 and 8 can be removed from the domain of y and obtain $D_y = \{2, 6, 10\}$.

A typical constraint programming system allows the programmer to take advantage of the existing



Constraint Programming, Fig. 1 Illustration of constraint propagation and domain reduction

propagators for built-in constraints that cause domain reductions, and to build one's own propagation and domain reduction schemes for user-defined constraints. Some systems, however, for example OPL built on top of ILOG Solver (ILOG 1999), are robust enough that large libraries of predefined constraints are provided as part of the constraint programming system, along with associated propagation and domain reduction algorithms, and it is often not necessary to create new constraints with specialized propagation and domain reduction algorithms.

Given a set of variables with their domains and a set of constraints on those variables, a constraint programming system will apply the constraint propagation and domain reduction algorithm in an iterative fashion to make the domains of each variable as small as possible, while making the entire system arc consistent. Given a constraint f_k as stated above and a variable x_j, a value $d \varepsilon D_j$ is consistent with f_k if there is at least one assignment of the variables such that $x_j = d$ and $f_k = 1$ with respect to that assignment. A constraint is then arc consistent if all of the values of all the variables involved in the constraint are consistent. A constraint system is arc consistent if all of the corresponding constraints are arc consistent. The term arc is used because the first CSPs were problems with constraints stated on pairs of variables, and this system could be viewed as a graph, with nodes corresponding to the variables and arcs corresponding to the constraints.

A number of algorithms have been developed to efficiently propagate constraints and reduce domains so as to create systems that are arc consistent. The predominant algorithm is called AC-5, developed by Van Hentenryck et al. (1992). This latter article unified the directions of the constraint satisfaction community and the logic programming community by introducing the concept of developing different algorithms for different constraints as implementations of the basic constraint propagation and domain reduction principle.

Programming Search

Given a CSP, the constraint propagation/domain reduction algorithm can be applied to reduce the domains of the variables so as to arrive at an arc consistent system. However, while this may determine if the CSP is infeasible, it does not necessarily find solutions of a CSP. To do this, one must program a search strategy. Traditionally, the search facilities provided by a constraint programming system have been based on depth-first search. The root node of the search tree contains the initial values of the variables. At each node, the user programs a *goal*, which is a strategy that breaks the problem into two (or more) parts, and decides which part should be evaluated first. A simple strategy might be to pick a variable and to try to set that variable to the different values in the variable's domain. This strategy creates a set of leaves in the search tree and creates what is called a *choice point*, with each leaf corresponding to a specific choice. The goal also orders the leaves among themselves within the choice point. In the next level of the tree, the results of the choice made at the leaf are propagated, and the domains are reduced locally in that part of the tree. This will either produce a smaller arc consistent system, or a proof that the choice made for this leaf is not possible. In this case, the system automatically backtracks to the parent and tries other leaves of that parent. The search, thus, proceeds in a depth-first

manner, until at a node low in the tree a solution is found, or until the entire tree is explored, in which case the CSP is found to be infeasible. The search strategy is enumerative, and, at each node, constraint propagation and domain reduction are used to help prune the search space.

A recent innovation in constraint programming systems is found in ILOG Solver 4.4 (ILOG 1999), where the idea of allowing the programmer to use other strategies beyond depth-first search is provided. Depth-first search has traditionally been used because in the context of computer programming, the issues regarding memory management are dramatically simplified. ILOG Solver 4.4 allows the programmer to use best first search (Nilsson 1971), limited discrepancy search (Harvey and Ginsberg 1995), depth-bounded discrepancy search (Walsh 1997), and interleaved depth-first search (Meseguer 1997). In ILOG Solver, the basic idea is that the user programs *node evaluators*, *search selectors*, and *search limits*. Node evaluators contain code that looks at each open node in the search tree and chooses one to explore next. Search selectors order the different choices within a node, and search limits allow the user to terminate the search after some global limit is reached (e.g., time, node count, etc.). With these basic constructs in place, it is then possible to easily program any search strategy that systematically searches the entire search space by choosing nodes to explore (i.e., programming node evaluators), dividing the search space at nodes (i.e., programming goals and creating choice points), and picking the choice to evaluate next within a specific node (i.e., programming search selectors). Constraint programming systems provide a framework for describing enumeration strategies for solving search problems in combinatorial optimization.

Constraint Programming and Branch and Bound

For those familiar with integer programming, the concept of search strategies should seem familiar. In fact, branch and bound, which is an enumerative search strategy, has been used to solve integer programs since the middle 1960s. Lawler and Wood (1966) present a survey, while the text by Garfinkel and Nemhauser (1972) describes branch and bound in the context of an enumerative procedure. In systems that have been developed for integer programming, users are often given the option of selecting a variable selection strategy and a node selection strategy. These are clearly equivalent to the descriptions of search electors and node evaluators described above.

There are two fundamental ways in which a constraint programming framework extends the basic branch and bound procedures. First, in a branch and bound procedure, two branches are created at each node after a variable x with a fractional value v has been chosen to branch on. The search space is then divided into two parts, by creating a choice point based on the two choices of $(x = \lfloor v \rfloor)$ and $(x \geq \lceil v \rceil)$. In the constraint programming framework, the choices that are created can be any set of constraints that divides the search space. For example, given two integer variables x_1 and x_2, a choice point could be created consisting of the three choices $(x_1 < x_2)$, $(x_1 > x_2)$, and $(x_1 = x_2)$.

The second way in which a constraint programming framework extends the basic branch and bound procedures is with respect to the variable selection strategy. In most branch and bound implementations, the variable selection strategy uses no knowledge about the problem to make the choice of variable to branch on. The integer program is treated in its matrix form, and different heuristics are used to choose the variable to branch on based on the solution of the linear programming relaxation that is solved at each node. In a constraint programming approach, the user specifies the branching strategy in terms of the formulation of the problem. Because a constraint program is a computer program, the decision variables of the problem can be treated as computer programming variables, and a strategy is programmed in the context of the problem formulation. Hence, to effectively apply constraint programming techniques, one uses problem-specific knowledge to help guide the search strategy so as to efficiently find a solution. In this way, a constraint programming system, when combined with a linear programming optimizer, can be viewed as a framework that allows users to program problem-specific branch and bound search strategies for solving mixed-integer programming problems. This capability has been available since 1996 by combining the products ILOG Solver for constraint programming and ILOG Planner for linear programming. Similar concepts also appeared in PROLOG III (Colmerauer 1990), CLP(R) (Jaffar and Lassez 1987), and CHIP (Dincbas et al. 1988).

Optimization in Constraint Programming

A constraint satisfaction problem was defined as a feasibility problem. With regard to optimization, constraint programming systems allow an objective function to be specified. Notationally, the objective function will be denoted as g: $D_1 \times D_2 \times \ldots \times D_n \rightarrow \Re$, so that at any feasible point to the CSP, the function $g(x_1, x_2, \ldots, x_n)$ can be evaluated, with the objective function to be minimized. A weakness of a constraint programming approach is that there is not necessarily a lower bound present when minimizing an objective function. This is unlike integer programming, where a lower bound exists due to the linear programming relaxation of the problem. Constraint programming systems offer two methods for optimizing problems, called standard and dichotomic search.

Standard and Dichotomic Search

The standard search procedure used is to first find a feasible solution to the CSP, while ignoring the objective function $g(x_1, x_2, v, x_n)$. Let $y_1, y_2, \ldots, y_n$ represent such a feasible point. The search space can then be pruned by adding the constraint $g(y_1, y_2, \ldots, y_n) > g(x_1, x_2, \ldots, x_n)$ to the system, and continuing the search. The constraint that is added specifies that any new feasible point must have a better objective value than the current point. As the search progresses, new points will have progressively better objective values. The procedure concludes until no feasible point is found. When this happens, the last feasible point can be taken as the optimal solution.

Dichotomic search depends on having a good lower bound L on the objective function $g(x_1, x_2, \ldots, x_n)$. Before optimizing the objective function, an initial feasible point is found, that determines an upper bound U on the objective function. A dichotomic search procedure is essentially a binary search on the objective function. The midpoint $M = (U + L)/2$ of the two bounds is computed, and a CSP is solved by taking the original constraints and adding the constraint $g(x_1, x_2, \ldots, x_n) < M$. If a new feasible point is found, then the upper bound is updated, and the search continues in the same way with a new midpoint M. If the system is found to be infeasible, then the lower bound is updated, and the search again continues with a new midpoint M. Dichotomic search is effective when the lower bound is strong, because the computation time to prove that a CSP is infeasible can often be large. The use of dichotomic search in cooperation with a linear programming solver might be effective if the linear programming representation can provide a good lower bound.

Construction Applications

Chad Perry
Queensland University of Technology,
Brisbane, Australia

Introduction

Due to their size and complexity, most construction projects would appear to offer a wide potential for MS/OR applications. For example, the standard critical path models of PERT, CPM and precedence diagrams are particularly successful in construction. However, apart from these models, MS/OR methods and models are not often used in construction. Schelle (1990, p. 111) summarizes, "In project management the large number of publications about operations research topics contrast to the small number of real applications."

This entry reviews three major areas of construction where MS/OR applications could occur — job estimation and tendering, project planning, and project management and control. Factors inhibiting the application of MS/OR in construction projects are discussed and possible future developments are canvassed.

Job Estimation and Tendering

Some MS/OR models have been applied to job estimation. Job estimation requires trade-offs between time and cost. Early MS/OR work assumed direct costs for each activity increased linearly with time, and therefore, used linear programming. But construction usually does not fit this assumption. Dynamic programming and integer linear programming have also been used, but the large number of variables and constraints of construction projects made them unworkable. Models based on heuristic and nonlinear curves have been found to be almost as accurate and more friendly for construction managers, and have been tried (Cusack 1985). In addition, the Line of Balance (LOB) model, originally developed for the U.S. Navy, is used to make trade-offs between alternative schedules, and a modified LOB model called Time Chainage is used in the U.K. for estimating schedules for construction of roads, bridges and other civil engineering projects (Wager and Pittard 1991).

Allied to job estimation is tendering, which must consider competitors' likely actions along with the bidder's decisions. It is a relatively more open and therefore more difficult system to model. Hence, although ARIMA and regression, plus other statistical and simulation models, have been developed to assist tendering, they have rarely been applied.

If tendering is considered from the selector's point of view, rather than a bidder's point of view, variables are not so uncertain because the selector will have certain information about all the bids.

Nevertheless, the complexity of construction projects again makes application of conventional MS/OR models difficult, especially as prior knowledge about bidders is an important choice factor. A hybrid model using linear programming, multiattribute utility, regression and expert systems seems appropriate here (Russell 1992).

Project Planning

While preparing a tender, construction managers must start to plan the project in more detail. The critical path models, integrated with cost control and reporting models, are widely used in construction for this purpose (Wager and Pittard 1991). Their application in complex construction projects has suggested theoretical extensions, for example, incorporating the stochastic relationship of cost with time. One such extension for the complex construction industry is a suite of PC programs, Construction Project Simulator (CPS), which incorporates productivity variability and external interferences to the construction process on site. It then produces bar charts, cost and resource schedules like the critical path models (Bennett and Ormerod 1984). However, most of these extensions have unrealistic data requirements and are rarely applied even if they are tried.

Modeling could be especially useful in planning tunnel construction projects. For example, Touran and Toshiyuki (1987) demonstrated a simulation model for tunnel construction and design. But model use is limited to very large projects.

Project planning usually involves more than cost minimization with constraints, for example, environmental considerations. Some MS/OR multi-objective models have provided assistance here. For example, Scott (1987) applied multi-objective valuation to roads construction, using a step-by-step procedure to evaluate all objectives, without having to assume all quantified data as being equally accurate and reliable.

Management and Control

After a project is planned, it must be managed and controlled. Linked with the project plan are straightforward accounting models. With increasing use of real time reporting, they allow closer management of costs. It is in this relatively stable field of managing and controlling the project after it has begun that conventional MS/OR models offer most promise, that is, at a tactical and relatively deterministic and repetitive level. For example, standard cost-minimization models could be applied to the management of construction equipment, to location and stocking of spare parts ware-houses, and to selecting material handling methods. In one of few actual MS/OR applications, Perry and Iliffe (1983) used a transhipment model to manage movement of sand during an airport construction project. Two other possible areas in where MS/OR models might be applied are multiple projects (where several projects are designed and built somewhat concurrently to minimize costs), and marketing.

In summary, although potential applications of MS/OR in construction appear at first glance to be plentiful, progress with actual MS/OR applications is slow. One reason for this is that risks in using unproven MS/OR models are high in commercial operations where claims resulting from mistakes can be taken to court. Moreover, each construction appears to be one-off, that is, the building is more or less different than previous ones of the constructor: at a different site with different subsurface conditions; involving different organizations and individuals with different goals; different weather; different material, labor requirements and shortages; different errors in estimates of time and cost; and different levels of interference from outside. Given this lack of standardization, MS/OR modeling has tended to move towards more general simulation models (which have large data requirements) or heuristic models. Still, MS/OR applications are few and although "computers are installed extensively throughout ... consultants and construction site offices ... their role appears to make the former manual processes more efficient rather than exploit the increased potential brought by the machine" (Brandon 1990, p. 285).

What does the future hold for MS/OR applications in the construction industry? A probable development is their increasing use in conjunction with user-friendly software on PCs. Research in the construction industry suggests that the key to successful implementation of research is a powerful intermediary like

construction managers. Developments in PC-based software such as simulations and expert systems, which assist rather than replace the experience-based knowledge of people like site managers, offer promise of more MS/OR applications, especially in the complex and expensive field of contractual disputes. These possibilities will be enhanced by interactive, three-dimensional graphical interfaces. In particular, expert systems should be used more frequently because they incorporate the existing knowledge of construction managers.

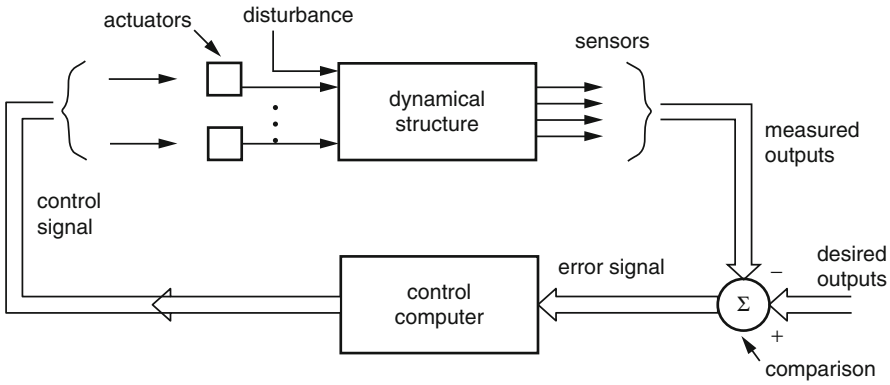
Control Theory

Andre Z. Manitius
George Mason University, Fairfax, VA, USA

Introduction

Although the use of control theory is normally associated with applications in electrical and mechanical engineering, it shares much of its mathematical foundations with operations research and management science. These foundations include



Control Theory, Fig. 1 Closed loop multivariate system

differential and difference equations, stochastic processes, optimization, calculus of variations, and others.

In application, control theory is concerned with steering dynamical systems to achieve desired results. Both types of systems to be controlled and the goals of control include a wide variety of cases. Control theory is strongly related to control systems engineering, which is fundamental to many advanced technologies. In a broader sense, control theoretic concepts are applicable not just to technological systems, but also to dynamical systems encountered in biomedical, economic and social sciences. Control theory has also had a fundamental impact on many areas of applied mathematics and continues to be a rich source of research problems.

Systems to be controlled may be of various forms: they could be mechanical, electrical, chemical, thermal or other systems that exhibit dynamical behavior. Control of such systems requires that the system dynamics be well understood. This is usually accomplished by formulating and analyzing a mathematical model of the system. Physical properties of the system play an important role in establishing the mathematical model. However, once the model is established, the control theoretic considerations are independent of the exact physical nature of the system. Since different physical systems often have similar mathematical models, similar control principles are applicable to them. For example, a mechanical system of interconnected masses and springs is described by the same mathematical model as an electrical circuit of interconnected capacitors and inductors. From the control theoretic point of view, the two systems can be treated in the same way.

The control of a system is usually accomplished by providing an input signal which affects the system behavior. Physically, the input signal often changes the energy flow in the system, much like the pilot's commands change the thrust of the engines in the aircraft. The conversion of input signals into physical variables, such as the energy of the mass flow, is done by devices called actuators. System response is measured by various instruments, called sensors. The measurements, called output signals, are fed to a controller, which usually means a control computer. The controller determines the successive values of the input signals that are then passed on to the actuators. While the control computer hardware is the physical location where the control decisions are being made, the essence of the control is a control algorithm imbedded in the computer software. The development of control algorithms is often based on sophisticated mathematical theory of control and on specific models of systems under control, Fig. 1.

One of the key difficulties of control is the uncertainty about the system model and system outputs. The uncertainty has several origins. Mathematical models of systems under control are based on many simplifying assumptions and thus contain errors due to approximations. Properties or parameters of the system may change in unpredictable ways. Systems may be subject to unknown external inputs, such as, gusts of winds acting on the aircraft. Output signals provided by sensors contain sensor noise or communication channel noise. By its very nature, the control problem formulation usually includes uncertain parameters and signals. The task of control theory is to provide solutions which guarantee, whenever possible, good system performance in spite of the uncertainties.

Historical Development

The first systematic study of feedback control of steam engines by J. C. Maxwell appeared in 1868. In 1893, A.M. Lyapunov published a first paper on the stability of motion, but his work made an impact on the control theory literature only 55 years later. When the first electronic amplifiers appeared in the long-distance telephone lines after World War I, high-gain feedback coupled with high-order dynamics of amplifiers led to stability problems. In 1932, H. Nyquist provided a method of feedback stability analysis based on the frequency response. In the late 1930s, devices for controlling aircraft were introduced. World War II gave a big boost to the field of feedback control. Norbert Wiener's theory of filtering of stochastic processes, combined with the servomechanism theory, provided a unified framework for the design of control mechanisms in aircraft and ships and became what is known as classical control theory.

In the late 1950s and in the 1960s, an extensive development of control theory took place, coinciding with manned space flight and other aerospace applications, and with the advent of computers. Bellman's principle of optimality embedded in Dynamic Programming, Pontryagin's Maximum Principle of Optimal Control, and the Kalman Filter, were invented between 1956 and 1960. State-space methods of analysis, based on differential equations and matrix computations, have become the main tools of what was then named modern control theory. Control theory played a crucial role in the success of the Apollo moon-landing project in 1969. In the 1970s, substantial progress was made in the control of systems governed by partial differential equations, adaptive control and nonlinear control. The applications of control theory became very diverse, including complex material processing, bio-medical problems, and economic studies. In the 1980s, robust control theory was formulated and reached a significant level of maturity. Robust control theory has by now provided a synthesis of the classical and the modern (state-space based) control theory.

In general, research in control aims at studying the limits of performance of feedback control systems in some advanced applications. Computational tools of control have been coded in MATLAB software system and in similar software. Control hardware has been revolutionized by microprocessors and new sensor and actuator technologies, such as smart materials. Some tools of the intelligent control approach have been applied to on-board guidance and navigation systems. Anti-lock brake systems, computerized car engine control, and geographic positioning systems are a few examples of systems where the principles and tools of control theory are at work.

Mathematical Models for Control and the Identification Issue

The most commonly used mathematical control is the linear state-space model. This is a system of first-order, time-invariant, linear differential equations with inputs and outputs. Such a linear system can be written as:

$$\begin{cases} \frac{d}{dt}x(t) = \boldsymbol{A}x(t) + \boldsymbol{B}u(t) \\ y(t) = \boldsymbol{C}x(t) + \boldsymbol{D}u(t) \end{cases}$$

where $\boldsymbol{x}(t) =$ state vector, $\boldsymbol{u}(t) =$ control, $\boldsymbol{y}(t) =$ output, and $\boldsymbol{A}, \boldsymbol{B}, \boldsymbol{C}, \boldsymbol{D}$ are matrices of appropriate dimensions.

In practical applications, engineers often use scalar or matrix transfer functions. These are rational functions of the complex variable s arising in the Laplace transform or the variable z from the Z-transform, the latter being used for discrete-time systems. There are close relationships between state-space and transfer-function models.

In the past, many other systems have been analyzed in the control theory literature, such as nonlinear ordinary differential systems, differential equations with delay, integro-differential equations, linear and nonlinear partial differential equations, stochastic differential equations, both ordinary and partial, semigroup theory, discrete-event systems, queueing systems, Markov chains, Petri nets, neural network models, and others. In many cases, research on those systems has resulted in precise mathematical conditions under which the main paradigms of linear system theory extend to those systems.

Given an existing physical system, one of the most challenging tasks is the determination of the mathematical model for control. This is usually done in one of two ways: either the model equations are derived from physical laws and the few unknown parameters are estimated from input and output data,

or a general model form is assumed with all the parameters unknown, which then requires a more extensive parameter estimation and model validation procedure. In either case, the overall step of model determination from experimental data is called system identification. Well developed methods and computer algorithms exist to assist the control designer in this task.

The Main Ideas

Feedback is a scheme in which the control of the system is based on a concurrent measurement of the system's output. Usually, the system output is being compared to a given desired value of the output and the control is adjusted so as to steer the system output closer to the desired value. Feedback creates a directed loop linking the output to the input.

Complicated systems may have many feedback loops, either nested or intersecting one another. Feedback results in a change of a system's internal dynamics and system's input–output characteristics. A system with a properly designed feedback is capable of responding correctly to input commands even in the presence of uncertainties about the model and the external perturbations. An effective feedback reduces the effects of uncertainties, regardless of their origin. Feedback is also being used to improve stability margins, eliminate or attenuate some undesirable nonlinearities, or to shape system's bandwidth. Some systems cannot even function in a stable way without feedback. An example is the fly-by-wire fighter jet in which the feedback control loop keeps the aircraft in a stable flight envelope. The mechanism of feedback is well understood in case of linear systems. However, feedback mechanisms in nonlinear systems, especially those with many degrees of freedom, remain the subject of continued investigations. In a broader sense, the concept of feedback may be used to interpret various closed-loop interactions taking place in dynamical systems in physics, biology, economics, etc. (e.g., see Franklin et al. 2006; SIAM 1988).

Optimal Control

In many cases, the goal of control may be mathematically formulated as the optimization of a certain performance measure. The tools of optimization theory and calculus of variations have been applied to derive certain optimal control principles. For example, one of the fundamental results valid for a broad class of linear systems with a quadratic performance measure says that the optimal control is accomplished by a linear feedback based on the measurement of the internal state vector of the system. Parameters of that linear feedback are obtained by solving a quadratic equation called the Riccati equation. Another fundamental result says that the control of linear systems with bounded control function and the transition time as a performance measure is accomplished by using only the extremum values of control (a bang-bang control). Solution of optimal control problems often requires iterative numerical computations to find a control that yields the best performance.

Robust Control

Control methods have been developed to design feedback that minimizes the effect of uncertainty. Systems of this type are called robust. For example, one can design a feedback which minimizes the norm of the transfer function from unwanted disturbances to the output. Another design of that type makes the feedback system maximally insensitive to parameter variations. One of the key ideas in robust control is the use of norms in the Hardy function space H_∞, for both signals and operators (transfer functions). A close connection between the minimum H_∞ norm solutions and the solutions of certain systems of matrix Riccati equations has been discovered.

Robust control theory is well understood for linear time invariant systems, and some results have been obtained for nonlinear systems. A link has been discovered between the game-theoretic approach to control problems with uncertainty and the linear and nonlinear robust control.

Stochastic Control

Stochastic control theory involves the study of control and recursive estimation problems in which the uncertainty is modeled by random processes. One of the most significant achievements of the linear theory

was the discovery of Kalman filtering algorithms and the separation principle of the optimal stochastic control. The principle states that under certain conditions the solution of the optimal stochastic control problem combines the optimal deterministic state feedback and the optimal filter estimate of the state vector, which are obtained separately from each other.

For nonlinear systems, Markov diffusions have become the tool of analysis. Stochastic optimal control conditions lead to certain nonlinear second order partial differential equations which may have no smooth solutions satisfying appropriate initial and boundary conditions. Weak solutions and viscosity solutions have recently been used to describe solutions to such optimal control problems.

Adaptive Control

One possible remedy against the uncertainty about the system and external signals is the use of adaptive feedback mechanism. During the system operation under a regular feedback, input and output signals can be processed to produce increasingly accurate estimates of system parameters which in turn can be used to adjust the regular feedback loop. Alternatively, the step of estimating the original system can be bypassed in favor of a direct tuning of the feedback controller to minimize the error. The control system built this way contains two feedback loops, one regular but with adjustable parameters, and one that provides the adjustment mechanism. Adaptive systems are inherently nonlinear.

The main theoretical issue is the question of stability of the adaptive feedback loop; stable adaptive feedback laws for certain classes of nonlinear systems have been discovered. In contrast, bursting phenomena, oscillations, and chaos have also been found in certain simple adaptive systems. Research efforts include the finding of robust adaptive control laws and at solving stochastic adaptive control problems for systems governed by some partial differential equations.

Intelligent Control

The term intelligent control is meant to describe control which includes decision making in uncertain environments, learning, self-organization, evolution of the control laws based on adaptation to new data, and to changes in the environment. An intelligent controller may deal with situations that require deciding which variables should be controlled, which models should be used, and which control strategy should be applied at any particular stage of operation. In some situations, no precise mathematical model of the system may exist, with the only information about the process being descriptive.

Intelligent control is a blend of control theory with artificial intelligence. In contrast to mathematical control theory, that uses precisely formulated models and control laws, intelligent control relies in many cases on heuristic models and rules. It is an area of research with few established paradigms. Tools of intelligent control includes expert systems, fuzzy set theory and fuzzy control algorithms, and artificial neural networks. Examples of systems where the intelligent control may become effective are autonomous robots and vehicles, flexible manufacturing systems, and traffic control systems.

Concluding Remarks

Among the main control theory challenges are: feedback control laws for nonlinear systems with many degrees of freedom, including systems governed by nonlinear partial differential equations (e.g., control of fluid flow); adaptive and robust control of such systems; control of systems based on incomplete models with learning and intelligent decision making; and feedback mechanisms based on vision and other non-traditional sensory data (SIAM 1988).

Control Variates

In stochastic or Monte Carlo simulation, a variance reduction technique whereby a simulated random variable with known expectation (the control variate) is used to construct a more precise estimator by combining it (usually linearly) with another more standard estimator.

Convex Combination

A weighted average of points (vectors). A convex combination of the points $x_1, \ldots, x_k$ is a point of the form $x = \alpha_1 x_1 + \ldots \alpha_k x_k$, where $\alpha_1 \geq 0, \ldots, \alpha_k \geq 0$, and $\alpha_1 + \ldots \alpha_k = 1$.

Convex Cone

A cone that is also a convex set.

Convex Function

A function that is never above its linear interpolation. Mathematically, a function $f(x)$ is a convex over a convex set S, if or any two points x_1 and x_2 in S and for any $0 \leq \alpha \leq 1$,

$$f[\alpha x_1 + (1-\alpha)x_2] \leq \alpha f(x_1) + (1-\alpha) f(x_2).$$

Convex Hull

The smallest convex set containing a given set of points S. The convex hull of a given set S is the intersection of all convex sets containing S. The convex hull of a given set of points S is the set of all convex combinations of set of points from S. If the set S is a finite set of points in a finite-dimensional space, then the convex hull is a polyhedron.

Convex Optimization

Yurii Nesterov
Université Catholique de Louvain (UCL),
Louvain-la-Neuve, Belgium

Introduction

Optimization problems arise naturally in many domains of Operations Research. Usually they come from some design or planning procedures facing to the limits on different resources (budget, raw materials, labor, time, etc.). The required amounts of these resources become the decision variables. It is convenient to represent them by a vector $x \in R^n$.

Very often, the results of the planning procedure can be characterized by certain functions $f_i(x)$, $i = 0, \ldots, m$, called the functional components of the problem. Choosing the most important characteristic, say f_0, as the objective function, the following is the standard formulation of the constrained optimization problem:

$$f^* = \min_{x \in Q} \{ f_0(x) : \; a_i \le f_i(x) \le b_i, i = 1, \ldots, m \}, \tag{1}$$

where $Q \subseteq R^n$ is a basic feasible set, and $[a_i, b_i] \subset R$ are the target intervals for different characteristics of the decision variables.

Clearly, the formulation (1) is very natural and very important for many areas of human activity. However, it can be shown that in its general form (1) this problem is numerically unsolvable. It is one of the most important results of the *Complexity Theory* for optimization problems, developed in Nemirovski and Yudin (1983). This theory studies the abilities of numerical methods in computing an approximate solution of optimization problems. Since the possibility of computing an exact solution is extremely rare in Nonlinear Numerical Analysis, the methods are treated as iterative procedures, which generate an answer by collecting some information on the particular problem instance.

The computational efforts of such methods are measured by the number of calls of oracle, the special unit which can compute the values and differential characteristics of functional components f_i at the requested point $x \in R^n$. It is assumed that the oracle is a Black Box, meaning that no information on its structure and intermediate computational results is available. At the same time, no bounds are introduced for the computational cost of iteration and for the volume of required memory. Nevertheless, it appears that the worst-case complexity bound for generating an approximate global solution to problem (1) with accuracy $\varepsilon > 0$ is of the order

$$O\left(\frac{1}{\varepsilon^n}\right) \tag{2}$$

calls of oracle. In this lower bound, ε represents the accuracy in estimating the optimal value of the objective function, and functional components of (1) are assumed to be Lipschitz continuous. Worst-case bound means that for each method from a reasonably wide class of optimization procedures there exists a very bad problem from our problem class, for which the number of calls is at least (2). Note that this bound destroys any hope for developing a reliable method for approximating a global solution to the general problem (1). Indeed, taking very moderate values for the parameters, say $\varepsilon = 0.01$ and $n = 20$, we get a computational cost which is intractable for any computer now and in a foreseen future.

Note that the main reason for the disastrous bound (2) is the ambitious intention to approach a global solution of the general problem (1). By stepping back and reducing the goal to finding a stationary point, for the unconstrained minimization problem

$$f^* = \min_{x \in R^n} f(x), \tag{3}$$

the stationary points satisfy the Fermat condition

$$\nabla f(x) = 0, \tag{4}$$

where ∇f denotes the gradient of function f. Thus, the goal now is to find $\bar{x} \in R^n$ with

$$\| \nabla f(\bar{x}) \| \le \varepsilon. \tag{5}$$

For function with Lipschitz continuous gradient,

$$\| \nabla f(x) - \nabla f(y) \| \le L \| x - y \|, \quad x, y \in R^n, \tag{6}$$

apply the simplest Gradient Method,

$$x_{k+1} = x_k - \frac{1}{L}\nabla f(x_k), \quad k \geq 0. \tag{7}$$

Then, after k iterations of the scheme,

$$\min_{0\leq i\leq k} \| \nabla f(x_i)\|^2 \leq \frac{L(f(x_0) - f^*)}{2(k+1)}.$$

Thus, the goal (5) can be reached in

$$O\left(\frac{1}{\varepsilon^2}\right) \tag{8}$$

iterations of method (7). As compared with (2), the estimate (8) does not depend on n. Thus, even for very large problems the goal (5) is reachable.

Since we are able to approach efficiently the stationary points of problem (3), the natural question is as follows:

What is the largest class of functions, for which the stationarity condition (4) *is a suffcient characterization of the global soution to* (3)*?*

Denoting this class of functions by $\mathcal{F}$, we could ask also for two other natural properties:

- If $f_i \in \mathcal{F}$ and $\alpha_i \geq 0$, then $\sum\limits_i \alpha_i f_i \in \mathcal{F}$.
- Any linear function belongs to $\mathcal{F}$.

Then, it can be shown, Section 2.1.1 in Nesterov (2004), that a differentiable function f belongs to $\mathcal{F}$ if and only if

$$f(y) \geq f(x) + \langle \nabla f(x), y - x\rangle, \quad x, y \in R^n, \tag{9}$$

where $\langle x, y\rangle \stackrel{\text{def}}{=} \sum\limits_{i=1}^{n} x^{(i)} y^{(i)}$. This is a definition of differentiable convex function on R^n.

This notion can be extended onto nondifferentiable functions defined onto the convex sets. A set $Q \subset R^n$ is called convex if

$$\begin{aligned} &x, y \in Q \quad \Rightarrow \\ &\quad x_\alpha \stackrel{\text{def}}{=} \alpha x + (1-\alpha) y \in Q, \ \alpha \in [0,1]. \end{aligned} \tag{10}$$

Function f is called convex if its epigraph is a convex set. That is

$$\begin{aligned} f(\alpha x + (1-\alpha)y) \leq \alpha f(x) + (1-\alpha) f(y), \\ x, y \in Q, \ \alpha \in [0,1]. \end{aligned} \tag{11}$$

Function f is called concave if $-f$ is convex.

Despite to the absence of usual differentiability and continuity, convex function possesses many interesting properties, especially at the interior points of its domain. At these points it is locally Lipschitz continuous and differentiable along any direction. Moreover, at any point x of its domain $\mathrm{dom} f$, there exists a special *set* of differential characteristics of this function called a subdifferential $\partial f(x) \subset R^n$. It is defined as follows:

$$f(y) \geq f(x) + \langle g_x, y - x\rangle, \quad x, y \in \mathrm{dom} f, \ g_x \in \partial f(x). \tag{12}$$

Subdifferential is a closed convex set, which is bounded for any interior point of $\mathrm{dom} f$. For differentiable functions, $\partial f(x) \equiv \{\nabla f(x)\}$. Convexity of functions is preserved by some natural operations (summation, multiplication by a positive constant, taking a maximum, etc.). All these operations are supported by corresponding operations with subdifferentials. Thus, in principal, the differential characteristics of convex functions are computable. Convex sets and convex functions are extensively studied in a special mathematical discipline called Convex Analysis, see Rockafellar (1970); Hiriart-Urruty and Lemarechal (1993).

The notion of convexity plays a central role in Operations Research and Optimization Theory. Using convex objects, we can write down the convex optimization problem:

$$f^* = \min_{x\in Q} \{ f_0(x) : \ f_i(x) \leq 0, \ i = 1, \ldots, m \}, \tag{13}$$

where Q is a closed convex set and all functions f_i, $i = 0, \ldots, m$, are convex. We will see below that this problem is generically tractable. It can be efficiently solved by different optimization methods.

Besides the convex optimization problems, there are two other important problem classes with convex structure.

Saddle point problems. In this setting, we need to find a solution of the following problem:

$$\min_{x\in Q_x} \max_{y\in Q_y} f(x, y), \tag{14}$$

where Q_x and Q_y are closed convex sets, and function $f(x, y)$ is convex in x and concave in y. For example,

we can write in this form a two-person zero-sum game. Note that optimization problem (13) is a particular case of problem (14):

$$f^* = \min_{x\in Q}\max_{y\in R^m_+}\left\{f_0(x) + \sum_{i=1}^m y^{(i)} f_i(x)\right\}.$$

For the saddle point problem (14), define a pair of primal-dual problems. Denote

$$f(x) = \max_{y\in Q_y} f(x,y), \quad \phi(y) = \min_{x\in Q_x} f(x,y).$$

Note that $f(x) \geq \phi(y)$ for all $x \in Q_x$, $y \in Q_y$. At the same time, under very mild assumptions there is zero duality gap:

$$f^* = \min_{x\in Q_x} f(x) = \max_{y\in Q_y} \phi(y).$$

Variational inequalities. Variational inequality problem (VI) is posed as follows:

$$\text{Find } x^* \in Q : \langle V(x^*), x - x^*\rangle \geq 0 \quad \forall x \in Q, \quad (15)$$

where Q is a closed convex set and $V : R^n \to R^n$. Point x^* is called the strong solution of VI. If $x_* \in Q$ and

$$\langle V(x), x - x_*\rangle \geq 0 \quad \forall x \in Q, \quad (16)$$

then x_* is called the weak solution of VI. For continuous operators, the sets of weak and strong solutions coincide. Not that the numerical schemes can approach only the set of weak solutions X_*, independently on existence of the strong ones. By definition, X_* is a closed convex set (may be empty).

The problem (15) has convex structure when the operator V is monotone:

$$\langle V(x) - V(y), x - y\rangle \geq 0 \quad \forall x, y \in Q. \quad (17)$$

Variational inequality problem with monotone operator is the most general (and most difficult) problem with convex structure. It includes, as a particular case, the saddle point problem (14).

An important example of monotone VI is the problem of finding the Nash equilibrium of a game with m players. Let $Q_i \subseteq R^{n_i}$, $i = 1, \ldots, m$, be the closed convex sets containing the feasible decision vectors of corresponding players. Assume that each player i has his own utility function $f_i(x_1, \ldots, x_m)$, which is convex in $x_i \in Q_i$, and jointly concave in all other variables $x_j \in Q_j$, $j \neq i$. The Nash equilibrium $x^* = (x_1^*, \ldots, x_m^*)$ is defined as follows:

$$x_i^* = \arg\min_{x_i\in Q_i} f_i(x_1^*, \ldots, x_i, \ldots, x_m^*), \quad i = 1, \ldots, m.$$

It can be shown that this point is a solution of corresponding VI with operator

$$V(x) = (\nabla_{x_1} f_1(x), \ldots, \nabla_{x_m} f_m(x)),$$
$$x = (x_1, \ldots, x_m) \in \prod_{i=1}^m Q_i.$$

This operator is monotone if function $\sum_{i=1}^m f_i(x)$ is convex.

From the modelling point of view, convexity is often a very natural property. Condition (10) implies that with two feasible decisions x and y, all intermediate variants x_α are feasible. Clearly, this assumption enormously facilitates the decision-making process. It is realized for a long time already, that even if the number of variables is relatively small, the problems with nonconvex or discrete feasible sets can be extremely difficult for human beings, e.g., "To be, or not to be?" Shakespeare (1602). For numerical methods, convexity is also a very favorable property.

Black-Box Optimization Methods

Nonsmooth Optimization

For explaining the main ideas of Black-Box optimization schemes, consider the simplest formulation of convex optimization problem,

$$\min_{x\in Q} f(x), \quad (18)$$

where $Q \subseteq R^n$ is a closed convex set, and f is a convex function defined on R^n. Black-box optimization methods approach the optimal solution of this problem by analyzing the answers of the oracle $(f(x_i), g_i \in \partial f(x_i))$ computed at the test points $\{x_i\}_{i=0}^\infty$. The simplest optimization strategy is

implemented in the (primal) Subgradient Method (Polyak 1967; Shor 1985):

$$x_{k+1} = \pi_Q(x_k - h_k g_k), \quad k \geq 0, \tag{19}$$

where $\pi_Q(x)$ is the Euclidean projection of x onto the convex set Q, and the apriori chosen step sized $\{h_k\}$ satisfy conditions

$$h_k > 0, \quad h_k \to 0, \quad \sum_{k=0}^{\infty} h_k = \infty.$$

Assuming that the subgradients of f are bounded on Q by constant M, and that $\| x_0 - x^* \| \leq R$, we can derive the optimal step size strategy for N-step process:

$$h_k = \frac{R}{M\sqrt{N+1}}, \quad k = 0, \ldots, N.$$

Then $\min\limits_{0 \leq k \leq N} f(x_k) - f^* \leq \frac{MR}{\sqrt{N+1}}$. Thus, in order to compute ε-solution of our problem, we need $\frac{M^2R^2}{\varepsilon^2}$ of calls of oracle. In accordance with Complexity Theory (Nemirovski and Yudin 1983), this efficiency estimate cannot be improved by the Black Box Methods working in a high-dimensional spaces (number of iterations never exceeds the dimension).

Unfortunately, the practical performance of the subgradient method coincides with its theoretical estimate, which is quite pessimistic. Therefore it is important to have numerical schemes which can accelerate on the particular problem instances. Note that by the Black Box Concept and inequality (12), after analyzing N test points, the full knowledge about the objective function is concentrated in the following inequality:

$$f(y) \geq f_N(x) \stackrel{\text{def}}{=} \max_{0 \leq i \leq N} [\, f(x_i) + \langle g_i, x - x_i \rangle], \quad x \in R^n. \tag{20}$$

Piece-wise linear function f_N is called the full model of our problem. It gives, for example, a computable lower bound for the optimal value of our problem:

$$f^* \geq f_N^* \stackrel{\text{def}}{=} \min_{x \in Q} f_N(x).$$

Note that $\hat{f}_N^* \stackrel{\text{def}}{=} \min\limits_{0 \leq k \leq N} f(x_k)$ gives us an upper bound for f^*. The models $f_N(x)$ are employed in so-called Bundle Methods, see Hiriart-Urruty and Lemarechal (1993). The most popular variant is the Level Method (Lemarechal et al. 1995):

$$Q_k = \{x \in Q : \; f_k(x) \leq \tfrac{1}{2}(\hat{f}_k^* + f_k^*)\},$$

$$x_{k+1} = \pi_{Q_k}(x_k), \quad k \geq 0.$$

The efficiency estimate for this method is the same as for the subragient scheme (the optimal one). However, its practical behavior usually is much better. Level Method can be also used for solving saddle point problems and variational inequalities.

For problem of moderate dimension, Complexity Theory provides us with lower complexity bound $O(n \ln \frac{1}{\varepsilon})$. Note that it has very weak dependence on ε. The methods which efficiency estimates depend polynomially on dimension and the logarithm of accuracy are called polynomial-time schemes.

In optimization, the methods which approach the above lower bound are based on idea of cutting planes. In accordance with (12), the optimal solution x^* satisfies the following condition:

$$\langle g_x, x - x^* \rangle \geq 0.$$

Therefore, after N iterations we know that

$$x^* \in \mathcal{L}_N \stackrel{\text{def}}{=} \{x \in Q : \; \langle g_k, x_k - x \rangle \geq 0, \; k = 0, \ldots, N\}.$$

The localization sets $\mathcal{L}_k$ can be used in different ways. The most straightforward strategy is implemented in the Method of Centers of Gravity (Newman 1960, Levin 1965):

$$x_{k+1} = \text{center\_of\_gravity}(\mathcal{L}_k), \quad k \geq 0.$$

It can be shown that this method has the optimal rate of convergence. However, its iteration is extremely expensive. An implementable version of this method is the famous Ellipsoid Method (Nemirovski and Yudin, 1983). It updates the outer

ellipsoidal approximations for the sets $\mathcal{L}_k$. For problem (18), the scheme is very simple:

$$\textbf{Initial settings}: R \geq \| x_0 - x^* \|, H_0 = R^2 \cdot I.$$

$$k\textbf{th iteration}: x_{k+1} = x_k - \frac{H_k g_k}{(n+1)\langle H_k g_k, g_k \rangle^{1/2}},$$

$$H_{k+1} = \frac{n^2}{n^2-1}\left(H_k - \frac{2H_k g_k g_k^T H_k}{(n+1)\langle H_k g_k, g_k \rangle}\right).$$

However, its efficiency estimate is not optimal: $O(n^2 \ln \frac{1}{\varepsilon})$. At this moment there exist several optimization methods with optimal efficiency estimate and reasonably small complexity of each iteration, see Nesterov (2004).

Smooth Optimization

Assume now that the objective function in problem (18) has Lipschitz-continuous gradient:

$$\| \nabla f(x) - \nabla f(y) \| \leq L \| x - y \|, \quad x, y \in Q. \quad (21)$$

The simplest scheme for solving this problem is the Primal Gradient Method:

$$x_{k+1} = \pi_Q\left(x_k - \frac{1}{L}\nabla f(x_k)\right), \quad k \geq 0.$$

Its rate of convergence is as follows: $f(x_k) - f^* \leq \frac{LR^2}{k+1}$. Thus, this scheme can compute ϵ-solution in $O(\frac{LR^2}{\varepsilon})$ iteration. Another possibility is to use Dual Gradient Method:

$$v_{k+1} = \arg\min_{v \in Q}\left\{\sum_{i=0}^{k}[f(v_i) + \langle \nabla f(v_i), v - v_i \rangle] + \frac{L}{2}\| v - v_0 \|^2\right\}, \quad k \geq 0.$$

Defining $x_k = \pi_Q\left(v_k - \frac{1}{L}\nabla f(v_k)\right)$, we get $\sum_{i=0}^{k}(f(x_k) - f^*) \leq \frac{L}{2}\| v_0 - x^* \|^2$. Finally, combining these two ideas, leads to the Fast Gradient Method (FGM):

$$v_k = \arg\min_{v \in Q}\left\{\sum_{i=0}^{k-1}\frac{i+1}{2}[f(y_i) + \langle \nabla f(y_i), v - y_i \rangle] + \frac{L}{2}\| v - x_0 \|^2\right\},$$

$$y_k = \frac{2}{k+2}v_k + \frac{k}{k+1}x_k, \quad x_{k+1} = \pi_Q(y_k - \frac{1}{L}\nabla f(y_k)), \quad k \geq 0. \quad (22)$$

It can be shown that $f(x_k) - f^* \leq \frac{2L\|x_0 - x^*\|^2}{(k+1)(k+2)}$, see Nesterov (2005). Thus, this method computes an ε-solution to problem (18) in $O(\frac{L^{1/2}R}{\varepsilon^{1/2}})$ iterations. Under assumption (21), this rate of convergence is optimal, Nemirovski and Yudin (1983). The first FGM was proposed in Nesterov (1983).

Second-Order Methods

If the second derivative of objective function is available, we can apply to problem (18) the second order schemes. Unfortunately, in this situation the classical Newton method does not allow the worst-case global complexity analysis. In order to get the full theoretical justification, we need to apply cubic regularization, Nesterov and Polyak (2006). Namely, let us assume that

$$\| \nabla^2 f(x) - \nabla^2 f(y) \| \leq K \| x - y \|, \quad x, y \in Q. \quad (23)$$

For problem (18) and (23), consider the following method:

$$x_{k+1} = \arg\min_{x \in Q}\left\{f(x_k) + \langle \nabla f(x_k), x - x_k \rangle + \frac{1}{2}\langle \nabla^2 f(x_k)(x - x_k), x - x_k \rangle + \frac{K}{6}\| x - x_k \|^3\right\}.$$

It converges as $f(x_k) - f^* \leq \frac{27K\|x_0 - x^*\|^2}{2(k+3)^2}$, see Nesterov and Polyak (2006). Using the ideas of Fast Gradient Methods, it can be accelerated up to the rate $f(x_k) - f^* \leq \frac{14K\|x_0 - x^*\|^2}{k(k+1)(k+2)}$, $k \geq 1$, see Nesterov (2008).

Structural Optimization

For Convex Optimization, black-box Complexity Theory has a hidden drawback. Indeed, in order to

apply the corresponding schemes, we need to be sure that our problem is convex (otherwise, the methods do not work). However, the only reliable way for checking convexity is the examination of its structure. If the function is constructed from convex elements by appropriate operations, we conclude that it is convex. Thus, the structure is visible at the preparatory stage. However, later it is ignored by numerical schemes.

Several systematic ways of using the structure of nonlinear convex optimization problems have been developed. We give two most important examples.

Polynomial-Time Interior-Point Methods

This theory is based on the notion of self-concordant function (Nesterov and Nemirovski, 1994).

Definition 1. *Let f be a closed convex function with open domain. It is called self-concordant* (sc) if $f \in C^3(\mathrm{dom} f)$ and

$$D^3 f(x)[h,h,h] \le 2\left(D^2 f(x)[h,h]\right)^{3/2}, \quad x \in \mathrm{dom} f,\ h \in R^n,$$

where $D^k f(x)[h,\ldots,h]$ denotes kth differential of f at x along direction h.

The central role in the analysis of sc-functions play the local norms defined by Hessians:

$$\| h \|_x = \langle \nabla^2 f(x)h, h\rangle^{1/2}, \quad \| s \|_x^* = \langle s, [\nabla^2 f(x)]^{-1} s\rangle^{1/2},$$
$$x \in \mathrm{dom}\, f,\ s,h \in R^n.$$

Define the Dikin ellipsoid $W_r(x) = \{y : \| y - x \|_x \le r\}$. Then $W_r(x) \subset \mathrm{dom} f$ for any $x \in \mathrm{dom}\, f$ and $r \in [0,1)$. Inside the Dikin ellipsoid, all Hessians are proportional. This feature facilitates the convergence analysis of the damped Newton method

$$x_0 \in \mathrm{dom} f, \quad x_{k+1} = x_k - \frac{[\nabla^2 f(x_k)]^{-1}\nabla f(x_k)}{1 + \| \nabla f(x_k) \|_{x_k}^*}, \quad k \ge 0.$$

It can be proved that all iterations of this scheme are feasible. They either decrease the value of f by an absolute constant, or converge quadratically. The region of quadratic convergence of this scheme is described by inequality $\| \nabla f(x) \|_x^* < \frac{1}{2}$. An important characteristic of the set $\mathrm{dom} f$ is the analytic center $x_f^* = \arg\min_x f(x)$. Its existence is equivalent to boundedness of f from below. Its uniqueness implies nondegeneracy of the Hessian at any feasible point.

An important class of sc-functions is formed by self-concordant barriers (scb) defined by inequality

$$\langle \nabla f(x), h\rangle^2 \le v\langle \nabla^2 f(x)h, h\rangle, \quad x \in \mathrm{dom} f,\ h \in R^n.$$

The value v is called the parameter of scb. Using such a barrier, we can solve the standard optimization problem

$$\min_{x \in Q} \langle c, x\rangle, \quad Q = \mathrm{Cl}\,(\mathrm{dom} f). \tag{24}$$

For that, we form the central trajectory $x^*(t) = \arg\min_x \{t\langle c, x\rangle + f(x)\}$, $t \ge 0$, and follow it by the Newton method. This can be done approximately by updating the points in the Euclidean neighborhood of the central path $\{x : \| tc + \nabla f(x) \|_x^* \le \frac{1}{4}\}$ using a predictor-corrector scheme. It can find an ε-solution of problem (24) in $O(v^{1/2}\ln\frac{v}{\varepsilon})$ iterations.

It can be proved that for any convex set in R^n there exists a scb with the parameter proportional to n. However, for its computation it is necessary to evaluate n-dimensional volumes. Therefore, in practice scb are constructed by analyzing the structure of functional components. Important examples of scb are as follows:

$$Q = \{y \in R^m : \langle a_i, y\rangle \le b_i,\ i = 1,\ldots,m\},$$
$$f(x) = -\sum_{i=1}^m \ln(b_i - \langle a_i, x\rangle), \quad v = m,$$
$$Q = \{X = X^T \in R^{n\times n} : X \succeq 0\},$$
$$f(X) = -\ln\det X, \quad v = n.$$

The most efficient interior-point methods are constructed for optimization problems in conic form. They allow infeasible start, long steps and eventual local quadratic convergence. In practice, the number of iterations of such schemes is often proportional to $\ln v$.

Smoothing Technique

The idea of this approach consists in approximating the nosmooth function by a smooth one, which can be efficiently minimized by FGM (22). It appears that

for functions with explicit max-representation this can be done in a systematic way (Nesterov, 2005). Assume that

$$f(x) = \max_{u \in Q_d} \{\langle Ax, u\rangle - \phi(u)\},$$

where Q_d is a convex set and ϕ is a convex function. Let us choose a prox-function d of the set Q_d (it is strongly convex with parameter one and attains its minimum at the center u_0 with $d(u_0) = 0$). Define

$$f_\mu(x) = \max_{u \in Q_d} \{\langle Ax, u\rangle - \phi(u) - \mu d(u)\}, \quad \mu \geq 0. \quad (25)$$

Then $f(x) \geq f_\mu(x) \geq f(x) - \mu D$ with $D = \max_{u \in Q_d} d(u)$. On the other hand, by Danskin Theorem, f_μ has Lipschitz continuous gradient with constant $L_\mu = \frac{1}{\mu} \| A \|^2$, where

$$\| A \| = \max_{x,u} \{\langle Ax, u\rangle : \| x \| = 1, \| u \| = 1\}$$

(norms for x and u are different). Thus, choosing $\mu = \Omega(\varepsilon)$, an ε-solution of problem (18) can be found by minimizing f_μ over Q by a fast gradient scheme. It will need at most $O(\frac{1}{\varepsilon})$ iterations instead of $O(\frac{1}{\varepsilon^2})$ iterations for a black-box method. This difference is due to the change of the structure of the oracle.

Of course, the smoothing technique is applicable only if the computation (25) can be done in a closed form. One of the most important examples is as follows:

$$f(x) = \max_{1 \leq i \leq n} x^{(i)}, \quad Q_d = \Delta_n = \{u \geq 0 : \sum_{i=1}^n u^{(i)} = 1\},$$
$$A = I, \quad \phi(u) = 0,$$

$$\| u \| = \sum_{i=1}^n |u^{(i)}|, \quad d(u) = \sum_{i=1}^n u^{(i)} \ln u^{(i)},$$
$$f_\mu(x) = \mu \ln \left(\frac{1}{n} \sum_{i=1}^n e^{x^{(i)}/\mu} \right).$$

Convex Polyhedron

A set of points defined by the intersection of a finite number of linear equations and/or inequalities.

See

- ▶ Polyhedron

Convex Set

A set of points that contains the line segment connecting any two of its point. Mathematically, the set S is convex if for all $0 \leq \alpha \leq 1$ and for all x_1 and x_2 in S, the point $\alpha x_1 + (1-\alpha)x_2$ is also in S.

Convexity Rows

The constraints in the decomposition algorithm master problems that require solutions to be convex combinations of the extreme points of the subproblems.

See

Convex-Programming Problem

A programming problem with convex objective function and convex inequality constraints. It is typically written as

$$\begin{aligned} &\text{Minimize } f(x) \\ &\text{subject to } g_i(x) \leq 0, \quad i = 1, ..., m, \end{aligned}$$

where the functions $f(x)$ and $g_i(x)$ are convex functions defined on Euclidean n-space.

Copula

A probability distribution function used to describe the dependence between random variables, which allows the joint cumulative distribution function CDF to be expressed in terms of the marginal CDFs and the copula. This representation enables the estimation of the marginals and the dependent behavior to be decoupled and the generation of the dependent random variables via the inverse transform method. Specifically, if $X_i \sim F_i$, $i = 1, \ldots, n$, where F_i are the marginal CDFs, the copula function is a mapping C: $[0,1]^n \rightarrow [0,1]$ given by (Nelsen 2010)

$$C(u_l, \ldots, u_n) = P(F(X_l) \leq u_l, \ldots, F(X_n) \leq u_n).$$

Thus, if the joint uniform random numbers $(U_1, \ldots, U_n)$ are generated according to C, the set of dependent random variates $(X_1, \ldots, X_n)$ can be generated by applying the corresponding inverse transform method to each component, i.e., $X_i = F_i^{-1}(U_i)$. The most well-known families of copulas are the Gaussian and the Archimedean.

Corporate Strategy

Arnoldo C. Hax[1] and Nicolas S. Majluf[2]
[1]Massachusetts Institute of Technology, Cambridge, MA, USA
[2]Pontificia Universidad Católica de Chile, Santiago, Chile

Introduction

A formal strategic planning process distinguishes three perspectives: corporate, business, and functional. These perspectives are different both in term of the nature of the decisions they address, as well as the organizational units and managers involved in formulating and implementing the corresponding action programs generated by the strategy formation process.

The corporate level deals with the tasks that cannot be delegated downward in the organization, because they need the broadest possible scope — involving the whole firm — to be properly addressed. The business level faces those decisions that are critical to establish a sustainable competitive advantage, leading toward superior economic returns in the industry where the business competes. The functional level attempts to develop and nurture the core competencies of the firm, the capabilities that are the sources of the competitive advantages.

This article deals exclusively with corporate strategic tasks (Hax and Majluf 1996). There are three different imperatives — leadership, economic, and managerial — that are useful to characterize these tasks, depending on whether the concern is with shaping the vision of the firm, extracting the highest profitability levels, or assuring proper coordination and managerial capabilities.

The Leadership Imperative

This imperative is commonly associated with the person of the CEO, who is expected to define a vision for the firm, and communicate it in a way that generates contagious enthusiasm.

The CEO's vision provides a sense of purpose to the organization, poses a significant but yet attainable challenge, and draws the basic direction to the pursuit of that challenge. Successful organizations invariable seem to have competent leaders who are able to define and transmit a creative vision, one that generates a spirit of success. In other words, success breeds success.

Hamel and Prahalad (1989) argued that the vision of the firm should carry with it an obsession that they refer to as Strategic Intent. It implies a sizable stretch for the organization that requires leveraging resources to reach seemingly unattainable goals.

Much has been written and said about leadership including the controversy on nature or nurture — whether leaders are born or made — and on the existence of common characteristics to describe successful leaders (Schein 1992; Kotter 1988). This literature is not reviewed here. Instead the concentration is on the economic and managerial imperatives of the corporate strategic tasks. Nonetheless, the set of corporate tasks that deal with the economic and managerial imperatives are the critical instruments to imprint the vision of the firm. The leadership capabilities are expressed and made tangible through the tasks that are discussed herein (Pfeffer 1992).

The Economic Imperative

This imperative is concerned with creating value at the corporate level. The acid test is whether the businesses of the firm are benefitting from being together, or if they would be better off as separate and autonomous units. From this point of view, the essence of corporate strategy is to assure that the value of the whole firm is bigger than the sum of the contributions of its businesses as independent units.

The economic imperative involves three central issues: the definition of the businesses of the firm; the identification and exploitation of interrelationships across those businesses, and the coordination of the business activities that allow sharing assets and skills (Porter 1987; Pearson 1989).

There are eight corporate tasks that are associated with the economic imperative of corporate strategy. The first one is the Environmental Scan at the Corporate Level, which allow us to start the reflection

of the firm's competitive position by a thorough understanding of the external forces that it is facing. One of the principal objectives of strategy is to seek a proper alignment between the firm and its environment. Therefore, it seems logical to start the corporate strategic planning process with a rigorous examination of the external environment.

The seven additional tasks imply critical strategic decisions seeking the attainment of corporate competitive advantages. They are mission of the firm, business segmentation, horizontal strategy, vertical integration, corporate philosophy, strategic posture of the firm, and portfolio management. The essence of these tasks are discussed next.

1. Environmental Scan at the corporate level — Understanding the external forces impacting the firm: The Environmental Scan provides an assessment of the distinct business opportunities offered by the geographical regions in which the firm operates. It also examines the general trends of the various industrial sectors related to the portfolio of businesses of the corporation. Finally, it describes the favorable and unfavorable impacts to the firm from technological trends, supply of human resources, as well as political, social, and legal factors. The output of the Environmental Scan is the identification of key opportunities and threats resulting from the impact of external factors.
2. The mission of the firm — Choosing competitive domains and the way to compete: The mission of the firm defines the business scope — products, markets, and geographical locations — as well as the unique competencies that determine its capabilities. The level of aggregation used to express this mission statement is very broad, because of the need to encompass all the critical activities and capabilities of the corporation.

   The mission of the firm defines the overall portfolio of businesses. It selects the businesses in which the firm will enter or exit, as well as the discretionary allocation of tangible and intangible resources assigned to them. The selection of a business scope at the level of the firm is often very hard to reverse without incurring in significant or prohibitive costs. The development of unique competencies shape the corporate advantage, namely, the capabilities that will be transferred across the portfolio of businesses.

   The mission of the firm involves two of the most essential decisions of corporate strategy: selecting the businesses of the firm, and integrating the business strategies to create additional economic value. Mistakes in these two categories of decisions could be painful, because the stakes that are assigned to the resulting bets are very high indeed.
3. Business segmentation — Selecting planning and organizational focuses: The mission of the firm defines its business scope, namely the products and services it generates, the markets it serves, and the geographical locations in which it operates. The business segmentation defines the perspectives or dimensions that will be used to group these activities in a way that will be managed most effectively. It adds planning and organizational focuses which are central for both the strategic analysis and the implementation of the business strategies. This concept is of great importance in the conduct of a formal strategic planning process, since the resulting businesses are the most relevant units of analysis in that process.
4. Horizontal strategy — Pursuing synergistic linkages across business units: One could argue that horizontal strategies are the primary sources for corporate advantage of a diversified firm. It is through the detection and realization of the existing synergy across the various businesses that significant additional economic value can be created. The value chain is the basic framework that is used to detect opportunities for sharing resources and activities across businesses (Porter 1985). The resulting degree of linkages among businesses determines their relative autonomy and independence.

   The mission of the firm defines the business scope; business segmentation organizes the businesses into planning and managerial units; horizontal strategies determines their degree of interdependence. Consequently, these tasks are highly linked. Moreover, the mission of the firm also defines the current and future corporate core competencies, which are the basis that supports the relationship among the various businesses, and the role to be played by horizontal strategy.
5. Vertical integration — Defining the boundaries of the firm: Vertical integration determines the breadth

of the value chain, as well as the intensity of each of the activities performed internally by the firm. It specifies the firm's boundaries, and establishes the relationship of the firm with its primary outside constituencies — suppliers. distributors, and customers.

The major benefits of vertical integration are realized through: cost reductions from economies of scale and scope; creation of defensive market power against suppliers and clients; and creation of offensive market power to profit from new business opportunities. The main deterrents of vertical integration are: diseconomies of scale from increases in overhead and capital investments; loss of flexibility; and administrative penalties stemming from more complex managerial activities (Stuckey and White 1993; Harrigan 1985; Walker 1988; Teece 1987).

6. Corporate philosophy — Defining the relationship between the firm and its stakeholders: The corporate philosophy provides a unifying theme and a statement of basic principles for the organization. First, it addresses the relationship between the firm and its employees, customers, suppliers, communities, and shareholders. Second, it specifies broad objectives for the firm's growth and profitability. Third, it defines the basic corporate policies; and finally, it comments on issues of ethics, beliefs, and rules of personal and corporate conduct.

   The corporate philosophy is the task that is most closely related to the leadership imperative, insofar as bringing a capability to articulate key elements of the CEO's vision.

7. Strategic posture of the firm — identifying the strategic thrusts, and corporate performance objectives: The strategic posture of the firm is a set of pragmatic requirements developed at the corporate level to guide the formulation of corporate, business, and functional strategies. The strategic thrusts characterize the strategic agenda of the firm. They identify all of the key strategic issues, and signal the organizational units responsible to respond to them. The corporate performance objectives define the key indicators used to evaluate the managerial results, and assign numerical targets as an expression of the strategic intent of the firm. The strategic posture captures the outputs of all of the previous tasks and use them as challenges to be recognized and dealt with in terms of action-driven issues.
8. Portfolio management — Assigning priorities for resource allocation and identifying opportunities for diversification and divestment: Portfolio management and resource allocation have always been recognized as responsibilities that reside squarely at the corporate level. As noted above, the development of core competencies shared by the various businesses of the firm constitute a critical source of corporate advantage. Those competencies are borne from resources that the firm should be able to nurture and deploy effectively, including: physical assets, like plant and equipment; intangible assets, like highly-recognized brands; and capabilities, like skills associated with product design and development.

   The heart of an effective resource allocation process is the capacity to create economic value. Sometimes, this value emerges from internal activities of the firm, other times it is acquired from external sources through mergers, acquisitions, joint ventures, and other forms of alliances. Even, on occasions, value can be created by divesting businesses that are not earning their cost of capital, i.e., they are destroying instead of adding value to the firm. Portfolio management deals with all of these critical issues.

   In the 1980s, most developed economies faced periods of stagnation which have forced firms to implement drastic restructuring policies. Restructuring leads to the realignment of physical assets (including divestment), human resources, and organizational boundaries of the various businesses with the intent of reshaping their structure and performance. Restructuring decisions are also part of portfolio management (Donaldson 1994).

The Managerial Imperative

This imperative is the major determinant for a successful implementation of corporate strategy. It involves two additional important corporate tasks: the design of the firm managerial infrastructure, and the management of its key personnel.

9. Managerial infrastructure — Designing and adjusting the organizational structure, managerial processes,

and systems in consonance with the culture of the firm to facilitate the implementation of strategy: Organizational structure and administrative systems constitute the managerial infrastructure of the firm. An effective managerial infrastructure is critical for the successful implementation of the strategies of the firm. Its ultimate objective is the development of corporate values, managerial capabilities, organizational responsibilities, and managerial processes to create a self-sustaining set of rules that allow the decentralization of the activities of the firm.

The term organizational architecture is commonly used to designate the design efforts that produce an alignment between the environment, the organizational resources, the culture of the firm, and its strategy (Nadler et al. 1992).

10. Human resources management of key personnel — selection, development, appraisal, rewards, and promotion: Regardless how large a corporation is, it will be always managed by a few key individuals. Percy Barnevik, the CEO of Asea Brown-Boveri (ABB), a successful global company, stated that one of ABB's biggest priority and crucial bottleneck is to create global managers. He immediately added, however, that a global company does not need thousands of them. At ABB, five hundred out of a total of fifteen thousand managers are enough to make ABB work well (Taylor 1991).

    Tom MacAvoy, the former President of Corning Glass-Works, used to talk, in a rather colorful way, about the need for one hundred centurions to run an organization. These are huge corporations, with operations in over one hundred countries. When it comes to identify the key personnel they need, the numbers are surprisingly small; yet, the process of identifying, developing, promoting, rewarding, and retaining them, is one of the toughest challenges that an organization faces.

The Fundamental Elements in the Definition of Corporate Strategy

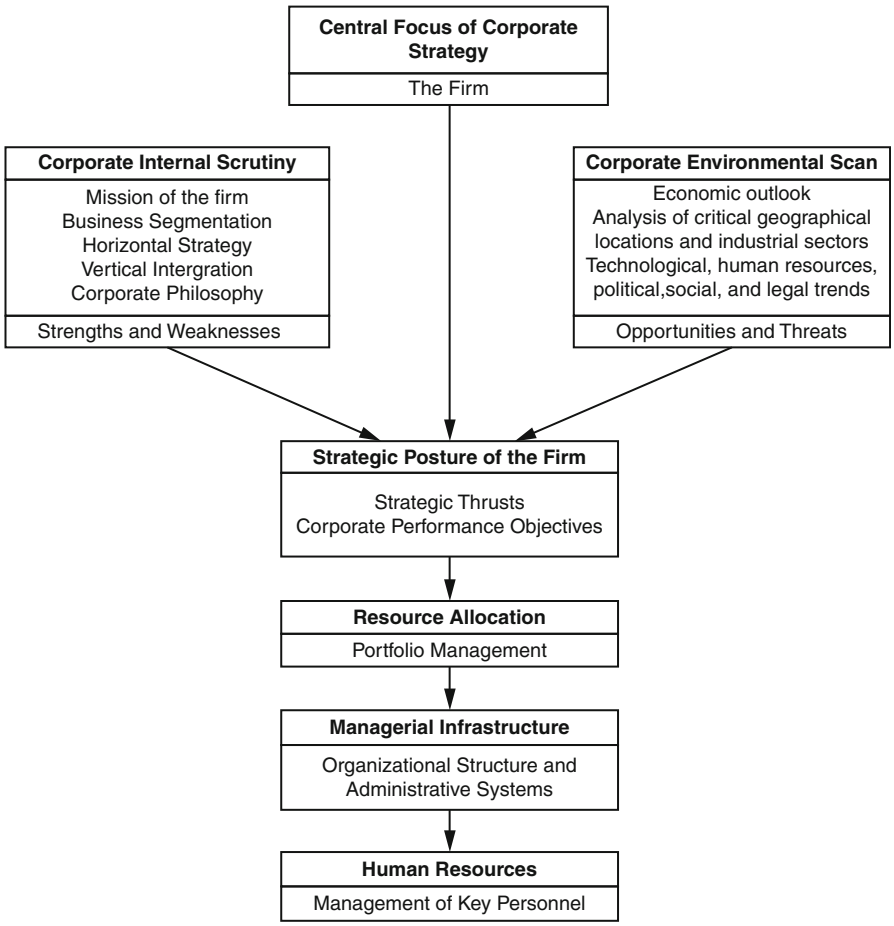
The corporate strategic tasks can be organized in a strategic planning framework, "The Fundamental Elements in the Definition of Corporate Strategy: The Ten Tasks" (Fig. 1).

The first element of the framework — The Central Focus of Corporate Strategy — consists in identifying the entity that is going to be part of the corporate strategic analysis. As opposed to the case of business strategy, where the unit of analysis is the Strategic Business Unit (SBU), corporate strategy can be applied at different levels in a large diversified organization. The amplest possible scope is the firm as a whole. There are circumstances, however, under which the scope of the analysis to a sector, group, or division of a given organization should be narrowed. These entities should encompass a number of different business units to be the subject of a meaningful corporate strategic analysis.

The next two elements of the framework are Corporate Environmental Scan and Corporate Internal Scrutiny. But, before addressing their collective tasks, it is important to note that throughout the corporate strategic analysis, existing conditions are contrasted with future ones. Thus, an underlying time frame is required to be spelled out at the beginning of the planning process.

In the case of the Corporate Environmental Scan, there are two different treatments of the future. When dealing with completely uncontrollable factors, there is a need to forecast their most likely trends to be able to understand their potential impacts. There are situations, however, in which the corporation would like to influence future events, especially when it can exercise some degree of control that will allow the future to be shaped to an advantage. By contrast, in all of the tasks that are part of the Internal Scrutiny, the future represents a state being directed at through a set of controllable decisions.

The Corporate Environmental Scan should be conducted first in the planning process, because it serves to frame the impacts resulting from the external environment. It has also the important role of transferring a common set of assumptions to the various businesses and functional managers of the firm, to serve as inputs in their own strategic planning efforts. It gives a sense of uniformity to the strategic planning thinking across all the key organizational units of the firm. This task culminates with the recognition of opportunities — the favorable impacts of the external environment which the corporation would like to seize — and threats — the unfavorable impacts which the corporation would like to neutralize.



Corporate Strategy, Fig. 1 The fundamental elements in the definition of corporate strategy: the ten tasks

The Corporate Internal Scrutiny captures the key actions and decisions the corporation has to address to gain a competitive position that is in line with the challenges generated by the external environment, and conducive to the development of a sustainable corporate advantage. This advantage is transferable to the various business units of the firm, and enhances its resources and capabilities. The tasks which are part of the Internal Scrutiny in our framework are:

- Mission of the Firm
- Business Segmentation
- Horizontal Strategy
- Vertical Integration
- Corporate Philosophy

In all of these decisions, the current state is contrasted with a desirable future one. The process then proceeds to define the challenges those changes generate for the formulation of corporate strategy. The Internal Scrutiny concludes with an overall statement of corporate strengths that the firm wishes to maintain and reinforce, as well as a statement of corporate weaknesses that the firm wishes to correct or eliminate.

The Corporate Environmental Scan and the Corporate Internal Scrutiny provide the basic inputs that will define the Strategic Posture of the firm. This task serves as a synthesis of the analysis conducted so far, and captures the strategic agenda of the firm. The strategic thrusts are a powerful expression of all of the issues that, from the perspective of the firm, need to be addressed to come out with an integrative strategy. The Corporate Performance Objectives define the key indicators that will be used to detect the operational and strategic effectiveness of the firm. The Strategic Posture is the essence of the formulation of the corporate strategy, and as such, it is a task that should receive the utmost attention. When properly conducted, the firm is able to frame the activities, responsibilities, and performance measurements that are critical for its superior strategic position.

The subsequent task, Resource Allocation and Portfolio Management, permits to backup the strategic actions implicit in the Strategic Posture of the firm with the necessary resources needed for their deployment. This leads to the realm of strategy implementation. These implementation efforts are reinforced strongly by the remaining two corporate tasks: Managerial Infrastructure and Human Resources Management of Key Personnel.

Introduction

Cost analysis is the process of estimating the individual and comparative costs of alternative ways of accomplishing an objective. The goal is not to forecast precisely accurate costs, but rather to reveal the extent to which one alternative costs more or less than another. A cost analysis is often conducted in conjunction with an effectiveness analysis to aid in the selection of one alternative over others.

Evolution

Cost analysis emerged as part of a broader initiative in the late 1940s and early 1950s to apply economic principles to the decision making process of the U.S. Department of Defense (DoD). A confluence of events following World War II resulted in a dramatic and enduring change in the way resource allocation decisions were made in public organizations. The development and evolution of cost-effectiveness analysis and cost analysis occurred nearly simultaneously and are closely related. Both types of analysis make use of operations research methods.

Operations research was invented and applied mainly by civilian scientists in support of the war effort. From its inception, operations research sought to "use scientific methods to get the most out of available resources" (Quade 1971). Immediately following the war, many of these scientists were retained by the Military Departments to apply newly developed quantitative methods to aid defense decisions. The forerunners of the RAND Corporation, the Institute for Defense Analyses (IDA), and the Center for Naval Analyses (CNA) were formed during this period.

After the war, separation of military responsibilities between the U.S. Armed Services broke down as a consequence of the rapid development of military technology and the different character of the military

threat (Smale 1967). The Services began competing for missions and disputes were settled via approval of budgets for new weapon systems. Competing systems were considered on the basis of cost-effectiveness. When equally effective weapon systems were compared, those estimated to cost the least won funding approvals. The analytical procedure applied to such decisions was first named weapon systems analysis, later shortened to systems analysis. The first documented systems analysis was accomplished in 1949 by the RAND Corporation and compared the B-52 to a turbo-prop bomber. The use of dollar costs as a proxy for real costs changed the basic systems analysis question from "Which weapon system is best for the job?" to "Given a fixed budget, which weapon system is most cost effective?" (Smale 1967; Novick 1988).

The birth of cost analysis as a separate activity occurred in the early 1950s and is attributed to Novick (1988), a cost analyst with the RAND Corporation. Novick pioneered weapon system cost analysis and is referred to as the father of cost analysis. Novick and his group at RAND are attributed with development of the fundamental building blocks of cost analysis. These include separation of total costs into cost elements, separation of one-time and recurring costs, development of cost estimating relationships, and development of conceptual costs or order-of-magnitude estimates used to compare future system proposals. Novick's group went on to invent parametric cost estimating, incremental costing, and "Total Force Costing" (Novick 1988; Hough 1989).

In the early 1960s, the Department of Defense established and implemented a centralized resource allocation process called the Planning, Programming and Budgeting System (PPBS). Under this system, future defense resources were allocated to missions in a systematic, rational manner using cost-effectiveness as the decision criterion. In 1961, a Systems Analysis Office was established within the Office of the Secretary of Defense (OSD) to help implement this new resource allocation procedure. In 1965, a Cost Analysis Division was established within the office of the Assistant Secretary of Defense, Systems Analysis. With this act, cost analysis gained a primary role in the examination of alternative force structures at the OSD level. Also in 1965, the PPBS system was extended to all federal agencies by President Lyndon Johnson.

The next few decades brought initiatives that strengthened the cost analysis capabilities of the DoD. The military departments established cost analysis offices at headquarters and major commands and staffed them, at least in part, with people trained and experienced in the methods of operations research. The DoD initiated systematic collection of cost information from defense contractors to provide defense cost analysts with records of cost experiences on major weapon system acquisitions. These records formed the bases of estimates of the costs of proposed systems at acquisition milestone decision points, strengthened the DoD's position during contract negotiations, and provided for DoD tracking of negotiated costs. In 1971, Deputy Secretary of Defense Packard instituted defense acquisition reforms that included establishment of the DoD Cost Analysis Improvement Group (Hough 1989), the requirement for independent parametric estimates for new systems acquisitions, formalization of cost analysis reviews at milestone decision points, and requirements for the military departments to improve their cost-estimating capabilities. As part of the Packard reform, cost was elevated to a principal design parameter with implementation of the "Design to Cost" initiative (Hough 1989). Ten years later, in 1981, Deputy Secretary of Defense Carlucci placed further demands on the DoD's cost analysis capabilities. He instituted the practice of "Multi-Year Procurement" based on benefit/risk analyses, "Budget to Most Likely or Expected Cost," budgeting more realistically for inflation, the use of economic production rates, the requirement to forecast business base at defense contractors' plants, increased efforts to quantify cost risk and uncertainty, and provision of greater incentives on design-to-cost goals by tying award fees to actual costs achieved in production.

Throughout the 1970s and 1980s, the practice of cost analysis continued to expand mainly in the public sector. The US government's cost analysis organizations grew in size by drawing people skilled in engineering, economics, operations research, accounting, mathematics, statistics, business, and related fields. Several focused educational programs were initiated to support this budding profession at military universities, including the Air Force Institute of Technology, the Naval Postgraduate School, and the Defense Systems Management College.

The 1990s brought a surge of activity in cost analysis with institutionalization of a Cost and Operational Effectiveness Analysis (COEA) as an integral part of the defense acquisition process. COEAs are required to be conducted and presented to the Defense Acquisition Executive at major milestone in the acquisition of a major weapon system.

Around the turn of the century, the DoD established a preference for the use of evolutionary acquisition strategies (DoD D5000.01) that promise to speed the delivery of advanced capabilities to warfighters while also providing follow-on improvements in capabilities as planned technological advances are achieved. Adoption of this approach provides cost analysts with the challenge of estimating the costs of systems that embody ultimate capabilities that cannot be fully defined at the beginning of the acquisition program.

Methods

Cost analysis is a sequential process: first identification, then measurement, and finally evaluation of alternatives. This involves the structuring and analysis of resource alternatives in a full planning context. In the case of defense, the size of the U.S. defense budget limits the dollars available to provide for the national defense. Monies spent on one mission/capability/weapon system are not available to spend on another. "Therefore, properly constructed cost estimates and cost analyses are essential because an accurate assessment of the cost of individual programs is the first necessary step towards understanding the comparative benefits of alternative programs and capabilities" (Smale 1967).

Economic costs are benefits lost and are often referred to as alternative costs or opportunity costs (Fisher 1970). An estimate of the economic cost of one choice, decision or alternative, within this context, is an estimate of the benefits that could otherwise have been obtained by choosing the best of the remaining alternatives. When constructed in this way, costs have the same dimension as benefits, and direct comparison is possible.

The following cost analysis concepts are briefly described here: the Work Breakdown Structure (WBS), Estimating Relationships (ER), and Cost Progress Curves. The treatment is not comprehensive in any sense and is provided to give those completely unfamiliar with the methods of cost analysis an idea of what is involved.

Work Breakdown Structure — Cost analysts break complex systems down into pieces before attempting to estimate their costs. A notion fundamental to this process is the Work Breakdown Structure (WBS) (U.S. Air Force Material Command 1993). The basic concept of a WBS is to represent an aircraft system, for example, as a hierarchical tree composed of hardware, software, facilities, data, services, and other work tasks. This tree completely defines the product and the work to be accomplished. It relates elements of work to each other and to the end product. Cost analysts usually estimate total systems costs as the sum of the costs of the individual elements of the WBS.

Estimating Relationships — Another tool that is fundamental to cost analysis is the estimating relationship (ER). In a broad sense, estimating relationships are transformation devices which permit cost analysts to go from basic inputs (e.g. descriptive information for some future weapon system) to estimates of the cost of output-oriented packages of military capability (Fisher 1970). More specifically, ERs are analytic devices that relate various categories of cost (e.g. dollars or physical units) to explanatory variables referred to as cost drivers. While taking many different forms, ERs are usually mathematical functions derived from empirical data using statistical analyses.

Cost Progress Curves — The basic notion of a learning curve is that, as a work procedure (e.g. sequence of steps/activities) is repeated, the person performing the procedure normally becomes better or more efficient at performing the procedure. The reduction in time or cost to perform the procedure is commonly attributed to learning. Cost analysts, who are more interested in reductions in cost, refer to this phenomenon as cost progress rather than learning.

The theory of cost progress curves states that as the total quantity of units (e.g. aircraft, wings, or fuselages) produced doubles, the cost per unit declines by some constant percentage. Wright (1936) empirically demonstrated the principle (Asher 1956). The standard mathematical model is a power function that relates manufacturing labor hours required to

produce a particular unit to the cumulative number of units produced. The functional form is simply:

$$C = aQ^b$$

where C is the number of hours required to produce unit Q, a is the labor hours required to produce the first unit, and b is a parameter that measures the amount of cost progress reflected in the data used to estimate the model parameters. The form is a hyperbolic function that is linear in logarithmic space. The characteristic of linearity in logarithmic space and the ease of application account for the general acceptance and popularity of the cost progress curve among cost analysts. The cost progress curve is applied widely by defense cost analysts when estimating the costs of alternative force sizes and compositions.

Professional Organizations

As cost analysis evolved over the past few decades, a number of professional organizations were formed to further advance cost analysis and related professional activities. The Cost-Effectiveness Technical Section of the Operations Research Society of America (now the Institute for Operations Research and the Management Sciences–INFORMS) was formed in 1956 to provide for the exchange of experiences in conducting such analyses. This organization has since changed its name to the Military Application Section (MAS) of INFORMS.

The National Estimating Society (NES) was formed in 1978. This organization's focus was on cost estimating from the perspective of the private sector. The formation of the Institute of Cost Analysis (ICA) in 1981 was referred to as the most significant event of the decade for DoD cost analysts (Hough 1989). ICA was dedicated to the furtherance of cost analysis in the public and private sectors. Both ICA and NES established programs under which the technical competence of members were certified, leading to a designation of Certified Cost Analyst or Certified Cost Estimator. ICA and NES subsequently merged to form the Society of Cost Estimating and Analysis (SCEA). SCEA continues the certification process by conferring the "Certified Cost Estimator/Analyst" designation to those who pass a qualifying examination.

Cost-Effectiveness Analysis

Norman Keith Womer
University of Missouri-St Louis, St. Louis, MO, USA

Introduction

Cost effectiveness analysis is a practical way of assessing the usefulness of public projects. The history of the subject can be traced to Dupuit's classic 1844 paper, "On the Measurement of the Utility of Public Works." The technique has been a mainstay of the Army Corps of Engineers since 1902. Recent variations of the technique have been labeled cost effectiveness analysis, cost benefit analysis, systems analysis, or merely analysis. It has been extensively applied to projects in defense, transportation, irrigation, waterways, and housing. Cost effectiveness analysis is required by law and regulation throughout the federal government to decide among certain alternative policies and projects. It has been recently required in federal regulations designed to protect human health, safety, or the environment. Despite this fact, the practice of cost effectiveness analysis is subject to criticism. Robert Dorfman (1996) declared, "Three prominent shortcomings of benefit-cost analysis as currently practiced are (1) it does not identify the population segments whom the proposed measure benefits or harms, (2) it attempts to reduce all comparisons to a single dimension, generally dollars and cents, and (3) it conceals the degree of inaccuracy or uncertainty in its estimates."

Cost effectiveness analysis (CEA) is the process of using theory, data, and models to examine a problem's relevant objectives and alternative means of achieving them. It is used to compare the costs, benefits, and risks of alternative solutions to a problem and to assist decision makers in choosing among them. The differences between cost effectiveness analysis and the discipline of operations research itself are subtle and, in some treatments, merely a matter of emphasis (see the discussion in Quade 1971). The convention adopted here is that operations research is a body of knowledge that includes all of the tools and methods that might be used in any study, while cost effectiveness analysis is a particular application of models and methods to a choice problem.

Sometimes CEA is portrayed as the combination of the difficult problem of measuring effectiveness with the rather mundane problem of cost estimation. In fact, cost measurement is an important issue. Cost effectiveness analysis provides a tool for effective resource allocation only when all the resource implications associated with each alternative — both direct and indirect — are included in the analysis. The opportunity cost of a proposed allocation of resources is the value of those resources in their best alternative use. The very concept of opportunity cost therefore requires knowledge of the goals and objectives, measures of effectiveness, the other alternatives and constraints of the organization. That is, to employ this basic concept of cost, a careful analysis of the problem must be accomplished.

Therefore, CEA must focus on the process of modeling both cost and effectiveness to develop relevant measures that shed light on the problem under study. Ultimately, CEA consists of methods for evaluating vectors of measures. In the process, CEA must grapple with issues like the scale of operations, risk, uncertainty, timing, and actions of other players.

The Role of Models

Figure 1, adapted from Quade (1971), portrays the elements of CEA. Models are used in CEA to aid in the evaluation of alternatives. These models often take the form of equations that relate the physical description of alternative systems to various impacts of their production and use. The models may concern the acquisition of the systems, their operation, or various circumstances associated with applying the system in an environment.

There are many assumptions in any analysis. One important class of assumptions that is often left unstated in CEAs concerns the behavior of key players in the process. Traditionally, CEAs have been based on rather mechanical models that relate a system's physical characteristics (e.g., weight and speed) to production cost. Any reference to behavior has often been confined to vague statements about efficiency. In fact, costs and benefits result only from actions. Thus, the motivation to act is an important part of modeling costs and benefits. Unfortunately, these behavioral assumptions are often not stated explicitly. Instead, they are frequently imbedded in detailed computer simulations that attempt to emulate the simultaneous operation of complex systems in realistic environments.

Incommensurable Impacts

The output of a suite of models may be a rather long list of measured system impacts. Some of the system impacts are measurable in units of effectiveness or costs, while others are external to our frame of reference. Generally, each of the impacts will be measurable in units that are unique to that impact, for example, number of lives lost, replacement cost of lost equipment, number of minutes of error free transmission accomplished, etc. Choice requires not only the objective consideration of the measurable impacts, but also the consideration of the often immeasurable externalities. As a result, it is important that the analyst carefully report both impact measures and their accuracy and those impacts that remain unmeasured. Choice also requires the explicit use of a criterion that evaluates the impacts and their relation to the choice problem at hand.

The Analyst and the Decision Maker

In doing analysis, the first and most important issue is to understand the decision maker's problem. Answering the question "What is the problem?" often requires understanding both the organization for which the analysis is performed and the physical system or structural change that is under study. The problem may be stated in different forms at different points in time and at different levels in the organization. Thus, understanding the problem requires understanding the objectives of the entire organization.

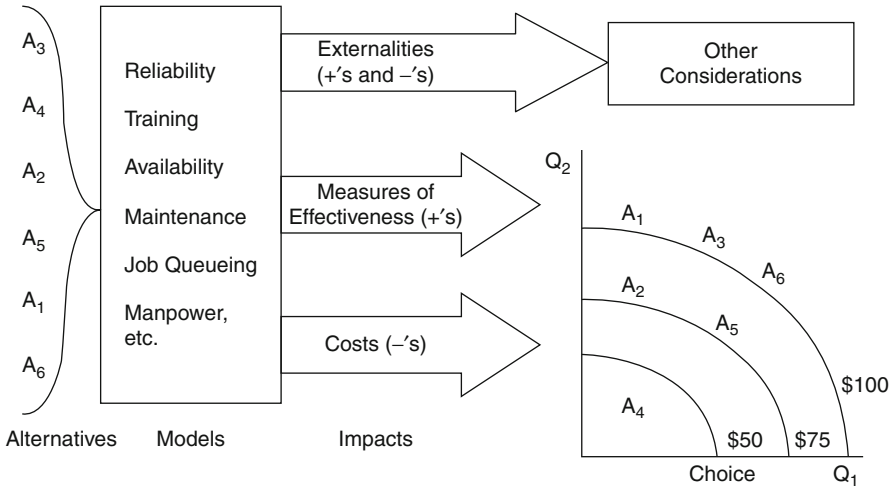
For example, consider the problem of analyzing the cost of a mission currently assigned to an aircraft system. What is the problem? Some candidates are:

- Should the existing system be replaced?
- What design should be chosen?
- Who should produce the system?
- How should the mission be performed?
- Is the mission affordable?

Often analysis is done with reference to one of these problems and then later the same study is applied to a different problem. Clearly, the alternatives, the risks, the objectives, and the cost are not independent of the problem being addressed.

Whose problem is this? It is the analyst who must choose the techniques, collect the data, model the processes, and measure the costs and outputs. It is the analyst who must justify the choices made in the particular context of the problem being addressed. Thus, it is the analyst who must be able to answer the question, "What is the Problem?"

If the role of the analyst is so large, what is left for the decision maker? The decision maker must also understand the problem and judge the value of the analysis. The decision maker must examine the completeness of the alternatives, evaluate the assumptions, examine the measurement of the impacts, and determine if risks are adequately addressed. All of these tasks are important. But the most important task of the decision maker is the task of evaluating the relative importance of the various positive and negative impacts. This includes not only the impacts that are internal to the organization but also the externalities. Evaluating the impacts also means dealing with their risks and uncertainties. The decision maker's values also include his or her attitudes toward risk. It is in this effort that the decision maker's role is uniquely different from that of the analyst.



Cost-Effectiveness Analysis, Fig. 1 The elements of cost-effectiveness analysis

Once the impacts have been evaluated, then choice can be merely a matter of adding them up and comparing the weighted impacts of each of the alternatives.

Criteria

Cost-benefit ratios — Cost effectiveness analysis often is implemented by classifying each impact of a system as either a cost or a benefit. Common units are then found for costs and for benefits and the discounted present value of each is calculated. Alternatives are compared by the ratio of these two measures.

Using a cost-benefit ratio to choose among alternatives presents several problems. Often, this approach leaves out relevant measures (i.e., treats them as the externalities depicted in Fig. 1) because those impacts cannot be evaluated in units that are comparable to the main impacts. Choosing units for the main impacts involves subjective decisions that trade-off relative measures of merit. For example, lives lost must be compared to visual pollution or environmental impact must be valued relative to economic loss. The person who determines common units for such diverse measures of merit is no longer playing the role of an analyst. That person is acting as the decision maker.

The alternative is to leave the various measures of merit uncombined. But a major problem occurs with ratio analysis when the analysis must consider multiple inputs and multiple outputs. Several ratios may be constructed but then it is not clear how these multiple ratios should be combined to determine the overall value of an alternative. Cost-benefit ratios provide the decision maker with little guidance on how to proceed in this case.

Another problem with ratio analysis is the constant returns to scale assumption that is implicit in calculating a cost-benefit ratio. By displaying the results in ratio form, the analyst implies that if the system is expanded or contracted the costs and the benefits both change proportionately. Unfortunately, the world is replete with examples of alternatives that violate such proportionality rules. The use of the incremental cost-effectiveness ratio recognizes this problem. Finally, ratio analysis does not lend itself to explicit treatments of risk and uncertainty, see Conigliani and Tancredi (2009).

Production functions — The production function approach to CEA can deal with variable returns to scale and with other nonlinearities in technology. Numerous estimates of costs and benefits for various alternatives at different scale levels are used to fit a nonlinear production function by regression. This technique can deal with several measures of input and can therefore overcome some of the difficulties of the cost-benefit ratio. Production functions can also incorporate risk described with random variables. But, the multiple regression production function also has some drawbacks. First, the use of regression tends to measure efficiency relative to average performance instead of best performance. That is, all the observations are pooled to fit the production function, a measure of average efficiency, then each alternative is compared to that average measure. Also, multiple regression requires that a single indicator for output

be used. Thus, multiple outputs must be combined into a single effectiveness indicator, similar to ratio analysis. This type of problem is especially severe in non-profit and governmental organizations where prices for outputs are unavailable or incomplete. Charnes and Cooper (1985) also criticized regression's lack of ability, "in identifying the underlying sources and amounts of inefficiencies."

Data envelopment analysis — Data envelopment analysis (DEA) provides an efficiency measure that offers some aid for the criterion problem. This linear-programming based measure has its origin in linear production theory. Golany (1988) pointed out that "DEA is quickly emerging as the leading method for efficient evaluation, in terms of both the number of research papers published and the number of applications to real world problems."

DEA is a procedure that has been designed specifically to measure relative efficiency in situations in which there are multiple measures of merit and there is no obvious objective way of aggregating measures of merit into a meaningful index of productive efficiency. Compared to regression, which averages the aggregate impact of a system, DEA is an extremal method. DEA calculates the efficiency of each alternative by comparing (via mathematical programming models) an alternative's measures of merit with the measures of merit of the other alternatives. Each alternative's measures of merit are weighed as favorably as possible. If the alternative is inefficient, DEA indicates which of its measures of merit imply its inefficiency. Also, DEA does not require the parametric specification of a production function; it derives an estimate of the production function directly from the observed data on elements of cost and effectiveness that are model outputs. DEA has been used to measure the productivity and efficiency of many organizations. It has been particularly useful for public sector organizations where market prices of outputs are not available. DEA has the potential to be extremely helpful in developing criteria in cost effectiveness analyses.

Advances — Contributions to the literature on CEA make explicit use of methods for analyzing risk and uncertainty, Conigliani and Tancredi, (2009); of dynamic models some using Markov models, Soares and Castro, (2010); and others using computable general equilibrium models, Löschel and Otto (2009).

Examples. Cost effectiveness analyses have been conducted in support of (and in opposition to) numerous significant national decisions. For example, the study of alternative delivery systems that resulted in the choice of the space shuttle, the series of studies on the Anti-Ballistic Missile, and the studies for and against the breakup of AT&T are classic studies that illustrate both the power and the fragility of this important concept.

Cramer's Rule

A formula for calculating the solution of a nonsingular system of linear equations. Cramer's rule states that the solution of the $(n \times n)$ nonsingular linear system $\boldsymbol{Ax} = \boldsymbol{b}$ is $x_i = det\ \boldsymbol{A_i(b)}/det\ \boldsymbol{A}$, $i = 1, \ldots, n$, where $det\ \boldsymbol{A}$ is the determinant of A, and $det\ \boldsymbol{A_i(b)}$ is the determinant of the matrix obtained by replacing the ith column of $\boldsymbol{A}$ by the right-hand side vector $\boldsymbol{b}$. This rule is inefficient for numerical computation and its main use is in theoretical analysis.

Crime and Justice

Arnold Barnett[1], Jonathan P. Caulkins[2] and Michael D. Maltz[3]
[1]Massachusetts Institute of Technology, Cambridge, MA, USA
[2]Carnegie Mellon University, Pittsburgh, PA, USA
[3]University of Illinois at Chicago, Chicago, IL, USA

Introduction

Ever since the publications of President Johnson's Commission on Law Enforcement and Administration of Justice (Government Printing Office 1967a, b), OR/MS professionals have investigated just about all facets of the U.S. national, state, and local aspects of crime and justice. There results have had a major influence all out of proportion to their numbers; OR/MS scholars have transformed the way many decision makers think about problems of crime and punishment. Of particular importance is the research of Blumstein and Larson (1969) on the total criminal justice system.

The OR/MS contribution pervades quantitative discussions about crime and justice systems. It has generated a more precise and transparent description of the crime problem than had hitherto been available. It has achieved uneven but sometimes magnificent successes in both identifying and implementing crime-reduction strategies. And it has enhanced the scientific rigor with which criminal justice policy experiments are analyzed and interpreted.

It is not commonly known that some of the most frequently used tools of OR/MS were developed because of crime and justice problems. In the early 19th century, France began to amass statistics on the operation of the criminal justice system (Daston 1988), and the richness of these data led statisticians to devise new techniques to analyze them. Stigler (1986) describes how Simeon Denis Poisson developed the statistical distribution that bears his name – arguably the union label of the OR/MS profession – while modeling conviction rates in French courtrooms. Similarly, Hacking (1990) shows how Poisson developed the law of large numbers by modeling the reliability of jurors in criminal trials.

As noted, the application of OR to crime and justice began in the mid-1960s, when operations researchers and systems analysts on the President's Crime Commission directed their talents to the science and technology aspects of the criminal justice system (Government Printing Office 1967b). Since then, the application of OR/MS ideas in this area has burgeoned (Maltz 1994). Some of the more salient roles played by OR/MS in this field are discussed in this article, especially how OR/MS has been used in analyzing crime statistics, offender behavior, and criminal justice system dynamics. Also described here are how queueing models and optimization techniques have been applied in criminal justice contexts, how OR/MS has caused (some) criminologists to rethink some of their conclusions, the growing role of Geographic Information Systems (GIS) in criminal justice, and how OR/MS is pioneering the extension of quantitative analysis to model offenders who do not fit the traditional street offender mold.

Homicide

In discussing crime, it is natural to start with the most serious offense – murder. Led by the FBI, those assessing homicide patterns had thought it sufficient to consider annual murder rates, expressed in killings per 100,000 citizens per year. The calculated rates had a reassuring quality about them: if 50 per 100,000 citizens were murdered last year, then the other 99,950 were not murdered. Thus, after Detroit had precisely that murder rate in 1973, *The New York Times* reported that "If you live in Detroit, the odds are 2000–1 (i.e., 99,950–50) that you will not be killed by

one of your fellow citizens. Optimists searching for perspective in the city's murder statistics insist that these odds are pretty good."

But some OR/MS scholars raised a question: why measure homicide risk per year as opposed to (say) per day, per month, or per decade? Given that an urban resident has a lifetime danger of being murdered, that would seem the natural time frame over which to measure the risk. And at an annual risk of 1 in 2000, a person with a natural lifespan of 70 years would face a lifetime murder risk of 1 in 28 (!!). Refinements of this raw calculation leave its result virtually unchanged (Barnett et al. 1975; 1980; Barnett and Schwartz 1989).

The idea of estimating lifetime risk of murder has come into general use: detailed projections appeared in the 1981 FBI *Uniform Crime Reports*, and such forecasts have since been incorporated into the actuarial projections of the (U.S.) Centers for Disease Control. There is now widespread awareness that homicide is not a tragic, rare phenomenon, but instead a critical public health problem.

Parallel reasoning is likewise being applied to the lifetime risk of imprisonment. For example, even though the probability of being sent to prison on any given day is small, Bonczar and Beck (1997) estimate that 5.1% of all persons in the U.S. and 28.5% of black males will serve time in prison at some point in their lives.

Offender Behavior

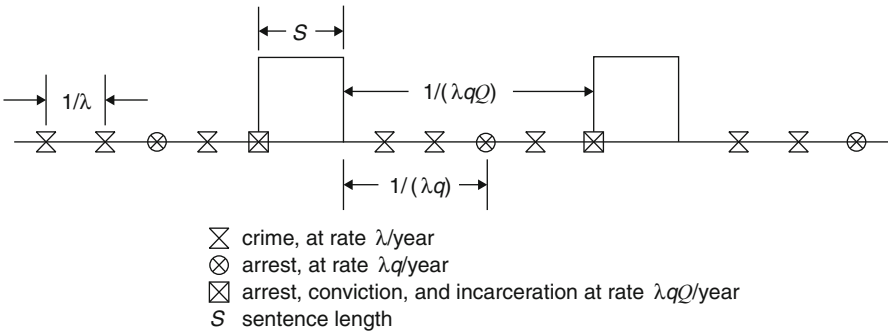
From the standpoint of public policy, it makes a great deal of difference whether existing crimes are committed by relatively few individuals who all offend frequently or by a large number who all offend rarely. OR/MS researchers have taken part in efforts to estimate the total number of offenders, some of whom may never be apprehended for their crimes (Greene and Stollmack 1981; Greene 1984). Of course, the offender population is highly diverse in terms of both frequency of criminal activity and types of crime committed (Chaiken and Chaiken 1982). A major OR/MS contribution to criminal justice has been in creating succinct models that can characterize both individual criminal behavior and the variation of that behavior across offenders.

Most offenders do not commit crimes according to some deterministic schedule. The exact nature of their crime-generation process is by and large unknown, but it is generally safe to say that the aggregate crime commission by a group of offenders can be modeled by the Poisson distribution. This distribution plays the same role in aggregating point processes that the normal distribution plays in aggregating continuous processes.

In highly influential work, Shinnar and Shinnar (1975) proposed a simple but insightful model of the crime and punishment process. The authors assumed that an active offender commits crimes at a Poisson rate λ per year over a career of length T years. If not arrested, the offender would commit on average λT career crimes. But things change if, like Shinnar and Shinnar, it is assumed that the offender's probability of arrest for each crime is q, that the probability of imprisonment given arrest is Q, and that the average sentence length per prison term is S. If career length T is long relative to sentence length S, then steady-state arguments imply that, under the revised scenario, the offender is free on average for only $1/\lambda qQ$ years between successive imprisonments (Fig. 1). Thus, because of detention, the offender is free and active only for fraction $(1/\lambda qQ)/(1/\lambda qQ + S)$ of the offender's career rather than for all of it. It follows that incapacitation has reduced the offender's total number of offenses by the proportion $S/(S + 1/\lambda qQ)$ compared to the number in a world free of punishment.

There are some gross simplifications in this model (for example, the career length T is assumed independent of the punishment policy in place). But it encapsulates in one equation the effects of all primary elements of the criminal justice system: the offender (via crime commission rate λ), the police (arrest probability q), the courts (chance of imprisonment given arrest, Q), and the correctional system (sentence length S). The model also provides guidance to those exploring empirical data (e.g., offenders' arrest, sentencing, and conviction records) about which quantities were especially worth trying to estimate.

OR/MS professionals like Blumstein and his colleagues worked to flesh out the description of the individual criminal career (Blumstein et al. 1986). They estimated key parameters like the proportion of citizens who participated at some time in criminal behavior, the frequency of crime-commission during the career, the degree to which offenders specialize by crime-type, and the duration of the criminal career.



Crime and Justice, Fig. 1 A (deterministic) criminal career

A simple model of the career might summarize it with four parameters: P, the fraction of individuals in a birth cohort who initiate criminal careers; A, the age of onset for the career; λ, the average annual crime commission rate while free and active, and ρ, the annual probability that the career ends. A macroscopic model could reflect diversity among offenders by assigning a population-wide distribution to each of these parameters, as does the model in Blumstein et al. (1993). (Other distributions about offense type would fill out the description; e.g., Chaiken and Chaiken 1982). Interestingly, offenders who differ greatly on some parameters may be quite similar on others. In a cohort of London multiple-offenders, for example, individuals appear to differ far more in their λ-values than their ρ -values (Barnett et al. 1987). Thus, their career lengths may diverge far less than do intensities of activity during their careers.

A common problem in criminal justice policy analysis has been estimating the effect of enhanced sentences on both crime rates and criminal justice spending. For example, Greenwood et al. (1994) used these Poisson models of criminal offending to predict the consequences of full-scale implementation of California's "Three-Strikes and You're Out" law, and Greenwood et al. (1999) use the model to help identify ways in which actual implementation deviated from that bench-mark.

As is shown in Fig. 1, many offenders continue to commit offenses despite their having been in correctional institutions. But not all do, and the extent of recidivism (commission of additional offenses) is an important concern in criminal justice research. OR/MS researchers have devised, calibrated, and tested probabilistic models that assess the likelihood that given offenders with given past records will again commit crimes within particular future time periods (Stollmack and Harris 1974; Harris et al. 1981; Maltz 1984; Ellerman et al. 1992). These flexible and mathematically-rich techniques allow frequent updating of the prognoses for particular individuals.

The Criminal Justice System (CJS)

With mathematical models, OR/MS professionals described the idea that the CJS – composed of police, courts, and corrections — is, in fact, a system (Government Printing Office 1967b), within which policy shifts in one component generally have consequences for the others. An increase in arrests aimed at reducing crime, for example, can first clog the courts and then overcrowd jails and prisons which, in turn, may be required to reduce surging inmate populations by instituting early release programs for those incarcerated. One of the earliest models to incorporate such feedback effects was the Justice System Interactive Model (JUSSIM), (Belkin et al. 1972); subsequent efforts include Cassidy (1985) and Morgan (1985). JUSSIM has since been updated and software written for personal computers by the U.S. Department of Justice to permit its widespread use (Institute for Law and Justice 1991).

While it is hoped that the CJS provides a fair and cost-effective way to reduce crime, there is a continuing national debate about whether this goal can be achieved. The aims of the CJS are to deter potential offenders from committing crime, to incapacitate those who have been convicted by imprisoning them, and to rehabilitate past offenders so that they are harmless in the future. Of course, the system might induce undesirable changes in criminal behavior, such as brutalization under

which an offender released from prison is more violent than ever before. Statistical investigations by OR/MS researchers have tried to estimate various net effects of the CJS on crime levels (Blumstein et al. 1978, 1986), as well as to assess the realism of specific attempts to estimate such effects from aggregate data (Barnett 1981).

Over the past many years, the number of people under criminal justice supervision in the U.S. has grown dramatically. Although crime rates have fallen, they were rising during much of the build-up in incarceration and, even if increased incarceration were contributing substantially to declining crime rates, it is clearly an expensive way to suppress crime, in both budgetary and human terms. Hence, there has been considerable interest in creating systems models that embrace not only the CJS, but also broader sets of interventions in a manner that allows different classes of interventions to be compared. The goal is to determine whether spending more money on violence prevention or drug treatment programs, for example, might be a more cost-effective way to reduce crime than would be spending more money on prisons and jails.

These analyses show that violence prevention programs are a promising alternative (Greenwood et al. 1996) and that prevention interventions offer a broad array of benefits. They also, however, find that there is a great deal of uncertainty associated with estimates of prevention's cost-effectiveness, even though many, many individual prevention programs have been evaluated (Caulkins et al. 1999). Importantly, the systems framework identifies the sources of the uncertainty and highlights why past evaluations have not been more informative. Some of the reasons are pedestrian, such as never reporting program costs or a focus on showing statistical significance of effects rather than estimating their magnitude. Others are more insightful, such as the fact that traditional evaluations often only consider effects on program participants, even though indirect effects on those not actually in the program are, in some cases, larger in aggregate.

Queueing Models

While everyone recognizes that crime rates vary from neighborhood to neighborhood and by time of day, OR/MS analysts have built probabilistic models that allow exploration of the consequences of such heterogeneity, especially with respect to practical issues of police deployment and staffing of 911 emergency centers (Larson 1972; Kolesar et al. 1975; Chelst 1978). From such models and OR/MS insights into queueing theory have come an unpleasant realization: randomness in the arrival times of calls for service can cause surprisingly large delays in responding to them. Getting six calls randomly distributed over a one-hour period, for example, can yield much slower responses than getting six calls spaced exactly ten minutes apart.

Queueing theory has been applied and extended in developing improved allocation methods for police patrol resources. Such formulations as the hypercube queueing model (Larson 1974; Larson and Odoni 1981; Larson and Rich 1987) and RAND's Patrol Car Allocation Model (Chaiken and Dormont 1978) have depicted with great accuracy how particular police response strategies affect mean response times, workload imbalance across officers, and a host of other performance measures. The models, which are used by many U.S. cities to set police dispatching strategies, allow the user to vary the number of patrol cars and the deployment rules, and then to observe on a computer screen the performance statistics under each scenario. Other OR/MS developments allow the user to set priorities in responding to calls for service and to analyze sending multiple vehicles to incidents (Green and Kolesar 1984). A review of this work is provided in Swersey (1994).

Optimization

Optimization, one of the strongest OR/MS specialties, has played a relatively small role in the profession's contribution to criminal justice. For example, limited success has attended OR/MS efforts to suggest optimal punishment policies. Under particular assumptions about crime-commission processes and their sensitivity to the sentencing strategy in place, Blumstein and Nagin (1978) and Barnett and Lofaso (1986) have worked out optimal allocations of prison space. But the verification of such assumptions — let alone the estimation of key model parameters — has not gone far enough that such models are taken very seriously. Associated attempts to estimate how prison populations vary with changes

in demography and sentencing policy have yielded prison population forecasts that do not immediately demonstrate the practicality of the models (Blumstein et al. 1980; Barnett 1987).

Perhaps the most famous OR/MS proposal for optimal prison sentencing was Greenwood's selective incapacitation scheme in which heavy sentences would be imposed on offenders with at least four of seven high-risk characteristics (Chaiken and Rolph 1980). But data analyses revealed difficulties with implementing such policies (Chaiken and Chaiken 1982; Greenwood and Turner 1987), including a high rate of false positives (people incarcerated to prevent projected future crimes that would never have occurred were they free). These false positives raise controversies about sentencing by conjecture and yield smaller crime-reduction benefits in practice than the strategy can achieve in theory.

A Sense of Ambiguity

Sometimes OR/MS people have contributed to criminal justice research less by what they said than by what they didn't say. OR/MS scholars approach data with a sense of ambiguity: an awareness that a particular empirical pattern is often consistent with a broad range of possibilities. Thus, they have usefully called out "not so fast!" when the most obvious interpretation of certain data was being treated as the only viable one. Four examples of such rescue activities are described below.

One case concerns the Kansas City Preventive Patrol Experiment conducted in the early 1970s. When not responding to calls to service, patrol cars drive randomly through their districts; in theory, such preventive patrol reduce crimes because would-be offenders realize that, even if their victims cannot contact the police, a patrol car might reach the crime scene purely by chance. That theory was called into doubt after Kansas City, in a prearranged experiment, acted to increase preventive patrol sharply in some beats and virtually eliminate it in others. When neither beat-by-beat crime rates nor citizen perceptions about police presence changed visibly during the (unannounced) experiment, some people saw preventive patrol as having lost any rationale.

arson (1975), however, demonstrated with detailed calculations that actual conditions during the Kansas City experiment were quite different from the anticipated ones. Patrol cars from high-activity beats were spending much of their time responding to calls for service from low-activity ones, which had been deprived of all local police vehicles. The upshot was that there was a great deal of police-car movement — often with sirens screaming — in the districts supposedly without preventive patrol, and surprisingly little increase in patrol in the districts supposedly saturated with it. Perhaps, Larson argued, the reason crime rates and citizen perceptions did not change was that police activity itself had not meaningfully changed.

A second example concerned the relationship, well-known to criminologists, between arrests and age. The graph of arrests vs. age is unimodal, reaching a peak in the late teens and then dropping off steadily and sharply. Given this curve, some people argued that it was not cost-effective to give long sentences to offenders convicted at age 30; such offenders, it was contended, were already far less active than at their primes and were unlikely to do much harm even if left on the streets.

But Blumstein et al. (1982) pointed out that such an analysis was vulnerable to a variant of the well-known ecological fallacy: Even if arrests in the aggregate were dropping rapidly with age, it did not follow that individual offenders exhibited this pattern. Having studied longitudinal data about individual offenders, they found that the drop in arrests with age reflected not less activity per year among active offenders, but rather a growing fraction of offenders who had retired from criminal activity. Statistically, an individual convicted at age 30, presumably still active at that age, would be expected, if allowed to go free, to commit as many crimes over the next several years as someone several years younger.

While citizens in the U.S. were debating in the mid-1970s whether to restore the death penalty, several economists came forth with historically-based analyses that purported to weed out extraneous factors and estimate how each execution affects the overall homicide level. The model, whose findings were cited by the U.S. Supreme Court, purported to show that each execution deterred eight homicides. But Barnett (1981) wondered whether the econometric models being used had sufficient explanatory power to fulfill their ambitious goals. Arguing that homicide levels were subject to roughly Poisson-level statistical

noise, he proposed a test of how well the econometric models could forecast state-by-state homicide levels in the very data sets used to calibrate them. The test results indicated that the predictions from all the models suffered large systematic errors of unknown cause and that, indeed, the errors were far larger than any reasonable estimate of the size of the effect the models sought to measure. Thus, Barnett concluded, the analyses were not sensitive enough to answer the question that motivated them.

A final example of ambiguity arises from a study that concluded that juvenile detention acts to reduce delinquency. The study found that an average Illinois male youth sent to a reformatory, though not cured of criminal activity by his stay there, was arrested far fewer times per month after his release than just prior to his detention. The decline was interpreted as the post-release suppression effect on incarceration: getting tough works.

Maltz and Pollock (1980), however, saw another possibility, tied to the phenomenon called regression-to-the-mean. Even if a youth commits crime at a steady frequency and has an unchanging probability of arrest per offense, varying luck in the arrest lottery will cause his observed arrest rate to fluctuate from month to month. But the authorities are especially likely to send him to a reformatory after an upsurge of arrests — that is, at a peak of the fluctuating pattern. Thus, even if the reformatory has no effect on his underlying pattern of criminal behavior, his post-detention arrests would likely fall in frequency compared to his unluckily high predetention levels. Tierney (1983) proposed a revision in their analysis that modified its result, but the work still showed that the suppression effect was quite possibly just an illusion.

These four examples show one of the primary assets of OR/MS thinking as applied to a field so data rich as the CJS. Although data may exhibit certain aggregate patterns, these patterns need not illuminate what is happening at the more detailed level that is, quite often, the appropriate focus of policy analysis. OR/MS analysts should never forget the importance of studying a problem's molecular structure.

Geographical Analyses

Location is a key attribute of crime. Crime is the result of a convergence in time and space of criminals and victims, in the absence of guardians. Land use types, physical geography, the built environment, population characteristics, and police resource allocations and tactics are among the location-based factors influencing crime. Until recently, there was limited capacity for analysts to consider geographical factors explicitly. (Even a panel data set with city-level information is aggregated both in the sense that all events within a city are pooled and in the sense that information about the relative proximity of different cities is usually ignored). The advent and development of geographic information systems (GIS) has changed this situation. GIS is an information technology that geocodes information and processes it spatially in order to facilitate analysis.

Geocoding takes three forms. GIS uses 1) rule bases and scoring to match text of crime incident street addresses with street addresses that already have locations (latitude/longitude coordinates or their flat projections) to place points on maps, 2) global positioning system instruments to read world coordinates of a point, and 3) spatial overlay of map boundary layers (e.g., police precincts, patrol beats, or uniform grid cells) on crime incident points to classify the points' area membership.

Spatial processing includes 1) integrating crime incidents and other factors affecting crime through location, 2) spatial overlay of points and reapportionment of area-based statistics to a consistent crime space/time series (e.g., counts of persons aged 14 to 25 and monthly robberies of persons by spatial grid cell), 3) proximity determination using spatial queries (e.g., all drug arrests within 1000 feet of schools), and 4) connectivity of streets for routing.

The geocoded and processed information can be used for a wide variety of decision support roles. Crime maps for analysis or communication (Maltz et al. 1991; Brantingham and Brantingham 1998) are among the most familiar, but crime forecasting (Foster and Gorr 1986; Gorr and Olligschlaeger 1994; Olligschlaeger 1998) is growing in importance, particularly in conjunction with computer statistics (COMSTAT) police management systems that need counter-factuals against which actual performance can be compared. Likewise, GIS can provide the real time data and detailed information about street networks that is needed to implement effectively some of the OR models described above. Examples

of these applications include patrol resource allocation and the design of administrative boundaries to balance workloads (Koper 1995), as well as queueing applications for routing emergency response (Green 1984; Larson and Rich 1987; Larson and McKnew 1982).

Consensual Crime

Originally the modern application of OR/MS efforts in crime and justice focused on the actions and consequences of the typical street offender who robbed, burglarized, assaulted, or killed strangers. OR/MS methods such as process control charts (Anderson and Diaz 1996), data envelopment analysis (Thanassoulis 1995), and simulation (Larson et al. 1993) continue to be applied in innovative ways to address these problems. But other OR/MS methods have also been finding their way into analyses of consensual crimes including corruption and drug trafficking.

Corruption is widespread among societies and institutions and has stimulated a small but vibrant literature at the intersection of management science and economics. An early standard reference on corruption is Rose-Ackerman (1978) who studied the economics of the supply and demand of bribes. These ideas have been applied to analyses of tax evasion (Chander and Wilde 1992), the distribution of bribes within a hierarchical bureaucracy (Hillman and Katz 1987), and a range of other situations reviewed by Andvig (1991) and Shleifer and Vishny (1993).

Understandably, researchers often approach corruption in game-theoretic terms. Static analyses are common (e.g., Basu et al. 1992; Mookherjee and Png 1995; Marjit and Shi 1998), in part because of their relative tractability, but some of the most exciting developments have involved dynamic optimization. For example, Dawid and Feichtinger (1996a) dynamically extend Akerlof's (1980) model. They find that, unless corruption is the globally dominant strategy, the solution is like that described by a so-called Schelling diagram (Schelling 1973; cf. also Andvig 1991). There are two locally stable equilibria, one where everyone is corrupt and this corruption is accepted, and another where the whole population is honest and corruption is uniformly condemned. The only intermediate equilibrium is unstable.

Likewise, Lui (1986) considers the impact of exogenous corruption deterrence on the (stationary) level of corruption and views anti-corruption campaigns as efforts to shift from an unfavorable to a favorable equilibrium. Feichtinger and Wirl (1994) endogenize these episodes of crusades against corruption. Antoci and Sacco (1995) use replicator dynamics to describe the changing behavior of a population where each individual can decide in each period whether the individual will act honestly or be corrupt. Bicchieri and Rovelli (1995) model the exchange of bribes as a system in which there are two types of players who play a sequence of repeated prisoner's dilemma games with randomly chosen opponents. Wirl et al. (1997) consider interaction between a corrupt politician and an investigative journalist in a differential game and calculate the open-loop Nash equilibrium, which generates interesting insights into the non-cooperative dynamic interaction of crime and enforcement. [Dawid and Feichtinger (1996b) extend the analysis for a similar model to a feedback Nash equilibrium]. Bicchieri and Duffy (1997) demonstrate how corruption can become cyclical under the assumption that politicians, in order to be reelected, have to compensate voters through material incentives.

Whereas corruption has been a problem through the ages, illicit drugs have risen to prominence during the last half of the 20th century. But the OR/MS community and OR/MS tools have already played a prominent role in this new area. Some of the applications have looked specifically at the relationship between drug use and predatory crime (Powers et al. 1991), but many focus explicitly on the production, distribution, sale, and consumption of the drugs themselves. Interdiction activities have received particular attention (Caulkins et al. 1993; Washburn and Wood 1995), perhaps because of the prominent role of the military in that sphere. But production in source countries (Kennedy et al. 1993), domestic distribution networks (Caulkins 1997), managing local enforcement operations (Caulkins 1993a; Naik et al. 1996; Baveja et al. 1997), and drug testing (Lattimore et al. 1996; Meyer and Savory 1997; Kaushal et al. 1998) have also been active research areas.

Just as the Poisson model of offending has been a workhorse in the analysis of predatory offenders, Markov models of drug demand (Everingham et al. 1995) and models of drug markets provide the framework for systems analyses that compare the

effectiveness of different drug control interventions. Typical findings include, for example, that treating heavy users is cost-effective (Rydell et al. 1996), and that mandatory minimum sentences are not (Caulkins 1993b; Caulkins et al. 1997).

The finding that treatment is cost-effective illustrates the importance of choosing the right objective function. Treating heavy users performs miserably if the performance measure is proportion of people treated who are abstinent two years later, but it dominates other available interventions when the performance measure is kilograms of cocaine consumption averted per million dollars spent. True, most people quickly drop out of treatment. They make relapse rates look awful and they contribute nothing to the numerator of a measure such as consumption averted per million dollars. They also, however, do not contribute much to the denominator. The system simply cannot waste that much money on someone who only stays in the program for a few days. Furthermore, relapse measures completely ignore the benefits of reductions in use while someone is in treatment. It turns out that even if 100% of heavy users relapsed, treatment would still be a cost-effective way to reduce drug use just on the basis of the in-treatment effect.

Dynamic models that examine how policies should vary over the course of a drug epidemic are an area of particular interest. Systems dynamics models (Homer 1993) take a descriptive approach to this issue, but an optimal control framework can also yield interesting insights. For example, Tragler et al. (2000) show that detecting the onset of a drug epidemic quickly is valuable because total costs are much lower if control begins early. They also show that sharp price declines, such as those observed in the 1980s for cocaine in the U.S., do not necessarily imply a policy failure; indeed it can be optimal to have such declines. Likewise Behrens et al. (1999) show that it is rarely optimal to advocate greater spending on demand-side interventions generally. Both prevention and treatment can play an important role in drug control, but probably not at the same time. Their comparative advantages come at different stages of an epidemic.

Concluding Remarks

It is not easy to quantify the overall OR/MS contribution to public safety and crime control. OR/MS research has brought about a deeper understanding of the crime problem and how it affects and is affected by the criminal justice system. Crime, however, has such deep psychological, cultural, economic, and social roots that there are limits to what mathematical models can be expected to accomplish on their own. But, likewise, there are limits to what less quantitative perspectives can accomplish on their own. Crime and justice are truly multi-disciplinary problems that are best addressed by multi-disciplinary collaborations, with OR/MS being an integral part of that collaboration.

Criterion Vector

► Multiobjective Programming

Critical Activity

A project work item on the critical path having zero float time.

See

► Critical Path
► Critical Path Method (CPM)
► Network Planning

Critical Path

The longest continuous path of activities through a project network from beginning to end. The total time elapsed on the critical path is the shortest duration of the project. The critical path will have zero float time, if a date for completion has not been specified. Any delay of activities on the critical path will cause a corresponding delay in the completion of the project. It is possible to have more than one critical path.

See

► Critical Path Method (CPM)
► Network Planning

Critical Path Method (CPM)

A project planning technique that is used for developing strategy and schedules for an undertaking using a single-time estimate for each activity of which the project is comprised. In its basic form, i.e., concerned with determining the critical path, that is, the longest sequence of activities through the project

network from beginning to end. CPM arose from a jointly sponsored venture of E.I. du Pont de Nemours and Company and the Sperry-Rand Corporation (Kelley 1961).

Critical Systems Thinking

Werner Ulrich
University of Fribourg, Fribourg, Switzerland
The Open University, Milton Keynes, UK

Introduction

Critical systems thinking (CST) is a development of systems thinking that aims to support good practice of all forms of applied systems thinking and professional intervention. In its simplest definition, CST is applied systems thinking in the service of good practice. Three essential ideas are as follows:

1. Professional practice in all its stages and activities, from the formulation of problems to the implementation of solutions and the evaluation of outcomes, involves choices that need to be made transparent and require systematic examination and validation.
2. Systems thinking, although it does not protect against the need for such choices, at least offers a methodological basis for examining them systematically.
3. Consequently, applied systems thinking should make it standard practice to employ not only a hard (quantitative, scientific) and/or a soft (qualitative, interpretive) but always also a systematically critical (reflective, questioning) perspective and mode of analysis.

Taking these three elements together, CST not only recognizes that all applied systems thinking involves choices in need of critical reflection but also draws on systems thinking itself as a source of systematic critical reflection and deliberation.

CST and OR

Critical systems thinking has essential roots in operations research and management science (OR/MS), along with some equally important roots in philosophy, social theory, and other disciplines. It has applications in OR/MS as well as in many other professional fields that it is increasingly influencing; among them are environmental planning and management, public policy analysis, information systems design, social planning, evaluation research, technology assessment and risk regulation, and others. Unlike most of these fields, OR/MS was from the outset conceived as applied systems thinking; its systems perspective was to distinguish it from conventional notions of applied science and professional intervention. Critical systems thinking may be understood as an expansion of that original idea. CST's focus is on the fundamental theoretical and normative assumptions that inform the formulation and analysis of problems within their contexts, rather than on the more technical aspects of model building, analysis, and validation, or on procedural aspects of project management and consensus formation.

Two Main Sources of CST Within OR/MS

Critical systems thinking developed from the confluence of two largely independent strands of thought about OR practice. The first strand originated in the 1970s at the University of California at Berkeley and can be regarded as a development of, and response to, Churchman's (1968, 1971, 1979) philosophy of social systems design, which itself was a development of his earlier pioneering work on OR/MS (Churchman et al. 1957). The second strand originated in the 1980s at the University of Hull in England and can be regarded as a response to the development, in British OR, of soft systems methodology (Checkland 1981, 1985; Checkland and Scholes 1990), along with a number of soft OR methods or problem structuring methods (Rosenhead 1989) and

some other approaches to complex and dynamic problem contexts (e.g., management cybernetics and viable systems diagnosis, Beer 1972, 1985), all of which not only led to a growing variety of methods and underlying research paradigms but also to a perception of paradigmatic insecurity or crisis in parts of the OR profession.

Two Key Issues of Critical Systems Thinking

CST responded to these developments in American and British OR/MS by focusing its methodological efforts on two key issues:

- The first issue emerged from recognizing that the way professionals understand and define problem contexts has value implications, in the practical sense that it may do more or less justice to the different views and needs of people. Professional practice cannot avoid, in every specific context of intervention, choices as to what views (observations, data) and what needs (concerns, interests) of people are to be considered relevant and what other views and needs should not or cannot be considered equally relevant. The question is: "What should constitute the basis of knowledge and values for rational practice?" When it comes to this normative core of practice, there is a need to support professionals and everyone else concerned in handling their assumptions in a transparent and self-critical way, as well as to deal adequately with the consequences these assumptions may have for the different parties concerned.
- The second issue emerged from recognizing that different problem situations put different demands on professional competence and accordingly also on the methods professionals use. Professional practice cannot avoid, in defining and employing its methods of analysis and intervention, assumptions about the nature of problem situations, particularly with respect to the kind of complexity that matters; for real-world complexity takes different forms and there is consequently no single best way to understand and handle it. The question is: "What are the assumptions, strengths, and weaknesses of different approaches and methods regarding the nature of problem contexts, that is, different kinds of social reality? When it comes to the variety of methodological options available today in applied systems thinking, there is a need to support professionals in handling these options in a theoretically informed and justifiable way.

Critical systems thinking, then, is the use of systems ideas for probing into these two different (though not entirely independent) sources of contextual selectivity, that is, assumptions that shape the understanding and handling of problem contexts—the selection of relevant facts and values, and the selection of adequate methodologies and methods. Both shape the way problems will be understood within their contexts. However, they place rather different demands on good practice. What assumptions different systems approaches make regarding the nature and complexity of problem contexts depends on their theoretical underpinnings and thus can be identified theoretically once and for all; good practice in this respect means informed methodology choice. By contrast, relevant facts and values need to be identified anew in each specific problem situation and therefore are mainly a responsibility of practice itself; good practice in this respect means reflective practice.

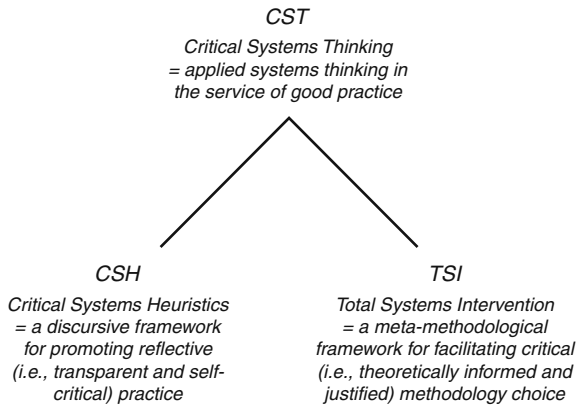
Two different strands of critical systems thinking have accordingly developed: critical systems heuristics (CSH) and total systems intervention (TSI). Their shared core idea is that systems thinking can be a useful source of critical reflection about contextual selectivity. A precise yet comprehensive definition of CST may therefore be formulated as follows.

Definition

Critical systems thinking (CST) is an application of systems thinking that aims to support good practice with regard to (a) the normative core of the knowledge and value basis that informs professional findings and conclusions and (b) the theoretical assumptions that inform the variety of methodologies and methods employed. The common denominator of (a) and (b) is that they both condition the perception of relevant problem contexts.

Terminology: CST, CSH, and TSI

The term "critical systems thinking" was coined in July 1989, when the originators of the two strands met at the 33rd Annual Conference of the International Society for the Systems Sciences (ISSS) in Edinburgh, Scotland, and decided to unite their efforts under the umbrella of critical systems



Critical Systems Thinking, Fig. 1 Critical systems thinking (CST) and its two strands—basic terminology (Source: Adapted from Ulrich 2003, 327)

thinking. Due to differing methodological conceptions and philosophical backgrounds, the cooperation between the two strands of CST remained a brief episode in the late 1980s and early 1990s; but the term CST has survived as a name for their shared interest in handling contextual assumptions critically.

Some confusion was subsequently caused by the circumstance that both strands have continued to refer to their efforts as critical systems thinking. For the sake of terminological clarity, it is advisable to use the term as a higher-level concept under which CSH and TSI may meaningfully be subsumed, rather than identifying it with either strand (Fig. 1).

Due to their separate development and also to different theoretical foundations, the two strands, despite their shared core idea and complementary ends, have brought forth partly incompatible frameworks for CST. They are therefore introduced separately. However, to facilitate comparison and synthesis, the account follows the same structure and uses the same criteria.

Critical Systems Heuristics (CSH): Facing the Normative Core of Professional Practice

CSH was fully worked out in the late 1970s at the University of California at Berkeley but became widely known only in the early 1980s, when the main theoretical work (Ulrich 1983) was published with some delay after the author's return to Switzerland. With a view to submitting his work to the test of practice, Ulrich assumed a position as chief policy analyst and evaluation researcher in the public sector and also returned to teaching at his home university, the University of Fribourg (Philosophical Faculty). This double experience in public policy making and university teaching has helped Ulrich to develop CSH continuously since. CSH has meanwhile found resonance and applications in many applied disciplines and is gradually evolving into a more comprehensive framework for reflective practice in the civil society (Ulrich 2000), critical pragmatism (Ulrich 2006 and 2007), and philosophy for professionals (Ulrich 2007).

Core Idea

Professional practice involves validity claims (e.g., to truth, rightness, sincerity, objectivity, rationality, and relevance) that have practical consequences but which it cannot fully justify. Applied systems thinking makes no exception, for its effort to appreciate the systemic nature of problems, and thus to gain a comprehensive or whole-systems view of problem situations, does not supersede the need for making value judgments as to what exactly is to be considered the problem to be dealt with (i.e., what merits improvement), what constitutes the relevant problem context (i.e., what is the sum total of the relevant facts and concerns), and wherein would consist a good solution (i.e., how to define improvement). No kind of systems methodology or other methodology can fully justify the answers to such inevitable questions as "whose problem is to be solved in the first place?" and "for whom should improvement be achieved and for whom should it not?" What is possible, however, is a conscious and careful handling of this normative core of all professional intervention.

Critical systems thinking as understood in CSH therefore begins with the idea that holistic or whole-systems thinking—the quest for comprehensiveness—is a meaningful effort but not a meaningful claim. Doing full and equal justice to the views and values of all the people concerned is an ideal; but applied systems thinking should not be expected to achieve ideals. To put it differently, holism is not a philosophically and methodologically credible source of justification, it is a problem. Hence, rather than trying to be holistic, CSH tries to support practice—professionals as well as ordinary citizens—in

appreciating the inevitable selectivity of the claims involved (e.g., to putting a problem well and to securing improvement) with regard to the facts (observations) and values (concerns) it takes to be relevant and on which its rationality and consequences depend.

In practical contexts of action, selectivity usually translates into partiality in the sense that different parties will be affected differently. CSH consequently also aims to help professionals and citizens in analyzing these consequences and how they may change if assumptions about relevant observations and concerns are modified. Good practice cannot avoid selectivity and partiality, but it will make it transparent to all those concerned how the selectivity of assumptions and the partiality of consequences depend on one another. It will give all the parties an opportunity to articulate their critique, and will then try to modify assumptions and consequences accordingly. Critical systems thinking, thus understood, is reflective practice—a methodologically disciplined effort to support such processes of critique systematically.

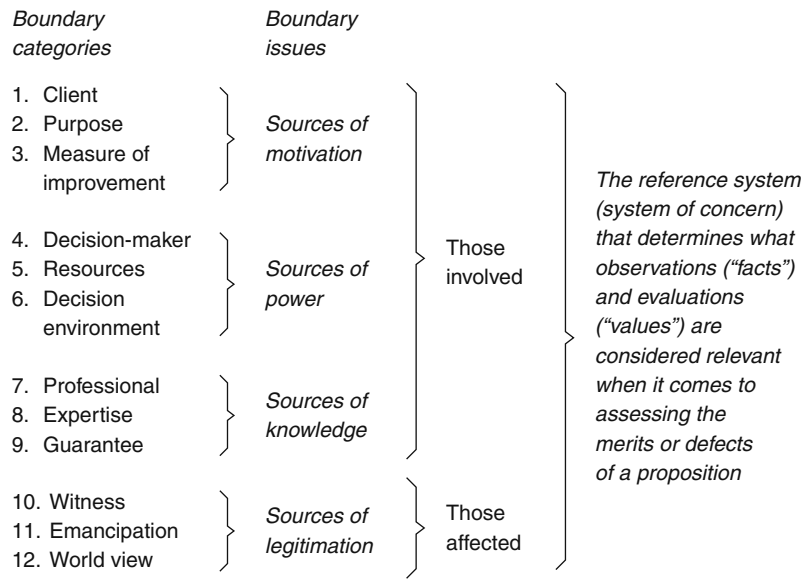
Methodological Approach

CSH is both a new philosophical foundation and a practical implementation of a discursive framework for value clarification and critique. Like the previously used concept of the normative core of rational practice, the term "value clarification" again refers to the selectivity of both considerations of facts (the empirical or knowledge basis of rational action) and of values (the normative or value basis of rational action) in contexts of practical action. The choice of the knowledge basis of professional interventions—of relevant data, judgments of fact, personal views, and other empirical conjectures (e.g., anticipated consequences of action)—has no less normative implications than does the choice of its value basis, that is, of relevant concerns, notions of improvement, and ethical standards. Both sources of selectivity and partiality demand a critical handling.

But applied systems thinking not only implies empirical and normative selectivity, it also holds a key to handling such selectivity critically. Systems thinking compels professionals, as well as everyone else concerned, to pay attention to the systems boundaries that delimit any specific system of interest. Systems thinking can thus be understood as a tool for reflecting about the boundaries of concern that (consciously or not) inform all analysis of problems and related proposals and arguments, regardless of whether systems terms are used in the first place or others. Systems thinking then becomes a source of critique—of questioning boundary assumptions and the ways they condition validity claims—rather than, as it is more usually understood, a source of justification, that is, a way of buttressing validity claims by more comprehensive considerations of fact and value.

In the terms of CSH, critical systems thinking can support professionals and all the parties concerned in identifying and questioning boundary judgments that delimit the reference systems for defining problems and relevant contexts, solution designs, evaluations, proposals for action, and so on. Boundary judgments determine for a number of basic boundary issues and related boundary categories what is to be considered and what is to be left out when it comes to defining relevant observations (judgments of fact) and concerns (judgments of value). A reference system is the set of boundary judgments that together define the context of application which a specific claim or proposal refers to and for which it is valid.

Boundary judgments are the perfect device for questioning the relevance and quality of reference systems; for unlike what one might assume at first glance, they define not just the scope of the context considered (i.e., how narrow or comprehensive it is delimitated) but equally its content, that is, what observations about that context are collected and taken to be relevant; how they are formulated, interpreted, and used; what importance is attached to them; and how well related conjectures are argued. This is so because any aspects of a problem situation that are not properly considered, say, because those involved argue incoherently or anticipate consequences incorrectly, or fail to do justice to the concerns of others, have in fact been excluded from the relevant knowledge and value basis. Even if one recognizes some aspects as relevant and agrees with others they should be considered but then fails to take them properly into account, due to lacking knowledge, to an error of judgment, or some communicative misunderstanding, or because those in control of the situation decide to suppress their discussion, the aspects are in fact (deliberately or not) excluded from the considered reference system. Thus the



Critical Systems Thinking, Fig. 2 Boundary categories of critical systems heuristics (Source: Ulrich 1983, 258)

argumentative quality of a validity claim or related discussion very well reflects itself in boundary judgments.

The main device to promote such argumentative quality is critical systems discourse, a dialogical form of boundary critique. Boundary critique is basically a systematic process of identifying the boundary judgments that are built into any specific validity claims, in an effort to unfold their normative core (selectivity) and what it may mean for the parties concerned (partiality). A second basic aim is to show that there are always options for defining boundary judgments, and to make it visible how different the claims in question may look in the light of such options. In cooperative settings where the parties are prepared to try and see whether they can agree on their boundary judgments, these can be modified accordingly. In controversial settings this may not be possible; boundary critique then gains a new meaning and consists in employing boundary judgments for critical purposes against those who are not prepared to disclose and question them or who even try to impose them on the basis of authority and power rather than argumentation. Critical systems discourse thus becomes a discursive process of challenging validity claims by demonstrating that and how they depend on boundary judgments that have not been declared or are imposed by nonargumentative means.

To be sure, selectivity, not comprehensiveness, is the fate of everyone who tries to solve problems and to do something about the state of the world. The point of boundary critique consists, in terms of CSH, in a critical turn of applied systems thinking and its notion of good professional practice. It recognizes that there is no objective but only a critical solution to the fundamental problem of practical reason, of how claims to rational practice can be justified in the face of their inevitable selectivity and partiality. The problem has remained unresolved in practical philosophy, the philosophical discipline concerned with the normative dimension of rational action, in that no theoretical solutions have been found that would at the same time be practicable. (A more complete account of the concept of a critical solution is given in Ulrich (1983, 2001, 2003).)

Methodological Core Principle

CSH's answer to the unresolved problem of practical reason is the principle of boundary critique. It says that both the meaning and the validity of claims depend on the reference system which these claims refer to and, hence, that one cannot understand and qualify (appreciate and criticize) their adequacy without examining the boundary judgments that define that reference system. The basic idea and aim of CSH, then, is to support systematic processes of boundary critique as a way to secure at least a critical solution of the problem of practical reason. To this end, there are 12 CSH boundary categories (Fig. 2).

These boundary categories stand for four crucial sources of selectivity built into all practice. Each boundary category translates into two boundary questions: one asking what is the case ("is" mapping, i.e., descriptive analysis) and the other what should be the case ("ought" mapping, i.e., normative analysis). This yields an extensive checklist of boundary questions that explicitly define the precise intent of each boundary category (Ulrich 1987, 1996, 2000; Ulrich and Reynolds 2010). They can be used, first, to identify boundary judgments systematically; second, to examine how alternative boundary judgments may change the way one sees problem definitions, findings, and conclusions, and thus what is considered to be adequate and rational; and third, to challenge any claims to knowledge, rationality, or improvement that rely on hidden boundary judgments or take them for granted.

The last-mentioned application leads to an argumentative employment of boundary judgments, known as polemical or emancipatory boundary critique, that creates an improved symmetry of critical competence among all the parties concerned, professionals and citizens alike, regardless of their theoretical knowledge or special expertise with respect to the problem at issue. As a practicable model of cogent critical argumentation (Ulrich 1983, 1993, 2000), it embodies a critical pragmatization of Habermas' (1973, 1979) ideal model of rational practical discourse (a model that underpins his discourse ethics and confines it to being a moral theory rather than a practicable model of moral justification). It constitutes a chief methodological backing of the critical turn of the concept of rational practice proposed above.

In sum, CSH can be defined as a methodological framework for boundary critique, that is, for identifying and debating boundary judgments, with the aim of securing at least a critical solution to the unsolved problem of practical reason—the question of how claims to rational practice can be justified despite the unavoidable selectivity and partiality of all practice. Despite its emancipatory implications (the aspect for which it is best known), CSH should not be misunderstood and used as an emancipatory systems approach only; its principle of systematic boundary critique is vital for sound professional practice in general, whatever importance may be attached to emancipatory issues. For the same reason, CSH does not aim to be a self-contained systems methodology, but is better understood as an approach that should inform all critical professional practice, whatever specific methodology is used.

Practical Implementation (Main Procedure)

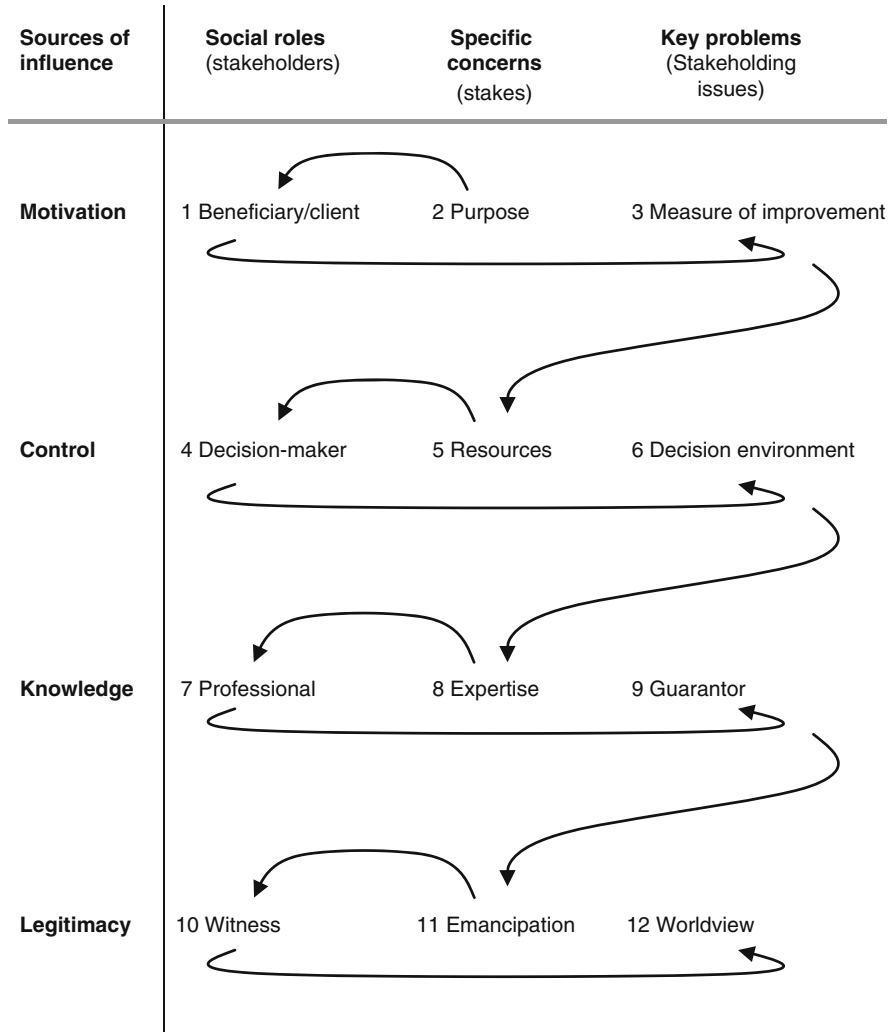
Boundary critique is best implemented as an iterative process of reflecting on, and discussing, the implications of alternative boundary judgments. When some boundary judgment changes, the reference system of which it is constitutive will change too; consequently, all other boundary judgments may need being reconsidered and adapted. However, iterative processes are not particularly easy to learn and to handle; experience with boundary critique suggests that it is useful for beginners to have available, and follow, a standard sequence for unfolding the boundary categories and questions of CSH (Fig. 3).

Total Systems Intervention (TSI) or Creative Holism (CH): Ensuring Informed Methodology Choice

TSI stems from work done at the University of Hull, England, in the mid and late 1980s, about the evolution of OR and systems thinking in terms of changing underlying theoretical assumptions. This work resulted in the early 1990s in the proposal of a meta-methodology for choosing among methodologies according to situational requirements (Flood and Jackson 1991; Jackson 1991). By that time CSH and TSI had joined their efforts under the new name of "critical systems thinking" (CST), after previously using different names such as critical systems approach (CSH) and critical management science (TSI). But due to differing notions of what critical practice was to mean, the two strands of CST ultimately found it difficult to integrate their approaches and consequently returned to developing their frameworks separately. Both have nevertheless continued to use the name critical systems thinking. Meanwhile, Jackson (2003; 2006b) refers to his work on critical systems thinking and practice as creative holism (CH).

Core Idea

Applied systems thinking depends for its choice of systems methodologies and methods on basic assumptions regarding the nature of the problem contexts (typically: organizational contexts) with



Critical Systems Thinking, Fig. 3 CSH's process of unfolding: a standard sequence of boundary critique (Source: Ulrich and Reynolds 2010, 259; Adapted from Reynolds 2007, 106)

which it is dealing. Some of these assumptions can usefully be captured in terms of a number of sociological paradigms for describing the nature of social reality as they have been analyzed, for example, by Burrell and Morgan (1979), as well as by organizational images or systems metaphors as they have been described most systematically by Morgan (1986). Different systems methodologies, because they usually are developed with different problem contexts in mind, can similarly be characterized in terms of underlying metaphors and paradigms. Hence, since the characteristics of both problem contexts and systems methodologies can be captured in terms of adequate paradigms and metaphors, it becomes possible to match contexts and methodologies in a systematic way and thus to support professionals in choosing among the increasing number of available systems methodologies and conforming methods that are best suited to deal with a problem situation at hand.

CST as understood in TSI/CH therefore begins with the idea that systems thinking—the attempt to understand organizational or societal problem contexts in systems terms—is meaningful only to the extent people are aware of the sociological paradigms and organizational metaphors that inform it. Since different systems methodologies rely on different paradigms and metaphors—that is, on different theoretical assumptions about the nature of problem contexts—applied systems thinking depends for its justification and rationality on paradigmatic fit between systems methodologies and problem contexts.

In applied OR/MS, as in other forms of applied research, the requirement of paradigmatic fit translates into a need for informing the selection and use of methodologies and methods by previous paradigm analysis as well as, where relevant, metaphor analysis, as a condition for doing justice to the nature of the problem context at issue. TSI/CH consequently puts its critical focus on the theoretical underpinnings of alternative research paradigms rather than on the normative core of professional practice, as does CSH. CST, thus understood, is about methodology choice—a theoretically informed way to support processes of matching methodologies and methods with problem contexts.

Methodological Approach

The basic strategy of TSI/CH can be described as a contingency approach to methodology choice, based on paradigm analysis and, to a lesser degree, also on metaphor analysis of the three major traditions of systems thinking thus far—hard, soft, and critical systems thinking. The idea is that there is no such thing as a best systems methodology and underpinning tradition of systems thinking; rather, situational aspects of the problem context at hand determine what tradition of systems thinking is best suited as a source of methodological guidance and specific methods or tools of intervention. In OR/MS, such an approach promises to resolve the OR in crisis debate of the 1970s and 1980s, for it allows hard and soft OR approaches to be seen as appropriate for dealing with different problem contexts rather than competing for the same ones.

Contingency frameworks are also called contingency theories, as they involve theoretical generalizations about the crucial aspects of the application domain to which the framework is to be applied. This theoretical device is often used in the social sciences (e.g., in management and organization theories) when a variety of approaches are required to handle a given class of problems, as the proper approach is dependent (contingent) on the situation or, more precisely, on a range of changing situations.

Applied to contexts of professional intervention, using a contingency approach implies that some independent (contextual) variables can be identified empirically which regularly, for reasons that can be explained theoretically, may be expected to condition the outcome of interventions. A contingency approach can then (and only then) make sure that the way one deals with a situation matches situational requirements and, on that basis, can also justify the credibility of the results. To the extent this condition is fulfilled, one can properly speak of a contingency theory. It follows that the crucial question for any contingency approach is whether it can identify and theoretically justify a small number of empirical dimensions (ideally only two) in terms of which the range of situations in question can be usefully classified, so that each type of empirical situation can then be identified in a relevant and reliable way.

Methodological Core Principle

TSI/CH's answer to the problem of ensuring paradigmatic fit between intervention approaches and problem contexts is a classification of problem contexts, and of systems methodologies assigned to them, called the system of systems methodologies (SOSM). It says that systems methodologies and conforming methods are well chosen if their underlying systems metaphor (machine, organism, etc.) and/or paradigm (functionalist, interpretive, etc.) match with the nature of the problem context, or more exactly, with assumptions about the kind of complexity that needs to be handled in the problem context. The basic idea and aim of TSI/CH, then, is to support systematic processes of informed methodology choice, as a way to secure paradigmatic fit between intervention methods and intervention contexts. To this end, TSI/CH proposes the SOSM (see Fig. 4).

There was an earlier, four-celled version of the SOSM (Jackson and Keys 1984) that is now often cited as the origin of the TSI strand of CST. However, it only distinguished hard and soft methodologies, and its discussion in that early paper did not yet introduce the notion of critical systems thinking.

CSH became known to Jackson and Keys shortly after publishing their 1984 paper. First hints at a planned extension of their work appeared in a few articles in the late 1980s (Jackson 1987, 1990); the extended SOSM was presented later in Flood and Jackson (1991) and Jackson (1991).

Due to the underlying logic of the SOSM, the extended scheme could not manage to include CSH except by constricting its notion of critical systems thinking considerably. This logic assumes that any

Systems dimension of contexts (increasing complexity)	Participants dimension of contexts (increasing diversity of values)		
	Unitary (paradigm: functional) **HARD SYSTEMS THINKING**	*Pluralist (paradigm: interpretive)* **SOFT SYSTEMS THINKING**	*Coercive (paradigm: emancipatory)* **EMANCIPATORY SYSTEMS THINKING**
Simple	*Simple-unitary problem contexts (systems metaphor: machine)* • Operations research (OR) • Systems engineering (SE) • Systems analysis (SA)	*Simple-pluralist problem contexts (systems metaphors: culture, coalition)* • Systems approach (Churchman) • Strategic assumption surfacing and testing (SAST)	*Simple-coercive problem contexts (systems metaphor: prison)* • Critical systems heuristics (CSH)
Complex	*Complex-unitary problem contexts (systems metaphors: organism, brain)* • Organizational cybernetics/ viable systems diagnosis (VSD) • Socio-technical systems thinking	*Complex-pluralist problem contexts (systems metaphors: culture, coalition)* • Interactive planning (Ackoff) • Soft systems methodology (SSM)	*Complex-coercive problem contexts (systems metaphor: prison)* • ?

Critical Systems Thinking, Fig. 4 The extended system of systems methodologies (SOSM) (Source: Adapted from Flood and Jackson 1991, 42; Jackson 1991, 29 and 31; 2000, 359)

methodology can be meaningfully assigned to a single type of problem context and to a conforming (dominant) theoretical paradigm. There is no room in such a scheme for an approach that focuses on the genuinely normative core of practice as such, whatever the theoretical paradigm adopted may be and the choice of methodology and conforming methods it may inspire. This makes it understandable why the extended SOSM rather arbitrarily assigned CSH a merely emancipatory purpose, as opposed to the critical purpose of the SOSM. To render this choice more plausible, CSH was associated with a prison metaphor, which then seemed to render CSH adequate for coercive problem contexts only and thus provided a rationale for assigning it to a specific emancipatory paradigm (for critical discussion and alternatives, see Ulrich 2003). In this way, CSH became in the SOSM scheme an apparently self-contained methodology that, quite against its original intentions, was to be chosen (or not) as an alternative to soft and hard systems methodologies. Its concern for the practical-normative side of all practice thus moved out of sight.

In British OR/MS, CSH was henceforth understood mainly through the lens of the SOSM, and critical systems thinking became widely identified with TSI. Consequently, CST was now almost the same as the SOSM—an updated contingency framework for methodology choice, as well as for continuing discussions about the evolution of OR/MS (e.g., Jackson 2006a). Both uses attracted much interest and the mentioned difficulties of the extended SOSM did not hamper its success in helping to raise awareness in the profession that there are options for conceiving of good professional practice. The discussion that the SOSM was able to generate in turn has helped to make CSH more known, so that its core principle of boundary critique is increasingly being recognized as an important, independent source of critical thought on practice. These diverse successes of the SOSM certainly have contributed to the comparatively high level of methodological awareness and discussion by which the OR/MS profession distinguishes itself from other fields, which has allowed it to pioneer soft and critical systems ideas that are now radiating into many other fields.

Practical Implementation (Main Procedure)

To support methodology choice in practice, the SOSM still needed to be embedded in a methodology, properly speaking, that is, a framework that would guide practitioners in asking relevant questions and proceeding systematically. This is what total systems intervention (TSI), a name adopted in 1991, is all about. It stands for the practical procedure of methodology choice and implementation that Flood and Jackson (1991) proposed on the basis of the SOSM. The aim is to provide a meta-methodology for methodology choice and implementation. The procedure may be employed in a linear or iterative way. Originally it consisted of three phases labeled creativity, choice, and implementation, to which Jackson (2003, 2006b) later, in the extended

Critical Systems Thinking, Table 1 The meta-methodology of TSI/CH: standard phases of methodology choice and use

Phase	Activity/Aim
(1) CREATIVITY	
Task	To identify major aims and issues of the problem context
Tools	Use of different metaphors and paradigms to gain different perspectives
Outcome	Appreciation of dominant and dependent metaphors/paradigms and related issues
(2) CHOICE	
Task	To choose appropriate systems methodologies and methods
Tools	Use of SOSM to reveal strengths and weaknesses of methodologies and methods
Outcome	Choice of dominant and dependent systems methodologies and methods
(3) IMPLEMENTATION	
Task	To arrive at and implement specific positive change proposals
Tools	Systems methodologies and methods used properly according to the logic of TSI/CH
Outcome	Relevant change according to the concerns of the different paradigms
(4) REFLECTION	
Task	To evaluate the intervention and ensure methodological learning
Tools	Understanding of the concerns of different paradigms regarding good practice
Outcome	Methodological progress

TSI total systems intervention = phases 1–3, *CH* creative holism = phases 1–4, *SOSM* system of systems methodologies
(Source: Adapted from Flood and Jackson 1991, 54; Jackson 1991, 276; 2000, 372; and 2006b, 654)

version he now prefers to call creative holism, added a fourth phase, Reflection (Table 1).

The creativity phase is intended to encourage consideration of what alternative systems paradigms and root metaphors might mean for thinking about a problem context at hand, so that a dominant metaphor could be identified as most adequate, that is, in effect, preference for a hard (functionalist), soft (interpretive), or critical (emancipatory) orientation. In the choice and implementation phases, a conforming particular systems methodology should then be chosen based on the SOSM and used to implement specific change proposals.

A new element in CH as compared to its predecessor TSI is the reflection phase, which brings in an element of reflective practice as CSH understands it, by looking at the outcomes of methodology choice and implementation rather than at its theoretical justification only. Although the underlying notion of evaluation is still not genuinely practical in the sense of CSH and practical philosophy, this development does promise to open up new chances for reflective practice.

Another new element, following a considerable amount of discussion in the literature about methodological complementarism or pluralism (Jackson 1997, 1999), mixing methods (Midgley 1997), and multi-methodology (Mingers and Gill 1997), is that creative holism, unlike TSI, no longer insists on choosing a single dominant paradigm. Instead, a combination of methodologies, or parts of methodologies and conforming methods, is now encouraged, which makes the framework more flexible and brings it closer to actual practice. As Jackson describes it, CH now is a "meta-methodological" framework that aims to help practitioners to "harness the various systems methodologies, methods and models" by being "multi-paradigm, multi-methodology and multi-method in orientation" (Jackson 2006b, 248 and 253).

A Summary Comparison of CSH and TSI

To provide an overview of the discussed aspects of critical systems thinking, Table 2 summarizes the accounts of CSH and TSI in a way that should facilitate comparison.

Concluding Remarks

The claim of professional practice to relevance, rigor, and rationality depends on many requirements. Among these, two crucial ones are putting the problem well

Critical Systems Thinking, Table 2 CSH and TSI compared

Aspect	CSH	TSI/CH
Core idea	Professional practice involves *validity claims* that cannot be justified theoretically but at least can be handled openly and critically in the process of intervention itself	Professional practice involves *methodological choices* that can be justified theoretically by analyzing underpinning research paradigms and systems metaphors
Critical focus	*Reflective practice:* surfacing the reference systems underpinning all judgments of fact and value and analyzing how they condition practical claims (e.g., problem definitions, relevant contexts, standards of improvement, and proposals for action)	*Paradigm analysis:* surfacing the theoretical underpinnings of alternative research paradigms (e.g., functionalist, interpretive, emancipatory, or post-modern) and analyzing how they condition different perceptions of problem contexts and suitable methodological choices
Approach	*Critical systems discourse:* a discursive framework for value clarification and critique	*Contingency theory:* a contingency framework for methodology choice and use
Methodological core principle	*Boundary critique:* unfolding the selectivity of reference systems	*Informed methodology choice:* matching systems methodologies with problem contexts
Main critical device	*Checklist of boundary questions:* a definition of boundary categories for "is" and "ought" mapping (i.e., descriptive and normative analysis) of reference systems	*System of systems methodologies* (SOSM): a classification of problem contexts and conforming systems methodologies
Implementation	A discursive *process of unfolding selectivity:* a standard sequence of boundary critique	A holistic *meta-methodology of paradigm analysis:* standard phases of methodology choice and reflection

CSH critical systems heuristics, *TSI/CH* total systems intervention/creative holism

and tackling it by means of adequate methods. In different ways, both of these embody crucial requirements of professional competence. Both of them stand for efforts to make sure that relevant issues are properly identified and the implications of related assumptions are made transparent and evaluated.

- *Putting problems well* is an issue that involves empirical (observational) as well as normative (ethical) problem structuring and reflection. The selection of relevant facts and values depends on a proper understanding of the problem, which is hardly achievable without questioning the scope and diversity of the social context that matters. It also depends on the extent to which justice is done in practice to the diversity of views and concerns of the different parties concerned. A problem may be ill defined so long as this normative core of any quest for rational practice is not well understood.
- *Choosing and employing methods properly* involves analysis and reflection about the demands of problem situations on the one hand and about the availability of methods that respond to these demands on the other. The selection of adequate methodologies and methods depends on a proper understanding of the theoretical and paradigmatic assumptions involved, which is hardly achievable without questioning the nature of the complexity that matters. It also depends on the extent to which the matching of such assumptions with specific situations is successful in practice. A methodology and conforming methods may be ill chosen so long as this theoretical core of the quest for rational practice is not well understood.

Neither effort replaces or precludes the other. Critical systems thinking, properly understood, aims to promote good practice with regard to both. To this end, the two strands of CST bring to bear within the field of OR/MS, and in the applied sciences in general, new philosophical and theoretical foundations, along with new practical tools for analyzing contextual complexity and diversity. CSH draws on practical philosophy and consequently conceives of rational practice in terms of discursive tools of value clarification and critique, in particular boundary critique and discourse. TSI/CH draws on organizational sociology and conceives of rational practice in terms of theoretically informed tools of methodology choice, in particular paradigm analysis and metaphor analysis.

Different as the resulting frameworks of CSH and TSI are, their shared concern remains the idea that

good professional practice depends crucially on making sure that problems are well put and methods of intervention are well chosen; and that to meet both requirements, it is essential to properly situate problems in their contexts and make sure one understands those contexts well. Formulated in everyday terms, the essential message of CST to professionals might thus be summarized as follows:

Critical Systems Thinking: Its Operational Imperative

As a professional intervening in a specific context, pay attention to your contextual assumptions and try to identify and examine them systematically, so as to understand them well. Then make sure everyone concerned understands them well too. Work toward mutual understanding about how problem definitions and solutions depend on and change with the facts and values considered relevant. Make sure divergent views and values are properly addressed. Adapt your choice of methodologies and methods to the amount of diversity that you find in the problem context, and to the resulting nature of the complexity that matters. Finally, whatever problem definitions and methods your professional practice ultimately relies on, reflect on the validity claims your professional findings and conclusions imply and how, if taken as a basis for action, they may affect the different parties concerned. Make boundary critique a standard practice to this end, and always remember that no professional intervention can do justice to all views and values, that is, can justify all its implications. But at least it can deal with this inevitable lack of complete justification in a transparent and self-reflecting way. This is what critical professional practice is all about.

Introduction

The cross-entropy (CE) method is a versatile Monte Carlo technique introduced by Rubinstein (1999, 2001), extending earlier work on variance minimization (Rubinstein 1997). A tutorial on the CE method is given in de Boer et al. (2005). A comprehensive treatment can be found in Rubinstein and Kroese (2004); see also Rubinstein and Kroese (2007, Chap. 8).

The CE method can be applied to two types of problems:

1. *Estimation*: Estimate $\ell = \mathbb{E}[H(\mathbf{X})]$, where $\mathbf{X}$ is a random object taking values in some set $\mathcal{X}$ and H is a function on $\mathcal{X}$. An important special case is the estimation of a probability $\ell = \mathbb{P}(S(X) \geq \gamma)$, where S is another function on $\mathcal{X}$.
2. *Optimization*: Optimize (i.e., maximize or minimize) $S(\mathbf{x})$ over all $\mathbf{x} \in \mathcal{X}$, where S is some objective function on $\mathcal{X}$.

In the estimation setting, the CE method can be viewed as an adaptive importance sampling procedure that uses the cross-entropy or Kullback–Leibler divergence as a measure of closeness between two sampling distributions. In the optimization setting, the optimization problem is first translated into a rare-event estimation problem, and then the CE method for estimation is used as an adaptive algorithm to locate the optimum.

Estimation

Consider the estimation of

$$\ell = \mathbb{E}_f[H(\mathrm{X})] = \int H(\mathrm{x}) f(\mathrm{x})\, \mathrm{dx}, \qquad (1)$$

where H is a real-valued function and f is the probability density function (pdf) of the random vector $\mathbf{X}$. It is assumed, for simplicity, that $\mathbf{X}$ is a continuous random variable. For the discrete case, replace the integral in (1) by a sum. Let g be another pdf—which must be nonzero for every $\mathbf{x}$ for which $H(\mathbf{x})\, f(\mathbf{x}) \neq 0$. Using the pdf g, ℓ can be represented as

$$\ell = \int H(\mathbf{x}) \frac{f(\mathbf{x})}{g(\mathbf{x})} g(\mathbf{x}) \mathrm{d}\mathbf{x} = \mathbb{E}_g \left[H(\mathbf{X}) \frac{f(\mathbf{X})}{g(\mathbf{X})} \right], \quad (2)$$

where the subscript g indicates that the expectation is taken with respect to g rather than f. Consequently, if $\mathbf{X}_1, \ldots, \mathbf{X}_N$ are independent random vectors with pdf g, written as $\mathbf{X}_1, \ldots, \mathbf{X}_N \sim_{\text{iid}} g$, then

$$\hat{\ell} = \frac{1}{N} \sum_{k=1}^{N} H(\mathbf{X}_k) \frac{f(\mathbf{X}_k)}{g(\mathbf{X}_k)} \quad (3)$$

is an unbiased estimator of ℓ—a so-called importance sampling estimator. The optimal importance sampling pdf, that is, the pdf g^* that minimizes the variance of $\hat{\ell}$, is proportional to $|H|\, f$ (see, e.g., Rubinstein and Kroese (2007, 132)), but is in general difficult to evaluate. The idea of the CE method is to choose the importance sampling pdf g in a specified class of pdfs such that the Kullback–Leibler divergence between the optimal importance sampling pdf g^* and g is minimal. The Kullback–Leibler divergence between two pdfs g and h is given by

$$\begin{aligned} \mathcal{D}(g,h) &= \mathbb{E}_g \left[\ln \frac{g(\mathbf{X})}{h(\mathbf{X})} \right] = \int g(\mathbf{x}) \ln \frac{g(\mathbf{x})}{h(\mathbf{x})} \, \mathrm{d}\mathbf{x} \\ &= \int g(\mathbf{x}) \ln g(\mathbf{x}) \, \mathrm{d}\mathbf{x} - \int g(\mathbf{x}) \ln h(\mathbf{x}) \, \mathrm{d}\mathbf{x}. \end{aligned} \quad (4)$$

In most cases of interest the function H is nonnegative, and the nominal pdf f is parameterized by a finite-dimensional vector $\mathbf{u}$; that is, $f(\mathbf{x}) = f(\mathbf{x}; \mathbf{u})$. It is then customary to choose the importance sampling pdf g in the same family of pdfs; thus, $g(\mathbf{x}) = f(\mathbf{x}; \mathbf{v})$ for some reference parameter $\mathbf{v}$. The CE minimization procedure then reduces to finding an optimal reference parameter vector, say $\mathbf{v}^*$, by cross-entropy minimization:

$$\begin{aligned} \mathbf{v}^* &= \operatorname*{argmin}_{\mathbf{v}} \mathcal{D}(g^*, f(\cdot; \mathbf{v})) \\ &= \operatorname*{argmax}_{\mathbf{v}} \int H(\mathbf{x}) f(\mathbf{x}; \mathbf{u}) \ln f(\mathbf{x}; \mathbf{v}) \, \mathrm{d}\mathbf{x} \\ &= \operatorname*{argmax}_{\mathbf{v}} E_{\mathbf{u}} H(\mathbf{X}) \ln f(\mathbf{X}; \mathbf{v}) \\ &= \operatorname*{argmax}_{\mathbf{v}} E_{\mathbf{w}} H(\mathbf{X}) \ln f(\mathbf{X}; \mathbf{v}) \frac{f(\mathbf{X}; \mathbf{u})}{f(\mathbf{X}; \mathbf{w})}, \end{aligned} \quad (5)$$

where $\mathbf{w}$ is any reference parameter. This $\mathbf{v}^*$ can be estimated via the stochastic counterpart of (5):

$$\hat{\mathrm{v}} = \operatorname*{argmax}_{\mathrm{v}} \frac{1}{N} \sum_{k=1}^{N} H(\mathrm{X}_k) \frac{f(\mathrm{X}_k; \mathrm{u})}{f(\mathrm{X}_k; \mathrm{w})} \ln f(\mathrm{X}_k; \mathrm{v}), \quad (6)$$

where $\mathbf{X}_1, \ldots, \mathbf{X}_N \sim_{\text{iid}} f(\cdot; \mathbf{w})$. The optimal parameter $\hat{\mathrm{v}}$ in (6) can often be obtained in explicit form, in particular when the class of sampling distributions forms an exponential family; see, for example, Rubinstein and Kroese (2007, 319–320). Indeed, analytical updating formulas can be found whenever explicit expressions for the maximal likelihood estimators of the parameters can be found, cf. de Boer et al. (2005, 36).

Example: Exponential Random Variables. Consider the case where $\mathbf{X}_1 = (X_1, \ldots, X_n)$ is a vector of independent exponential random variables with expectations $u_1, \ldots, u_n$. Let $\mathbf{u} = (u_1, \ldots, u_n)$ and let $\mathbf{v} = (v_1, \ldots, v_n)$ be the reference parameter of the importance sampling pdf $f(\mathbf{x}; \mathbf{v})$, given by

$$f(\mathbf{x}, \mathbf{v}) = \prod_{i=1}^{n} \frac{\mathrm{e}^{-x_i / v_i}}{v_i}.$$

Hence, under this importance sampling pdf, $X_1, \ldots, X_n$ are again independent and exponentially distributed, but now with expectations $v_1, \ldots, v_n$. Writing $H_k = H(\mathbf{X}_k)$ and the likelihood ratio $W_k = f(\mathbf{X}_k; \mathbf{u}) / f(\mathbf{X}_k; \mathbf{w})$ in (6), the optimal parameter $\hat{\mathrm{v}}$ is found by maximizing

$$\begin{aligned} &\sum_{i=1}^{n} \sum_{k=1}^{N} H_k W_k \ln f(\mathbf{X}_k; \mathbf{u}) \\ &= \sum_{i=1}^{n} \sum_{k=1}^{N} H_k W_k \left(\frac{-X_{ki}}{v_i} - \ln v_i \right), \end{aligned} \quad (7)$$

where X_{ki} is the i-th component of $\mathbf{X}_k$. This maximum can be found by differentiating and equating to zero the right-hand side of (7) for each v_i, resulting in the equations

$$\sum_{k=1}^{N} H_k W_k \left(\frac{X_{ki}}{v_i^2} - \frac{1}{v_i} \right) = 0, \quad i = 1, \ldots, n,$$

from which it follows that

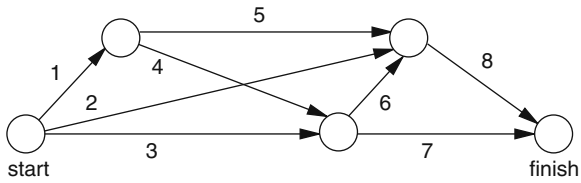
$$\hat{v}_i = \frac{\sum_{k=1}^{N} H_k W_k X_{ki}}{\sum_{k=1}^{N} H_k W_k}, \quad i = 1, \ldots, n. \tag{8}$$

Often $\ell = \mathbb{P}(S(\mathrm{X}) \geqslant \gamma)$ for some function S and level γ, in which case $H(\mathbf{x})$ takes the form of an indicator function: $H(\mathrm{x}) = I_{\{S(\mathrm{x}) \geqslant \gamma\}}$; that is, $H(\mathbf{x}) = 1$ if $S(\mathbf{x}) \geqslant \gamma$, and 0 otherwise. A complication in solving (6) occurs when ℓ is a rare-event probability; that is, a very small probability (say less than 10^{-4}). Then, for moderate sample size N, most or all of the values $H(\mathbf{X}_k)$ in (6) are zero, and the maximization problem becomes useless. In that case a multilevel CE procedure is used, where a sequence of reference parameters and levels is constructed with the goal that the former converges to $\mathbf{v}^*$ and the latter to γ. This leads to the following algorithm; see, for example, Rubinstein and Kroese (2007, 238).

Algorithm 1 (CE Algorithm for Rare-Event Estimation).

1. *Define* $\hat{\mathbf{v}}_0 = \mathbf{u}$. *Let* $N^{\mathrm{e}} = \lceil \varrho N \rceil$. *Set* $t = 1$ (*iteration counter*).
2. *Generate* $\mathbf{X}_1, \ldots, \mathbf{X}_N \sim_{\mathrm{iid}} f(\cdot; \hat{\mathbf{v}}_{t-1})$. *Calculate* $S_i = S(\mathbf{X}_i)$ *for all* i, *and order these from smallest to largest:* $S_{(1)} \leq \ldots \leq S_{(N)}$. *Let* $\hat{\gamma}_t$ *be the sample* $(1 - \varrho)$*-quantile of performances; that is,* $\hat{\gamma}_t = S_{(N - N^{\mathrm{e}} + 1)}$. *If* $\hat{\gamma}_t > \gamma$, *reset* $\hat{\gamma}_t$ *to* γ.
3. *Use the* **same** *sample* $\mathbf{X}_1, \ldots, \mathbf{X}_N$ *to solve the stochastic program* (6), *with* $\mathbf{w} = \hat{\mathbf{v}}_{t-1}$. *Denote the solution by* $\hat{\mathbf{v}}_t$.
4. *If* $\hat{\gamma}_t < \gamma$, *set* $t = t + 1$ *and reiterate from Step 2; otherwise, proceed with Step 5.*
5. *Let* T *be the final iteration counter. Generate* $\mathbf{X}_1, \ldots, \mathbf{X}_{N_1} \sim_{iid} f(\cdot; \hat{\mathbf{v}}_T)$ *and estimate* ℓ *via importance sampling, as in* (3).

Apart from specifying the family of sampling pdfs, the sample sizes N and N_1, and the rarity parameter ϱ (typically between 0.01 and 0.1), the algorithm is completely self-tuning. The sample size N for determining a good reference parameter can usually be chosen much smaller than the sample size N_1 for the final importance sampling estimation, say $N = 1000$ versus $N_1 = 100{,}000$. Under certain technical conditions the deterministic version of Algorithm 1 is guaranteed to terminate (reach level γ) provided that ϱ is chosen small enough; see Sect. 3.5 of Rubinstein and Kroese (2004).



Cross-Entropy Method, Fig. 1 A stochastic activity network

Example: Rare-Event Probability Estimation. A stochastic activity network is a frequently used tool in project management to schedule concurrent activities. Each arc corresponds to an activity and is weighted by the duration of that activity. The maximal project duration corresponds to the length of the longest path in the graph. Figure 1 shows a stochastic activity network with eight activities. Suppose the durations of the activities are independent exponential random variables $X_1, \ldots, X_8$, each with mean 1.

Let $S(\mathbf{X})$ denote length of the longest path in the graph; that is,

$$\begin{aligned} S(\mathbf{X}) = \max\{&X_1 + X_4 + X_6 + X_8,\ X_1 + X_4 + X_7,\ X_1 \\ &+ X_5 + X_8,\ X_2 + X_8,\ X_3 + X_6 + X_8,\ X_3 + X_7\} \end{aligned}$$

Suppose the objective is to estimate the rare-event probability $\mathbb{P}(S(\mathbf{X}) \geq 20)$ using importance sampling where the random vector $\mathbf{X} = (X_1, \ldots, X_8)$ has independent exponentially distributed components with mean vector $\mathbf{v} = (v_1, \ldots, v_8)$. Note that the nominal pdf is obtained by setting $v_i = 1$ for all i. At the t-th iteration of the multilevel CE Algorithm 1, the solution to (6) with $H(\mathbf{X}) = \mathrm{I}_{\{S(\mathbf{X}) \geq \hat{\gamma}_t\}}$, using (8), is given by

$$\hat{v}_{t,i} = \frac{\sum_{k=1}^{N} \mathrm{I}_{\{S(\mathrm{X}_k) \geq \hat{\gamma}_t\}} W_k X_{ki}}{\sum_{k=1}^{N} \mathrm{I}_{\{S(\mathrm{X}_k) \geq \hat{\gamma}_t\}} W_k}, \tag{9}$$

where $\mathbf{X}_1, \ldots, \mathbf{X}_N \sim_{\mathrm{iid}} f(\cdot; \hat{\mathbf{v}}_{t-1})$, $W_k = f(\mathbf{X}_k; \mathbf{u}) / f(\mathbf{X}_k; \hat{\mathbf{v}}_{t-1})$, and X_{ki} is the i-th element of $\mathbf{X}_k$.

Cross-Entropy Method, Table 1 Convergence of the sequence $\{(\hat{\gamma}_t, \hat{\mathbf{v}}_t)\}$

t	$\hat{\gamma}_t$	$\hat{v}_t$							
0	–	1	1	1	1	1	1	1	1
1	7.32	1.93	1.12	1.39	1.83	1.32	1.81	1.37	1.96
2	12.01	3.33	1.09	1.58	2.98	1.50	2.95	1.58	3.32
3	20	5.03	1.00	1.88	4.63	1.51	4.73	1.47	5.14

Table 1 lists the successive estimates for the optimal importance sampling parameters obtained from the multilevel CE algorithm, using $N = 10^5$ and $\varrho = 0.1$.

The last step in Algorithm 1 gives an estimate of $4.15 \cdot 10^{-6}$ with an estimated relative error of 1%, using a sample size of $N_1 = 10^6$. A typical crude Monte Carlo estimate (i.e., taking $\mathbf{v} = \mathbf{u} = (1,1,\ldots,1)$) using the same sample size is $3 \cdot 10^{-6}$, with an estimated relative error of 60%, and is therefore of little use.

For large-size activity networks the accurate estimation of the optimal parameters via (9) runs into problems due to the degeneracy behavior of the likelihood ratio; cf. Rubinstein and Kroese (2007, 133). For such systems it is recommended to estimate the optimal CE parameters by drawing samples directly from g^*, for example, via Markov chain Monte Carlo; see Chan (2010).

Optimization

Let $\mathcal{X}$ be an arbitrary set of states and let S be a real-valued performance function on $\mathcal{X}$. Suppose the goal is to find the maximum of S over $\mathcal{X}$, and the corresponding maximizer $\mathbf{x}^*$ (assuming, for simplicity, that there is only one). Denote the maximum by γ^*, so that

$$S(\mathbf{x}^*) = \gamma^* = \max_{\mathbf{x} \in \mathcal{X}} S(\mathrm{X}). \tag{10}$$

Associate with the above problem the estimation of the probability $\ell = \mathbb{P}(S(\mathbf{X}) \geq \gamma)$, where $\mathbf{X}$ has some probability density $f(\mathbf{x}; \mathbf{u})$ on $\mathcal{X}$ (e.g., corresponding to the uniform distribution on $\mathcal{X}$) and γ is some level. Thus, for optimization problems, randomness is purposely introduced in order to make the model stochastic, as in the estimation setting. If γ is chosen close to the unknown γ^*, then ℓ is typically a rare-event probability, and the CE approach of section "Estimation" can be used to find an importance sampling distribution close to the theoretically optimal importance sampling density, which concentrates all its mass on point $\mathbf{x}^*$. Sampling from such a distribution thus produces optimal or near-optimal states. Note that the final level $\gamma = \gamma^*$ is generally not known in advance, in contrast to the rare-event simulation setting. The CE method for optimization produces a sequence of levels $\{\hat{\gamma}_t\}$ and reference parameters $\{\hat{\mathbf{v}}_t\}$ such that the former tends to the optimal γ^* and the latter to the optimal reference vector $\mathbf{v}^*$ corresponding to the point mass at $\mathbf{x}^*$; see, for example, Rubinstein and Kroese (2007) p. 251.

Algorithm 2 (CE Algorithm for Optimization).

1. *Choose an initial parameter vector* $\hat{\mathbf{v}}_0$. *Let* $N^{\mathrm{e}} = \lceil \varrho N \rceil$. *Set* $t = 1$ (*level counter*).
2. *Generate* $\mathbf{X}_1, \ldots, \mathbf{X}_N \sim_{\mathrm{iid}} f(\cdot; \hat{\mathbf{v}}_{t-1})$. *Calculate the performances* $S(\mathbf{X}_i)$ *for all* i, *and order them from smallest to largest:* $S_{(1)} \leq \ldots \leq S_{(N)}$. *Let* $\hat{\gamma}_t$ *be the sample* $(1 - \varrho)$*-quantile of performances; that is,* $\hat{\gamma}_t = S_{(N-N^{\mathrm{e}}+1)}$.
3. *Use the* **same** *sample* $\mathbf{X}_1, \ldots, \mathbf{X}_N$ *and solve the stochastic program*

$$\max_{\mathbf{v}} \frac{1}{N} \sum_{k=1}^{N} I_{\{S(X_k) \geq \hat{\gamma}_t\}} \ln f(\mathbf{X}_k; \mathbf{v}). \tag{11}$$

Denote the solution by $\hat{\mathbf{v}}_t$.

4. *If some stopping criterion is met, stop; otherwise, set* $t = t + 1$, *and return to Step 2.*

To run the algorithm, one needs to provide the class of sampling pdfs, the initial vector $\hat{\mathbf{v}}_0$, the sample size N, the rarity parameter ϱ, and the stopping criterion. Any CE algorithm for optimization involves thus the following two main iterative phases:

1. *Generate* a random sample of objects in the search space $\mathcal{X}$ (trajectories, vectors, etc.) according to a specified probability distribution.
2. *Update* the parameters of that distribution, based on the N^{e} best performing samples (the so-called elite samples), using CE minimization.

Note that Step 5 of Algorithm 1 is missing in Algorithm 2. Another main difference between the two algorithms is that the likelihood ratio term $f(\mathbf{X}_k; \mathbf{u})/f(\mathbf{X}_k; \hat{\mathbf{v}}_{t-1})$ in (6) is missing in (11).

Often a smoothed updating rule is used, in which the parameter vector $\hat{\mathbf{v}}_t$ is taken as

$$\hat{\mathbf{v}}_t = \alpha\,\tilde{\mathbf{v}}_t + (1-\alpha)\hat{\mathbf{v}}_{t-1}, \tag{12}$$

where $\tilde{\mathbf{v}}_t$ is the solution to (11) and $0 \le \alpha \le 1$ is a smoothing parameter. Many other modifications can be found in Kroese et al. (2006), Rubinstein and Kroese (2004, 2007). When there are two or more optimal solutions, the CE algorithm typically "fluctuates" between the solutions before focusing on one of the solutions. The effect that smoothing has on convergence is discussed in detail in Costa et al. (2007). In particular, it is shown that with appropriate smoothing the CE method converges and finds the optimal solution with probability arbitrarily close to 1. Necessary conditions and sufficient conditions under which the optimal solution is generated eventually with probability 1 are also given. Other convergence results, including a proof of convergence along the lines of the convergence proof for simulated annealing can be found in Margolin (2005). The CE method is also effective for solving noisy optimization problems, for example, when the objective function value is obtained via simulation. Typical examples may be found in Alon et al. (2005) and Cohen et al. (2007).

Combinatorial Optimization

When the state space $\mathcal{X}$ is finite, the optimization problem (10) is often referred to as a discrete or combinatorial optimization problem. For example, $\mathcal{X}$ could be the space of combinatorial objects such as binary vectors, trees, paths through graphs, permutations, etc. To apply the CE method, one needs to first specify a convenient parameterized random mechanism to generate objects $\mathbf{X}$ in $\mathcal{X}$. An important example is where $\mathbf{X} = (X_1, \ldots, X_n)$ has independent components such that $X_i = j$ with probability p_{ij}, $i = 1, \ldots, n$, $j = 1, \ldots, m$. In that case, the CE updating rule (see de Boer et al. 2005, 56) at the t-th iteration is

$$\hat{p}_{t,ij} = \frac{\sum_{k=1}^{N} \mathbf{I}_{\{S(\mathbf{X}_k) \ge \hat{\gamma}t\}}\, \mathbf{I}_{\{X_{ki}=j\}}}{\sum_{k=1}^{N} \mathbf{I}_{\{S(\mathbf{X}_k) \ge \hat{\gamma}t\}}}, \quad i = 1, \ldots, n, \quad j = 1, \ldots, m, \tag{13}$$

where $\mathbf{X}_1, \ldots, \mathbf{X}_N$ are independent copies of $\mathbf{X} \sim \{\hat{p}_{t-1,ij}\}$ and X_{ki} is the *i-th* element of $\mathbf{X}_k$. Thus, the updated probability $\hat{p}_{t,ij}$ is simply the number of elite samples for which the i-th component is equal to j, divided by the total number of elite samples.

A possible stopping rule for combinatorial optimization problems is to stop when the overall best objective value does not change over a number of iterations. Alternatively, one could stop when the sampling distribution has "degenerated" enough. For example, when in (13) the $\{\hat{p}_{t,ij}\}$ differ less than some small $\varepsilon > 0$ from the $\{\hat{p}_{t-1,ij}\}$.

Example: Max-Cut Problem. The max-cut problem in a graph can be formulated as follows. Given a weighted graph $G(V, E)$ with node set $V = \{1, \ldots, n\}$ and edge set E, partition the nodes of the graph into two subsets V_1 and V_2 such that the sum of the (nonnegative) weights of the edges going from one subset to the other is maximized. Let $C = (C(i, j))$ be the matrix of weights. The objective is to maximize

$$\sum_{(i,j)\in V_1 \times V_2} (C(i,j) + C(j,i)) \tag{14}$$

over all cuts $\{V_1, V_2\}$. Such a cut can be conveniently represented by a binary cut vector $\mathbf{x} = (1, x_2, \ldots, x_n)$, where $x_i = 1$ indicates that $i \in V_1$. Let $\mathcal{X}$ be the set of cut vectors and let $S(\mathbf{x})$ be the value of the cut represented by $\mathbf{x}$, as given in (14).

To maximize S via the CE method one can generate the random cut vectors by drawing each component (except the first one, which is set to 1) independently from a Bernoulli distribution, that is, $\mathbf{X} = (1, X_2, \ldots, X_n) \sim \text{Ber}(\mathbf{p})$, where $\mathbf{p} = (1, p_2, \ldots, p_n)$. Given an elite sample set $\mathcal{E}$, with size N^{e}, the updating formula (13) is then:

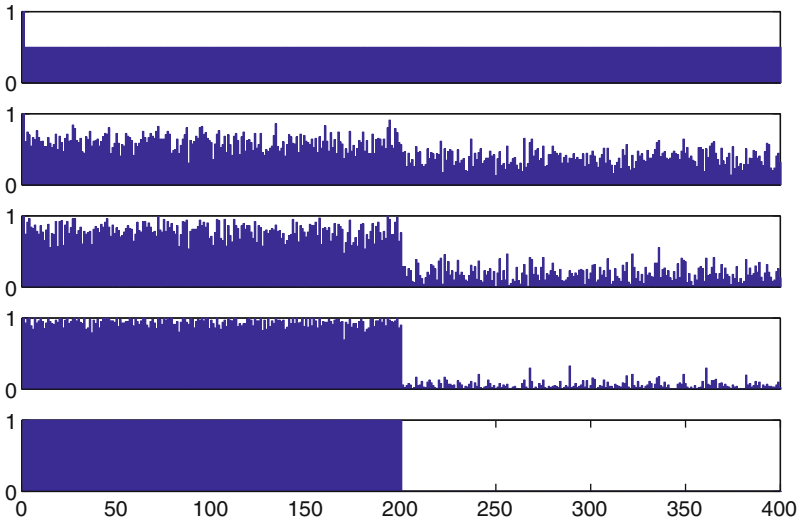
$$\hat{p}_{t,i} = \frac{\sum_{\mathbf{X}\in\mathcal{E}} X_i}{N^{\text{e}}}, \qquad i = 2, \ldots, n. \tag{15}$$

That is, the updated success probability for the *i-th* component is the mean of the i-th components of the vectors in the elite set.

Figure 2 illustrates the evolution of the Bernoulli parameters for a max-cut problem from de Boer et al. (2005) of dimension $n = 400$, for which the optimal solution is given by $\mathbf{x}^* = (1, \ldots, 1, 0, \ldots, 0)$.

Continuous Optimization

When the state space is continuous, in particular when $\mathcal{X} = \mathbb{R}^n$, the optimization problem is often referred to



Cross-Entropy Method, Fig. 2 Sequence of reference vectors for a synthetic max-cut problem with 400 nodes. Iterations 0, 5, 10, 15, and 20 are displayed

as a continuous optimization problem. The sampling distribution on $\mathbb{R}^n$ can be quite arbitrary and does not need to be related to the function that is being optimized. The generation of a random vector $\mathbf{X} = (X_1, \ldots, X_n) \in \mathbb{R}^n$ is most easily performed by drawing the coordinates independently from some 2-parameter distribution. In most applications, a normal (Gaussian) distribution is employed for each component. Thus, the sampling distribution for $\mathbf{X}$ is characterized by a vector of means $\boldsymbol{\mu}$ and a vector of standard deviations $\boldsymbol{\sigma}$. At each iteration of the CE algorithm, these parameter vectors are updated simply as the vectors of sample means and sample standard deviations of the elements in the elite set; see, for example, Kroese et al. (2006).

Algorithm 3 (CE for Continuous Optimization: Normal Updating).

1. ***Initialize***: *Choose* $\hat{\boldsymbol{\mu}}_0$ *and* $\hat{\boldsymbol{\sigma}}_0^2$. *Set* $t = 1$.
2. ***Draw***: *Generate a random sample* $\mathbf{X}_1, \ldots, \mathbf{X}_N$ *from the* $\mathrm{N}(\hat{\boldsymbol{\mu}}_{t-1}, \hat{\boldsymbol{\sigma}}_{t-1}^2)$ *distribution.*
3. ***Select***: *Let* $\mathcal{I}$ *be the indices of the* N^{e} *best performing (= elite) samples.*
   Update: *For all* $j = 1, \ldots, n$ *let*

$$\tilde{\mu}_{t,j} = \sum_{i \in \mathcal{I}} X_{ij} / N^{\mathrm{e}} \tag{16}$$

and

$$\tilde{\sigma}_{t,j}^2 = \sum_{i \in \mathcal{I}} (X_{ij} - \tilde{\mu}_{t,j})^2 / N^{\mathrm{e}}. \tag{17}$$

4. ***Smooth***:

$$\hat{\boldsymbol{\mu}}_t = \alpha \tilde{\boldsymbol{\mu}}_t + (1-\alpha)\hat{\boldsymbol{\mu}}_{t-1}, \quad \hat{\boldsymbol{\sigma}}_t = \alpha \tilde{\boldsymbol{\sigma}}_t + (1-\alpha)\hat{\boldsymbol{\sigma}}_{t-1} \tag{18}$$

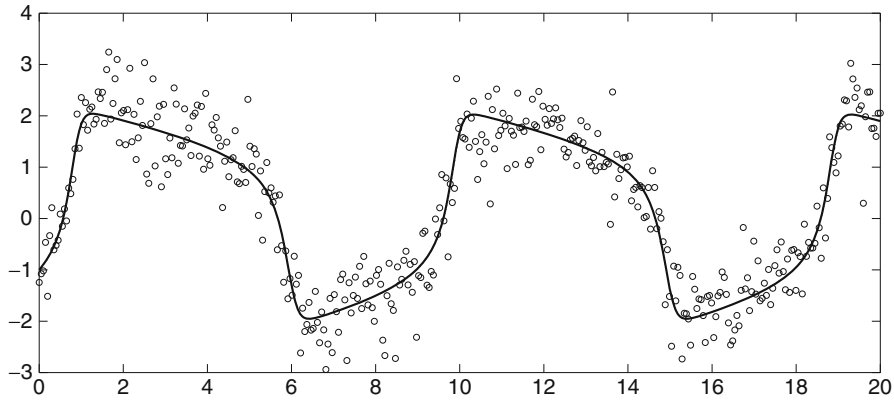
5. *If* $\max_j \{\hat{\sigma}_{t,j}\} < \varepsilon$ stop *and return* $\boldsymbol{\mu}_t$ *as an approximate solution. Otherwise, increase* t *by* 1 *and return to Step 2.*

For constrained continuous optimization problems, where the samples are restricted to a subset $\mathcal{X} \subset \mathbb{R}^n$, it is often possible to replace the normal sampling with sampling from a truncated normal distribution while retaining the updating formulas (16–17). An alternative is to use a beta distribution. Instead of returning $\hat{\boldsymbol{\mu}}_t$ as the final solution, one often returns the overall best solution generated by the algorithm.

Smoothing, as in Step 4, is often crucial to prevent premature shrinking of the sampling distribution. Instead of using a single smoothing factor, it is often useful to use separate smoothing factors for $\hat{\boldsymbol{\mu}}_t$ and $\hat{\boldsymbol{\sigma}}_t$. An alternative is to use dynamic smoothing for $\hat{\boldsymbol{\sigma}}_t$:

$$\alpha_t = \beta - \beta\left(1 - \frac{1}{t}\right)^q, \tag{19}$$

where q is an integer (typically between 5 and 10) and β is a smoothing constant (typically between 0.8 and 0.99). Another approach is to inject extra variance into the sampling distribution, for example, by increasing the components of $\boldsymbol{\sigma}$, once the distribution has degenerated; see Botev and Kroese (2004). Finally, significant speed up can be achieved by



Cross-Entropy Method, Fig. 3 Simulated data for the FitzHugh–Nagumo model and a fitted curve obtained via the CE method

using a parallel implementation of CE; see, for example, Evans et al. (2007).

Example: Parameter Estimation for Differential Equations. Consider the FitzHugh–Nagumo differential equations:

$$\frac{\mathrm{d}V_t}{\mathrm{d}t} = c\left(V_t - \frac{V_t^3}{3} + R_t\right),$$
$$\frac{\mathrm{d}R_t}{\mathrm{d}t} = -\frac{1}{c}(V_t - a + bR_t), \qquad (20)$$

which model the behavior of certain types of neurons (Nagumo et al. 1962). Ramsay et al. (2007) consider estimating the parameters a, b, and c from noisy observations of (V_t) by using a generalized smoothing approach. The simulated data in Fig. 3 correspond to the values of V_t obtained from (20) at times 0, 0.05, . . . , 20.0, adding Gaussian noise with standard deviation 0.5. The true parameter values are $a = 0.2$, $b = 0.2$, and $c = 3$. The initial conditions are $V_0 = -1$ and $R_0 = 1$.

Estimation of the parameters via the CE method can be established by minimizing the least-squares performance

$$S(\mathbf{x}) = \sum_{i=0}^{400} (y_i - V_{0.05i}(\mathbf{x}))^2,$$

where $\{y_i\}$ are the simulated data, $\mathbf{x} = (a, b, c, V_0, R_0)$, and $V_t(\mathbf{x})$ is the solution to (20) for parameter vector $\mathbf{x}$. Algorithm 3 was implemented with $\hat{\boldsymbol{\mu}}_0 = (0, 0, 5, 0, 0)$, $\hat{\boldsymbol{\sigma}}_0 = (1,1,1,1,1)$, $N = 100$, $N^e = 10$, and $\varepsilon = 0.001$. Constant smoothing parameters $\alpha_1 = 0.9$ and $\alpha_2 = 0.5$ were used for the $\{\hat{\boldsymbol{\mu}}_t\}$ and the $\{\hat{\boldsymbol{\sigma}}_t\}$, respectively. The following solution was found (note that the initial condition was assumed to be unknown): $\hat{a} = 0.19$, $\hat{b} = 0.21$, $\hat{c} = 3.00$, $\hat{V}_0 = -1.02$, and $\hat{R}_0 = 1.02$. The smooth curve in Fig. 3 gives the corresponding estimated curve, which is practically indistinguishable from the true one.

Curse of Dimensionality

The situation that arises in such areas as dynamic programming, control theory, integer programming, combinatorial problems, and, in general, time-dependent problems in which the number of states and/or data storage requirements increases exponentially with small increases in the problems' parameters or dimensions; sometimes referred to as combinatorial explosion.

Customer Distribution

The probability distribution of the state of the process that customers observe upon arrival to a queueing system. In general, it is not the same as the distribution seen by a random outside observer; but the two distributions are the same for queueing systems with Poisson arrivals (PASTA). Since customers entering a queue must also exit, the probability distribution seen by arriving customers who are accepted is the same as that for the number of customers left behind by the departures.

Cutting Stock Problems

Robert W. Haessler
University of Michigan, Ann Arbor, MI, USA

Introduction

Solid materials such as aluminum, steel, glass, wood, leather, paper and plastic film are generally produced in larger sizes than required by the customers for these materials. As a result, the producers or primary converters must determine how to cut the production units of these materials to obtain the sizes required by their customers. This is known as a cutting stock problem. It can occur in one, two or three dimensions depending on the material. The production units may be identical, may consist of a few different sizes, or may be unique. They may be of consistent quality throughout or may contain defects. The production units may be regular (rectangular) or irregular. The ordered sizes may be regular or irregular. They may all have the same quality requirements or some may have different requirements. They may have identical or different timing requirements which impact inventory. The first

Some examples follow:

- cutting rolls of paper from production reels of the same diameter.
- cutting rectangular pieces of glass from rectangular production sheets.
- cutting irregular pieces of steel from rectangular plates.
- cutting rectangular pieces of leather from irregular hides.
- cutting dimensional lumber from logs of various size.

There are two other classes of problems which are closely related to the above cutting problems. The first is the layout problem. An example of this would be the problem of determining the smallest rectangle which will contain a given set of smaller rectangles without overlap. Solving this problem is essentially the same as being able to generate a cutting pattern in the discussion of cutting stock problems which follows. The second type of problem, which in many cases can be solved by the same techniques as cutting stock problems, is the (bin) packing problem. A one-dimensional example of this would be to determine the minimum number of containers required to ship a set of discrete items where weight and not floor space or volume is the determinant of what can be placed in the container. If floor space or volume is the key determinant, then the problem is equivalent to a two or three-dimensional cutting stock problem in which guillotine cuts are not required. Even though the following discussions focuses on cutting stock problems, it is also applicable to solving both packing and layout problems.

Although cutting stock problems are relatively easy to formulate, many of them especially those with irregular shapes, are difficult to solve; there are no efficient solution procedures available. The major difficulty has to do with the generation of feasible low trim loss cutting pattern. As will be discuseed below, this ranges from being simple in one-dimension to complex in two-dimensions, even with regular shapes.

The first known formulation of a cutting stock problem was given in 1939 by the Russian economist Kantorovich (1960). The first and most significant advance in solving cutting problems was the seminal

work of Gilmore and Gomory (1961, 1963) in which they described their delayed pattern generation technique for solving the one-dimensional trim loss minimization problem using linear programming. Since that time, there has been an explosion of interest in this application area. Sweeney and Paternoster (1992) have identified more than 500 papers which deal with cutting stock and related problems and applications. The primary reasons for this activity are that cutting stock problems occur in a wide variety of industries, there is a large economic incentive to find more effective solution procedures, and it is easy to compare alternative solution procedures and to identify the potential benefits of using a proposed procedure.

Cutting stock problems are introduced with a discussion of the one-dimensional problem and the techniques available for solving it. The article concludes with an extension to the regular two dimensional problem.

One-Dimensional Problems

An example of a one-dimensional cutting stock problem is the trim loss minimization problem that occurs in the paper industry. In this problem, known quantities of rolls of various widths and the same diameter are to be slit from stock rolls of some standard width and diameter. The objective is to identify slitting patterns and their associated usage levels that satisfy the requirements for ordered rolls at the least possible total cost for scrap and other controllable factors. The basic cutting pattern feasibility restriction in this problem is that the sum of the roll widths slit from each stock roll must not exceed the usable width of the stock roll.

Let R_i be the nominal order requirements for rolls of width W_i, $i = 1, \ldots, n$, to be cut from stock rolls of usable width UW. We have RL_i and RU_i as lower and upper bounds on the order requirement, for customer order i, reflecting the general industry practice of allowing overruns or underruns within specified limits. Depending on the situation, R_i may be equal to RL_i and/or RU_i. All orders are for rolls of the same diameter. This problem can be formulated as follows, with X_j as the number of stock rolls to be slit using pattern j and T_j as the trim loss incurred by pattern j:

$$\text{minimize} \sum_j T_j X_j \tag{1}$$

$$\text{s.t } RL_i \leq \sum_j A_{ij} X_j \leq RU_i \text{ for all } i \tag{2}$$

$$T_j = UW - \sum_i A_{ij} W_i \tag{3}$$

$$X_j \geq 0, \quad \text{integer.} \tag{4}$$

where A_{ij} is the number of rolls of width W_i to be slit from each stock roll that is processed using pattern j. In order for the elements A_{ij}, $i = 1, \ldots, n$, to constitute a feasible cutting pattern, the following restrictions must be satisfied:

$$\sum_i A_{ij} W_i \leq UW, \tag{5}$$

$$A_{ij} \geq 0, \quad \text{integer} \tag{6}$$

Note that the objective in this example is simply to minimize trim loss. In most industrial applications, it is necessary to consider other factors in addition to trim loss. For example, there may be a cost associated with pattern changes and, therefore, controlling the number of patterns used to satisfy the order requirements would be an important consideration.

Because optimal solutions to integer cutting stock problems can be found only for values of n smaller than typically found in practice, heuristic procedures represent the only feasible approach to solving this type of problem. Two types of heuristic procedures have been widely used to solve one-dimensional cutting stock problems. One approach uses the solution to a linear programming (LP) relaxation of the integer problem above as its starting point. The LP solution is then modified in some way to provide a integer solution to the problem. The second approach is to generate cutting patterns sequentially to satisfy some portion of the remaining requirements. This sequential heuristic procedure (SHP) terminates when all order requirements are satisfied.

Linear Programming Solutions

Almost all LP-based procedures for solving cutting stock problems can be traced back to Gilmore and Gomory (1961, 1963). They described how the next pattern to enter the LP basis could be found by solving

an associated knapsack problem. This made it possible to solve the trim loss minimization problem by linear programming without first enumerating every feasible slitting pattern. This is extremely important because a large number of feasible patterns may exist when narrow widths are to be slit from a wide stock roll. Pierce (1964) showed that in such situations the number of slitting patterns can easily run into the millions. Because only a small fraction of all possible slitting patterns need to be considered in finding the minimum trim loss solution, the delayed pattern generation technique developed by Gilmore and Gomory made it possible to solve trim loss minimization problems in much less time than would be required if all the slitting patterns were input to a general-purpose linear programming algorithm.

A common LP relaxation of the integer programming problem given in (1)–(3) can be stated as follows:

$$\text{minimize} \sum_j X_j \tag{7}$$

$$\text{s.t} \sum_j A_{ij} X_j \geq RU_i \text{ for all } i, \tag{8}$$

$$X_j \geq 0, \quad \text{integer}. \tag{9}$$

Let U_i be the dual variable associated with constraint i. Then the dual of this problem can be stated as:

$$\text{minimize} \sum_i R_i U_i \tag{10}$$

$$\text{s.t.} \sum_i A_{ij} U_i \leq 1 \tag{11}$$

$$U_i \geq 0. \tag{12}$$

The dual constraints in (11) provide the means for determining if the optimal LP solution has been obtained or if there exists a pattern which will improve the LP solution because the dual problem is still infeasible.

The next pattern $\boldsymbol{A} = (A_1, \ldots, A_n)$ to enter the basis, if one exists, can be found by solving the following knapsack problem:

$$Z = \text{maximize} \sum_i U_i A_i \tag{13}$$

$$\text{s.t.} \sum_i W_i A_i \leq UW \tag{14}$$

$$A_i \geq 0, \quad \text{integer} \tag{15}$$

If $Z \leq 1$, the current solution is optimal. If $Z > 1$, then **A** can be used to improve the LP solution.

Once found, the LP solution can be modified in a number of ways to obtain integer values for the X_j which satisfy the order requirements. One common approach is to round the LP solution down to integer values, then increase the values of X_j by unit amounts for any patterns whose usage can be increased without exceeding RU_i. Finally, new patterns can be generated for any rolls still needed using the sequential heuristic described in the next section.

Sequential Heuristic Procedures (SHP)

With an SHP, a solution is constructed one pattern at a time until all the order requirements are satisfied. The first documented SHP capable of finding better solutions than those found manually by schedulers was described by Haessler (1971). The key to success with this type of procedure is to make intelligent choices as to the patterns which are selected early in the SHP. The patterns selected initially should have low trim loss, high usage and leave a set of requirements for future patterns which will combine well without excessive side trim.

The following procedure is capable of making effective pattern choices in a variety of situations:

1. Compute descriptors of the order requirements yet to be scheduled. Typical descriptors would be the number of stock rolls still to be slit and the average number of ordered rolls to be cut from each stock roll.
2. Set goals for the next pattern to be entered into the solution. Goals should be established for trim loss, pattern usage, and number of ordered rolls in the pattern.
3. Search exhaustively for a pattern that meets those goals.
4. If a pattern is found, add this pattern to the solution at the maximum possible level without exceeding R_i, for all i. Reduce the order requirements and return to 1.
5. If no pattern is found, reduce the goal for the usage level of the next pattern and return to 3.

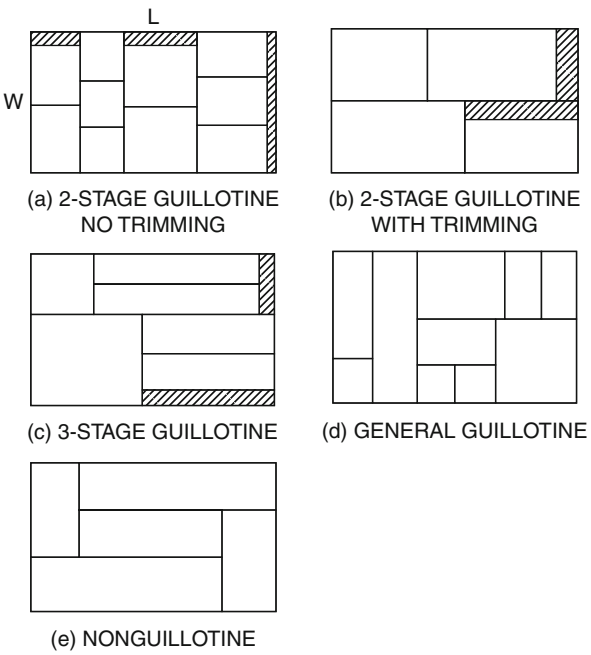
The pattern usage goal provides an upper bound on the number of times a size can appear in a pattern. For example, if some ordered width has an unmet requirement of 10 rolls and the pattern usage goal is 4, that width may not appear more than twice in a pattern. If after exhaustive search no pattern satisfies the goals set, then at least one goal, most commonly pattern usage, must be relaxed. This increases the number of patterns to be considered. If the pattern usage goal is changed to 3 in the above example, then the width can appear in the pattern three times. Termination can be guaranteed by selecting the pattern with the lowest trim loss at the usage level of one.

The primary advantage of this SHP is its ability to control factors other than trim loss and to eliminate rounding problems by working only with integer values. For example, if there is a cost associated with a pattern change, a sequential heuristic procedure which searches for high usage patterns may give a solution which has less than one-half the number of patterns required by an LP solution to the same problem. The major disadvantage of an SHP is that it may generate a solution which has greatly increased trim loss because of what might be called ending conditions. For example, if care is not taken as each pattern is accepted and the requirements reduced, the widths remaining at some point in the process may not have an acceptable trim loss solution. Such would be the case if only 34-inch rolls are left to be slit from 100-inch stock rolls.

Rectangular Two-Dimensional Problems

The formulation of a higher dimensional cutting stock problem is exactly the same as that of the one-dimensional problem given in (1)–(4). The only added complexity comes in trying to define and generate feasible cutting patterns. The simplest two-dimensional case is one in which both the stock and ordered sizes are rectangular. Most of the important issues regarding cutting patterns for rectangular two-dimensional problems can be seen in the examples shown in Fig. 1.

One important issue not covered in Fig. 1 is a limit on the number of times an ordered size can appear in a pattern. This generally is a function of the maximum quantity of pieces, RU_i, required for order i. If R_i is small, it is just as important for the two-dimensional case as the one dimensional case that the number of times size i appears in a pattern should be limited. This becomes less important as R_i becomes larger and as the difference between RU_i and RL_i becomes larger.



Cutting Stock Problems, Fig. 1 Sample cutting patterns

The cutting pattern shown in Fig. 1(a) is an example of two-stage guillotine cuts. The first cut can be in either the horizontal or vertical direction. A second cut perpendicular to the first, yields a finished piece. Figure 1(b) is similar except a third cut can be made to trim the pieces down to the correct dimension. Figure 1(c) shows the situation in which the third cut can create 2 ordered pieces.

For simple staged cutting such as shown in Fig. 1 (a, b, c), Gilmore and Gomory (1965) showed how cutting patterns can be generated by solving two one-dimensional knapsack problems. To simplify the discussion, assume that the orientation of each ordered piece is fixed relative to stock piece and the first guillotine cut on the stock pieces must be along the length (larger dimension) of the stock piece. For each ordered width W_k, find the contents of a strip of width W_k and length L which gives the maximum contribution to dual infeasibility:

$$Z_k = \text{maximize} \sum_{i \varepsilon I_k} U_i A_{ik} \qquad (16)$$

$$\text{s.t.} \sum_{i \varepsilon I_k} L_i A_{ik} \leq L \tag{17}$$

$$A_{ik} \geq 0, \text{ integer.} \tag{18}$$

$$I_k = \{i | W_i \leq W_k\}. \tag{19}$$

Next find the combination of strips which solve the problem

$$Z = \text{maximize} \sum_k Z_k A_k \tag{20}$$

$$\sum_k W_k A_k \leq W \tag{21}$$

$$A_k \geq 0, \quad \text{integer.} \tag{22}$$

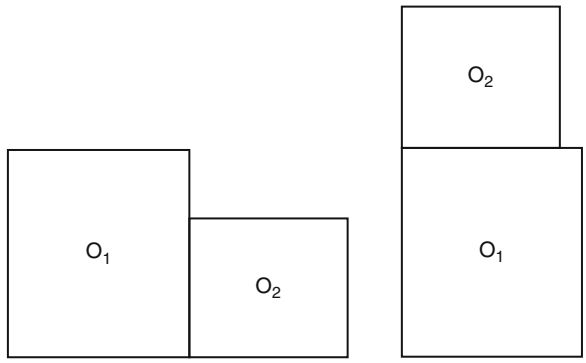
Any pattern for which Z is greater than one will yield an improvement in the LP solution.

The major difficulty with this approach is the inability to limit the number of times an ordered size appears in a pattern. It is easy to restrict the number of times a size appears in a strip and to restrict the number of strips in a pattern. The problem is that small ordered sizes with small quantities may end up as filler in a large number of different strips. This makes the two-stage approach to developing patterns ineffective when the number of times a size appears in a pattern must be limited.

Wang (1983) developed an alternative approach to generating general guillotine cutting patterns which limits the number of times a size appears in a pattern. She combined rectangles in a horizontal and vertical build process as shown in Fig. 2 where O_i is an ordered rectangle of width W_i and length L_i.

She used an acceptable value for trim loss, B, rather than the shadow price of the ordered sizes to drive her procedure which is as follows:

- Step 1
  - (a) Choose a value for B the maximum acceptable trim waste.
  - (b) Define $L^{(O)} = F^{(O)} = \{O_1, O_2, \ldots, O_n\}$, and set $K = 1$.
- Step 2
  - (a) Compute $F^{(K)}$ which is the set of all rectangles T satisfying (i) T is formed by a horizontal or vertical build of two rectangles from $L^{(K-1)}$, (ii) the amount of trim waste in T does not exceed B, and (iii) those rectangles O_i, appearing in T do not violate the constraints on the number of times a size can appear in a pattern.



(a) Horizontal build of O_1 and O_2 (b) Vertical build of O_1 and O_2

Cutting Stock Problems, Fig. 2 Guillotine cutting patterns

  - (b) Set $L^{(K)} = L^{(K-1)} UF^{(K)}$. Remove any equivalent (same component rectangles) rectangle patterns from $L^{(K)}$.
- Step 3. If $F^{(K)}$ is non-empty, set $K = K + 1$ and go to Step 2; otherwise, set $M = K - 1$, and choose the rectangle in $L^{(M)}$ which has the smallest total trim waste when placed in the stock rectangle.

Concluding Remarks

It is clear that moving from one to two-dimensions causes significant difficulty in the pattern generating process. This is all the more alarming in light of the fact that only rectangular shapes were considered.

This clearly suggests that there is much more research needed on procedures for solving two-dimensional cutting stock problems. An alternative worth considering, especially in those cases where there are many different ordered sizes with small order quantities, might be to first select a subset of orders to consider by solving a one-dimensional knapsack problem as in (13)–(15) based on area and then see if the resulting solution can be put together into a feasible two-dimensional pattern. Wang's algorithm seems to be ideal for this purpose inasmuch as the trim loss in the pattern would be known.

A candidate set of items to be included in the next pattern could be found by solving the following problem:

$$Z = \text{maximize} \sum_i U_i A_i \tag{23}$$

$$\sum_i AR_i A_i \leq UAR \text{ for all } i \quad (24)$$

$$A_i \leq b_i \quad (25)$$

$$A_i \geq 0, \quad \text{integer.} \quad (26)$$

where AR_i is the area of ordered rectangle i, UAR is the usable area of the stock rectangle, and b_i is the upper limit on the number of times order i can be included in the pattern.

The candidate pattern $(A_1, \ldots, A_n)$ could then be tested for feasibility using Wang's procedure. If the AR_i are small, the chances are that there will be little trim loss in the candidate patterns generated. This may require that UAR be reduced to force some trim loss to make it more likely that feasible patterns are found.

Cybernetics and Complex Adaptive Systems

Andrew P. Sage
George Mason University, Fairfax, VA, USA

Introduction

Cybernetics is a term that is occasionally used in the literature of such areas as systems engineering and OR/MS to denote the study of control and communication in, and, in particular between humans, machines, organizations, and society. The word cybernetics comes from the Greek word *Kybernetes*, which means controller, or governor, or steersman. The first modern use of the term was due to Professor Norbert Wiener, an MIT professor of mathematics, who made many early and seminal contributions to mathematical system theory (Wiener 1949). The first book formally on this subject was titled *Cybernetics* and published in 1948 (Wiener 1948). In this book, Wiener defined the term as "control and communication in the animal and the machine." This emphasized the concept of feedback control as a construct presumably of value in the study of neural and physiological relations in the biological and physical sciences. In the historical evolution of cybernetics, major concern was initially devoted to the study of feedback control and servomechanisms, studies which later evolved into the area of control systems or control engineering (Singh 1990). Cybernetic concerns also have involved analog and digital computer development, especially computer

efforts that were presumed to be models of the human brain and the combination of computer and control systems for purposes of automation and remote control (Ashby 1952, 1956; George 1971; Lerner 1976).

There were a number of other early influences on cybernetics, including artificial intelligence (AI). The two are quite different subjects, however. Artificial Intelligence is generally concerned with endowing computers with machine intelligence such that they can emulate certain forms of human behavior, generally cognitive behavior. Cybernetics is an epistemological subject that is fundamentally concerned with limits on how we know what we know. It seeks to understand systems in a variety of media — technological, biological, social, or organizational — and descriptions of these limits as a most important result. So while AI seeks to endow computers with human cognitive capabilities, a subject associated with much controversy (Dreyfus 1992), cybernetics is much more concerned with using computational capabilities to develop models of systems based on the information, feedback, and control properties of these systems. In a cybernetic system, information and knowledge are attributes of interactions that occur within the system. It was the initial presumed resemblance, at a neural or physiological level, between physical control systems and the central nervous system and human brain that concerned Wiener. He and close associates, Warren McCulloch, Arturo Rosenblueth, and Walter Pitts, were the initial seminal thinkers in this new field of cybernetics. Soon, it became clear that it was fruitless to study control independent of information flow; cybernetics thus took on an identification with the study of communications and control in humans and machines. An influence in the early notions of cybernetics was the thought that physical systems could be made to perform better by, somehow, enabling them to emulate human systems at the physiological or neural level. Thus, early efforts in what is now known as neural networks began as cybernetic studies.

Another early concept explored in cybernetics was that of homeostasis, which has come to be known as the process by which systems maintain their level of organization in the face of disturbances, often occurring over time, and generally of a very large scale (Ashby 1952). Cybernetics soon became concerned with purposive organizational systems, or viable systems, as contrasted with systems that are static over time and purpose (Beer 1979). Further, organizations operate in the face of incomplete and redundant information by establishing useful patterns of communications (Beer 1979). Thus, organizations can potentially be modeled and have been modeled as cybernetic systems (Steinbrunner 1974).

Cybernetics has often been viewed as a way of looking at systems, or as a philosophical perspective concerning inquiry, as contrasted with a very specific method. This is perhaps much more the case now than during the very early history of use of the term. An excellent collection of Norbert Wiener's original papers on cybernetics studies is contained in Volume IV of an edited anthology (Masani 1985). Fundamental to any cybernetic study is the notion of modeling, and, in particular, the interpretation of the results of a modeling effort as theories that have normative or predictive value. Today, there is little explicit or implicit agreement concerning a precise definition for cybernetics. Some users of the term cybernetics infer that the word implies a study of control systems. Some uses refer to modeling only at the neural and physiological level. Some refer to cognitive ergonomic modeling without necessary consideration of, or connection to, neuronal level elements. Other uses of the word are so general that cybernetics might seem to infer either nothing, or everything. Automation, robotics, artificial intelligence, information theory, bionics, automata theory, pattern recognition and image analysis, control theory, communications, human and behavioral factors, and other topics have all, at one time or another, been assumed to be a portion of cybernetics.

Complex adaptive systems (CAS) involve phenomena associated with interactions of many individual agents that self-organize at higher aggregate system levels. This results in emergent and adaptive properties that are not exhibited by the individual agents. These systems are cybernetic like systems that receive data and information from their environments, find regularities in the data and information, and then identify internal models that process this data and information in order to describe and forecast likely futures. These systems are

evolutionary in the sense that these internal models are subject to selection pressures based on particular environmental conditions and this results in changes to the structure and parameters associated with the internal models. These systems function best under conditions between chaos and order, sometimes referred to as at the edge of chaos (Langton 1990) or self-organized criticality (Bak and Chen 1991; Bak 1996). The emergent characteristics of a particular complex system (Holland 1996) are often equivalent to individual agents acting in a higher level complex system. Adaptation occurs when either the functional or structural properties of an agent change in such a manner as to improve survival probabilities in the environment of the agent. Often the only way to study these complex adaptive systems is through computer simulation.

Definition of Cybernetics and Complex Adaptive Systems

The notion of the physiological aspects of the human nervous system as playing a necessarily critical role in modern cybernetics has all but vanished, except in very specialized classic works. This does not suggest that interest in neural type studies has vanished as there is much interest today in neural networks and related subjects (Freeman and Skapura 1991; Zurada 1992). A much more cognitive perspective is now prevalent, at least in many systems engineering views of cybernetics. In this article, cybernetics is defined as the study of the communication and control processes associated with human-machine interaction in systems that are intended to support accomplishment of purposeful tasks. While this is not a universally accepted definition of cybernetics, it is a useful one for many systems engineering studies involving human-system interaction through communications and control (Sage 1992). Complex systems theory is a general approach to understanding the overall behavior of system comprised of many nonlinearly interacting parts. The complex systems approach tries to construct minimal underlying rule sets from which desired behaviors naturally emerge. Complex adaptive system theory also assumes that systems are composed of interacting agents that continually adapt by changing their internal rules as the environment, and their experience in that environment, evolve over time. Systems transition naturally between equilibrium points through environmental adaptation and self-organization. A complex adaptive system behaves and evolves according to three key principles: (1) order is emergent as opposed to predetermined, (2) the system's history is irreversible, and (3) the system's future is generally unpredictable. Complex adaptive systems are complex systems consisting of many nonlinearly interacting parts or agents. These agents can adapt to changing environments where each agent typically exists within a nested hierarchy of agents within agents.

The purpose of this article is to discuss cybernetics and complex adaptive systems, and the design of support systems based on these concepts for such purposes as knowledge support to humans. Especial concern is with the human-system interactions that occur in such an effort. Thus, the discussions here are particularly relevant to knowledge-based system design concerns relative to human-machine cybernetic problem solving tasks, such as fault detection, diagnosis and correction. These are very important concerns for a large number of knowledge-support systems engineering applications that require fundamentally cognitive support to humans in supervisory control tasks (Sage 1991, 1992, 1995; Sheridan 1992; Rasmussen 1986; Rasmussen et al. 1994).

The need for humans to monitor and maintain the conditions necessary for satisfactory operation of systems and to cope with poorly structured and imprecise knowledge is greater than ever. Ultimately, these primarily cognitive efforts, which involve a great variety of human problem solving activities, are often translated into physical control signals for controlling or manipulating some physical process. As a consequence of this, there are a number of human interface issues that naturally occur between the human and the machines over which the human must exercise control. Many advances in information technology result in systems that enable a significant increase in the amount of information that is available for judgment and decision-making tasks at the problem solving level. Even the highest quality information, however, will generally be associated with considerable uncertainty, imprecision, and other forms of imperfections. Above all else, there is

a major need for information to be associated with context such that it becomes knowledge useful for judgment and choice. The contemporary use of information technology has led to and is expected to continue to lead to major organizational transformations in the future (Harrington 1991; Scott Morton 1991; Davenport 1993; Drucker 1995, 1998.

Cybernetics, Complex Adaptive Systems, and Systems Management

A human-machine cybernetic system may be defined as a functional synthesis of a human system and a technological system or machine. The interaction and functional interdependence between these two elements pre-dominantly characterize human-machine systems. The introduction of communication and control concerns results in a cybernetic system. All kinds of technological systems, regardless of their degree of complexity, may be viewed as parts of a human-machine cybernetic system: industrial plants, vehicles, manipulators, prostheses, computers or management information systems. A human-machine system may, of course, be a subsystem that is incorporated within another system. For example, a decision support system may be incorporated as part of a larger enterprise management, process control, or computer-aided design system that also involves human interaction. This use of the term human-machine cybernetic system corresponds, therefore, to a specific way of looking at technological systems through the integration of technological systems and human-enterprise systems, generally through a systems management or systems engineering process.

The overall purpose of any human-machine cybernetic system is to provide a certain function, product, or service with reasonable cost under constraint conditions and disturbances. This concept involves and influences the human, the machine, and the processes through which they function as an integrated whole. The primary inputs to a human-machine cybernetic system are a set of purposeful performance objectives that are typically translated into a set of expected values of performance, costs, reliability, and safety. Also, the design must be such that an acceptable level of workload and job satisfaction is maintained. It is on the basis of these that the human is able to perform the following activities (Sage 1992):

1. Identify task requirements, such as to enable determination of the issues to be examined further and the issues to be not considered;
2. Identify a set of hypotheses or alternative courses of actions which may resolve the identified issues to be resolved;
3. Identify the probable impacts of the alternative courses of action;
4. Interpret these impacts in terms of the objectives or inputs to the task;
5. Select an alternative for implementation and implement the resulting control;
6. Monitor performance such as to enable determination of how well the integrated combination of human and system are performing.

Many researchers have described activities of this sort in a number of frameworks that include behavioral psychology, organizational management, human factors, systems engineering, operations research and management science.

Many questions can be raised concerning the use of information for judgment and choice activities, as well as activities that lead to the physical control of an automated process. Any and all of these questions can arise in different application areas. These questions relate to the control of technological systems. They concern the degree of automation with respect to flexible task allocation. They also concern the design and use of computer-generated displays. Further, they relate to all kinds of human-computer interaction concerns, as well as management tasks at different organizational levels: strategic, tactical, and operational. For example, computer-based support systems to aid human performance continue to invade more and more areas of the engineering of systems: design, operation, maintenance, and management. The importance of augmenting hardware and micro-level programming aspects of system design to architectural and software systems management considerations is great. The integrated consideration of systems engineering and systems management for software productivity is expressed by the term software systems engineering (Sage and Palmer 1990).

Human tasks in human-machine cybernetic systems can be condensed into three primary categories: (1) controlling (physiological); (2) communicating

(cognitive), and (3) problem solving (cognitive) (Johannsen et al. 1983). In addition, there exists a monitoring or feedback portion of the effort that enables learning over time. Ideally, but not always, the humans involved learn well. There needs to be metalevel learning, or learning how to learn if improvements are to truly be lasting, as contrasted with only specific task performance learning. Associated with the rendering of a single judgment and the associated control implementation, the human monitors the result of the effect of these activities. The effect of present and past monitoring is to provide an experiential base for present problem conceptualization. In the categorization above, activities 1 through 4 may be viewed as problem (finding and) solving, activity 5 involves implementation or controlling, and activity 6 involves communications or monitoring and feedback in which responses to the question "How good is the process performance?" enables improvement and learning through iteration. Of course, the notion of information flow and communication is involved in all of these activities.

These three human task categories are fairly general. Controlling should be understood in a much broader sense than in many control theory studies. Controlling in this narrower sense includes open loop vs. closed-loop and continuous vs. intermittent controlling, as well as discrete tasks such as reaching, switching and typing. It is only through these physiological aspects of controlling that outputs of the human-machine cybernetic system can be produced. Controlling, in the sense of the cognitive ergonomic concerns that support human information processing and associated judgment and choice, is also included. Although human functions on a cognitive level can and do play a role in control implementation, their major importance occurs in problem solving activities. Tasks such as fault detection, fault diagnosis, fault compensation or managing, and planning are particularly important in problem solving. Fault detection concerns the identification of a potential difficulty concerning the operation of a system. Fault diagnosis is concerned with identification of a set of hypotheses concerning the likely cause of a system malfunction, and the evaluation and selection of a most likely cause. It is primarily a cognitive activity. Fault compensation or managing is concerned with solving problems in actual failure situations. This may occur through the use of rules that are based on past experience, and the updating of certain rules based on the results of their present application. It is accomplished with the objective of returning the overall system to a good operating state. Fault compensation or managing involves both cognitive and physiological activities. Planning is a cognitive activity concerned with solving possible future problems in the sense of mentally generating a sequence of appropriate alternatives. Appropriate planning involves the use of knowledge perspectives, knowledge principles, and knowledge practices (Sage 1992). They are based on experiential familiarity with analogous situations and are often expressed in the form of and through the use of skills, rules, and formal knowledge based reasoning efforts (Rasmussen 1986; Rasmussen et al. 1994). Human error issues are of particular importance, especially those concerned with the design of systems that cope with human error through avoidance and amelioration efforts (Reason 1990).

Many of these systems can only be described as complex. While some components of them may be naturally adaptive, they often need to be engineered to possess adaptive characteristics. The subject of complex adaptive systems is closely related to that of complexity theory. Complexity theory (Kaufman 1995; Axelrod 1997; Holland 1998) is a field of study that has evolved from five major knowledge areas: mathematics, physics, biology, organizational science, and computational intelligence and engineering. Fundamentally, a system is complex if it cannot be understood through simple cause-and-effect relationships or other standard methods of systems analysis. In a complex system, the interplay of individual elements cannot be reduced to the study of individual elements considered in isolation. Often, several different models of the complete system, each at a different level of abstraction, are needed.

There are several sciences of complexity, and they generally deal with approaches to understanding the dynamic behavior of units that range from individual organisms to the largest technical, economic, social, and political organizations. Often, such studies involve complex adaptive systems and hierarchical systems, are multidisciplinary in nature, and involve or are at the limits of scientific knowledge (Arthur 1994; Coveney and Highfield 1995; Arthur et al. 1997; Epstein 1997).

Complexity studies attempt to pursue knowledge and discover features shared by systems described as complex. These include studies such as complex adaptive systems, complex systems theory, complexity theory, dynamic systems theory, complex nonlinear systems, and computational intelligence. Many scientific studies, prior to the development of simulation models and complexity theory, involved the use of linear models. When a study resulted in anomalous behavior, the failure was often incorrectly blamed on noise or experimental error. It is now recognized that such errors may reflect inherent inappropriateness of linear models — and linear thinking. Meeting the modeling challenge is complicated by the fact that not all critical phenomena cannot be fully understood, or even anticipated, based on analysis of the decomposed elements of the overall system. Complexity not only arises from there being many elements of the system, but also from the possibility of collective behaviors that even the participants in the system could not have anticipated (Casti 1997).

Thus, many critical phenomena can only be studied once they emerge. In other words, the only way to identify such phenomena is to let them happen. The challenge is to create ways to recognize the emergence of unanticipated phenomena and be able to manage their consequences, especially in situations where likely consequences are highly undesirable. One measure of system complexity is the complexity of the simulation model necessary to effectively predict system behavior (Casti 1997). The more the simulation model must embody the actual system to yield the same behavior, the more complex the system. In other words, outputs of complex systems cannot be predicted accurately based on models with typical types of simplifying assumptions. Consequently, creating models that will accurately predict the outcomes of complex systems is very difficult. A model can be created, however, that will accurately simulate the processes the system will use to create a given output.

This awareness has profound impacts for organizational efforts. For example, it raises concerns related to the real value of creating organizational mission statements and plans with expectations that these plans will be inexorably executed and missions thereby realized. It may be more valuable to create a model of an organization's planning processes themselves, subject this model to various input scenarios, and use the results to generate alternative output scenarios. The question then becomes one of how to manage an organization where this range of outputs is possible.

Interestingly, most studies of complex systems often run completely counter to the trend toward increasing fragmentation and specialization in most disciplines. Complexity studies tend to reintegrate the fragmented interests of most disciplines into a common pathway. This needed transdisciplinarity (Wilson 1998) provides the basis for creating a cohesive systems ecology (Sage 1998) to guide the use of information technology for managing complex systems. Whether they be human-made systems, human systems, or organizational systems, the use of systems ecology could more quickly lead to organizing for complexity (McMaster 1996), and associated knowledge and enterprise integration.

An important aspect of complex systems is path dependence (Arthur 1994). The essence of this phenomenon begins with a supposedly minor advantage or inconsequential head start in the marketplace for some technology, product, or standard. This minor advantage can have important and irreversible influences on the ultimate market allocation of resources, even if market participants make voluntary decisions and attempt to maximize their individual benefits. Such a result is not plausible with classical economic models that assume that the maximization of individual gain leads to market optimization unless the market is imperfect due to the existence of such effects as monopolies. Path dependence is a failure of traditional market mechanisms and suggests that users are locked into a sub-optimal product, even though they are aware of the situation and may know that there is a superior alternative.

This type of path lock-in is generally attributed to two underlying drivers: 1) network effects, and 2) increasing returns of scale. Both of these drivers produce the same result, namely that the value of a product increases with the number of users. network effects, or network externalities, occur because the value of a product for an individual consumer may increase with increased adoption of that product by other consumers. This, in turn, raises the potential value for additional users. An example is the telephone, which is only useful if at least one other person has one as well, and becomes increasingly

beneficial as the number of potential users of the telephone increases.

Increasing returns of scale imply that the average cost of a product decreases as higher volumes are manufactured. This effect is a feature of many knowledge-based products where high initial development cost dominates low marginal production and distribution cost. Thus, the average cost per unit decreases as the sales volume increases and the producing company is able to continuously reduce the price of the product. The increasing returns to scale, associated with high initial development costs and the low sales price, create barriers against market entry by new potential competitors, even though they may have a superior product.

The controversy in the late 1990s over the integration of the Microsoft Internet Explorer with the Windows Operating System may be regarded as a potential example of path dependence, and appropriate models of this phenomenon can potentially be developed using complexity theory. These would allow exploration of whether network effects and increasing returns of scale can potentially reinforce the market dominance of an established but inferior product in the face of other superior products, or whether a given product is successful because its engineers have carefully and foresightedly integrated it with associated products such as to provide a seamless interface between several applications.

Information technology enables systems where the interactions of many loosely structured elements can produce unpredictable and uncertain responses that may be difficult to control. The challenge is to understand such systems at a higher level. Control is likely to involve design and manipulation of incentives to participate and rewards for collaborative behaviors. It may be impossible and probably undesirable to control behaviors directly. The needed type of control is similar to policy formulation. Success depends on efficient experimentation much more than possibilities for mathematical optimization due to the inherent complexities that are involved. Thus, insights from complexity theory may be brought to bear on these situations (Merry 1995).

Information access and utilization, as well as management of the knowledge resulting from this process, are complicated in a world with high levels of connectivity and a wealth of data, information, and knowledge. The underlying problem is the usually tacit assumption that more information is inherently good to have. What users should do with this information and how value is provided by this usage are seldom clear. The result can be large investments in information technology with negligible improvements of productivity (Harris 1994). One of the major needs in this regard is to support bilateral transformations between tacit and explicit knowledge (Nonaka 1994; Nonaka and Takeuchi 1995).

Prior to the development of simulation models and complexity theory, most studies involved use of linear models and assumed time-invariant processes (i.e., ergodicity). Most studies also assumed that humans use deductive reasoning and techno-economic rationality to reach conclusions. But, information imperfections and limits on available time often suggest that rationality must be bounded. Other forms of rationality and inductive reasoning are necessary.

There are a number of descriptive models of human problem solving and decision making. Generally, the appropriate model depends upon the contingency task structure, characteristics of the environment, and the experiential familiarity of humans with tasks and environment. Thus, the context surrounding information and the experiential familiarity of users of the information is most important. In fact, it is the use of information within the context of contingency task structures and the environment that results in the transformation from information to knowledge.

It is appropriate to interpret knowledge in terms of context and experience by sensing situations and recognizing patterns. Features similar to previously recognized situations can thus be discerned. The problem can then be simplified by using these to construct internal models, hypotheses, or schemata to use on a temporary basis. Simplified deductions are attempted based on these hypotheses and one acts accordingly. Feedback of results from these interactions enables more to be learned about the environment and the nature of the task at hand. Hypotheses are revised, reinforcing appropriate ones and discarding poor ones. This use of simplified models is a central part of inductive behavior (Holland et al. 1986).

Models of inductive processes can be constructed in the following way. A collection of generally heterogeneous agents is first determined. It is assumed that the agents are able to form hypotheses based on mental models or subjective beliefs. Further, each agent is assumed to monitor performance relative to a personal

set of belief models. These models are based on the results of actions, as well as prior beliefs and hypotheses. Through this iterative procedure, learning takes place as agents discern which hypotheses are most appropriate. Hypotheses, or models, are retained not because they are correct, but because they have worked in the past. Agents differ in their approach to problems and the way in which they subjectively converge to a set of useful hypotheses.

This process may be modeled as a complex adaptive system. As noted, models cannot be created that will accurately predict the outcomes of many complex systems. But, a model can often be created that will accurately simulate the processes the system uses to create outputs. The major constructs associated with such models are: the interactions and feedback relations between the various agents whose choices depend upon the decisions of others, and linearity and return to scale considerations. There are many implications associated with these models. Among them are questions of steady state versus continued evolutionary behavior, the nature and possibility of time-invariant processes (ergodicity), and questions of path dependence.

The Design of Cybernetic and Complex Adaptive Systems

All of this has major implications with respect to the design of systems for the human user and for associated cybernetic and complex adaptive systems as well. It requires, for appropriate system design, an understanding of human performance in problem solving and decision-making tasks. This understanding has to be at a descriptive level, predicting what humans will likely do in particular situations. It has to be at a normative level, understanding what would be best performance under restrictive axiomatic conditions that will generally not exist in practice. Also, this understanding has to be at a prescriptive level such that humans can be aided in various real-world cognitive tasks. This requires much attention to the evolutionary and emergent properties of systems.

Technological advances have changed and will continue to change the specific design requirements for human-machine cybernetic systems needed in any given application area. This is especially true due to the many advances made possible through modern information technologies, for industrial plants with integrated automated manufacturing capabilities, and for aids to cognitive activities in strategic planning, design, or operational activities. Office automation systems and information systems for observation, planning, executive support, management, and command and control tasks in business, defense, and medicine are similarly influenced by efforts in human-machine cybernetic and complex adaptive systems. These involve not only the operation of technological and management oriented information systems by highly skilled and knowledgeable personnel, but also systems that are intended for use by the less skilled. A major use for new generation systems is to provide computer assistance for the maintenance of existing systems and for the design of new systems of all types.

The methods and tools for supporting emergence of a theory of complex systems that will fully satisfy the requirements posed by systems that must intentionally operate satisfactorily at the edge of chaos will always be in a state of continuous evolution. There seems little question that the methods of operations research and management science, especially those associated with modeling and simulation of large systems, have and will play a major role in the theory of design of cybernetic and complex adaptive systems. Addressing the key challenges requires utilizing many of the concepts, principles, methods, and tools of OR/MS. In addition, it will require a new, broader perspective on the nature of information access and utilization, as well as knowledge management. Fortunately, OR/ MS is an inherently dynamic field of study. However, achieving the goal of cybernetic and complex adaptive system understanding and development capability will require much attention to the integration of OR/MS approaches with those in disciplines not often involved in OR/MS studies and the development of knowledge unity and integration perspectives.

Cycle

A path in a graph (network) joining a node to itself.

See

- ▶ Chain
- ▶ Path

Cyclic Queueing Network

A closed network of queues in which customer routing is serial.

See

- ▶ Networks of Queues
- ▶ Queueing Theory

Cyclic Service Discipline

When a congestion system with several different locations (service centers) of customers are served by a single service facility. For a given period of time determined by an a priori rule, the service process only works on customers from (at) a given location and then switches to the next group when the period is over.

See

- ▶ Queueing Theory

Cycling

A situation where the simplex algorithm cycles (circles) repeatedly through some sequence of bases and corresponding basic feasible solutions. This can occur at a degenerate extreme point solution where several bases correspond to the same extreme point.

See

- ▶ Anticycling Rules
- ▶ Degeneracy
- ▶ Linear Programming
- ▶ Simplex Method (Algorithm)

D

Dantzig-Wolfe Decomposition Algorithm

A variant of the simplex method designed to solve block-angular linear programs in which the blocks define subproblems. The problem is transformed into one that finds a solution in terms of convex combinations of the extreme points of the subproblems.

See

- ▶ Block-Angular System
- ▶ Decomposition Algorithms

Data Envelopment Analysis

William W. Cooper
The University of Texas at Austin, Austin, TX, USA

Introduction

DEA (Data Envelopment Analysis) is a data oriented approach for evaluating the performance of a collection of entities called DMUs (Decision Making Units) which are regarded as responsible for converting inputs into outputs. Examples of its uses have included hospitals and U.S. Air Force Wings, or their subdivisions, such as surgical units and squadrons. The definition of a DMU is generic and flexible. The objective is to identify sources and to estimate amounts of inefficiency in each input and output for every DMU included in a study. Uses that have been accommodated include: (i) discrete periods of production in a plant producing semiconductors in order to identify when inefficiency occurred; and (ii) marketing regions to which advertising and other sales activities have been directed in order to identify where inefficiency occurred. Inputs as well as outputs may be multiple and each may be measured in different units.

A variety of models have been developed for implementing the concepts of DEA, for example, the following dual pair of linear programming models:

$$\begin{aligned} \min\ & h_0 = \theta_0 - \varepsilon\left(\sum_{i=1}^{m} s_i^- + \sum_{r=1}^{s} s_r^+\right) \\ \text{subject to } & 0 = \theta_0 \mathrm{x_{i0}} - \sum_{\mathrm{j=1}}^{\mathrm{n}} \mathrm{x_{ij}}\,\lambda_{\mathrm{j}} - \mathrm{s_i^-} \\ & y_{r0} = \sum_{j=1}^{n} y_{rj}\,\lambda_j - s_r^+ \\ & 0 \le \lambda_j,\ s_r^+,\ s_i^- \end{aligned} \tag{1a}$$

and

$$\begin{aligned} \max\ & y_0 = \sum_{r=1}^{s} \mu_r\, y_{r0} \\ \text{subject to } & 1 = \sum_{\mathrm{i=1}}^{\mathrm{m}} \mathrm{v_i\, x_{i0}} \\ & 0 \ge \sum_{r=1}^{s} \mu_r y_{rj} - \sum_{i=1}^{m} v_i x_{ij} \\ & \varepsilon \le \mu_r,\ v_i \end{aligned} \tag{1b}$$

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

where x_{ij} = observed amount of input i used by DMU_j and y_{rj} = observed amount of output r produced by DMU_j, with $i = 1, \ldots, m$; $r = 1, \ldots, s$; $j = 1, \ldots, n$. All inputs and outputs are assumed to be positive. (This condition may be relaxed (Charnes et al. 1991).

Efficiency

The orientation of linear programming has changed here from ex-ante uses, for planning, and apply it to choices already made ex-post, for purposes of evaluation and control. To evaluate the performance of any DMU, (1) is applied to the input–output data for all DMUs in order to evaluate the performance of *each* DMU in accordance with the following definition:

> *Efficiency — Extended Pareto-Koopmans Definition* : Full (100%) efficiency is attained by any DMU if and only if none of its inputs or outputs can be improved without worsening some of its other inputs or outputs.

This definition has the advantage of avoiding the need for assigning a priori weights or other measures of relative importance to any input or output. In most management or social science applications, the theoretically possible levels of efficiency will not be known. For empirical use, the preceding definition is therefore replaced by the following:

> *Relative Efficiency*: A DMU is to be rated as fully (100%) efficient if and only if the performances of other DMUs do not show that some of its inputs or outputs can be improved without worsening some of its other inputs or outputs.

To implement this definition, it is necessary only to designate any DMU_j as DMU_0 with inputs x_{i0} and outputs y_{r0} and then apply (1) to the input and output data recorded for the collection of DMU_j, $j = 1, \ldots, n$. Leaving this $DMU_j = DMU_0$ in the constraints insures that solutions will always exist with an optimal $\theta_0 = \theta_0* \leq 1$. The above definition applied to (1) then gives

> *DEA Efficiency*: The performance of DMU_0 is fully (100%) efficient if and only if, at an optimum, both (i) $\theta_0* = 1$, and (ii) all slacks $= 0$ in (1a) or, equivalently, $\sum_{r=1}^{s} \mu_r^* y_{r0} = 1$ in (1b), where * represents an optimal value.

A value $\theta_0^* < 1$ shows (from the data) that a non-negative combination of other DMUs could have achieved DMU_0's outputs at the same or higher levels while reducing *all* of its inputs. Non-zero slacks similarly show where input reductions or output augmentations can be made in DMU_0's performance without altering other inputs or outputs. These non-zero slacks show where changes in *mixes* could have improved performance in each of DMU_0's inputs or outputs, while a $\theta_0^* < 1$ shows "technical inefficiency" in which *all* inputs could have been reduced in the same proportion. (This is a so-called input-oriented model. An output-oriented model can be similarly formulated by associating a variable φ_0 with all outputs to be maximized DMU_0. The measures are reciprocal, i.e., $\varphi_0^* \; \theta_0^* = 1$, so this topic is not developed here.)

Many applications to many different kinds of entities engaged in complex activities with no clearly defined bottom line have been reported in many publications by many different authors in many different countries. Examples include applications to schools (including universities), police forces, military units, and country performances (including United Nations evaluations of country performances). See, for example, Emrouznejad et al. (2008) who list more than 1,600 published papers by more than 2,500 different authors in more than 40 different countries. Also see Berber et al. (2011) and Cooper et al. (2009).

Farrell Measure

The scalar θ_0^* is sometimes referred to as the Farrell measure after M.J. Farrell (1957). Notice, however, that a value of $\theta_0^* = 1$ does not completely satisfy the above definition of Relative Efficiency if any of the associated slacks, s_i^{+*} or s_r^{+*}, in (1) are positive — because any such non-zero slack provides an opportunity for improvement which may be used without affecting any other variable, as should be clear from the primal problem which is shown in (1a).

There is a need to insure that an optimum with $\theta_0^* = 1$ and all slacks zero is not interpreted to mean that full (100%) efficiency has been attained when an alternate solution with $\theta_0^* = 1$ and some slacks positive is also available. To see how this is dealt with, attention is called to the fact that the slack variables s_i^- and s_r^+ in the objective of the primal (minimization) problem, (1a), are each multiplied by

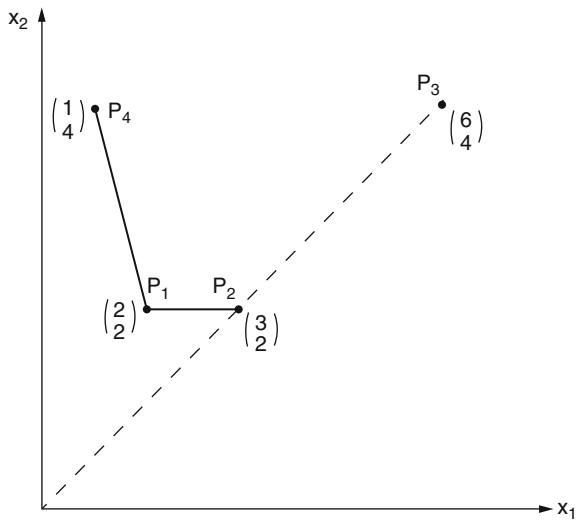
$\varepsilon > 0$ which is a non-Archimedean infinitesimal — the reciprocal of the "big M" associated with the artificial variables in ordinary linear programming — so that choices of slack values *cannot* compensate for any increase they might cause in θ_0. This accords pre-emptive status to the minimization of θ_0, and DEA computer codes generally handle optimizations in a two-stage manner which avoids the need for specifying ε explicitly. Formally, this amounts to minimizing the value of θ_0 in stage 1. Then one proceeds in a second stage to maximize the sum of the slacks with the condition $\theta_0 = \theta_0^*$ fixed for the primal in (1a). Since the sum of the slacks is maximized, one can be sure that a solution with all slacks at zero in the second stage means that DMU_0 is fully efficient if the first stage yielded $\theta_0^* = 1$.

N.B. Weak efficiency is another term used instead of Farrell efficiency when attention is restricted to (i) in DEA Efficiency above. It is also referred to as a measure of technical efficiency. However, when (1a) is used, this might be referred to as purely technical efficiency in order to distinguish these inefficiencies from the mix inefficiencies associated with changes in the proportions used that are then associated with non-zero slack. The term technical efficiency can then be used to comprehend both purely technical and mix inefficiencies as determined by reference to technical conditions without recourse to prices, costs, and/or subjective evaluations.

Example

Figure 1 is a geometric portrayal of four DMUs interpreted as points $P_1, \ldots, P_4$, with coordinate values corresponding to the amounts of two inputs which each DMU used to produce the same amount of a single output. P_3 is evidently inefficient compared to P_2 because it used more of both inputs to achieve the same output. In fact, its Farrell measure of inefficiency relative to P_2 can be determined via the formula

$$\theta_0 = \frac{d(0,\ P_2)}{d(0,\ P_3)} = \frac{\sqrt{3^2 + 2^2}}{\sqrt{6^2 + 4^2}} = \frac{1}{2},$$



Data Envelopment Analysis, Fig. 1 DEA efficiencies

where $d(.,.)$ refers to the Euclidean, or l_2, measure of distance.

Referred to as a radial measure of efficiency in the DEA literature, θ_0 is really a ratio of two distance measures, namely, the distance along the ray from the origin to the point being evaluated relative to the distance from the origin to the frontier measured along this same ray. This same value of θ_0 is obtained, and hence this same radial measure, by omitting the slacks and rewriting the primal problem in (1a) in the following inequality form,

$$\begin{aligned} &\text{minimize } \theta_0 \\ &\text{subject to} \\ &6\theta_0 \ \geq\ 2\lambda_1 + 3\lambda_2 + 6\lambda_3 + 1\lambda_4 \\ &4\theta_0 \ \geq\ 2\lambda_1 + 2\lambda_2 + 4\lambda_3 + 4\lambda_4 \\ &1 \ \leq\ 1\lambda_1 + 1\lambda_2 + 1\lambda_3 + 1\lambda_4 \\ &0 \ \leq\ \lambda_1,\ \ldots,\ \lambda_4, \end{aligned} \tag{2}$$

where the third constraint reflects the output $y = 1$ which was produced by each of these DMUs.

An optimum is achieved with $\theta_0^* = 1/2$, $\lambda_2^* = 1$ and this designates P_2 for the evaluation of P_3. However, it is also needed to take account of the slack possibilities. This is accomplished without specifying $\varepsilon > 0$ explicitly by proceeding to

a second stage by using the thus obtained value of θ_0^* to form the following problem:

$$\begin{aligned}
&\text{maximize } s_1^- + s_2^- + s^+ \\
&\text{subject to} \\
&0 = -6\theta_0 + 2\lambda_1 + 3\lambda_2 + 6\lambda_3 + 1\lambda_4 + s_1^- \\
&0 = -4\theta_0 + 2\lambda_1 + 2\lambda_2 + 4\lambda_3 + 4\lambda_4 + s_2^- \\
&-1 = -1\lambda_1 - 1\lambda_2 - 1\lambda_3 - 1\lambda_4 + s^+ \\
&0.5 = \theta_0 \\
&0 \le \lambda_1, \ldots, \lambda_4, s_1^-, s_2^-, s^+
\end{aligned} \tag{3}$$

Following through in this second stage, with $\theta_0^* = 0.5$, it can be found that $\lambda_2^* = 1$ and $s_1^{-*} = 1$, with all other variables zero. This solution is interpreted to mean that the evidence from other DMUs (as exhibited by P_1's performance) shows that P_3 should have been able (a) to reduce both inputs to one-half their observed values, as given by the value of θ_0, and should also have been able (b) to reduce the first input by the additional amount given by $s_1^{-*} = 1$.

This slack, $s_1^{-*} = 1$, represents the excess amount of the first input used by P_2, and it, too, must be accounted for if the above definition of relative efficiency is to be satisfied. In fact, using the primal in (1a) to evaluate P_2, it will be found that it is also inefficient with $\theta_1{}^* = 1$ and $\lambda^* = s_1^{-*} = 1$. The use of (1a) to determine whether the conditions (i) and (ii) for relative efficiency are satisfied has a further consequence in that it insures that only efficient DMUs enter into the solutions with positive coefficients in the basis sets that are used to effect efficiency evaluations. Computer codes that have been developed for DEA generally use this property to reduce the number of computations by identifying all such members of an optimal basis as efficient and, hence, not in need of further evaluation.

As can be seen from Fig. 1, P_1 dominates P_2 and hence also dominates P_3. Only P_1 and P_4 are not dominated and hence can be regarded as efficient when DEA is restricted to dominance, as in Bardhan et al. (1996). However, if an assumption of continuity is added, then the entire line segment connecting P_1 and P_4 becomes available for use in effecting efficiency evaluations. This line segment is referred to as the efficiency frontier. The term efficient frontier is appropriate because it is not possible to move from one point to another on the line connecting P_1 and P_4 without worsening one input to improve the other input.

Given the assumption of continuity, points not on the efficiency frontier are referred to it for evaluation. Even when not dominated by actually observed performances, the nonnegative combinations of λ_j^* and slack values will locate points on the frontier which can be used for effecting efficiency evaluations of any DMU in the observation set.

The following formulas, called the CCR projection formulas, may be used to move points up to the efficiency frontier:

$$\begin{cases} \hat{x}_{i0} = \theta_0^* \hat{x}_{i0} - s_i^{-*} \le \hat{x}_{i0}, & i = 1, \ldots, m \\ \hat{y}_{r0} = y_{r0} + s_r^{+*} \ge y_{r0}, & r = 1, \ldots, s \end{cases} \tag{4}$$

where each $(\hat{x}_{i0}, \hat{y}_{i0})$ represents a point on the efficiency frontier obtained from (x_{i0}, y_{r0}), DMU_0's observed values. The point on the efficiency frontier thus obtained from these CCR projections is the point used to evaluate (x_{i0}, y_{r0}), $i = 1, \ldots, m$; $r = 1, \ldots, s$, for any DMU_0.

Ratio Form Models

The name Data Envelopment Analysis is derived from the primal (minimization) problem (1a) by virtue of the following considerations. The objective is to obtain as tight a fit as possible to the input–output vector for DMU_0 by enveloping its observed inputs from below and its observed outputs from above. As can be seen from (1a), an optimal envelopment will always involve a touching of the envelopment constraints to at least one of DMU_0's inputs and one of its outputs.

The primal problem, (1a), is said to be in envelopment form. The dual problem, (1b), is said to be in multiplier form by reference to the values of μ and v as dual multipliers. The objective is to maximize y_0, which is called the virtual output. This maximization is subject to the condition that the corresponding virtual input is unity, that is, $\sum_{i=1}^{m} v_i x_{i0} = 1$, as given in the first constraint. The other constraints require that the virtual output cannot exceed virtual input for any of the DMU_j, $j = 1, \ldots, n$, that is,

$$\sum_{r=1}^{s} \mu_r y_{rj} \le \sum_{i=1}^{m} v_i x_{ij} \quad j = 1, \ldots, n.$$

Finally, the conditions $\mu_r, v_i \geq \varepsilon > 0$ mean that every input and every output is to be assigned "some" positive value in this "multiplier" form, where as previously noted, the value of ε need not be specified explicitly.

To add interpretive power for the use in DEA, all of the variables in (1b) are multiplied, the (dual) problem of (1a), by $t > 0$ and then introduce new variables defined in the following manner:

$$\mu_r = t\mu_r \geq t\varepsilon, \; v_i = tv_i \geq t\varepsilon, \qquad t = \sum_{i=1}^{m} tv_i \, x_{i0}. \tag{5}$$

Multiplying and dividing the objective of the dual problem in (1b) by $t > 0$ and then multiplying all constraints by t gives the following model, which accords a ratio form to the DEA evaluations:

$$\begin{aligned} \max \quad & \frac{\sum_{r=1}^{s} u_r \, y_{r\,0}}{\sum_{i=1}^{m} v_i \, x_{i0}} \\ \text{subject to} \quad & \frac{\sum_{r=1}^{s} \mathrm{u_r y_{rj}}}{\sum_{i=1}^{m} \mathrm{v_i \, x_{ij}}} \leq 1, \quad \mathrm{j} = 1, \ldots, \mathrm{n} \\ & \frac{u_r}{\sum_{i=1}^{m} v_i x_{i0}} \geq \varepsilon, \quad r = 1, \ldots, s \\ & \frac{v_i}{\sum_{i=1}^{m} v_i \, x_{i0}} \geq \varepsilon, \quad i = 1, \ldots, m. \end{aligned} \tag{6}$$

An immediate corollary from this development is

$$0 \leq \frac{\sum_{r=1}^{s} u_r^* y_{r0}}{\sum_{i=1}^{m} v_i^* x_{i\,0}} = \sum_{r=1}^{s} u_r^* y_{r0} = \theta_0^* \qquad -\sum_{i=1}^{m} s_i^{-*} + \sum_{r=1}^{s} s_r^{+*} \leq 1, \tag{7}$$

where "*" designates an optimal value. Thus, in accordance with the theory of fractional programming, as given in Charnes and Cooper (1962), the optimal values in (6) and (1b) are equal.

The formulation (6) has certain advantages. For instance, Charnes and Cooper (1985) used it to show that the optimal ratio value in (6) is invariant to the units of measure used in any input and any output and, hence, this property carries over to (1b). Equation 6 also add interpretive power and provide a basis for unifying definitions of efficiency that stretch across various disciplines. For instance, as shown in Charnes et al. (1978), the usual single-output to single-input efficiency definitions used in science and engineering are derivable from (6). It follows that these definitions contain an implicit optimality criterion. The relation of (6) to (4), established via fractional programming, also relates these optimality conditions to the definitions of efficiency used in economics. (See the above discussion of Pareto-Koopmans efficiency.) This accords a ratio form (as well as a linear programming form) to the DEA evaluations.

As (6) makes clear, DEA also introduces a new principle for determining weights. In particular the weights are not assigned a priori, but are determined directly from the data. A best set of weights is determined for each of the $j,\ldots, n$ DMUs to be evaluated. Given this set of best weights the test of inefficiency for any DMU_0 is whether any other DMU_j achieved a higher ratio value than DMU_0 using the latter's best weights [Care needs to be exercised in interpreting these weights, since (a) their values will in general be determined by reference to different collections of DMUs and (b) when determined via (1), allowance needs to be made for non-zero slacks. See the discussion in Charnes et al. (1989), where dollar equivalents are used to obtain a complete ordering to guide the use of efficiency audits by the Texas Public Utility Commissions].

DEA also introduces new principles for making inferences from empirical data. This flows from its use of n optimizations — to come as close as possible to *each* of n observations — in place of other approaches, as in statistics, for instance, which uses a single optimization to come as close as possible to all of these points. In DEA, it is also not necessary to specify the functional forms explicitly. These forms may be nonlinear and they may be multiple (differing, perhaps, for each DMU) provided they satisfy the mathematical property of isotonicity (Charnes et al. 1985).

Other Models

The models in (1) and (6) are a subset of several DEA models that are now available. Thus, DEA may be regarded as a body of concepts, and methods which unite these models and their uses to each other. These concepts, models and methods comprehend extensions to identify scale, and allocative and other inefficiencies.

By virtue of the already described relations between (6) and (1) the models are referred to as the CCR ratio model. Other models include the additive model, namely,

$$\begin{aligned} &\max \sum_{i=1}^{m} s_i^- + \sum_{r=1}^{s} s_r^+ \\ &\text{subject to} \\ &0 = \hat{x}_{i0} - \sum_{j=1}^{n} \hat{x}_{ij}\lambda_j - s_i^- \\ &\hat{y}_{r0} = \sum_{j=1}^{n} \hat{y}_{rj}\lambda_j - s_r^+ \\ &0 \le \lambda_j,\ s_r^+,\ s_i^-;\ \ \forall i, j, r \end{aligned} \tag{8}$$

for which the conditions for efficiency are given by Additive Model Efficiency: DMU_0 is fully (100%) efficient if and only if all slacks are zero — namely, $s_i^{-*}, s_r^{+*} = 0, \forall\, i, r$ in (8).

With the constraint $\sum_{j=1^n} \lambda_j = 1$ adjoined, the model (8) becomes "translation invariant." That is, as shown by Ali and Seiford (1990), the solution to (8) is not altered if the original data $(\hat{x}_{ij},\hat{y}_{rj})$ are replaced by new data

$$\begin{aligned} \hat{x}'_{ij} &= \hat{x}'_{ij} + d_i, \quad i = 1, \ldots, m \\ \hat{y}'_{rj} &= \hat{y}'_{rj} + c_r, \quad r = 1, \ldots, s \end{aligned} \tag{9}$$

where the d_i and c_r are arbitrarily constants. This property can be of value in treating negative data since most theorems in DEA assume that the data are positive or at least semi-positive. See Pastor (1996) for examples and extensions of the Ali-Seiford theorems. Theorems like the following from Ahn et al. (1988) relate the additive models to their CCR counterparts.

Theorem: A DMU_0 will be evaluated as fully (100%) efficient by the CCR model if and only if it is rated as fully (100%) efficient by the corresponding additive model.

Note, however, that the CCR and additive models use different metrics, so they need not identify the same sources and amounts of inefficiency in an inefficient DMU.

The additive model (8) can also be related to another class, called multiplicative models (Charnes et al. 1982). An easy way is to assume that the $(\hat{x}_{ij},\hat{y}_{rj})$ are stated in logarithmic units. Taking antilogs then gives

$$\begin{aligned} x_{i0} &= a_i^* \prod_{j=1}^{n} x_{ij}^{\lambda_j^*}, \quad i = 1, \ldots, m, \\ y_{r0} &= b_r^* \prod_{j=1}^{n} y_{rj}^{\lambda_j^*}, \quad r = 1, \ldots, s, \end{aligned} \tag{10}$$

where $a_i^* = e^{s-*i}$, $b_r^* = e^{s+*r}$, and the (x_{ij}, y_{rj}) are stated in natural units. Each x_{i0}, y_{r0} is thus generated by a Cobb-Douglas process with estimated parameters given by the starred values of the variables.

To relate these results to a ratio form for efficiency evaluation, the dual to (8) is written as

$$\begin{aligned} &\min \sum_{i=1}^{m} v_i \hat{x}_{i0} - \sum_{r=1}^{s} \mu_r \hat{y}_{r0} \\ &\text{subject to} \\ &\sum_{i=1}^{m} v_i \hat{x}_{ij} - \sum_{r=1}^{s} \mu_r \hat{y}_{rj} \ge 0, \quad j = 1, \ldots, n \\ &v_i,\ \mu_r \ge 1, \quad i = 1, \ldots, m; \quad r = 1, \ldots, s, \end{aligned} \tag{11}$$

where the $(\hat{x}_{ij}, \hat{y}_{rj})$ are stated in logarithmic units. Recourse to antilogarithms then produces

$$\begin{aligned} &\max \prod_{r=1}^{s} \hat{y}_{r0}^{\mu r} \Big/ \prod_{i=1}^{m} \hat{x}_{i0}^{v_i} \\ &\text{subject to} \\ &\prod_{r=1}^{s} \hat{y}_{rj}^{\mu r} \Big/ \prod_{i=1}^{m} \hat{x}_{i0}^{v_i} \le 1, \quad j = 1, \ldots, n \\ &v_i, \mu_r \ge 1, \quad i = 1, \ldots, m; \quad r = 1, \ldots, s, \end{aligned} \tag{12}$$

and we once again make contact with a ratio form for effecting efficiency evaluations.

To obtain conditions for efficiency, antilogs to (8) are applied and (10) is used to obtain

$$\max \frac{\prod_{r=1}^{s} e^{s_r^{+*}}}{\prod_{i=1}^{m} e^{-s_i^{-*}}} = \frac{\prod_{r=1}^{s}\prod_{j=1}^{n} y_{rj}^{\lambda_j^*}/y_{r0}}{\prod_{i=1}^{m}\prod_{j=1}^{n} x_{ij}^{\lambda_j^*}/x_{i0}} \geq 1. \qquad (13)$$

The lower bound on the right is obtainable if and only if all slacks are zero. Thus the efficiency conditions for the multiplicative model are the same as for the additive model.

An interpretation of (13) can be secured by noting that

$$\left(\prod_{j=1}^{n} y_{rj}^{\lambda_j^*}\right)^{1\Big/\sum_{j=1}^{n}\lambda_j^*}, \quad \left(\prod_{j=1}^{n} x_{ij}^{\lambda_j^*}\right)^{1\Big/\sum_{j=1}^{n}\lambda_j^*}$$

represent weighted geometric means of outputs and inputs, respectively. Thus (13) is a ratio of the product of weighted geometric totals relative to the outputs and inputs which each of these expressions is evaluating.

It is necessary to note that the results in (13) are not units invariant (i.e., they are not dimension free in the sense of dimensional analysis) except in the case of constant returns to scale (see Thrall, 1996). This property, when wanted, can be secured by adjoining $\sum_{j=1^n}\lambda_j = 1$ to (8). See also Charnes et al. (1983). To conclude this discussion it is noted that the expression on the left of (13) is simpler and easier to interpret and the computations from (8) are straightforward.

The class of multiplicative models has not been much used, possibly because other models are easier to comprehend. Even allowing for this, however, they have potentials for use either on their own or in combination with other DEA models as when, for instance, returns to scale characterization are needed that differ from those which are available from other types of DEA models. See Banker and Maindiratta (1986) for further discussion of such uses.

Extensions and Uses of Dea Models

1. *Returns to Scale* — There is an extensive literature on returns to scale and their uses in DEA which reflects two different approaches. One approach, due to Färe et al. (1985, 1994) proceeds in an axiomatic manner and employs only radial measures. The other approach is based on mathematical programming. Conceptualized by Banker et al. (1984), it was subsequently ex-tended (and made wholly rigorous) by Banker and Thrall (1992). As might be expected, equivalences between the two approaches have been established in (among other places) Banker et al. (1996). See also Banker et al. (1998).
2. *Returns to Scope* — Partly because of difficulty in assembling data in pertinent forms, the literature on returns to scope is relatively sparse in DEA. Indeed, a bare beginning has been made in Chapter 10 of Färe et al. (1994).
3. *Assurance Regions and Allocative Inefficiency* — Many other developments have occurred and continue to occur. Thompson, Dharmapala and Thrall and their associate introduced the now widely used concept of assurance regions (Thompson et al. 1986; Dyson and Thanassoulis, 1988). This approach uses a priori knowledge to set upper and lower bounds on the values of the multiplier variables in DEA models like (1b). This can alleviate problems encountered in treating allocative or price efficiency either because (i) exact data on prices, costs, etc., are not available, or (ii) because the presence of wide variations in these data make the use of exact value a questionable undertaking. See Schaffnit et al. (1997), where limiting arguments are used to establish an exact relation between allocative efficiency and the bounds used in assurance region approaches.
4. *Cone Ratio Envelopments* — In a similar spirit, but in a different manner, Charnes et al. (1990) and their associates developed what they refer to as a cone-ratio envelopment approach. In contrast to the assurance region treatments of bounds on the variables, these cone-ratio approaches utilize a priori information to adjust the data. This makes it possible to take account of complex (multiple) considerations that might otherwise be difficult to articulate. See Brockett et al. (1997), who show how to implement the Basle Agreement, which was recently adopted by U.S. bank regulators to treat multiple risk factors in banking by adjusting the data reported in the FDIC call reports. These regulations are rigid and ill-fitting, so Brockett

et al. (1997) provide an alternative Cone-ratio envelopment approach which uses results from excellent banks (that are also found to be efficient) to adjust the call-report data for other banks in a use of DEA to effect such risk-adjusted evaluations.

5. *Exogenous and Categorical Variables* — Other important developments include methods for treating input or output values which are exogenously fixed for some, or all, DMUs. Developed by Banker and Morey (1986a) for treating demographic variables as important inputs in different locations for a chain of fast food outlets, these methods have found widespread use in many other applications. Similar remarks apply to the Banker and Morey (1986b) introduction of methods for treating categorical (classificatory) variables in work which has since been modified and extended by other authors; see Neralić and Wendell (2000).
6. *Statistical Treatments* — Various attempts have recently been made to join statistical and probabilistic characterizations to the deterministic models and methods of inference in DEA. For instance, using relatively mild postulates, Banker (1993) has shown that (i) DEA estimators of θ_0^* are statistically consistent; (ii) DEA estimates maximize the likelihood of obtaining the corresponding true values; and (iii) these properties hold under fairly general structures that do not require assumptions about the parametric forms of the probability density functions. See pages 272–275 in Banker and Cooper (1994) for a succinct discussion. See also Korostelev et al. (1995), who show that the rates of convergence are slow.

   Simar and Wilson (1998) utilize bootstrap procedures to study sampling properties of the efficiency measures in DEA. Unlike Banker, who restricts his analysis to the single output case, this bootstrap approach accommodates multiple outputs as well as multiple inputs. Omitted, however, is any treatment of nonzero slacks. Brockett and Golany (1996) also approach the topic of statistical characterizations by means of Mann–Whitney rank order statistics, but do not note that need for explicitly stating a ranking principle. This is needed because (as noted above) the DEA efficiency scores are generally determined relative to different reference sets (or peer groups) of efficient DMUs. (For a discussion of how this problem is treated for the efficiency audits conducted by Texas Public Utility Commission, see Charnes et al. 1989).
7. Probabilistic Models — Alternate approaches via chance constrained programming were initiated by Land et al. (1994) and have been ex-tended by others to include the use of joint chance constraints in addition to the conditional chance constraints used by Land, Lovell and Thore (Olesen and Petersen 1995; Cooper et al. 1998). Of special interest is the use of chance constraints to obtain a satisficing approach for efficiency evaluation, as in Cooper et al. (1996), where the term satisficing is used in the sense of H.A. Simon's (1957) behavioral characterizations in terms of (i) achievement of a satisfactory level of efficiency, and (ii) a satisfactory probability (=chance) of achieving this level. Finally, allowance is also made for situations in which these levels or probabilities may need to be revised because the data show that they are not possible of attainment.
   Unlike the statistical characterizations described in item 6, these chance constrained programs generally require knowledge of the parameters as well as the forms of the probability functions so that here, too, there is more work to be done. See Jagannathan (1985) for a start.
8. *Cross-Checking* — As noted in the earlier discussions, the inference principles in DEA differ from those in statistics. This suggests additional possibilities for their joint use. One such possibility is to use the two approaches as cross checks on each other to help avoid what is referred to as methodological bias in Charnes et al. (1988). See also Ferrier and Lovell (1990).
9. *Complementary Uses* — Another possibility is to use statistics and DEA in a complementary manner. An example is provided by Arnold et al. (1996), who applied this strategy in a two-stage manner to a study of Texas public schools as follows. At stage 1, DEA is used to identify efficient schools; then, at stage 2, these results are incorporated as dummy variables in an OLS (Ordinary Least Squares) regression. This yielded very satisfactory results on data which had previously yielded unsatisfactory results with an OLS regression. A subsequent simulation study by Bardhan et al. (1998)

compares this approach not only to OLS but also to stochastic frontier regressions (i.e., regressions which apply statistical principles to obtain frontier estimates for efficiency evaluations). Using observations that reflected mixtures of efficient and inefficient performances the OLS and SF approaches always failed to provide correct estimates whereas, with only one minor exception, the complementary two-stage use of DEA and statistics always yielded estimates that did not differ significantly from the true parameter values.

Sources and References

As the above discussions suggest, many important developments have been effected in DEA since its initiation by Charnes et al. (1978). These developments have occurred pari passu with numerous and widely varied applications of DEA which are being reported from many different parts of the world. See the bibliography by Seiford (1994). For a comprehensive text, see Cooper et al. (1999).

Data Mining

Syam Menon[1] and Ramesh Sharda[2]
[1]The University of Texas at Dallas, Richardson, TX, USA
[2]Oklahoma State University, Stillwater, OK, USA

Introduction

When Wal-Mart installed their 24 terabyte data warehouse, it was among the largest in the world. Just a few years later, they were adding over a billion rows of data a day (Babcock 2006), and operating a 5 petabyte database (Lai 2008). An even more striking example is eBay, which started with a 14 terabyte database in 2002. It has since been adding over 40 terabytes of auction and purchase data every day into a data warehouse that is expected to exceed 20 petabytes by 2011. Clearly, as the cost of capturing data has decreased and easier-to-use data capture tools have become available, the volumes of data being accumulated have grown at a very rapid pace. Technological developments, with the evolution of the Internet playing a fundamental role, have enabled an increase in the volume of traditional data being recorded. Further, such developments have made possible the capture of information in far greater detail than ever before (based on barcodes or RFID, for example) and often of information that was not easily recordable before, such as eye or mouse movements.

What is Data Mining?

The availability of large data repositories has resulted in significant developments in the methodologies to analyze them, both in terms of the technology available for analysis, and in terms of its mainstream acceptance. From what was a relatively esoteric technology at the close of the 20th century, data mining – defined succinctly as "the science of extracting useful information from large data sets" (Hand et al. 2001) – has developed into a powerful set of tools indispensable to most organizations. In fact, it is gradually morphing into a key component of the merger of quantitative techniques into a new label called business analytics.

Many of the techniques used in data mining have their roots in traditional statistics, artificial intelligence, and machine learning. Developments in data mining techniques went hand-in-hand with developments in data warehousing and online analytical processing (OLAP). From the early 1990s when data mining started being viewed as a viable business solution, the cost of computing has dropped steadily, while processing power has increased. This made the benefits of data mining apparent, and triggered many companies to start using it regularly.

Commercial applications of data mining abound. A 2010 poll of data miners (conducted by KDNuggets) listed customer relations management, banking, healthcare, and fraud detection as the top four fields where data mining is applied. It is also commonly used in finance, direct marketing, insurance, and manufacturing. In fact, it has become common practice in almost every industry to discern new knowledge from data; only the extent of penetration varies across industries.

This is, of course, in addition to the vast quantities of data collected in the non-business world. It has found application in disciplines as varied as astronomy, genetics, healthcare, and education, just to name a few. The U.S. Department of Homeland Security applies data mining for a variety of purposes, including the comparison of "traveler, cargo, and conveyance information against intelligence and other enforcement data by incorporating risk-based targeting scenarios and assessments," and "to improve the collection, use, analysis, and dissemination of information that is gathered for the primary purpose of targeting, identifying, and preventing potential terrorists and terrorist weapons from entering the United States" (DHS 2009).

The availability of new types of data has opened up additional opportunities for selective extraction of useful information. Data originating from the Web can be mined based on content, network structure, or usage (e.g., when was a page used and by whom). There has been considerable interest in the mining of text from a variety of perspectives – to filter e-mail, to gain intelligence about competitors, to analyze the opinions of movie viewers to better understand movie reviews, as well as the mining of social network data both in terms of user behaviors and networks, including text mining of comments. The analysis of audio and video files is another difficult but promising

avenue for data mining. Speech recognition technologies have improved significantly. But, audio mining goes much further by providing users the ability to search and index the digitized audio content in a variety of contexts like news and webcasts, recorded telephone conversations, office meetings, and archives in libraries and museums.

How Does Data Mining Work?

Most of the general ideas applicable to modeling of any kind hold true for data mining as well. To work effectively, data mining requires clearly stated objectives and evaluation criteria. The process (often referred to as the Knowledge Discovery in Databases – or KDD – process) entails various critical steps. All data need to be cleaned to eliminate noise and correct errors. As data usually come from multiple, heterogeneous sources, there has to be a logical process of data integration. Once an objective has been identified for analysis, all appropriate data needs to be retrieved from the storage warehouse(s). If necessary, extracted data may need to be transformed into a form amenable for mining. Once all these preprocessing steps are completed, relevant data mining techniques can be applied. As with any analysis technique, the output from the mining process usually needs to be interpreted by the analyst after imposing as much domain knowledge as possible to intelligently glean useful information. Any model that is built should be tested and validated before putting to full use. Additionally, the KDD process has to be iterative for it to be beneficial. The knowledge discovered through mining can be used to obtain feedback from the user which in turn can be used to improve the mining process.

Data mining tasks fall into two main groups – descriptive tasks that characterize properties of the data being analyzed, and predictive tasks which make predictions about new data points based on inferences made from existing data. Data mining algorithms traditionally fall into one of three categories — classification and prediction, clustering, and association discovery. Other functionalities like data characterization and outlier analysis are also common, as are applications that form key components of recommender systems. Data visualization plays an important role in many of these techniques by guiding the users in the right direction. Some of these techniques are described briefly below.

Classification. Classification, or supervised induction, is perhaps the most common of all data mining activities. The objective of classification is to analyze the historical data stored in a database and to automatically generate a model that can predict future behavior. This induced model consists of generalizations over the records of a training data set, which help distinguish predefined classes. The hope is that this model can then be used to predict the classes of other unclassified records. When the output variable of interest is categorical, the models are referred to as classifiers, while models where the output variable is numerical are called prediction models.

Tools commonly used for classification include neural networks, decision trees, and if-then-else rules that need not have a tree structure. Statistical tools like logistic regression are also commonly used. Neural networks involve the development of mathematical structures with the ability to learn. They tend to be most effective where the number of variables involved is large and the relationships between them too complex and imprecise. It can easily be implemented in a parallel environment, with each node of the network doing its calculations on a different processor. There are disadvantages as well. It is usually very difficult to provide a good rationale for the predictions made by a neural network. Also, training time on neural networks tends to be considerable. Further, the time needed for training tends to increase as the volume of data increases, and in general, such training cannot be done on very large databases. These and other factors have limited the acceptability of neural networks for data mining.

Decision trees (DTs) classify data into a finite number of classes, based on the values of the variables. DTs are comprised of essentially a hierarchy of if-then statements and are thus significantly faster than neural nets. Logistic regression models are used for binary classification, with multinomial logistic models being used if there are more than two output categories.

Clustering. Most clustering algorithms partition the records of a database into segments where members of a segment share similar qualities. In fact, clustering is sometimes referred to as unsupervised classification. Unlike in classification, however, the clusters are unknown when the algorithm starts. Consequently,

before the results of clustering techniques are put to actual use, it might be necessary for an expert to interpret and potentially modify the suggested clusters. Once reasonable clusters have been identified, they could be used to classify new data. Not surprisingly, clustering techniques include optimization; we want to create groups, which have maximum similarity among members within each group and minimum similarity among members across the groups. Another common application is market basket analysis.

Association Discovery. A special case of association rule mining looks at sequences in the data. Sequence discovery has many applications, and is a significant sub-field in itself. It can be to conduct temporal analysis to identify customer behavior over time, to identify interesting genetic sequences, for website re-design, and even for intrusion detection.

Visualization. The insights to be gained from visualizing the data cannot be over-emphasized. This holds true for most data analysis techniques, but is of special relevance to data mining. Given the sheer volume of data in the databases being considered, visualization in general is a difficult endeavor. It can be used, however, in conjunction with data mining to gain a clearer understanding of many underlying relationships.

Recommender Systems. Many companies claim that a substantial portion of their revenues are a result of effective recommendations. Among the better known examples are Amazon.com, which was one of the earlier proponents of recommender systems, and Netflix, which claims that "roughly two-thirds of the films rented were recommended to subscribers by the site" (Flynn 2006). The impact and importance of a well implemented recommendation system is exemplified by the fact that Netflix offered a million-dollar prize for anyone who could improve their recommendation accuracy by at least 10%. A variety of techniques exist for making recommendations, with user and item based collaborative filtering being the most common.

Other Relevant Aspects

Software. There are many large vendors of data mining software. Some of the key commercial packages include SAS Enterprise Miner, IBM SPSS Modeler (Formerly SPSS Clementine), Oracle, DigiMine, Microsoft SQL Server, SAP Business Objects. Weka is a well reputed freeware out of The University of Waikato in New Zealand. Another open source data mining software is Rapid Miner.

Privacy. Data mining has been restricted in its impact due to privacy concerns. In particular, in privacy concerns when applying data mining to healthcare data. A contested court case concerns the mining of physicians' prescription history to increase drug sales; some states are trying to limit access to this information (Field 2010). The fundamental issue underlying these concerns relate to the intent behind data collection. For example, while consumers explicitly agree to the use of data collected for bill payment for that specific purpose, they may not know or want to agree to the use of their data for mining – that would go beyond the original intent for which the data were acquired.

Another area of data mining privacy concerns counterterrorist information Claburn (2008). A report dealing with the balance between privacy and security by the National Research Council recommends that the U.S. government rethink its approach to counterterrorism in light of the privacy risks posed by data mining.

Although some work has been done to incorporate privacy concerns explicitly into the mining process, this is still a developing field. In all likelihood, the matter of privacy in the context of data mining will be an issue for some time. A simple solution is unlikely. These issues will probably be resolved only through a blend of legislation and additional research into privacy preserving data mining.

The Role of Operations Research

Data mining algorithms are a heterogeneous group, loosely tied together by the common goal of generating better information. Operations research is concerned with making the best use of available information. By selecting the appropriate definition of information, operations research has been playing a significant role on both sides of the data mining engine. Formulations for clustering and classification were introduced in the 1960s and 70s (Ólafsson 2006). Nonlinear programming solution techniques have been adapted for faster training in neural network applications. Scalability, the ability to deal with

large amounts of data, is a difficult and important issue in data mining, one in which OR could play a significant role.

The lack of reliable data (or of the data itself) is a common problem faced by operations researchers trying to get a good model to work in the real world. This problem becomes more acute when data needs to be deciphered from terabytes of stored information. Data mining tools make accessing and processing the data easier and may provide more reliable data to the OR modeler. There are opportunities for operations research to be applied at a more fundamental level as well. Ultimately, as with any analysis tool, the outputs of data mining models are only as good as the inferences the analyst can make from them. OR techniques can be of assistance in making the best use of the outputs obtained. For example, research has been conducted to improve recommendations by combining information from multiple association rules, and to provide the best set of recommendations to maximize the likelihood of purchase. Similarly, combining information on prior purchase histories and revenue optimization models enables a new blend of practical business decision making. As noted, this integration of data mining and optimization has been labeled business analytics. IBM and other major vendors are developing new business groups focused on analytics that arise from combinations of organizations in optimization and data mining (Turban et al. 2010, pp. 78).

Concluding Remarks

By detecting patterns hitherto unknown, data mining techniques could suggest new modes to pursue old objectives. They could even allow the formulation of better, more sophisticated models in the wake of new information. In general, the gains to be made from exploiting newly discovered information are significantly higher than the marginal improvements that can be made by improving existing solution procedures. As the volume and types of data being collected increase, so will the need for better tools to analyze the data. Consequently, the future of data mining seems to be full of possibilities. The enthusiasm for discovering new information, however, needs to be tempered with the need to address privacy concerns, as not doing so could have long term repercussions on the parties involved.

Data Warehousing

Paul Gray
Claremont Graduate University, Claremont, CA, USA

Introduction

The data warehouse is one of the key information infrastructure resources for Operations Researchers. Its difference from the conventional transactional database, which is used to keep track of individual events, is shown in Table 1.

The typical transaction database contains details about individual transactions such as the purchase of merchandise or individual invoices sent or paid.

Data Warehousing, Table 1 Data warehouse vs. transaction database

Data Warehouse	Subject oriented	Integrated	Time-variant	Non-volatile
Transaction Database	Transaction oriented	Un-integrated	Current status	Changes as trans- actions occur

Transactional databases are concerned with operations while data warehouses are organized by subject. For example, operational data in a bank focuses on transactions involving loans, savings, credit cards, and trust accounts, while the data warehouse is organized around customer, vendor, product, and activity history.

The continually changing transactional data is not in the form needed for planning, managing, and analyzing. That is where the data warehouse comes in.

The classic data warehouse is defined as "a subject oriented, integrated, non-volatile, time variant, collection of data to support management's decisions" (Inmon 1992, p. 29).

The characteristics of the data warehouse that were summarized in Table 1 are given in more detail in Table 2.

In addition, the characteristics of the data itself are different, as shown in Table 3.

Data warehouses are really databases that provide both aggregated and detailed data for decision making. They are usually physically separated from both the organization's transaction databases and its operational systems.

Note that data normalization, which is used in transactional databases, makes sure that an individual data point appears once and only once. Normalization is not required conceptually in data warehouses. Some data warehouse designs, however, do normalize their data.

Data Warehousing, Table 2 Data warehouse characteristics

Subject orientation	Data are organized by how users refer to it, not by client
Data Integration	Data are organized around a common identifier, consistent names, and the same values throughout. Inconsistencies are removed.
Time	Data provide time series and focus on history, rather than current status.
Non-volatile	Data can be changed only by the upload process, not by the user.

Data Warehousing, Table 3 Characteristics of data in the warehouse

Summarized	In addition to current operational data when needed, data summaries used for decision making are also stored.
Larger database	Time series implies much more data is included.
Not normalized	Data can be redundant.
Metadata	Includes data about how the data is organized and what it means.
Sources of input data	Data comes from operational systems

Flow of Data

The flow of data into and out of the data warehouse follows these steps:

1. Obtain inputs
2. Clean inputs
3. Store in the warehouse
4. Provide output for analysis

Inputs to the data warehouse are the first step in what is called the extract, transform, and load process (ETL). Data sources, often from what are called legacy systems, push data to the warehouse rather than the warehouse pulling data from the sources. The sources send updates to the data warehouses at pre-specified intervals. This operation is performed on a fixed schedule where the interval between updates can range from nearly real time to once a day or longer, depending on the source.

Each source may have its own convention for what to call things and may even use different names and/or different metrics. For example, different transactional databases may store gender as (m, f), (1, 0), (x, y), (male, female) or may have different names for the same person (e.g., S. Smith, Sam Smith, and S. E. Smith). To overcome inconsistencies and to make

sure that users see only one version of the truth, data cleansing is performed by the warehouse on the input.

Data cleansing involves changing the input data so that it meets the warehouse's standards. Specialized software (usually referred to as ETL) makes the input data extracted from the sources consistent (e.g., in format, scaling, and naming) with the way data is stored in the warehouse. For example, the warehouse standardizes on one of the formats for gender and translates all other versions to the standard. Transformation uses metadata (i.e., data about the data) to accomplish this. The data are loaded (i.e., stored) in the warehouse only after they are cleansed. The goal is to establish a single value of the truth within the warehouse.

The data warehouse is used for analytics and routine reporting. Both create information useful to managers and professionals. Analytics refers to using models and performing computations on the data. Routine reporting refers to creating, documents, tables, and graphics, usually on a repetitive schedule. Routine outputs include dashboards (which mostly present status), scorecards (which show how well goals are being met), and alerts (which notify managers when current values are outside prescribed limits).

What is in the Data Warehouse

The data warehouse contains not only the current detail data that was transferred from the legacy systems, but also lightly summarized or highly summarized data, as well as old detail data. Metadata are usually also stored in the data warehouse.

The current detail data reflects the most recent happenings and is usually stored on disk. Detail data is voluminous and is stored at higher levels of granularity. Granularity refers to the level of detail provided in the data warehouse. The more detail provided, the higher the level of granularity. The highest level is transaction data such as is required for data mining. For decision support, analysis, and planning, the level of granularity can be much lower. Granularity is an important trade-off because the higher the level of granularity, the more data must be stored, the greater the level of detail available, and the more computing needs to be done, even for problems that do not use that level of granularity. For example, if a gasoline company records every motorist's stop at its stations, it can use the credit transaction to understand its customers detailed buying patterns. For total sales by station, that level of granularity is not needed.

Lightly summarized data is generally used at the analyst level, whereas highly summarized data (which is compact and easily accessible) is used by senior managers. The choice of summarization level involves tradeoffs because the more highly summarized the data, the more the data is actually accessed and used, the quicker it is to retrieve, but the less detail is available for understanding it. One way to speed query response time is to pre-calculate aggregates which are referred to often, such as annual sales data.

To keep storage requirements within reason, older data are moved to lower cost storage with much slower data retrieval. An aging process within the data warehouse is used to decide when to move data to mass storage.

Metadata contains two types of information:

1. What the user needs to know to be able to access the data in the warehouse. It tells the user what is stored in the warehouse and where to find it.
2. What information systems personnel need to know about how data is mapped from operational form to warehouse form, i.e., what transformations occurred during input and the rules used for summarization.

Metadata keeps track of changes made converting, filtering, and summarizing data, as well as changes made in the warehouse over time, e.g., data added, data no longer collected, and format changes.

Warehouse Data Retrieval and Analysis

The data stored in the data warehouse are optimized for speedy retrieval through on-line analytical processing (OLAP). The retrieval methods depend on the data format. The three most common are:

- Relational OLAP (ROLAP), which works with relational databases
- Multidimensional OLAP (MOLAP) for data stored in multi-dimensional arrays
- Hybrid OLAP (HOLAP) which works with both relational and multidimensional databases.

OLAP involves answering multidimensional questions such as the number of units of Product

A sold in California at a discount to resellers in November (i.e., product, state, terms of sale, customer class, time).

To enable relational databases (that store data in two dimensions) to deal with multidimensionality, two types of tables are introduced: fact tables that contain numerical facts, or dimension tables that contain pointers to the fact tables and show where the information can be found. A separate dimension table is provided for each dimension (e.g., market, product, time). Fact tables tend to be long and thin and the dimension tables tend to be small, short, and wide. Because a single fact table is pointed to by several dimension tables, the visualization of this arrangement looks like a star and hence is called a star schema. A variant, used when the number of dimensions is large and multiple fact tables share some of the same dimension tables, is called a snowflake schema.

Multidimensionality allows analysts to slice and dice the data, i.e., to systematically reduce a body of data into smaller parts or views that yield more information. Slice and dice is also used to refer to the presentation of warehouse information in a variety of different and useful ways.

Why a Separate Warehouse?

A fundamental tenet of data warehouses is that their data are separate from operational data. The reasons for this separation are:

Performance. Requests for data for analysis are not uniform. At some times, for example, when a proposal is being written or a new product is being considered, huge amounts of data are required. At other times, the demand may be small. The demand peaks create havoc with conventional on-line transaction systems because they slow them down considerably, keeping users (and often customers) waiting.

Data Access. Analysis requires data from multiple sources. These sources are captured and integrated by the warehouse.

Data Formats. The data warehouse contains summary and time-based data as well as transaction data. Because the data are integrated, the information in the warehouse is kept in a single, standard format.

Data Quality. The data cleansing process of ETL creates a single version of the truth.

Other Forms of Data Warehouses

As organizations found new ways of using the warehouse, they created specialized forms for specific uses. Among these are:

- Data marts
- Operational data stores
- Real-time warehouses
- Data warehouse appliances
- Data warehouses in the cloud
- Separate data warehouses for casual and power users

Data marts are a small-scale version of a data warehouse that include all the characteristics of an enterprise data warehouse, but are much smaller in size and cost. Data marts can be independent or dependent.

- Independent data marts are typically stand-alone units used by departments or small strategic business units that often support only specific subject areas. A data mart is appropriate if it is the only data warehouse for a small or medium sized firm. Multiple independent data marts become a problem rather than a solution if they differ from department to department. Integrating them so that there is only a single value of the truth throughout the organization is difficult, particularly if a comprehensive data warehouse is later attempted.
- Dependent data marts, such as those used by analytics groups, contain a subset of the warehouse data needed by a particular set of users. To maintain a single value of the truth, care is taken that the dependent data mart does not change the data from the warehouse.

An Operational Data Store (ODS) is a data warehouse for transaction data. It is a form of data warehouse for operational use. The ODS is used where some decisions need to be made in near real-time and require the characteristics of a warehouse (e.g., clean data). The ODS is subject oriented and integrated like the warehouse but, unlike the data warehouse, information in an ODS can be changed and updated rather than retained forever. Thus, an ODS contains current and near-current information, but not much historical data.

When data moves from legacy systems to the ODS, the data are re-created in the same form as in the warehouse. Thus, the ODS converts data, selects among sources, may contain simple summaries of the

current situation for management use, alters the key structures and the physical structure of the data, as well as its internal representation. Loading data into a data warehouse from an ODS is easier than loading from individual legacy systems, because most of the work on the data has been performed. It contains much less data than a data warehouse but also includes some that is not stored in the data warehouse. The ODS is usually loaded more frequently by data sources than the warehouse to keep it much more current. For example, the Walmart ODS receives information every 15 minutes.

The real-time data warehouse is used to support ongoing analysis and actions. A form of operational data store, real time data warehouses are closely tied to operational systems. They hold detailed, current data and try to use even shorter times between successive loadings than operational data stores. With these data warehouses, enterprises can respond to customer interactions and changing conditions in real time. For example, credit card companies use it to detect and stop fraud as it happens, a transportation company uses it to reroute its vehicles, and online retailers use it to communicate special offers based on a customer's Web surfing or mobile phone behavior. The real-time data warehouse is an integral part of both short-term (tactical) and long-term (strategic) decisions.

The real-time data warehouse changes the decision support paradigm, which has long been associated with strategic decision making. It supplies support for operational decision making such as customer-facing (direct interactions or communications with customers) and supply chain applications.

A data warehouse appliance is similar in concept to an all-in-one PC, i.e., it integrates the physical components of a data warehouse (servers, storage, operating system) with a database management system and software optimized for the data warehouse. These low-cost appliances are designed to provide terabyte to petabyte capacity warehouses.

Cloud computing refers to using the networked, on-demand, shared resources available through the Internet for virtual computing. Typically, rather than each firm owning its own warehouse, a third-party vendor provides a centralized service to multiple clients based on hardware and software usage. Although, as of 2010 - no data warehouse in the cloud exists, some inferences can be drawn. Agosta (2008) argues that in cloud computing the data in a warehouse will have to be location independent and transparent rather than being a centralized, non-volatile repository. Furthermore, the focus will be on distributed data marts and analytics rather than large data stores because of the problems and costs in moving the huge amounts of data in a warehouse to the cloud.

Data warehouses attract two types of users (Eckerson 2010):

- Casual users. These users are executives and other knowledge workers who consume information but do not usually create it. Their use is mostly static. They check dashboards, monitor regular reports, respond to alerts, and only occasionally dig deeper into the warehouse to create ad hoc reports.
- Power users. These users explore the data and build models. Conventional reports are insufficient for their needs. They model data in unique ways and supplement warehouse contents with data obtained from other sources.

In most organizations, the conventional data warehouse is used by both types of users despite their different needs. Some organizations, however, are moving to separate warehouses, one for each type of user. The conventional data warehouse feeds its data to the one for the power users, so that there is still only one version of the truth. In these organizations, conventional data warehouses continue to serve casual users whose requirements are mostly static. The idea is that performance gains are achieved by creating a separate warehouse customized to power users. Over the years, the special warehouses for power users have operated under a variety of names such as exploration data warehouse (for number crunching) (Inmon 1998), prototype data warehouse (for new approaches to warehouse design), and data warehouse sandbox. Eckerson (2010) describes to three types of sandbox architectures for analytics: physical, virtual, and desktop.

The physical sandbox is built around a data warehouse appliance or a specialized database with rapid access (e.g., columnar or massively parallel processing) that contains a copy of the data in the warehouse. Complex queries from the data warehouse are offloaded and used, together with data not stored in the warehouse. The result is that runaway queries (so large that they overload the warehouse) do

not slow the warehouse and analysts can safely and easily explore large amounts of data.

The virtual sandbox is created inside the warehouse by using workload management utilities. Again, data can be added to that available in the warehouse. The advantage is that warehouse data does not need to be replicated. The disadvantage is that care must be taken to keep processing for casual and power users separate.

In desktop sandboxes, analysts are provided with powerful in-memory desktop databases that can be downloaded from the warehouse. Analysts gain local control and fast performance but much less data scalability than in physical or virtual sandboxes.

Applications

Data warehousing is central to data mining and business intelligence. Other applications include:

- Customer churn prediction
- Decision support
- Financial forecasting
- Insurance fraud analysis
- Logistics and inventory management
- Trend analysis

Decision Analysis

David A. Schum
George Mason University, Fairfax, VA, USA

Introduction

The term decision analysis identifies a collection of technologies for assisting individuals and organizations in the performance of difficult inferences and decisions. Probabilistic inference is a natural element of any choice made in the face of uncertainty. No single discipline can lay claim to all advancements made in support of these technologies. Operations research, probability theory, statistics, economics, psychology, artificial intelligence, and other disciplines have contributed valuable ideas now being exploited in various ways by individuals in many governmental, industrial, and military organizations. As the term decision analysis suggests, complex inference and choice tasks are decomposed into smaller and presumably more manageable elements, some of which are probabilistic and others preferential or value-related. The basic strategy employed in

decision analysis is divide and conquer. The presumption is that individuals or groups find it more difficult to make holistic or global judgments required in undecomposed inferences and decisions than to make specific judgments about identified elements of these tasks. In many cases we may easily suppose that decision makers are quite unaware of all of the ingredients that can be identified in the choices they face. Indeed, one reason why a choice may be perceived as difficult is that the person or group charged with making this choice may be quite uncertain about the kind and number of judgments this choice entails. One major task in decision analysis is to identify what are believed to be the necessary ingredients of particular decision tasks.

The label decision analysis does not in fact provide a complete description of the activities of persons who employ various methods for assisting others in the performance of inference and choice tasks. This term suggests that the only thing accomplished is the decomposition of an inference or a choice into smaller elements requiring specific judgments or information. It is, of course, necessary to have some process by which these elements can be reassembled or aggregated so that a conclusion or a choice can be made. In other words, we require some method of synthesis of the decomposed elements of inference and choice. A more precise term for describing the emerging technologies for assistance in inference and choice would be the term decision analysis and synthesis. This fact has been noted in an account of progress in the field of decision analysis (Watson and Buede 1987). As it happens, the same formal methods that suggest how to decompose an inference or choice into more specific elements can also suggest how to reassemble these elements in drawing a conclusion or selecting an action.

Processes and Stages of Decision Analysis

Human inference and choice are very rich intellectual activities that resist easy categorization. Human inferences made in natural settings (as opposed to contrived classroom examples) involve various mixtures of the three forms of reasoning that have been identified: (1) deduction (showing that some conclusion is necessary), (2) induction (showing that some conclusion is probable), and (3) abduction (showing that something is possibly or plausibly true). There are many varieties of choice situations that can be discerned. Some involve the selection of an action or option such as where to locate a nuclear power plant or a toxic waste disposal site. Quite often one choice immediately entails the need for another and so we must consider entire sequences of decisions. It is frequently difficult to specify when a decision task actually terminates. Other decisions involve determining how limited resources may best be allocated among various demands for these resources. Some human choice situations involve episodes of bargaining or negotiation in which there are individuals or groups in some competitive or adversarial posture. Given the richness of inference and choice, analytic and synthetic methods differ from one situation to another as observed in several surveys of the field of decision analysis (von Winterfeldt and Edwards 1986; Watson and Buede 1987; Clemen 1991; Shanteau et al. 1999). Some general decision analytic processes can, however, be identified.

Most decision analyses begin with careful attempts to define and structure an inference and/or decision problem. This will typically involve consideration of the nature of the decision problem and the individual or group objectives to be served by the required decision(s). A thorough assessment of objectives is required since it is not possible to assist a person or group in making a wise choice in the absence of information about what objectives are to be served. It has been argued that the two central problems in decision analysis concern uncertainty and multiple conflicting objectives (von Winterfeldt and Edwards 1986, pp. 4–6). A major complication arises when, as usually observed, a person or a group will assert objectives that are in conflict. Decisions in many situations involve multiple stakeholders and it is natural to expect that their stated objectives will often be in conflict. Conflicting objectives signal the need for various tradeoffs that can be identified. Problem structuring also involves the generation of options, actions, or possible choices. Assuming that there is some element of uncertainty, it is also necessary to generate hypotheses representing relevant alternative states of the world that act to produce possibly different consequences of each option being considered. The result is that when an action is selected we are not certain about which consequence or outcome will occur.

Another important structuring task involves the identification of decision consequences and their attributes. The attributes of a consequence are measurable characteristics of a consequence that are related to a decision maker's asserted objectives. Identified attributes of a consequence allow us to express how well a consequence measures up to the objectives asserted in some decision task. Stated in other words, attributes form value dimensions in terms of which the relative preferability of consequences can be assessed. There are various procedures for generating attributes of consequences from stated objectives (e.g., Keeney and Raiffa 1976, pp. 31–65). Particularly challenging are situations in which we have multiattribute or vector consequences. Any conflict involving objectives is reflected in conflicts among attributes and signals the need for examining possible tradeoffs. Suppose, for some action A_i and hypothesis H_j, vector consequence $\boldsymbol{C}\mathrm{v}_{ij}$ has attributes $\{A_1, A_2, \ldots, A_r, \ldots, A_s, \ldots, A_t\}$. The decision maker may have to judge how much of A_r to give up in order to get more of A_s; various procedures facilitate such judgments. Additional structuring is necessary regarding the inferential element of choice under uncertainty. Given some exhaustive set of mutually exclusive hypotheses or action-relevant states of the world, the decision maker will ordinarily use any evidence that can be discovered that is relevant in determining how probable are each of these hypotheses at the time a choice is required. No evidence comes with already-established relevance, credibility, and inferential force credentials, these credentials have to be established by argument. The structuring of complex probabilistic arguments is a task that has received considerable attention (e.g., see Pearl 1988; Neapolitan 1990; Schum 1990, 1994).

At the structural stage just discussed, the process of decomposing a decision is initiated. On some occasions such decomposition proceeds according to formal theories of probability and value taken to be normative. It may even happen that the decision of interest can be represented in terms of some existing mathematical programming or other formal technique common in operations research. In some cases the construction of a model for a decision problem proceeds in an iterative fashion until the decision maker is satisfied that all ingredients necessary for a decision have been identified. When no new problem ingredients can be identified the model that results is said to be a requisite model (Phillips 1982, 1984). During the process of decomposing the probability and value dimensions of a decision problem it may easily happen that the number of identified elements quickly outstrips a decision maker's time and inclination to provide judgments or other information regarding each of these elements. The question is: how far should the process of divide and conquer be carried out? In situations in which there is not unlimited time to identify all conceivable elements of a decision problem, simpler or approximate decompositions at coarser levels of granularity have to be adopted.

In most decision analyses there is a need for a variety of subjective judgments on the part of persons involved in the decision whose knowledge and experience entitles them to make such judgments. Some judgments concern probabilities and some concern the value of consequences in terms of identified attributes. Other judgments may involve assessment of the relative importance of consequence attributes. The study of methods for obtaining dependable quantitative judgments from people represents one of the most important contributions of psychology to decision analysis (for a survey of these judgmental contributions, see von Winterfeldt and Edwards 1986). After a decision has been structured and subjective ingredients elicited, the synthetic process in decision analysis is then exercised in order to identify the best conclusion and/or choice. In many cases such synthesis is accomplished by an algorithmic process taken as appropriate to the situation at hand. Modern computer facilities allow decision makers to use these algorithms to test the consequences of various possible patterns of their subjective beliefs by means of sensitivity analyses. The means for defending the wisdom of conclusions or choices made by such algorithmic methods re-quires consideration of the formal tools used for decision analysis and synthesis.

Theories of Analysis and Synthesis

Two major pillars upon which most of modern decision analysis rests are theories of probabilistic reasoning and theories of value or preference. A very informative summary of the roots of decision theory has been provided by Fishburn (1999). It is safe to say that the conventional view of probability, in which Bayes' rule appears as a canon for coherent or

rational probabilistic inference, dominates current decision analysis. For some body of evidence $\boldsymbol{E}$v, Bayes' rule is employed in determining a distribution of posterior probabilities $P(H_k|\boldsymbol{E}\text{v})$, for each hypothesis H_k in an exhaustive collection of mutually exclusive decision-relevant hypotheses. The ingredients Bayes' rule requires, prior probabilities (or prior odds) and likelihoods (or likelihood ratios), are in most cases assumed to be assessed subjectively by knowledgeable persons. In some situations, however, appropriate relative frequencies may be available. The subjectivist view of probability, stemming from the work of Ramsey and de Finetti, has had a very sympathetic hearing in decision analysis (see Mellor 1990, and de Finetti 1972, for collections of the works of Ramsey and de Finetti).

Theories of coherent or rational expression of values or preferences stem from the work of von Neumann and Morgenstern (1947). In this work appears the first attempt to put the task of stating preferences on an axiomatic footing. Adherence to the von Neumann and Morgenstern axioms places judgments of value on a cardinal or equal-interval scale and are often then called judgments of utility. These axioms also suggest methods for eliciting utility judgments and they imply that a coherent synthesis of utilities and probabilities in reaching a decision consists of applying the principle of expected utility maximization. This idea was extended in the later work of Savage (1954), who adopted the view that the requisite probabilities are subjective in nature. The canon for rational choice emerging from the work of Savage is that the decision maker should choose from among alternative actions by determining which one has the highest subjective expected utility (SEU). Required aggregation of probabilities is assumed to be performed according to Bayes' rule. In some works, this view of action-selection is called Bayesian decision theory (Winkler 1972; Smith 1988).

Early works by Edwards (1954, 1961) stimulated interest among psychologists in developing methods for probability and utility elicitation; these works also led to many behavioral assessments of the adequacy of SEU as a description of actual human choice mechanisms. In a later work, Edwards (1962) proposed the first system for providing computer assistance in the performance of complex probabilistic inference tasks. Interest in the very difficult problems associated with assessing the utility of multiattribute consequences stems from the work of Raiffa (1968). But credit for announcing the existence of the applied discipline now called decision analysis belongs to Howard (1966, 1968).

Decision Analytic Strategies

There are now many individuals and organizations employed in the business of decision analysis. The inference and decision problems they encounter are many and varied. A strategy successful in one context may not be so successful in another. In most decision-analytic encounters, an analyst plays the role of a facilitator, also termed high priests (von Winterfeldt and Edwards 1986, p. 573). The essential task for the facilitator is to draw out the experience and wisdom of decision makers while guiding the analytic process toward some form of synthesis. In spite of the diversity of decision contexts and decision analysts, Watson and Buede (1987, pp. 123–162) were able to identify the following five general decision analytic strategies in current use. They make no claim that these strategies are mutually exclusive.

1. Modeling. In some instances decision analysts will focus upon efforts to construct a conceptual model of the process underlying the decision problem at hand. In such a strategy, the decision maker(s) being served not only provide the probability and value ingredients their decision requires but are also asked to participate in constructing a model of the context in which this decision is embedded. In the process of constructing these often-complex models, important value and uncertainty variables are identified.
2. Introspection. In some decision analytic encounters, a role played by the facilitator is one of assisting decision makers in careful introspective efforts to determine relevant preference and probability assessments necessary for a synthesis in terms of subjective expected utility maximization. Such a process places great emphasis upon the reasonableness and consistency of the often large number of value and probability ingredients of action selection.
3. Rating. In some situations, especially those involving multiple stakeholders and multiattribute consequences, any full-scale task decomposition would be paralytic or, in any case, would not provide the timely decisions so often required.

In order to facilitate decision making under such circumstances, models involving simpler probability and value assessments are often introduced by the analyst. In some forms of decision analysis, many of the difficult multiattribute utility assessments are made simpler through the use of various rating techniques and by the assumption of independence of the attributes involved.

4. Conferencing. In a decision conference the role of the decision analyst as facilitator (or high priest) assumes special importance. In such encounters, often involving a group of persons participating to various degrees in a decision, the analyst promotes a structured dialogue and debate among participants in the generation of decision ingredients such as options, hypotheses and their probability, and consequences and their relative value. The analyst further assists in the process of synthesis of these ingredients in the choice of an action. The subject matter of a decision conference can involve action selection, resource allocation, or negotiation.
5. Developing. In some instances, the role of the decision analyst is to assist in the development of strategies for recurrent choices or resource allocations. These strategies will usually involve computer-based decision support systems or some other computer-assisted facility whose development is justified by the recurrent nature of the choices. The study and development of decision support systems has itself achieved the status of a discipline (Sage 1991). An active and exciting developmental effort concerns computer-implemented influence diagrams stemming from the work of Howard and Matheson (1981). Influence diagram systems can be used to structure and assist in the performance of inference and/or decision problems and have built-in algorithms necessary for the synthesis of probability and value ingredients (e.g., Shachter 1986; Shachter and Heckerman 1987; Breese and Heckerman 1999). Such systems are equally suitable for recurrent and nonrecurrent inference and choice tasks.

Controversies

As an applied discipline, decision analysis inherits any controversies associated with theories upon which it is based. There is now a substantial literature challenging the view that the canon for probabilistic inference is Bayes' rule (e.g., Cohen 1977, 1989; Shafer 1976). Regarding preference axioms, Shafer (1986) has argued that no normative theories of preference have in fact been established and that existing theories rest upon an incomplete set of assumptions about basic human judgmental capabilities. Others have argued that the probabilistic and value-related ingredients required in Bayesian decision theory often reflect a degree of precision that cannot be taken seriously given the imprecise or fuzzy nature of the evidence and other information upon which such judgments are based (Watson et al. 1979). Philosophers have recently been critical of contemporary decision analysis. Agreeing with Cohen and Shafer, Tocher (1977) argued against the presumed normative status of Bayes' rule. Rescher (1988) argued that decision analysis can easily show people how to decide in ways that are entirely consistent with objectives that turn out not to be in their best interests. Keeney's work (1992) took some of the sting out of this criticism. Others (e.g., Dreyfus 1984) question whether or not decomposed inference and choice is always to be preferred over holistic inference and choice; this same concern is reflected in other contexts such as law (Twining 1990, pp. 238–242). So, the probabilistic and value-related bases of modern decision analysis involve matters about which there will be continuing dialogue and, perhaps, no final resolution. This acknowledged, decision makers in many contexts continue to employ the emerging technologies of decision analysis and find, in the process, that very complex inferences and choices can be made tractable and far less intimidating.

Decision Analysis in Practice

James E. Matheson
SmartOrg, Inc., Menlo Park, CA, USA

Introduction

Decision analysis (DA) is all about practice, as the title of Ronald Howard's defining paper (Howard 1966; presented in 1965) was "Decision Analysis: Applied Decision Theory." He went on to elaborate: "Decision analysis is a logical procedure for the balancing of the factors that influence a decision. The procedure

incorporates uncertainties, values, and preferences in a basic structure that models a decision. Typically it includes technical, marketing, competitive, and environmental factors. The essence of the procedure is the construction of a structural model of the decision in a form suitable for computation and manipulation; the realization of this model is often a set of computer programs."

In about 1968, a program of DA was begun at Stanford Research Institute. This group rapidly grew into a major department called the Decision Analysis Group dedicated to helping decision makers in organizations, both industry and government, reach good decisions, while also consolidating these experiences and doing research on DA methodology (Howard and Matheson 1983). This group was the most intensive DA consulting group through the early 1980s. One of the powerful new methodological tools invented by this group was the Influence Diagram (see entry). DA practice has always developed new tools and approaches based on the challenges of real problems.

At the end of the next decade, with this experience behind him, Professor Howard goes on to say (Howard 1980), "Decision Analysis, as I have described it, is, as a formalism, a logical procedure for decision making. When Decision Analysis is practiced as an applied art the formalism interacts with the intuitive and creative facilities to provide understanding of the nature of the decision problem and therefore guidance in selecting a desirable course of action. I know of no other formal-artistic approach that has been so effective in guiding decision-makers."

In this sense there is no real theory of DA. Its philosophy is grounded in decision theory and systems engineering, with more recent contributions from psychology, but in the end it is an applied art. This Decision Engineering approach is discussed in depth in an INFORMS tutorial (Matheson 2005). This article describes some of the keys to good application and the kinds of positive changes DA promotes in the organizations that adopt it.

A Decision: The Defining Element

A decision is defined as an irrevocable allocation of resources. Exactly what is meant by irrevocable depends on the context. If a single individual—the decision maker (DM)—makes and executes a decision, then the decision and the irrevocable action are one – the individual might decide to take one path versus another along a road. Traveling down the new path is an irrevocable decision in the sense that changing the decision would require going back to the junction and taking the second path, but at a later time. However, when an organizational DM takes a big strategic decision, the DM asks many other people to take later irrevocable actions, which might not even be fully specified at that time of the original decision (for example, asking someone to find an appropriate company and acquire it). In these settings, a decision is often defined as a commitment to allocate resources, which opens new questions of possible execution failure and nested or sequential decisions. In any case, the decisions at hand provide the focus for DA, which distinguishes DA from all kinds of studies and statistical analyses that are not directly serving decisions. This means that, once the decision arena has been defined, the DM can guide all subsequent activity, such as modeling and information gathering, on its ability to inform better decisions. Issues that might make a great deal of difference to the outcome, but do not have the potential to change the decision taken, are unimportant, while issues of less impact but that do inform the decision are of greater importance. The DM uses this sort of decision sensitivity to intuitively and analytically guide the whole process, and to do what is most important to making a decision in the limited time and resources available to make it.

Framing: The Perceived Situation

Perhaps the biggest decision failure is a careful analysis of the wrong problem. Often a decision arises in an organization as just another tactical decision, when actually new strategies are called for – but strategy is not the prerogative or in the comfort zone of those considering the decisions. Thus, old products and whole companies are displaced by competitors who perceived the situation differently, and who were able to act in new ways. Also, executives spend most of their time and energy operating efficiently and find it difficult to "waste time" on strategy or to get into a strategic mind set. The beginning of a DA should review the decision frame, possibly bringing in outside perspectives

and new team members, often expanding the frame, and then reviewing that frame at key points during the process. When a DA process gets stuck, reframing maybe in order (Matheson 1990).

Outcomes: What are the Results

In the face of uncertainty, the decision maker (DM) is forced to distinguish between decisions – what can be done, outcomes – what happens, and preferences – what is wanted. The DM wants good outcomes, but can only control the quality of the decisions, not the outcomes. For example, the DM may invest $10,000 in a venture having only a 10% chance of returning $10,000,000, and considers that a good investment. Quite likely, however, the bad outcome may occur. Clearly, the quality of this decision cannot be judged by its outcome; a bad outcome should not dissuade the DM from looking for similar good investments later. Given this distinction between decision quality and outcome quality, there is a need for a definition of a good decision – DA itself is that definition!

In many organizational cultures, champions are asked to claim that investment proposals are sure things and guarantee that they will succeed. On course, many of these investments fail, but inconsistency does not stop this irrational culture from persisting. However, organizations that can overcome a culture of hiding from uncertainty and instead actually search for the hidden uncertainties in their investments often outperform those that do not. Good DA vets these uncertainties, assesses their probabilities and impacts, and determines what to do about them, such as information gathering and hedging, or even creating new alternatives, before proceeding to recommend the primary decision – a principle called embracing uncertainty (Matheson and Matheson 1998).

There are well established procedures for assessing uncertainties and avoiding well-known biases, such as the work on probability assessment processes by Spetzler and Staël von Holstein (1975). Most practical decision analyses, however, do not require such careful assessment; three points, say 10-50-90 percentiles, are so much better than one single and often biased point. It is essential that those three points not be biased. Most of the de-biasing techniques of Spetzler and Staël von Holstein (1975) are useful preparation before assessing even a three-point distribution. Perhaps the most useful technique is backcasting, as it simultaneously eliminates all sorts of biases.

Preferences: What is Wanted

Because only one thing can be maximized, a good or optimal decision cannot be defined without being clear about value trade-offs that create a single measure to maximize. In most commercial decision analyses, it is best to reduce all values to monetary ones. In fact, seeking a monetary value scale is always a good practice, because money can often be spent to create better alternatives or seek better information, and, without a monetary scale, the DM cannot evaluate those efforts. There is a story about a Swedish executive who had promised the residents of a town that he would never close their factory, but, under hard times, he was facing heavy losses by keeping it open. He was asked by a decision analyst if he would close it if he were losing a million dollars a year, to which he quickly answered, "of course not – this is Sweden where we owe that much to the community." He was then asked if he would close the plant if it were losing a hundred million dollars a year, to which he replied, "it would be our duty to close it as the country and our company cannot sustain such heavy losses." After haggling over the price, he realized that the high monetary value he had just made explicit allowed him to visualize new alternatives, where he would close the plant, pay some additional closing costs to the community and guarantee workers jobs in other factories. He ultimately took these actions and saved his company from financial ruin. Being forced to make a monetary value tradeoff enabled him to invent to better alternatives. He was not valuing things like higher employment on an absolute scale. He was only assessing a tradeoff value in the context of his specific decision – this value is personal and subjective, just like probability, in this case not his own, but one he expresses as a fiduciary of the company he represents. Converting values to monetary equivalents is an excellent practice, because it establishes how much money could be afforded to build new alternatives – money is a common denominator to translate disparate values.

Decision Analysis in Practice, Fig. 1 Risk tolerance in millions of dollars as measured from *top* executives of three publically traded companies, A, B, and C

Size Measure	A	B	C	Approximate Ratio to Risk Tolerance
Net Sales	2,300	16,000	31,000	15:1
Net Income	120	700	1,900	1:1
Equity	1,000	6,500	12,000	6:1
Market Value	940	4,600	9,900	5:1
Risk Tolerance	150	1,000	2,000	

What about value over time? In a simple case, a highly rated company regularly adjusts or rebalances its financial capital at a weighted cost of capital of R%. If the company has opportunities (or preferences) that imply a value other than R%, the company should rearrange its investments using its banking relationships until its needs are exactly in line with the financial rate of R%. At that point, the company's own time preferences are exactly the same as the financial rate. Because of this harmonization process, this cost of capital becomes the company's own time value of money. Another way to state this observation is that the company should invest to maximize net present value (NPV) at its cost of capital, and then spread that NPV over time optimally using financial transactions at the same rate, separating investment funding and usage decisions.

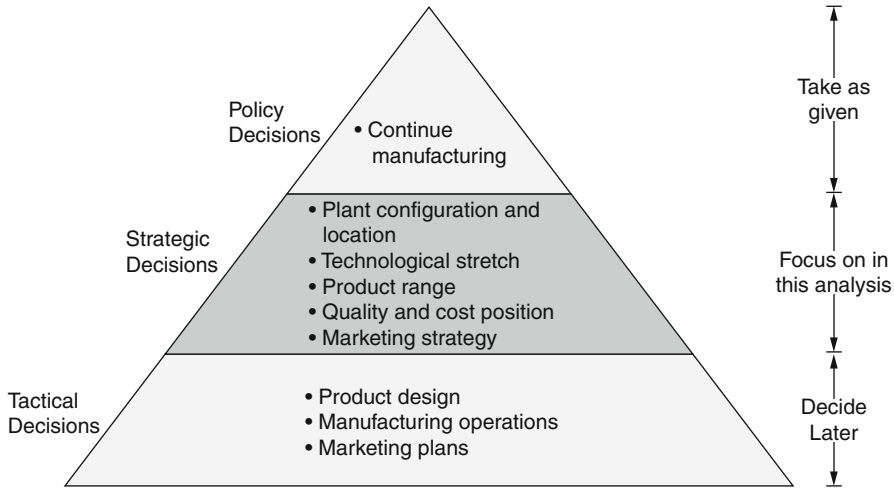
How should preferences under uncertainty be treated? Assuming that each uncertainty has been characterized satisfactorily in the form of probability distributions over NPV, which investment should be picked? If the company is large enough to undertake many investments of this size during each year, then maximizing the expected value is a reasonable way to maximize long-term economic-value creation. However, if the range of the uncertainties could impact the financial structure or soundness of the company, it would be wise for it to be risk averse. Some financial pundits argue that companies traded on the stock market should not be risk averse as the shareholders can diversify. There are many arguments against this position, including the actual behavior of most companies, the cost of bankruptcy or other financial distress, the inability of the shareholder to gain information and change positions quickly (lack of liquidity), but, perhaps most significantly, are the availability of risk hedging options to the company that are not available to shareholders. The risk attitude of the company is assessed by asking series of questions about which of several hypothetical investments they would undertake or reject. This attitude is almost always captured as the risk tolerance, say expressed in millions of dollars, which is the parameter of an exponential utility function:

$$U(x) = -ae^{(-x/\rho)} \text{ where } a > 0 \text{ and } \rho = \text{risk tolerance}$$

One test question to determine the risk tolerance is considering a hypothetical but typical investment, in terms of complexity and time duration, where there is a 0.5 probability of winning the risk tolerance and a 0.5 probability of losing one-half that amount. The risk tolerance is then adjusted until the DM is indifferent between taking and rejecting this investment.

There are good arguments that risk tolerance should be set for the total organization and not for a division or a project. One advantage of being a division of a large organization is to be able to use the corporate risk tolerance, which a similar stand-alone organization could not do. Figure 1 compares the measured risk tolerances of three large corporations, which were all engaged in a joint venture. This chart can be used to get an initial approximation for other public companies, commonly by estimating risk tolerance as 1/6 of shareholders' equity or 1/5 of the market value of outstanding shares of stock.

Investments with a range of outcomes on the order of the risk tolerance need explicit treatment using utility theory. Investments with a range of outcomes less than of 10% of the risk tolerance should usually be evaluated using expected values, and investments with a range of outcomes larger than the risk tolerance should be avoided, partnered, or treated by a very



Decision Analysis in Practice, Fig. 2 Decision hierarchy for a plant modernization decision

experienced decision analyst. The author has seen one such case in a lifetime of professional practice. If the exponential utility will not suffice, the analysis is in very deep water indeed! In dealing with uncertainties large enough to require risk aversion, there is a need to beware of dependencies among uncertainties in other investments or the background cash flow of the organization. Hedging and diversification impacts are likely to overshadow other considerations.

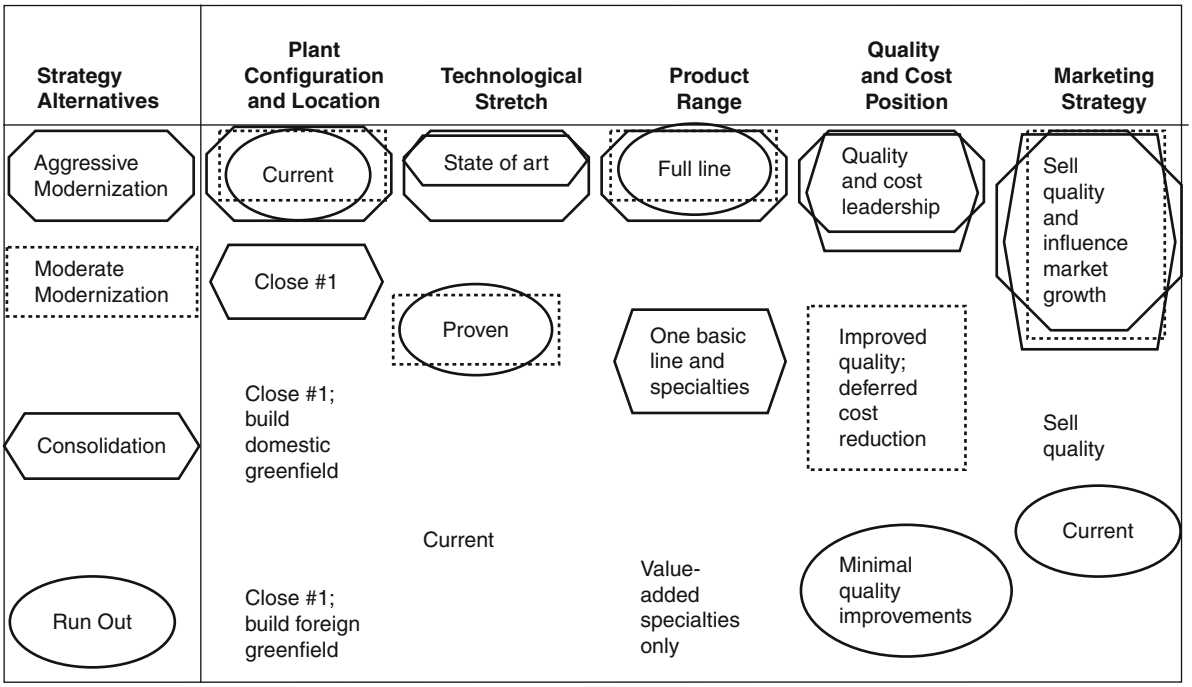
Alternatives: What Can be Done

In simple decisions problems, such as classroom examples, a limited number of well-specified alternatives are given. In most real situations, however, new alternatives can and should be created to uncover more valuable ones. Part of the natural reluctance of organizations to generate and consider new alternatives is that the decision problems arise out of situations where natural alternatives are evident. In addition, those product or investment champions and others who have made an emotional investment by picking winners prematurely, see alternative generation as a waste of time or even a direct threat. There are many ways to create new alternatives, but a simple one is to use the project team itself in a session with a ground rule that at least five new significantly different alternatives must be developed. There are many tools to stimulate creativity, most requiring that a wealth of information and new possibilities be put on the table before evaluating them; such as examples of what others have been done, what competitors are saying, what consumers are asking for. After the analysis enters the financial modeling stage; sensitivity analysis should also be used to drive the discussion of alternatives that minimize risk (hedge or diversify) or take advantage of uncertainties.

For situations with complex multidimensional alternatives, decision hierarchies and strategy tables are extremely useful. The decision hierarchy for a plant modernization decision (Fig. 2) identifies the strategic decisions under consideration, the policy decisions that are not currently being questioned, and the tactical or implementation decisions which will be made or optimized after the strategy is selected. The list of identified strategic decisions are further specified in the columns of the strategy table, illustrated in Fig. 3. The columns list specific mutually-exclusive alternatives for each strategy variable. Thus, a selection of one item from each column constitutes a well-specified strategic alternative. The special column at the left gives names and symbols for each alternative, which is read by following its symbol across the columns. Further descriptions of these tools can be found in Matheson and Matheson (1998) and McNamee and Celona (2007).

Decision Modeling: Analyzing as Simply as Possible

The process of DA uses the decision to be made as a guide to cut through many complex modeling issues. Often details, such as numerous market segments or



Decision Analysis in Practice, Fig. 3 Strategy table for a plant modernization decision

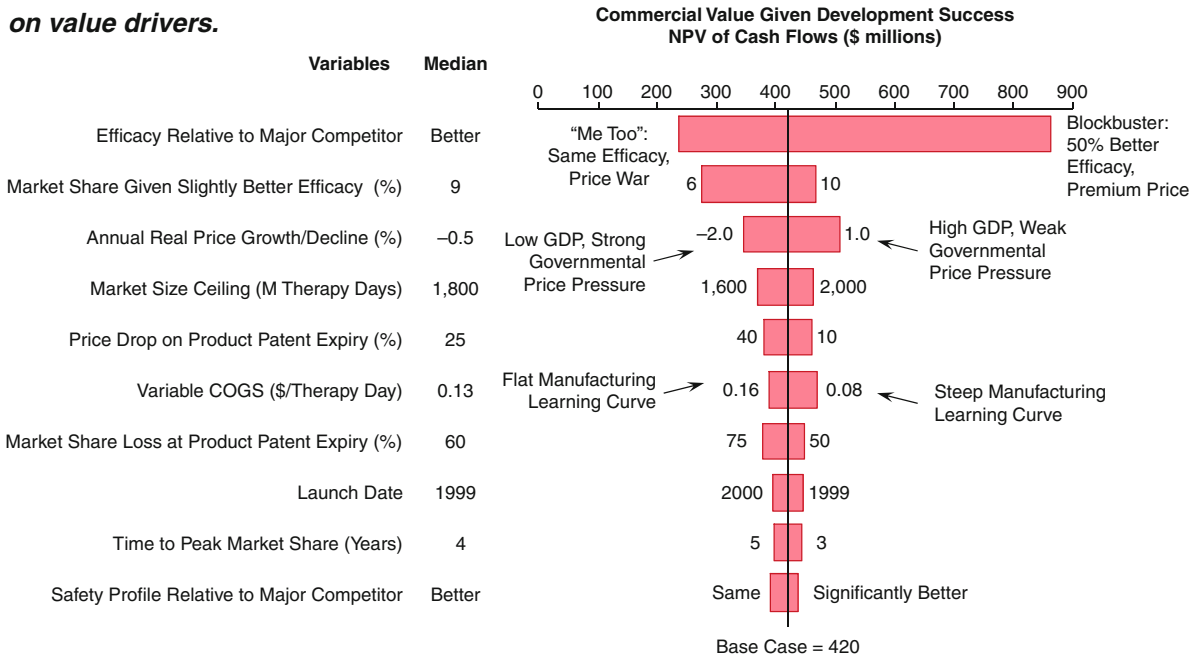
multiple product generations, can be treated with multipliers, followed by sensitivity analysis to the value of those multipliers, to determine if something important was missed. Verisimilitude is unimportant, only the impact on gaining clarity of action. Good modeling for decision making is an important professional task, see McNamee and Celona, (2007).

A special kind of sensitivity analysis called a tornado chart (Fig. 4) is a key tool for checking the model and gaining new insights. Each uncertain variable is varied one at a time over the range of the low (10 percentile) and high (90 percentile) assessments, to determine the range of (deterministic) NPV resulting from different runs of the model, usually while holding the other values at their medians. Notice that output ranges of each variable correspond to the same range of uncertainty on their inputs, so if the results are arranged in a decreasing order of the output ranges, they are also in order of the impact of each uncertainty on value, as in Fig. 4. Since for independent variables, the uncertainty ranges should add as the square root of the sum of the squares, only the first several results are big contributors, which often produces insight into which factors are driving risk, as well as ideas for how to reduce that risk. More sophisticated tornado diagrams overlay results for multiple alternatives to give insight into which uncertainties could actually cause a decision switch, as these would be the most critical to learn more about.

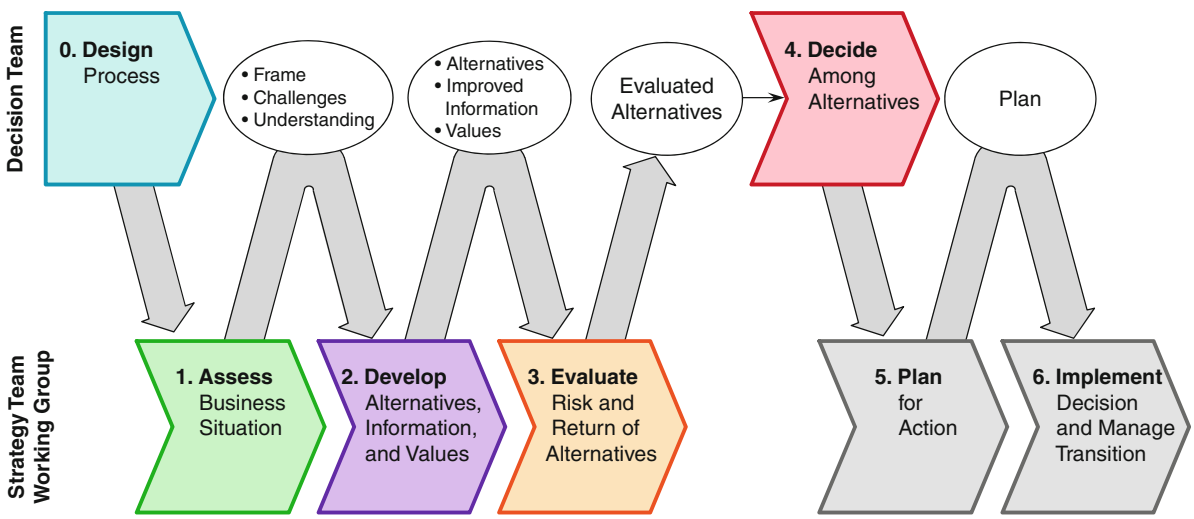
Commitment to Action: Getting It Done

The author has decided to diet many times, without actually following through. And that is only dealing with himself! It is much more difficult to align an organization to carry out the chosen action. A good analysis sets the stage for implementation success at the beginning by the choice of individuals involved in reaching the decision. It is natural not to put the potential naysayers on the decision making or the decision analyzing team, but if they are not chosen, they will often veto the result, overtly if they have the power and covertly if not. It is best to put any skeptical person with veto power on the team, even if only in a review board role, and require that they raise their issues during the analysis process rather than objecting later – speak up or forever hold your peace. In this way they have the opportunity to inform the team of their

Dealing effectively with uncertainty builds trust in the evaluation framework and helps focus attention on value drivers.



Decision Analysis in Practice, Fig. 4 Tornado chart



Decision Analysis in Practice, Fig. 5 Dialog decision process

important issues, which can be taken into account during the analysis, and they acquire a deeper understanding of the decision situation by participating, giving them a much better chance of ultimately buying in to the conclusions. It gives them needed psychological time and space to reconsider and revise long held convictions. Also, put key implementers on the team so they understand and buy

Decision Analysis in Practice, Fig. 6 Decision quality chain

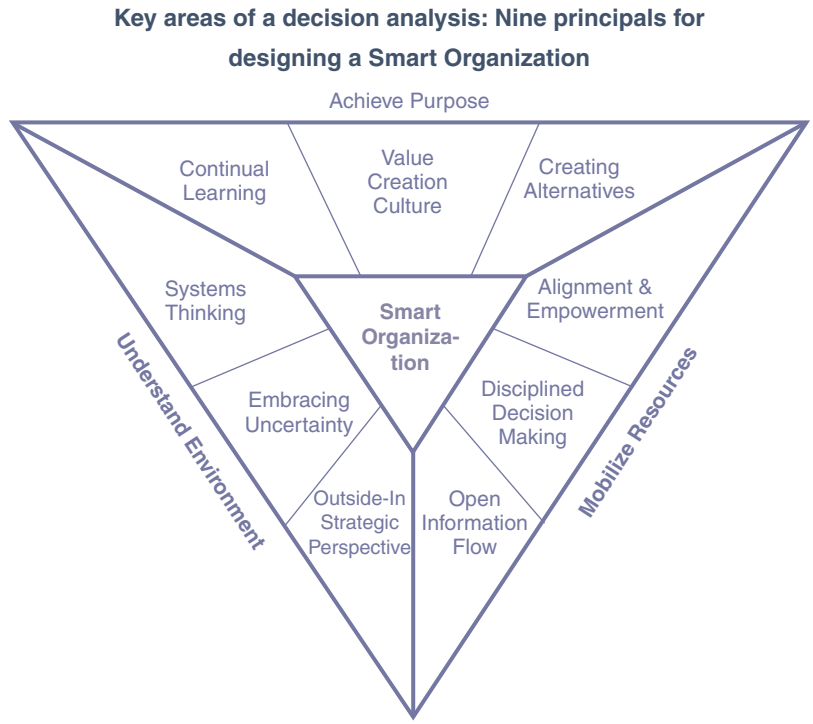
into what they are asked to implement. The Dialog Decision Process (Fig. 5) was devised to organize all of these actors into a highly workable project structure.

The Decision Quality Chain

The key elements described above are often arranged in a decision quality chain (Fig. 6), originally proposed by Carl Spetzler (Keelin and Spetzler 1992). The metaphor of a chain is used to express that the chain is only as good as its weakest link – that is the most important one; the weakest link changes as the DA proceeds. Decision analysts sometimes use a spider diagram to score progress at each team review (Keelin et al. 2009).

Embedding Good Decision-Making Skills into Organizations

The book, *The Smart Organization*, (Matheson and Matheson 1998), describes "Nine Principles of a Smart Organization" that characterizes a set of habits and a mindset conducive to good decisions, Fig. 7. This book also presents an organizational IQ test to measure compliance with these norms. These tests have been administered to thousands of organizations. The payoff for being a smart organization was striking – organizations in the top quartile of IQ were over five times more likely to be in the top quartile of financial performance, as reported in Matheson and Matheson (2001). Organizations with high scores have patterns of behavior that enable them to spontaneously see the need for decisions, request and frame appropriate decision analyses, and conduct and participate in decision analyses more efficiently and effectively. A few organizations are leading the way by integrating DA into their organizational DNA. Among them, most notably, has been Chevron, which won the annual Decision Analysis Society's Practice Award (2010) for "The implementation of Decision Analysis Practice at Chevron: 20 years of building a DA culture." Matheson and Matheson (2007) discuss how DA principles can become the basis of the Decision Organization.



Decision Analysis in Practice, Fig. 7 Nine principals (Matheson and Matheson 1998)

Concluding Remarks

DA has evolved from specialized high-level consulting to changing culture and embedding processes into organizational routines. The various roles that a DA professional might be called upon to play include:

1. Decision Analyst - responsible for processing numbers,
2. Decision Facilitator - responsible for meetings,
3. Decision Consultant - responsible for attaining commitment,
4. Decision Engineer - responsible for process, systems and organizational design,
5. Decision Change Agent - responsible for personal, organizational, and cultural change necessary for routine, high quality decision making.

Decision Maker (DM)

An individual (or group) who is dissatisfied with some existing situation or with the prospect of a future situation and who possesses the desire and authority to initiate actions designed to alter the situation. In the literature, the letters DM are often used to denote decision maker.

Decision Making and Decision Analysis

Dennis M. Buede
Innovative Decisions, Inc., Vienna, VA, USA

Introduction

Decision making is a process undertaken by an individual or organization. The intent of this process is to improve the future position of the individual or organization, relative to current projections of that future position, in terms of one or more criteria. Most scholars of decision making define this process as one that culminates in an irrevocable allocation of resources to affect some chosen change or the continuance of the status quo. The most commonly allocated resource is money, but other scarce resources are goods and services, and the time and energy of talented people.

Once the concept of making a decision is accepted as a human action, an immediate question is "what is the difference between a good and a bad decision?" The common tendency is to attribute good decisions to situations in which good outcomes were obtained. This approach, however, implies that good decisions cannot be recognized when they are made, but only after the outcomes are observed (which may be seconds or decades later). This common tendency also implies that good decisions have nothing to do with the decision-making process; throwing a dart at a chart of alternatives may lead, on occasion, to good outcomes, while long, hard thought about values and uncertainties does not always yield good outcomes. So leaders in the decision analysis field have defined a good decision as one that is consistent with the values and uncertainties of the decision maker (DM) after considering as many relevant alternatives as possible within the appropriate time frame and with the available information. The belief is that better outcomes will be more likely, but are not guaranteed, with a sound decision making process than throwing darts at a chart of alternatives.

Three primary decision modes have been identified by Watson and Buede (1987): (1) choosing one option from a list, (2) allocating a scarce resource(s) among competing projects, and (3) negotiating an agreement with one or more adversaries. Decision analysis is the common analytical approach for the first mode, optimization using decision analysis concepts of value objectives for the second, and a host of techniques have been applied to negotiation decisions.

The three major elements of a decision that cause decision making to be troublesome are the creative generation of options; the identification and quantification of multiple conflicting criteria, as well as time and risk preference; and the assessment and analysis of uncertainty associated with the causal linkage between alternatives and objectives. To claim to have made a good decision, the DM must be able to defend how these three elements were addressed.

Many DMs claim to be troubled by the feeling that there is an, as yet unidentified, alternative that must surely be better than those so far considered. The development of techniques for identifying such alternatives has received considerable attention (Keller and Ho 1988; Keeney 1992). Additional research has been undertaken to identify the pitfalls in assessing probability distributions that represent the uncertainty of a DM (Edwards et al. 2007). Research has also focused on the identification of the most appropriate preference assessment techniques (Edwards et al. 2007). Keeney (1992) has advanced

concepts for the development and structuring of a value hierarchy for key decisions. Very little research has been done on the issue of causal linkages between alternatives and the objectives.

The making of a good decision requires a sound decision making process. However, doing research on competing decision processes, with sound validation using ground truth, is not possible. It is not possible to create multiple versions of reality so that the DM can try the preferred alternative from competing decision processes to identify which would have turned out best. Researchers have proposed multi-phased processes for decision making, e.g., (Howard 1968; Witte 1972; Mintzberg et al. 1976). The common phases include: intelligence or problem definition, design or analysis, choice, and implementation. A weakness in one phase in the decision making process often cannot be compensated for by strengths in the other phases. In general, the decision-making process must address the development of a reasoned set of objectives and associated preference structure; decision alternatives; and the facts, data, opinions, and judgments needed to relate the alternatives to the value model. Then, of course, the logic of evaluating the alternatives in light of the value structure must be sound.

Decision Analysis

The field of decision analysis involves both analysis and synthesis. Analysis is a process for dividing a problem into parts and performing some quantitative assessment of those parts. Synthesis then combines those assessments into a macro assessment. Decision analysis provides an integrating framework for doing this assessment, as well as the theory and techniques for doing the analyses of the parts. These parts are traditionally values (objectives for improving the DM's situation), alternatives (resources the DM can expend to change the world), and the linkage between the alternatives and the values (the facts and uncertainties within the DM's world). Nonetheless, experienced decision analysts often ask the DM for a holistic assessment of the alternatives prior to showing the analysis results (as part of the synthesis process) so that the analysis results can be compared to this holistic standard and the differences noted and examined. Often this comparison to the holistic assessment identifies some issues that were missed in the analysis.

Decision analysis has its roots in many fields. Some of the most obvious are operations research, engineering, business, psychology, probability and statistics, and logic. Fishburn (1999) provides a well-documented summary of these roots of decision analysis. Von Neumann and Morgenstern (1947) provided the first axiomatic structure for decision making, incorporating both probabilistic and value preferences into a principle of expected utility maximization. Savage (1954) recognized the need for subjective probabilities to be combined with subjective utility judgments, leading to subjective expected utility (SEU). Since decision making involves trying to predict how the future world will evolve, the subjectivist approach to uncertainty is the primary perspective adopted in decision analysis. De Finetti (1972) provides a detailed review of the subjectivist approach. Bayes' rule is often required in the computation of expected utility, i.e., Bayesian decision theory is used to describe the decision analysis process (Smith 1988). Interestingly, Bayesian probability and subjectivist probability are used interchangeably. Howard (1966, 1968), Raiffa (1968), and Edwards (1962) all made important contributions in transforming an academic theory into a practical discipline to guide DMs through the difficulties of real world decision making.

Values represent what the DM wants to improve in the future. As an example, when considering the purchase of a new car, the DM may be weighing reduced cost in the future against improved safety, comfort, prestige, and performance. The context of this decision and, therefore, the values, is the likely uses of a car for commuting, long distance travel, errands, etc. Keeney (1992) provides a structure for thinking about how to separate out the ends (or fundamental) objectives from the means objectives. Several authors have defined the mathematics behind the quantification of a value structure for the analysis of alternatives, see Keeney and Raiffa (1976), French (1986), and Kirkwood (1997). In general, the quantification of preferences must deal with tradeoffs among objectives, risk preference introduced by uncertainty, and time preference introduced by achieving payoffs across the objectives at different points in time. Besides having complex issues to quantify, the DM must deal with subjective

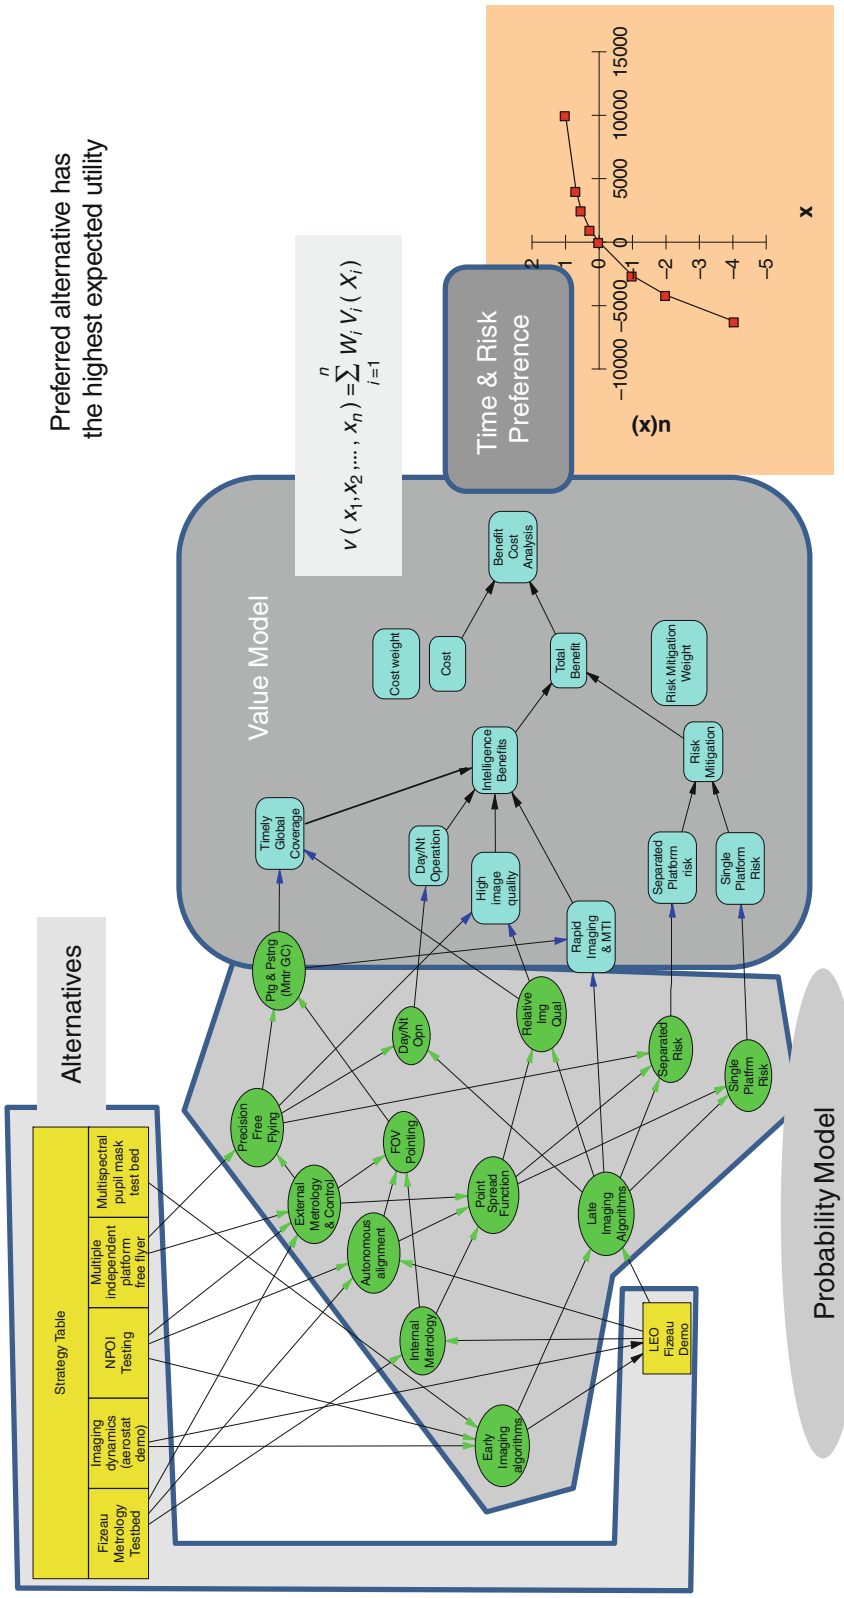
judgments, because there can be no source of preference information other than human judgment. Those approaches that attempt to avoid human judgment are throwing the proverbial baby out with the bath water.

Alternatives are the actions (expenditures of resources) that the DM can take now and into the future. In general, the set of alternatives also includes what are termed options or delayed actions that the DM can decide to take in the future if certain events occur between now and the time associated with the option. The space of alternatives is commonly defined over a discrete set, though there is nothing in the theory of decision analysis that precludes a continuous selection set. Various processes have been used to define this set of alternatives, including brainstorming activities. The most commonly discussed approach is called a strategy table or morphological box (Buede 2009). The strategy table divides the alternative space (including any options) into a discrete number of elements or components. For each element, multiple possible selections are defined. The combination of elements and choices within each element are analogous to a buffet dinner during which each diner selects zero, one or more choices from each element and places them onto a plate. If we require each diner to take one and only one selection from each of N elements of the dinner, there are (n_1 x n_2 x ... x n_N) possible dinners that could be selected. When the choice process is broaden to include no selection or several selections from each element, the number of possible dinners grows. (Note: it is also possible that some of these combinations are impossible or very negatively valued.) Typically, members of the decision-making team are asked to pick five to fifteen representative and interesting selections from the large number of possible selections for the analysis to consider. Often, the evaluation of the initial selection of alternatives from the strategy table will be followed by a second selection of alternatives from the strategy table, with a second round of analysis for this new set. The second set (and possibly a third set) would examine alternatives more like those that did well in the first evaluation and less like those that did poorly.

The linkage between the alternatives and values (both certain and uncertain) is the third element of analytic decomposition of decision analysis. Some parts of this linkage may be well known and deterministic, such as a specific cost of a car, a defined amount of money to purchase. Other parts of this linkage may not be well known, thus requiring the development of a probability distribution; for example, the same car with a known purchase price may not have such a well-known operating cost over the next five to ten years. In some cases, we can develop a probability distribution for this intermediate variable which has a known relationship to a measure for the relevant objective. In other cases, the relationship to one of the objectives may also be probabilistic, requiring the development of an influence diagram with chance nodes separating some or all of the alternatives from the objectives, see Fig. 1.

Once the analytical structure has been built by decomposing the decision problem into such constructs as alternatives, value models, and uncertainties, there is a need to compute (or synthesize) the expected utility of each possible alternative, and to answer additional questions that the DM may have. Examples of common questions are: there is some disagreement about what the risk preference (or time preference or value trade-offs or probabilities) should be, does this make any difference?; alternatives 1 and 2 are much better than the rest, but are very close in expected utility, what are the major differences between these two alternatives?; if one cannot be sure about some parameter's value in the model, will changing it by x% change the order of the alternatives in terms of expected utility? This whole process of computing the results and posing/answering questions regarding the meaning of the analysis and the robustness of the parameters in the analysis is called synthesis. This is exactly why a quantitative model is so much more helpful than a qualitative model. A qualitative model cannot provide these answers without a great deal of fuzziness, leading to continued discussion and argument.

A common criticism of decision analysis is that those involved cannot provide the preference and probabilistic numbers reliably and consistently. Many years of research has demonstrated this conclusively (Edwards et al. 2007; von Winterfeldt and Edwards 1986; Watson and Buede 1987). The real question, however, is not whether humans can provide these judgments accurately, but whether inaccurate judgments for a specified quantitative model leads to a better conversation about the decision being made than does a meandering, fuzzy conversation that starts and stops many times without having such a model or



Decision Making and Decision Analysis, Fig. 1 Representative Influence Diagram

any other anchor guiding it. Those who have participated in such meandering, fuzzy conversations have been often left with an empty feeling that there is no real agreement or understanding about the implications of the decision. As long as the key DMs have been involved in the quantitative modeling and understand the results of the synthesis, it is possible to argue that the quantitative analysis, with all of it flaws, has produced useful insights into the decision and provides an accurate audit trail about what was known and not known at the time of decision. The quantitative model is, however, a model and thus subject to the famous quote: "Essentially, all models are wrong, but some are useful" (Box and Draper 1987, p 424).

Decison Analytic Strategies

Many individuals and consulting companies have aided DMs and their organizations to arrive at better decisions. Watson and Buede (1987, pp. 123-159) identified five strategies: (1) modeling, (2) introspection, (3) rating, (4) conferencing, and (5) developing. A sixth strategy that is added here is aggregating mathematically.

1. **Modeling**. The modeling strategy involves building complex representations (models) that link the selection of specific options or alternatives to the values of the DM so that the expected utility across time of each option can be calculated. These models may be decision trees, influence diagrams (Shachter 1986) or simulation models. This approach runs the risk that the DM cannot understand the modeling and, therefore, does not gain the important insights from the model nor trust the results.
2. **Introspection**. The introspection strategy requires deep thought about (i.) the multiple-objective utility function across competing objectives, and (ii.) the joint probability distribution that relates the alternatives to these objectives. This approach is characterized by a question and answer process involving the decision analyst and a single DM (Keeney 1977). This approach does not benefit from additional opinions and expertise beyond the single DM.
3. **Rating**. The rating strategy is the simplest and most used. This strategy typically involves the assumption of an additive value model across multiple objectives, while ignoring time and risk preference, and a deterministic relationship between each alternative, the set of objectives, and their measures. Edwards (1971) introduced this approach under the acronym SMART, but later changed it to SMARTS to reflect the importance of using swing weights rather than importance weights. This approach ignores the complexities of value issues and uncertainty relating the alternatives to the objectives, and uses an ad hoc approach towards gathering information from other participants and experts.
4. **Conferencing**. The conferencing strategy employs simple models as used in Rating with a carefully constructed group (Phillips 2007). The advantage of the simple model is that it is transparent enough to the group to be trusted, and can then focus group discussions across the spectrum of concerns characterized by the objectives, allowing the appropriate experts to weigh in on their topics of expertise. This approach assumes the complexity of the problem is being addressed by the collection of individuals in their reasoning processes, but always runs the risks that the collective reasoning process has interpreted the complexity incorrectly. This alternative reasoning process is difficult to document and scrutinize. Other conferencing approaches exist that utilize computer technology extensively (Nunamaker et al. 1993). These technological approaches to conferencing emphasize giving every participant a chance to enter their inputs via keypads, often limiting discussion. The critical issue is information transfer via open discussion versus group domination by a few individuals. The collective reasoning process is even harder to assess when individuals are communicating via key pads.
5. **Developing.** The developing strategy involves the development of a decision support system that will be used by an individual or collection of individuals for a specific class of decisions over time. This approach usually adopts either a modeling or rating approach to be embed inside the decision support system, along with access to a changing database (see Sauter (1997) for a summary). There continues to be a wide variety of software implementations that serve as a basis for these decision support systems.
6. **Aggregating mathematically**. There are a number of academics and some practitioners who believe a group is best supported by analyzing the decision

from each individual's perspective, and then creating a mathematical aggregation of those individual perspectives. These approaches have been categorized as: social choice theory, group utility analysis, group consensus, and game theory.

Decision Problem

The basic decision problem is as follows: Given a set of r alternative actions $A = \{a_1,\ldots, a_r\}$, a set of q states of nature $S = \{s_1,\ldots, s_q\}$, a set of rq outcomes $O = \{o_1, \ldots, o_{rq}\}$, a corresponding set of rq payoffs $P = \{p_1,\ldots, p_{rq}\}$, and a decision criterion to be optimized, $f(a_j)$, where f is a real-valued function defined on A, choose an alternative action a_j that optimizes the decision criterion $f(a_j)$.

Decision Support Systems (DSS)

Andrew Vazsonyi
University of San Francisco, San Francisco, CA, USA

Introduction

Throughout history there has been a deeply embedded conviction that, under the proper conditions, some people are capable of helping others come to grips with problems in daily life. Such professional helpers are called counselors, psychiatrists, psychologists, social workers, and the like. In addition to these professional helpers, there are less formal helpers, such as ministers, lawyers, teachers, or even bartenders, hairdressers, and cab drivers.

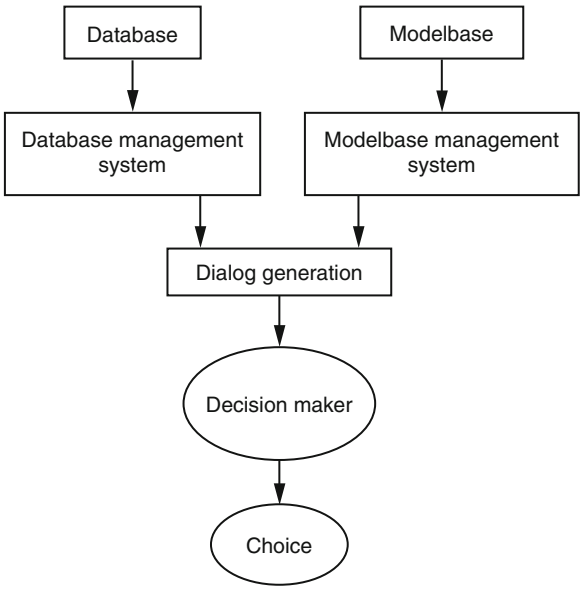
The proposition that science and quantitative methods, such as those used in OR/MS, may help people is relatively new, and is still received by many with deep skepticism. There are some disciplines overlapping and augmenting OR/MS. One important one is called decision support systems (DSS).

Before discussion of DSS, it is to be stressed that the expression is used in a different manner by different people, and there is no general agreement of what DSS really is. Moreover, the benefits claimed by DSS are in no way different from the benefits claimed by OR/MS. To appreciate DSS, a pluralistic view must be taken of the various disciplines offered to help managerial decision making.

Features of Decision Support Systems

During the early 1970s, under the impact of new developments in computer systems, a new perspective about decision making appeared. Keen and Morton (1973) coined the expression decision support systems, to designate their approach to the solution of managerial problems. They postulated a number of distinctive characteristics of DSS, especially the five listed below:

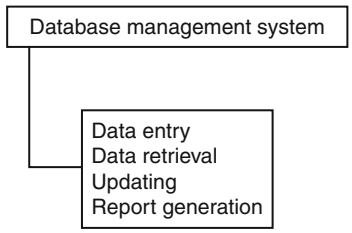
- A DSS is designed for specific decision makers and their decision tasks,
- A DSS is developed by cycling between design and implementation,
- A DSS is developed with a high degree of user involvement,
- A DSS includes both data and models, and
- Design of the user-machine interface is a critical task in the development of a DSS.



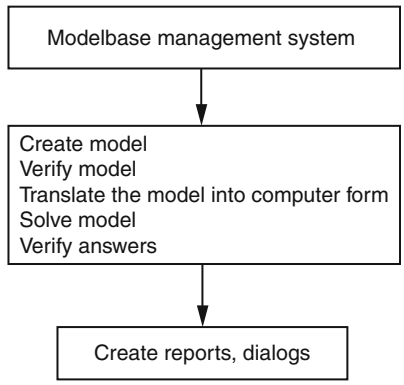
Decision Support Systems (DSS), Fig. 1 Components of a DSS

Figure 1 shows the structure and major components of a DSS. The database holds all the relevant facts of the problem, whether they pertain to the firm or to the environment. The database management system (Fig. 2) takes care of the entry, retrieval, updating, and deletion of data. It also responds to inquiries and generates reports.

The modelbase holds all the models required to work the problem. The modelbase management system (Fig. 3) assists in creating the mathematical model, and in translating the human prepared mathematical model into computer understandable form. The critical process of the modelbase management system is finding the solution to the mathematical model. The system also generates



Decision Support Systems (DSS), Fig. 2 Database management system



Decision Support Systems (DSS), Fig. 3 Modelbase management system

reports and assists in the preparation of computer-human dialogs.

While OR/MS stresses the model, DSS stresses the computer-based database. DSS emphasizes the importance of the user-machine interface, and the design of dialog generation and management software.

Advocates of DSS assert that by combining the power of the human mind and the computer, DSS is capable of enhancing decision making, and that DSS can grapple with problems not subject to the traditional approach of OR/MS.

Note that DSS stresses the role of humans in decision making, and explicitly factors human capabilities into decision making. A decision support system accepts the human as an essential subsystem. DSS does not usually try to optimize in a mathematical sense, and bounded rationality and satisficing provide guidance to the designers of DSS.

Designing Decision Support Systems

The design phases of DSS are quite similar to the phases of the design, implementation, and testing of other systems. It is customary to distinguish six phases, although not all six phases are required for every DSS.

1. During the systems analysis and design phase, existing systems are reviewed and analyzed with the objective of establishing requirements and needs of the new system. Then it is established whether meeting the specifications is feasible from the technical, economical, psychological, and social points of view. Is it possible to overcome the difficulties, and are opportunities commensurate with costs? If the answers are affirmative, meetings with management are held to obtain support. This phase produces a conceptual design and master plan.
2. During the design phase, input, processing, and output requirements are developed and a logical (not physical) design of the system is prepared. After the logical design is completed and found to be acceptable, the design of the hardware and software is undertaken.
3. During the construction and testing phase, the software is completed and tested on the hardware system. Testing includes user participation to assure that the system will be acceptable both from the points of view of the user and management, if they are different.
4. During the implementation phase, the system is retested, debugged, and put into use. To assure final user acceptance, no effort is spared in training and educating users. Management is kept up-to-date on the progress of the project.
5. Operation and maintenance is a continued effort during the life of the DSS. User satisfaction is monitored, errors are uncovered and corrected, and the method of operating the system is fine-tuned.
6. Evaluation and control is a continued effort to assure the viability of the system and the maintenance of management support.

A Forecasting System

Connoisseur Foods is a diversified food company with several autonomous subdivisions and subsidiaries (adapted from Alter 1980, and Turban 1990). Several of the division managers were old-line managers relying on experience and judgment to make major decisions. Top management installed a DSS to provide quantitative help to establish and monitor levels of such marketing

efforts as advertising, pricing, and promotion. The DSS model was based on S-shaped response functions of marketing conditions to such decision functions as advertising. The curves were derived by using both historical data and marketing experts. The databases for the farm products division contained about 20 million data items on sales both in dollars and number of units for 400 items sold in 300 branches.

The DSS assisted management in developing better marketing strategies and more competitive positions. Top management, however, stated that the real benefit of the DSS was not so much the installation of isolated systems and models, but the assimilation of new approaches in corporate decision making.

A Portfolio Management System

The trust division of Great Eastern Bank employed 50 portfolio managers in several departments (adapted from Alter 1980 and Turban 1990). The portfolio managers controlled many small accounts, large pension funds, and provided advice to investors in large accounts. The on-line DSS portfolio management system provided information to the portfolio managers.

The DSS includes lists of stocks from which the portfolio managers could buy stocks, information, and analysis on particular industries. It is basically a data retrieval system that could display portfolios, as well as specific information on securities.

The heart of the system is the database that allowed portfolio managers to generate reports with the following functions:

- Directory by accounts,
- Table to scan accounts,
- Graphic display of breakdown by industry and security for an account,
- Tabular listing of all securities within an account,
- Scatter diagrams between data items,
- Summaries of accounts,
- Distribution of data on securities,
- Evaluation of hypothetical portfolios,
- Performance monitoring of portfolios,
- Warnings if deviations from guidelines occur; and
- Tax implications.

The benefits of the systems were better investment performance, improved information, improved presentation formats, less clerical work, better communication, improved bank image, and enhanced marketing capability.

Concluding Remarks

Advocates of DSS claim that DSS deals with unstructured or semistructured problems, while OR/MS is restricted to structured problems. Few workers in OR/MS would agree.

At the onset, it is frequently the case that a particular business situation is confusing, and, to straighten it out, a problem must be instituted and the problem must be structured. Thus, whether OR/ MS or DSS or both are involved, attempts will be made to structure as much of the situation as possible.

The problem will be structured by OR/MS or DSS to the point that some part of the problem can be taken care of by quantitative methods and computers, and some others are left to human judgment, intuition, and opinion. There may be a degree of difference between OR/MS and DSS: OR/MS may stress optimization, the model base; DSS the database.

Attempts to draw the line between DSS and OR/MS are counterproductive. Those who are dedicated to help management in solving hard problems need to be concerned with any and all theories, practices, and principles that can help. To counsel management in the most productive manner requires that no holds be barred when a task is undertaken.

The principles of DSS are often used without mention in simulation programs. Moreover, as in the spirit of DSS, the user-machine interface is often visual, given the animation capability of modern computers. Thus, managerial decisions may be influenced not only by using traditional quantitative measures, but also by judging customer perceptions.

Decision Trees

Stuart Eriksen[1], Candice H. Huynh[2] and L. Robin Keller[2]

[1]Santa Ana, CA, USA

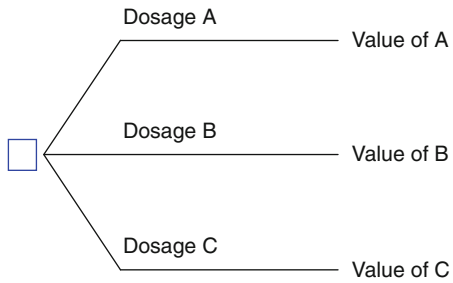
[2]University of California, Irvine, CA, USA

Introduction

A decision tree is a pictorial description of a well-defined decision problem. It is a graphical representation consisting of nodes (where decisions are made or chance events occur) and arcs (which connect nodes). Decision trees are useful because they provide a clear, documentable, and discussible model of either how the decision was made or how it will be made.

The tree provides a framework for the calculation of the expected value of each available alternative. The alternative with the maximum expected value is the best choice path based on the information and mind-set of the decision makers at the time the decision is made. This best choice path indicates the best overall alternative, including the best subsidiary decisions at future decision steps, when uncertainties have been resolved.

The decision tree should be arranged, for convenience, from left to right in the temporal order in which the events and decisions will occur. Therefore, the steps on the left occur earlier in time than those on the right.



Decision Trees, Fig. 1 The choice of drug dosage

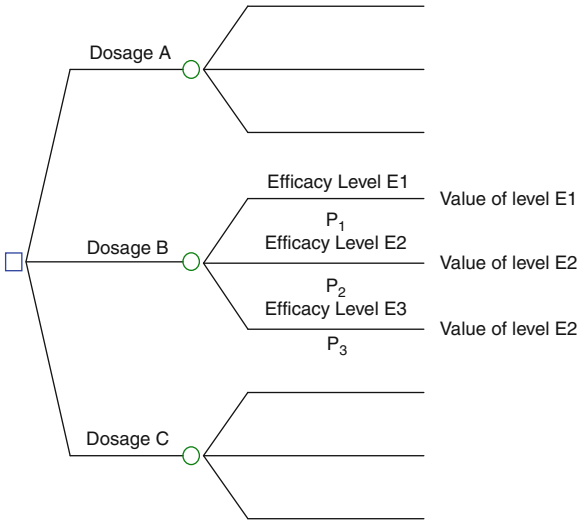
Decision Nodes

Steps in the decision process involving decisions between several choice alternatives are indicated by decision nodes, drawn as square boxes. Each available choice is shown as one arc (or path) leading away from its decision node toward the right. When a planned decision has been made at such a node, the result of that decision is recorded by drawing an arrow in the box pointing toward the chosen option. As an example of the process, consider a pharmaceutical company president's choice of which drug dosage to market. The basic dosage choice decision tree is shown in Fig. 1. Note that the values of the eventual outcomes (on the far right) will be expressed as some measure of value to the eventual user (for example, the patient or the physician).

Chance Nodes

Steps in the process which involve uncertainties are indicated by circles (called chance nodes), and the possible outcomes of these probabilistic events are again shown as arcs or paths leading away from the node toward the right. The results of these uncertain factors are out of the hands of the decision maker; chance or some other group or person (uncontrolled by the decision maker) will determine the outcome of this node. Each of the potential outcomes of a chance node is labeled with its probability of occurrence.

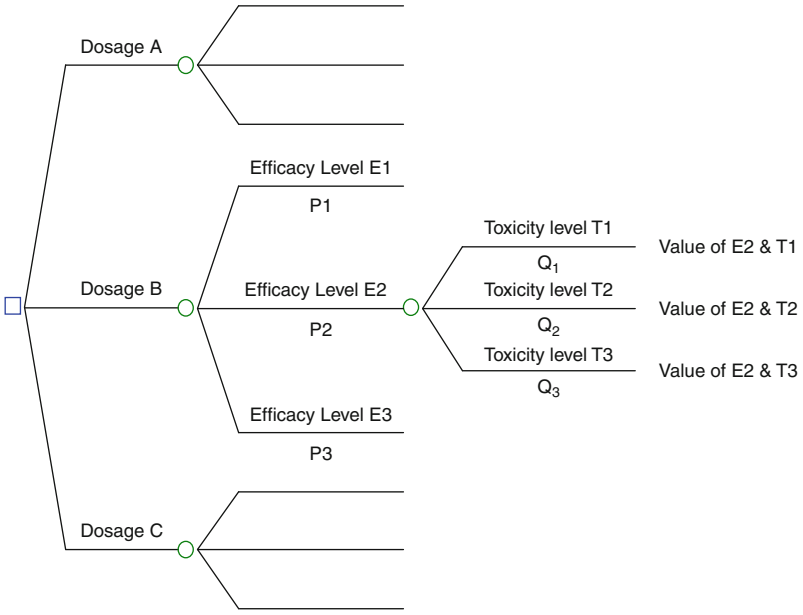
All possible outcomes must be indicated, so the sum of the potential outcome probabilities of a chance node must equal 1.0. Using the drug dose selection problem noted above, the best choice of dose depends on at least one probabilistic event: the level of performance of the drug in clinical trials, which is a proxy measure of the efficacy of the drug. A simplified decision tree for that part of the firm's decision is shown in Fig. 2. Note that each dosage choice has a subsequent efficacy chance node similar to the one shown, so the expanded tree would have nine outcomes. The probabilities (p_1, p_2, and p_3) associated with the outcomes are expected to differ for each dosage.



Decision Trees, Fig. 2 The choice of drug dosage based on efficacy outcome

There are often several nodes in a decision tree; in the case of the drug dosage decision, the decision will also depend on the toxicity as demonstrated by both animal study data and human toxicity study data, as well as on the efficacy data. The basic structure of this more complex decision is shown in Fig. 3. The completely expanded tree has 27 eventual outcomes and associated values. Notice that although not always the case, here the probabilities (q_1, q_2, and q_3) of the toxicity levels are independent of the efficacy level.

One use of a decision tree is to clearly display the factors and assumptions involved in a decision. If the decision outcomes are quantified and the probabilities of chance events are specified, the tree can also be analyzed by calculating the expected value of each alternative. If several decisions are involved in the problem being considered, the strategy best suited to each specific set of chance outcomes can be planned in advance.



Decision Trees, Fig. 3 The choice of dosage based on uncertain efficacy and toxicity

Probabilities

Estimates of the probabilities for each of the outcomes of the chance nodes must be made. In the simplified case of the drug dose decision above, the later chance node outcome probabilities are modeled as being independent of the earlier chance nodes. While not intuitively obvious, careful thought should show that the physiological factors involved in clinical efficacy must be different from those involved in toxicity, even if the drug is being used to treat that toxicity. Therefore, with most drugs, the probability of high human toxicity is likely independent of the level of human efficacy. In the more general non-drug situations, however, for sequential steps, the latter probabilities are often dependent conditional probabilities, since their value depends on the earlier chance outcomes.

For example, consider the problem in Fig. 4, where the outcome being used for the drug dose decision is based on the eventual sales of it. The values of the eventual outcomes now are expressed as sales for the firm.

The probability of high sales depends on the efficacy as well as on the toxicity, so the dependent conditional probability of high sales is the probability of high sales given that the efficacy is level 2 and toxicity is level 2, which can be written as $p_{(\text{High Sales}|\text{E2\&T2})}$.

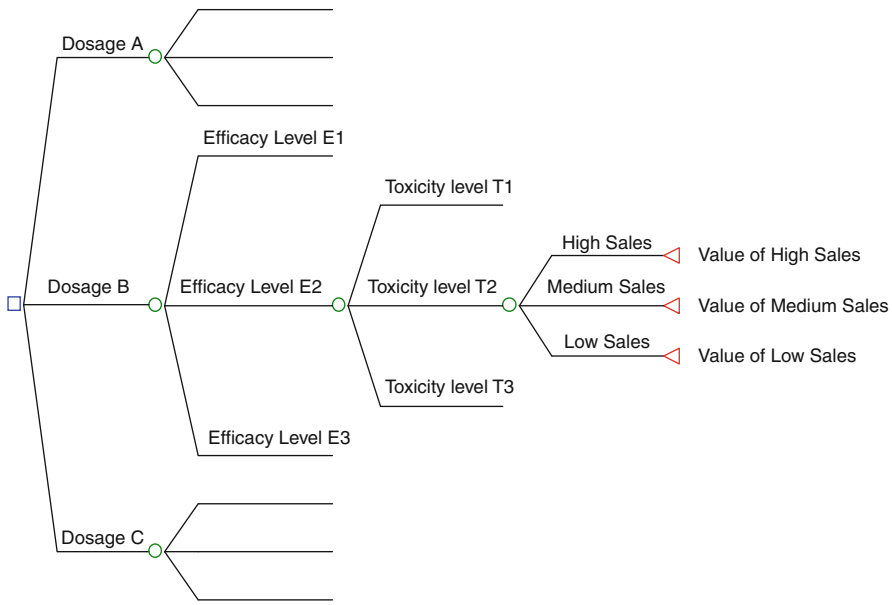
Outcome Measures

At the far right of the tree, the possible outcomes are listed at the end of each branch. To calculate numerical expected values for alternative choices, outcomes must be measured numerically and often monetary measures will be used. More generally, the utility of the outcomes can be calculated. Single or multiple attribute utility functions have been elicited in many decision situations to represent decision makers' preferences for different outcomes on a numerical (although not monetary) scale.

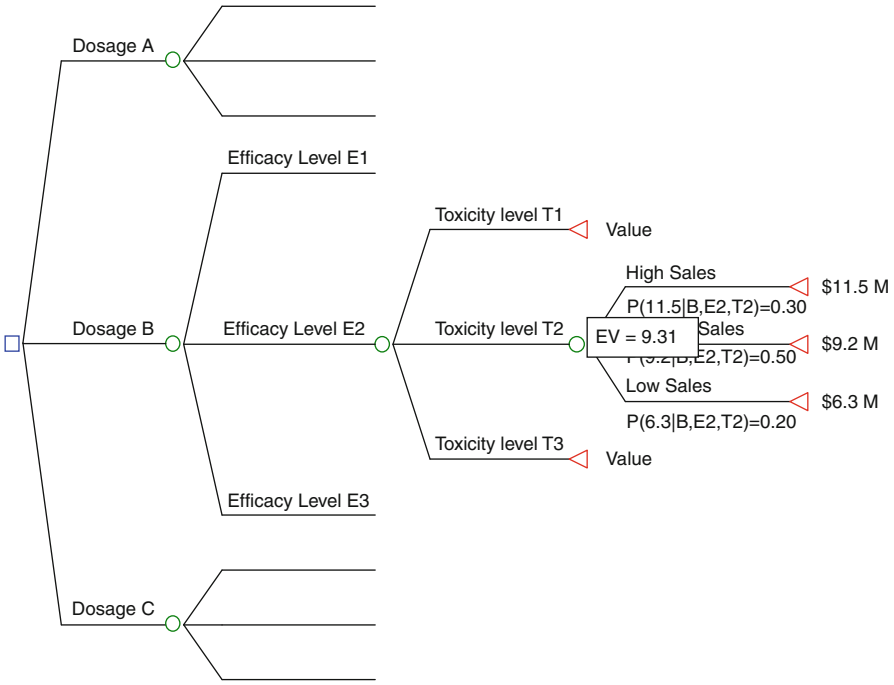
The Tree as an Aid in Decision Making

The decision tree analysis method is called fold-back and prune. Beginning at a far right chance node of the tree, the expected value of the outcome measure is calculated and recorded for each chance node by summing, over all the outcomes, the product of the probability of the outcome times the measured value of the outcome. Figure 5 shows this calculation for the first step in the analysis of the drug-dose decision tree.

This step is called folding back the tree since the branches emanating from the chance node are folded



Decision Trees, Fig. 4 The choice of dosage based on efficacy and toxicity and their eventual effect on sales

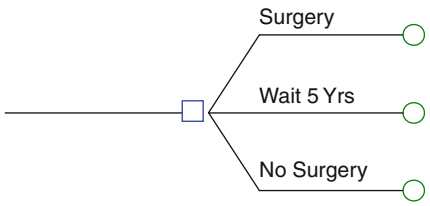


Decision Trees, Fig. 5 The first step, calculating the expected value of the chance node for sales: EV = 0.3(11.5) + 0.5(9.2) + 0.2(6.3) = 9.31

up or collapsed, so that the chance node is now represented by its expected value. This is continued until all the chance nodes on the far right have been evaluated. These expected values then become the values for the outcomes of the chance or decision nodes further to the left in the diagram. At a decision node, the best of the alternatives is the one with the maximum expected value, which is then recorded by drawing an arrow towards that choice in the decision node box and writing down the expected value associated with the chosen option. This is referred to as pruning the tree, as the less valuable choices are eliminated from further consideration. The process continues from right to left, by calculating the expected value at each chance node and pruning at each decision node. Finally the best choice for the overall decision is found when the last decision node at the far left has been evaluated.

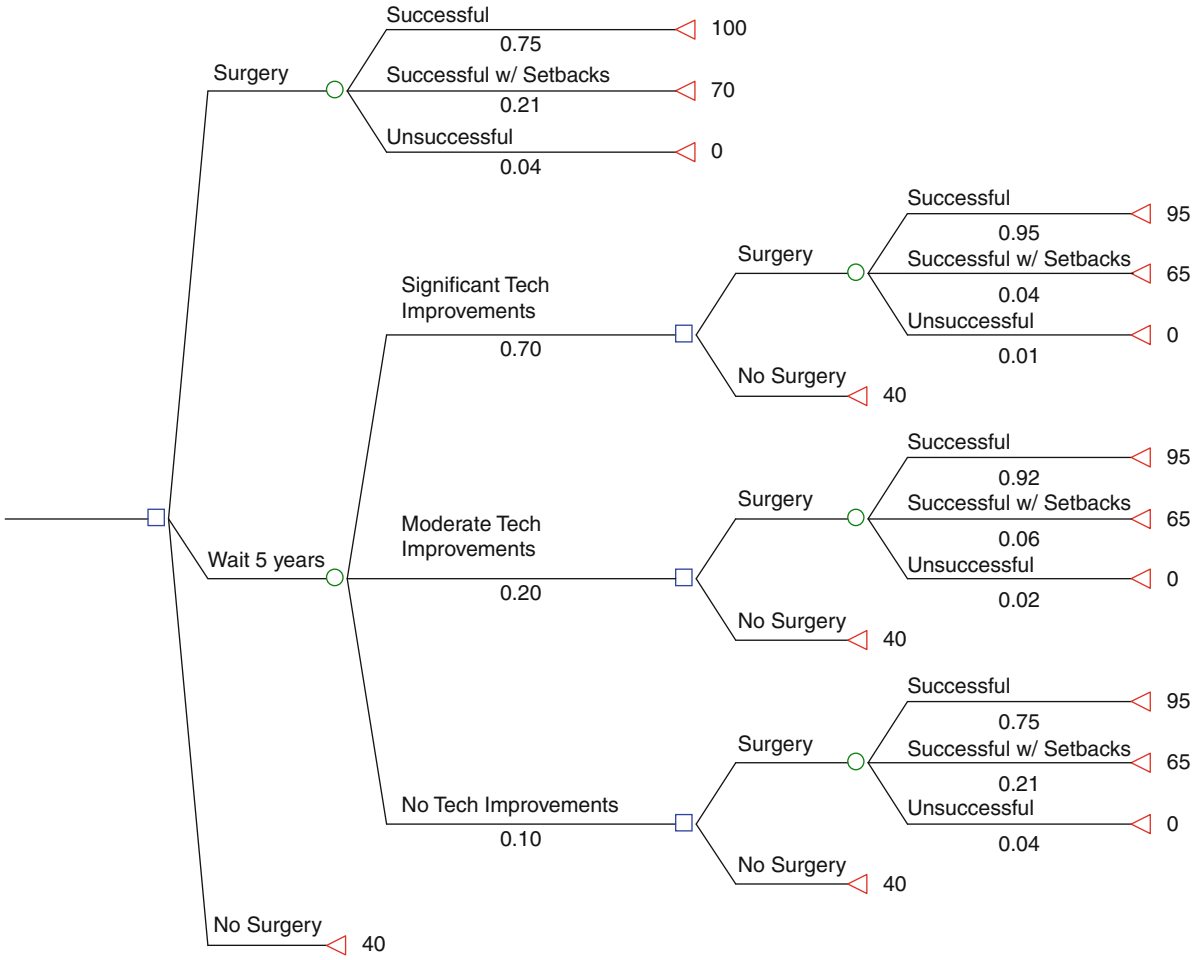
Example

In this example, a decision faced by a patient who is considering laser eye surgery to improve her vision will be considered. The basic decision process is shown in Fig. 6. The initial decision a patient encounters is whether to: have the surgery, wait for more technological advances, or not have the surgery at all.



Decision Trees, Fig. 6 The initial decision point

Suppose that if a patient chooses to wait at the first decision node, she will observe the outcome of possible technological advances at the first chance node, and then will have to make the decision of whether to have the surgery or not. Figure 7 shows a detailed decision tree of this patient's decision process. The entries at the end of the branches can be seen as a measure of health utility to the patient, on a 0-100 scale, where 100 is the best level of health utility. Other patients can customize this tree to their personal circumstances using a combination of chance and decision nodes.



Decision Trees, Fig. 7 Complete mapping of the decision process of whether or not to have lasik surgery

Following the method of folding back the tree, the expected health utility of having the surgery immediately is 89.70, waiting 5 years is 91.74, and not having the surgery at all is 40.00, where the calculation of each chance node is the expected health utility. And so waiting 5 years is the optimal decision for the patient in this example.

Deep Uncertainty

Warren E. Walker[1], Robert J. Lempert[2] and Jan H. Kwakkel[1]
[1]Delft University of Technology, Delft, The Netherlands
[2]RAND Corporation, Santa Monica, CA, USA

Introduction

The notion of uncertainty has taken different meanings and emphases in various fields, including the physical sciences, engineering, statistics, economics, finance, insurance, philosophy, and psychology. Analyzing the notion in each discipline can provide a specific historical context and scope in terms of problem domain, relevant theory, methods, and tools for handling uncertainty. Such analyses are given by Agusdinata (2008), van Asselt (2000), Morgan and Henrion (1990), and Smithson (1989).

In general, uncertainty can be defined as limited knowledge about future, past, or current events. With respect to policy making, the extent of uncertainty clearly involves subjectivity, since it is related to the satisfaction with existing knowledge, which is colored by the underlying values and perspectives of the policymaker and the various actors involved in the policy-making process, and the decision options available to them.

Shannon (1948) formalized the relationship between the uncertainty about an event and information in "A Mathematical Theory of Communication." He defined a concept he called entropy as a measure of the average information content associated with a random outcome. Roughly speaking, the concept of entropy in information theory describes how much information there is in a signal or event and relates this to the degree of uncertainty about a given event having some probability distribution.

Uncertainty is not simply the absence of knowledge. Funtowicz and Ravetz (1990) describe uncertainty as a situation of inadequate information, which can be of three sorts: inexactness, unreliability, and border with ignorance. However, uncertainty can prevail in situations in which ample information is available (Van Asselt and Rotmans 2002). Furthermore, new information can either decrease or increase uncertainty. New knowledge on complex processes may reveal the presence of uncertainties that were previously unknown or were understated. In this way, more knowledge illuminates that one's understanding is more limited or that the processes are more complex than previously thought (van der Sluijs 1997).

Uncertainty as inadequacy of knowledge has a very long history, dating back to philosophical questions debated among the ancient Greeks about the certainty of knowledge, and perhaps even further. Its modern history begins around 1921, when Knight made a distinction between risk and uncertainty (Knight 1921). According to Knight, risk denotes the calculable and thus controllable part of all that is unknowable. The remainder is the uncertain – incalculable and uncontrollable. Luce and Raiffa (1957) adopted these labels to distinguish between decision making under risk and decision making under uncertainty. Similarly, Quade (1989) makes a distinction between stochastic uncertainty and real uncertainty. According to Quade, stochastic

LOCATION	LEVEL	Complete Certainty	Level 1	Level 2	Level 3	Level 4	Level 5	Total ignorance
	Context		A clear enough future 	Alternate futures (with probabilities) 	Alternate futures with ranking 	A multiplicity of plausible futures 	An unknown future

	System outcomes		A point estimate for each outcome	A confidence interval for each outcome	Several sets of point estimates, ranked according to their perceived likelihood	A known range of outcomes	Unknown outcomes; know we don't know	
	Weights on outcomes		A single set of weights	Several sets of weights, with a probability attached to each set	Several sets of weights, ranked according to their perceived likelihood	A known range of weights	Unknown weights; know we don't know	

Deep Uncertainty, Fig. 1 The progressive transition of levels of uncertainty from complete certainty to total ignorance

uncertainty includes frequency-based probabilities and subjective (Bayesian) probabilities. Real uncertainty covers the future state of the world and the uncertainty resulting from the strategic behavior of other actors. Often, attempts to express the degree of certainty and uncertainty have been linked to whether or not to use probabilities, as exemplified by Morgan and Henrion (1990), who make a distinction between uncertainties that can be treated through probabilities and uncertainties that cannot. Uncertainties that cannot be treated probabilistically include model structure uncertainty and situations in which experts cannot agree upon the probabilities. These are the more important and hardest to handle types of uncertainties (Morgan 2003). As Quade (1989, p. 160) wrote: "Stochastic uncertainties are therefore among the least of our worries; their effects are swamped by uncertainties about the state of the world and human factors for which we know absolutely nothing about probability distributions and little more about the possible outcomes." These kinds of uncertainties are now referred to as deep uncertainty (Lempert et al. 2003), or severe uncertainty (Ben-Haim 2006).

Levels of Uncertainty

Walker et al. (2003) define uncertainty to be "any departure from the (unachievable) ideal of complete determinism."

For purposes of determining ways of dealing with uncertainty in developing public policies or business strategies, one can distinguish two extreme levels of uncertainty—complete certainty and total ignorance—and five intermediate levels (e.g. Courtney 2001; Walker et al. 2003; Makridakis et al. 2009; Kwakkel et al. 2010d). In Fig. 1, the five levels are defined with respect to the knowledge assumed about the various aspects of a policy problem: (a) the future world, (b) the model of the relevant system for that future world, (c) the outcomes from the system, and (d) the weights that the various stakeholders will put on the outcomes. The levels of uncertainty are briefly discussed below.

Complete certainty is the situation in which everything is known precisely. It is not attainable, but acts as a limiting characteristic at one end of the spectrum.

Level 1 uncertainty (A clear enough future) represents the situation in which one admits that one is not absolutely certain, but one is not willing or able to measure the degree of uncertainty in any explicit way (Hillier and Lieberman 2001, p. 43). Level 1 uncertainty is often treated through a simple sensitivity analysis of model parameters, where the impacts of small perturbations of model input parameters on the outcomes of a model are assessed.

Level 2 uncertainty (Alternate futures with probabilities) is any uncertainty that can be described adequately in statistical terms. In the case of uncertainty about the future, Level 2 uncertainty is often captured in the form of either a (single) forecast (usually trend based) with a confidence interval or multiple forecasts (scenarios) with associated probabilities.

Level 3 uncertainty (Alternate futures with ranking) represents the situation in which one is able to enumerate multiple alternatives and is able to rank the alternatives in terms of perceived likelihood. That is, in light of the available knowledge and information there are several different parameterizations of the system model, alternative sets of outcomes, and/or different conceivable sets of weights. These possibilities can be ranked according to their perceived likelihood (e.g. virtually certain, very likely, likely, etc.). In the case of uncertainty about the future, Level 3 uncertainty about the future world is often captured in the form of a few trend-based scenarios based on alternative assumptions about the driving forces (e.g., three trend-based scenarios for air transport demand, based on three different assumptions about GDP growth). The scenarios are then ranked according to their perceived likelihood, but no probabilities are assigned, see Patt and Schrag (2003) and Patt and Dessai (2004).

Level 4 uncertainty (Multiplicity of futures) represents the situation in which one is able to enumerate multiple plausible alternatives without being able to rank the alternatives in terms of perceived likelihood. This inability can be due to a lack of knowledge or data about the mechanism or functional relationships being studied; but this inability can also arise due to the fact that the decision makers cannot agree on the rankings. As a result, analysts struggle to specify the appropriate models to describe interactions among the system's variables, to select the probability distributions to represent uncertainty about key parameters in the models, and/or how to value the desirability of alternative outcomes (Lempert et al. 2003).

Level 5 uncertainty (Unknown future) represents the deepest level of recognized uncertainty; in this case, what is known is only that we do not know. This ignorance is recognized. Recognized ignorance is increasingly becoming a common feature of life, because catastrophic, unpredicted, surprising, but painful events seem to be occurring more often. Taleb (2007) calls these events "Black Swans." He defines a Black Swan event as one that lies outside the realm of regular expectations (i.e., "nothing in the past can convincingly point to its possibility"), carries an extreme impact, and is explainable only after the fact (i.e., through retrospective, not prospective, predictability). One of the most dramatic recent Black Swans is the concatenation of events following the 2007 subprime mortgage crisis in the U.S. The mortgage crisis (which some had forecast) led to a credit crunch, which led to bank failures, which led to a deep global recession in 2009, which was outside the realm of most expectations. Another recent Black Swan was the level 9.0 earthquake in Japan in 2011, which led to a tsunami and a nuclear catastrophe, which led to supply chain disruptions (e.g., for automobile parts) around the world.

Total ignorance is the other extreme on the scale of uncertainty. As with complete certainty, total ignorance acts as a limiting case.

Lempert et al. (2003) have defined deep uncertainty as "the condition in which analysts do not know or the parties to a decision cannot agree upon (1) the appropriate models to describe interactions among a system's variables, (2) the probability distributions to represent uncertainty about key parameters in the models, and/or (3) how to value the desirability of alternative outcomes. They use the language 'do not know' and 'do not agree upon' to refer to individual and group decision making, respectively. This article includes both individual and group decision making in all five of the levels, referring to Level 4 and Level 5 uncertainties as 'deep uncertainty', and assigning the 'do not know' portion of the definition to Level 5 uncertainties and the 'cannot agree upon' portion of the definition to Level 4 uncertainties.

Decision Making Under Deep Uncertainty

There are many quantitative analytical approaches to deal with Level 1, Level 2, and Level 3 uncertainties. In fact, most of the traditional applied scientific work in the engineering, social, and natural sciences has been built upon the supposition that the uncertainties result from either a lack of information, which "has led to an emphasis on uncertainty reduction through ever-increasing information seeking and processing" (McDaniel and Driebe 2005), or from random variation, which has concentrated efforts on stochastic processes and statistical analysis. However, most of the important policy problems faced by policymakers are characterized by the higher levels of uncertainty, which cannot be dealt with through the use of probabilities and cannot be reduced by gathering more information, but are basically unknowable and unpredictable at the present time. And these high levels of uncertainty can involve uncertainties about all aspects of a policy problem — external or internal developments, the appropriate (future) system model, the parameterization of the model, the model outcomes, and the valuation of the outcomes by (future) stakeholders.

For centuries, people have used many methods to grapple with the uncertainty shrouding the long-term future, each with its own particular strengths. Literary narratives, generally created by one or a few individuals, have an unparalleled ability to capture people's imagination. More recently, group processes, such as the Delphi technique (Quade 1989), have helped large groups of experts combine their expertise into narratives of the future. Statistical and computer simulation modeling helps capture quantitative information about the extrapolation of current trends and the implications of new driving forces. Formal decision analysis helps to systematically assess the consequences of such information. Scenario-based planning helps individuals and groups accept the fundamental uncertainty surrounding the long-term future and consider a range of potential paths, including those that may be inconvenient or disturbing for organizational, ideological, or political reasons.

Despite this rich legacy, these traditional methods all founder on the same shoals: an inability to grapple with the long term's multiplicity of plausible futures. Any single guess about the future will likely prove wrong. Policies optimized for a most likely future may fail in the face of surprise. Even analyzing a well-crafted handful of scenarios will miss most of the future's richness and provides no systematic means to examine their implications. This is particularly true for methods based on detailed models. Such models that look sufficiently far into the future should raise troubling questions in the minds of both the model builders and the consumers of model output. Yet the root of the problem lies not in the models themselves, but in the way in which models are used. Too often, analysts ask what will happen, thus trapping themselves in a losing game of prediction, instead of the question they really would like to have answered: Given that one cannot predict, which actions available today are likely to serve best in the future?

Broadly speaking, although there are differences in definitions, and ambiguities in meanings, the literature offers four (overlapping, not mutually exclusive) ways for dealing with deep uncertainty in making policies, see van Drunen et al. (2009).

Resistance: plan for the worst conceivable case or future situation,

- *Resilience*: whatever happens in the future, make sure that you have a policy that will result in the system recovering quickly,
- *Static robustness*: implement a (static) policy that will perform reasonably well in practically all conceivable situations,
- *Adaptive robustness*: prepare to change the policy, in case conditions change.

The first approach is likely to be very costly and might not produce a policy that works well because of Black Swans. The second approach accepts short-term pain (negative system performance), but focuses on recovery.

The third and fourth approaches do not use models to produce forecasts. Instead of determining the best predictive model and solving for the policy that is optimal (but fragilely dependent on assumptions), in the face of deep uncertainty it may be wiser to seek among the alternatives those actions that are most robust — that achieve a given level of goodness across the myriad models and assumptions consistent with known facts (Rosenhead and Mingers 2001). This is the heart of any robust decision method. A robust policy is defined to be one that yields outcomes that are deemed to be satisfactory according to some selected

assessment criteria across a wide range of future plausible states of the world. This is in contrast to an optimal policy that may achieve the best results among all possible plans but carries no guarantee of doing so beyond a narrowly defined set of circumstances. An analytical policy based on the concept of robustness is also closer to the actual policy reasoning process employed by senior planners and executive decision makers. As shown by Lempert and Collins (2007), analytic approaches that seek robust strategies are often appropriate both when uncertainty is deep and a rich array of options is available to decision makers.

Identifying static robust policies requires reversing the usual approach to uncertainty. Rather than seeking to characterize uncertainties in terms of probabilities, a task rendered impossible by definition for Level 4 and Level 5 uncertainties, one can instead explore how different assumptions about the future values of these uncertain variables would affect the decisions actually being faced. Scenario planning is one approach to identifying static robust policies, see van der Heijden (1996). This approach assumes that, although the likelihood of the future worlds is unknown, a range of plausible futures can be specified well enough to identify a (static) policy that will produce acceptable outcomes in most of them. It works best when dealing with Level 4 uncertainties. Another approach is to ask what one would need to believe was true to discard one possible policy in favor of another. This is the essence of Exploratory Modeling and Analysis (EMA).

Long-term robust policies for dealing with Level 5 uncertainties will generally be dynamic adaptive policies—policies that can adapt to changing conditions over time. A dynamic adaptive policy is developed with an awareness of the range of plausible futures that lie ahead, is designed to be changed over time as new information becomes available, and leverages autonomous response to surprise. Eriksson and Weber (2008) call this approach to dealing with deep uncertainty Adaptive Foresight. Walker et al. (2001) have specified a generic, structured approach for developing dynamic adaptive policies for practically any policy domain. This approach allows implementation to begin prior to the resolution of all major uncertainties, with the policy being adapted over time based on new knowledge. It is a way to proceed with the implementation of long-term policies despite the presence of uncertainties. The adaptive policy approach makes dynamic adaptation explicit at the outset of policy formulation. Thus, the inevitable policy changes become part of a larger, recognized process and are not forced to be made repeatedly on an ad hoc basis. Under this approach, significant changes in the system would be based on an analytic and deliberative effort that first clarifies system goals, and then identifies policies designed to achieve those goals and ways of modifying those policies as conditions change. Within the adaptive policy framework, individual actors would carry out their activities as they would under normal policy conditions. But policymakers and stakeholders, through monitoring and corrective actions, would try to keep the system headed toward the original goals. McCray et al. (2010) describe it succinctly as keeping policy "yoked to an evolving knowledge base." Lempert et al. (2003, 2006) propose an approach called Robust Decision Making (RDM), which conducts a vulnerability and response option analysis using EMA to identify and compare (static or dynamic) robust policies. Walker et al. (2001) propose a similar approach for developing adaptive policies, called Dynamic Adaptive Policymaking (DAP).

Some Applications of Robust Decision Making (RDM) and Dynamic Adaptive Policymaking (DAP)

RDM has been applied in a wide range of decision applications, including the development of both static and adaptive policies. The study of Dixon et al. (2007) evaluated alternative (static) policies considered by the U.S. Congress while debating reauthorization of the Terrorism Risk Insurance Act (TRIA). TRIA provides a federal guarantee to compensate insurers for losses due to very large terrorist attacks in return for insurers providing insurance against attacks of all sizes. Congress was particularly interested in the cost to taxpayers of alternative versions of the program. The RDM analysis used a simulation model to project these costs for various TRIA options for each of several thousand cases, each representing a different combination of 17 deeply uncertain assumptions about the type of terrorist attack, the factors influencing the pre-attack distribution of insurance coverage, and any post-attack compensation

decisions by the U.S. Federal government. The RDM analysis demonstrated that the expected cost to taxpayers of the existing TRIA program would prove the same or less than any of the proposed alternatives except under two conditions: the probability of a large terrorist attack (greater than $40 billion in losses) significantly exceeded current estimates and future Congresses did not compensate uninsured property owners in the aftermath of any such attack. This RDM analysis appeared to help resolve a divisive Congressional debate by suggesting that the existing (static) TRIA program was robust over a wide range of assumptions, except for a combination that many policymakers regarded as unlikely. The analysis demonstrates two important features of RDM: (1) its ability to systematically include imprecise probabilistic information (in this case, estimates of the likelihood of a large terrorist attack) in a formal decision analysis, and (2) its ability to incorporate very different types of uncertain information (in this case, quantitative estimates of attack likelihood and qualitative judgments about the propensity of future Congresses to compensate the uninsured).

RDM has also been used to develop adaptive policies, including policies to address climate change (Lempert et al. 1996), economic policy (Seong et al. 2005), complex systems (Lempert 2002), and health policy (Lakdawalla et al. 2009). An example that illustrates RDM's ability to support practical adaptive policy making is discussed in Groves et al. (2008) and Lempert and Groves (2010). In 2005, Southern California's Inland Empire Utilities Agency (IEUA), that supplies water to a fast growing population in an arid region, completed a legally mandated (static) plan for ensuring reliable water supplies for the next twenty-five years. This plan did not, however, consider the potential impacts of future climate change. An RDM analysis used a simulation model to project the present value cost of implementing IEUA's current plans, including any penalties for future shortages, in several hundred cases contingent on a wide range of assumptions about six parameters representing climate impacts, IEUA's ability to implement its plan, and the availability of imported water. A scenario discovery analysis identified three key factors — an 8% or larger decrease in precipitation, any drop larger than 4% in the rain captured as groundwater, and meeting or missing the plan's specific goals for recycled waste water — that, if they occurred simultaneously, would cause IEUA's overall plan to fail (defined as producing costs exceeding by 20% or more those envisioned in the baseline plan). Having identified this vulnerability of IEUA's current plan, the RDM analysis allowed the agency managers to identify and evaluate alternative adaptive plans, each of which combined near-term actions, monitoring of key supply and demand indicators in the region, and taking specific additional actions if certain indicators were observed. The analysis suggested that IEUA could eliminate most of its vulnerabilities by committing to updating its plan over time and by making relative low-cost near-term enhancements in two current programs. Overall, the analysis allowed IEUA's managers, constituents, and elected officials, who did not all agree on the likelihood of climate impacts, to understand in detail vulnerabilities to their original plan and to identify and reach consensus on adaptive plans that could ameliorate those vulnerabilities.

An example of DAP comes from the field of airport strategic planning. Airports increasingly operate in a privatized and liberalized environment. Moreover, this change in regulations has changed the public's perception of the air transport sector. As a result of this privatization and liberalization, the air transport industry has undergone unprecedented changes, exemplified by the rise of airline alliances and low cost carriers, an increasing environmental awareness, and, since 9/11, increased safety and security concerns. These developments pose a major challenge for airports. They have to make investment decisions that will shape the future of the airport for many years to come, taking into consideration the many uncertainties that are present. DAP has been put forward as a way to plan the long-term development of an airport under these conditions (Kwakkel et al. 2010a). As an illustration, a case based on the current challenges of Amsterdam Airport Schiphol has been pursued. Using a simulation model that calculates key airport performance metrics such as capacity, noise, and external safety, the performance of an adaptive policy and a competing traditional policy across a wide range of uncertainties was explored. This comparison revealed that the traditional plan would have preferable performance only in the narrow bandwidth of future developments for which it was optimized. Outside this bandwidth, the adaptive policy had superior performance. The analysis further revealed

that the range of expected outcomes for the adaptive policy is significantly smaller than for the traditional policy. That is, an adaptive policy will reduce the uncertainty about the expected outcomes, despite various deep uncertainties about the future. This analysis strongly suggested that airports operating in an ever increasing uncertain environment could significantly improve the adequacy of their long-term development if they planned for adaptation (Kwakkel et al. 2010b, 2010c).

Another policy area to which DAP has been applied is the expansion of the port of Rotterdam. This expansion is very costly and the additional land and facilities need to match well with market demand as it evolves over the coming 30 years or more. DAP was used to modify the existing plan so that it can cope with a wide range of uncertainties. To do so, adaptive policy making was combined with Assumption-Based Planning (Dewar 2002). This combination resulted in the identification of the most important assumptions underlying the current plan. Through the adaptive policy making framework, these assumptions were categorized and actions for improving the likelihood that the assumptions will hold were specified (Taneja et al. 2010).

Various other areas of application of DAP have also been explored, including flood risk management in the Netherlands in light of climate change (Rahman et al. 2008), policies with respect to the implementation of innovative urban transport infrastructures (Marchau et al. 2008), congestion road pricing (Marchau et al. 2010), intelligent speed adaptation (Agusdinata et al. 2007), and magnetically levitated (Maglev) rail transport (Marchau et al. 2010).

Degeneracy

The situation in which a linear-programming problem has a basic feasible solution with at least one basic variable equal to zero. If the problem is degenerate, then an extreme point of the convex set of solutions may correspond to several feasible bases. As a result, the simplex method may move through a sequence of bases with no improvement in the value of the objective function. In rare cases, the algorithm may cycle repeatedly through the same sequence of bases and never converge to an optimal solution. Anticycling rules, and perturbation and lexicographic techniques prevent this risk, but usually at some computational expense.

Degeneracy Graphs

Tomas Gal
Fern Universität in Hagen, Hagen, Germany

Introduction

For a given linear-programming problem, primal degeneracy means that a basic feasible solution has at least one basic variable equal to zero. The problem is dual degenerate if a nonbasic variable has its reduced cost equal to zero (the condition for a multiple optimal solution to exist). Primal degeneracy may arise when there are some (weakly) redundant constraints (Karwan et al. 1983) or the structure of the corresponding convex polyhedral feasible set causes an extreme point to become overdetermined.

In nonlinear programming, such points are sometimes called singularities (Guddat et al. 1990). Here, constraint redundancy is equivalent to the failure of the linear independence constraint qualification of the binding constraint gradients, which, in general, leads to the nonuniqueness of optimal Lagrange multipliers (Fiacco and Liu 1993).

We focus here on primal degeneracy in the linear case: it is associated with multiple optimal bases and it allows for basis cycling to occur, that is, the nonconvergence of the simplex method due to the repeating of a sequence of nonoptimal feasible bases.

Let σ, called the degeneracy degree, be the number of zeros in a basic feasible solution. Also, let $U_{\min}$ and $U_{\max}$ be the minimal and the maximal number of possible bases associated with a degenerate vertex, respectively (Kruse 1986). To illustrate how many bases can be associated with a degenerate vertex, Table 1 shows, for some values for n, the number of (decision) variables, the associated values of σ, $U_{\min}$ and $U_{\max}$.

Historical Background

Soon after the simplex method had been invented by George Dantzig, he recognized that degeneracy in the primal problem could cause a cycle of bases to occur. In fact, Dantzig's original convergence proof of the simplex method assumed that all basic feasible solutions were nondegenerate. In the Fall of 1950, Dantzig made the first suggestion of a nondegeneracy procedure in a lecture on linear programming (LP) (Dantzig 1963). Charnes (1952) proposed a so-called perturbation method to prevent cycling. Since then, many variants of nondegeneracy and anticycling methods have been developed. For a review of degeneracy and its influence on computation, see Gal (1993).

In the end of the 1970s, a unifying approach to the analysis of degeneracy problems was proposed in terms of degeneracy graphs (Gal 1985). These graphs are used to define the connections among the bases associated with a degenerate vertex. From Table 1, it obvious that for real-world problems, with large numbers of constraints and variables, such systems of connections might have quite complex structures. It was felt that the language of graph theory could be applied to good advantage in explaining the relationships between degenerate bases.

Since they were first proposed, degeneracy graphs have become an important topic of research (Geue 1993; Kruse 1986; Niggemeier 1993; Zörnig 1993). In these works, the general theory of degeneracy graphs has been developed, the possibilities for their application to transportation, integer programming and other problems have been studied, and algorithmic aspects to solve various degeneracy problems have been investigated.

The main problem that led to the idea of using a graph theoretical representation was the so called

Degeneracy Graphs, Table 1 Values for σ, $U_{\min}$, $U_{\max}$

n	σ	$U_{\min}$	$U_{\max}$
5	3	16	56
10	5	12	3003
50	5	752	3.48×10^{6}
50	40	6.59×10^{12}	5.99×10^{25}
100	30	3.865×10^{10}	2.61×10^{39}
100	50	2.93×10^{16}	2.01×10^{40}
100	80	1.33×10^{25}	3×10^{52}

neighboring problem: Given a vertex of a convex polytope, find all neighboring vertices. This is not a problem if the given vertex is nondegenerate. It becomes a problem (Table 1) when the given vertex is degenerate.

Degeneracy Graphs

Given a σ-degenerate vertex $\boldsymbol{x}^{\mathrm{o}}$; to this vertex the set

$$B^{\mathrm{o}} = \{B | B \text{ feasible basis of } x^{\mathrm{o}}\}$$

is assigned. Denote

$$\begin{gathered}\text{by ‘‘} \leftarrow + \rightarrow \text{’’ a pivot} - \text{step with a positive} \\ \text{pivot } (\text{a positive pivot} - \text{step}) \\ \text{by ‘‘} \leftarrow - \rightarrow \text{’’ a pivot} - \text{step with a negative} \\ \text{pivot } (\text{a negative pivot} - \text{step}) \\ \text{by ‘‘} \leftarrow \rightarrow \text{’’ a pivot} - \text{step if any nonzero} \\ \text{pivot can be used } (\text{pivot} - \text{step}).\end{gathered}$$

The graph of a polytope X is the undirected graph

$$G(X) := G = (V, E),$$

where

$$V = \{B | B \text{ is a feasible basis of the corresponding system of equations}\}$$

and

$$E = \{\{B, B'\} \subseteq V | B \leftarrow + \rightarrow B'\}.$$

The degeneracy graph (DG) that is used to study various degeneracy problems with respect to a degenerate vertex is defined as follows. Let $\boldsymbol{x}^{\mathrm{o}} \in X \subset \Re^n$ be a σ-degenerate vertex. Then the (undirected) graph

$$G(x^{\mathrm{o}}) := G^{\mathrm{o}} = (B^{\mathrm{o}}, E^{\mathrm{o}})$$

where

$$E^{\mathrm{o}} = \{\{B_u, B_v\} \subseteq B^{\mathrm{o}} | B_u \longleftrightarrow B_v\}, u, v \in \{1, \ldots, U\}, U_{\min} \leq U \leq U_{\max} \qquad (1)$$

and U, the degeneracy power of $\boldsymbol{x}^{\mathrm{o}}$, is called the general $\sigma \times n - G$ of $\mathbf{x}^{\mathrm{o}}$. If, in (1), the operator is $\leftarrow + \rightarrow$ or $\leftarrow - \rightarrow$, then the corresponding graph is called the positive or negative DG of $\boldsymbol{x}^{\mathrm{o}}$, respectively.

These notions have been used to develop a theory of the DG. For example: the diameter, d, of a general DG satisfies $d \leq \min\{\sigma, n\}$; a general DG is always connected; a formula to determine the number of nodes of a DG has been developed; the connectivity of a DG is ≥ 2; every pair of nodes in any DG lies on a cycle (Zörnig 1993).

An interesting consequence of this theory is that every degenerate vertex can be exited in at most d (diameter) steps. Other theoretical properties of DGs help in explaining problems in, for example, sensitivity analysis with respect to a degenerate vertex (Gal 1997; Kruse 1993). Also, this theory helps to work out algorithms to solve the neighborhood problem and to determine all vertices of a convex polytope (Gal and Geue 1992; Geue 1993; Kruse 1986). With respect to a degenerate optimal vertex of an LP-problem, algorithms to perform sensitivity analysis and parametric programming have been developed (Gal 1995). Also, the connection between weakly redundant constraints, degeneracy and sensitivity analysis has been studied (Gal 1992).

Concluding Remarks

Degeneracy graphs have been applied to help solve the neighborhood problem, to explain why cycling in LP occurs, to develop algorithms to determine two-sided shadow prices, to determine all vertices of a (degenerate) convex polyhedron, and to perform sensitivity analysis under (primal) degeneracy. DGs can be used in any mathematical-programming problem that uses some version of the simplex method or, more generally, in any vertex searching method.

Delphi Method

James A. Dewar and John A. Friel
RAND Corporation, Santa Monica, CA, USA

Introduction

The Delphi method was developed at the RAND Corporation from studies on decision making that began in 1948. The seminal work, "An Experimental Application of the Delphi Method to the Use of Experts," was written by Dalkey and Helmer (1963).

The primary rationale for the technique is the age-old adage "two heads are better than one," particularly when the issue is one where exact knowledge is not available. It was developed as an alternative to the traditional method of obtaining group opinions — face-to-face discussions. Experimental studies had demonstrated several serious difficulties with such discussions. Among them were: (1) influence of the dominant individual (the group is highly influenced by the person who talks the most or has most authority); (2) noise (studies found that much communication in such groups had to do with individual and group interests rather than problem solving); and (3) group pressure for conformity (studies demonstrated the distortions of individual judgment that can occur from group pressure).

The Delphi method was specifically developed to avoid these difficulties. In its original formulation it had three basic features: (1) anonymous response — opinions of the members of the group are obtained by formal questionnaire; (2) iteration and controlled feedback — interaction is effected by a systematic exercise conducted in several iterations, with carefully controlled feedback between rounds; and (3) statistical group response — the group opinion is defined as an appropriate aggregate of individual opinions on the final round.

Procedurally, the Delphi method begins by having a group of experts answer questionnaires on a subject of interest. Their responses are tabulated and fed back to the entire group in a way that protects the anonymity of their responses. They are asked to revise their own answers and comment on the group's responses. This constitutes a second round of the Delphi. Its results are tabulated and fed back to the group in a similar manner and the process continues until convergence of opinion, or a point of diminishing returns, is reached. The results are then compiled into a final statistical group response to assure that the opinion of every member of the group is represented.

In its earliest experiments, Delphi was used for technological forecasts. Expert judgments were obtained numerically (e.g., the date that a technological advance would be made), and in that case it is easy to show that the mean or median of such judgments is at least as close to the true answer as half of the group's individual answers. From this, the early proponents were able to demonstrate that the Delphi method produced generally better estimates than those from face-to-face discussions.

One of the surprising results of experiments with the technique was how quickly in the successive Delphi rounds that convergence or diminishing returns is achieved. This helped make the Delphi technique a fast, relatively efficient, and inexpensive tool for capturing expert opinion. It was also easy to understand and quite versatile in its variations. By 1975, there were several hundred applications of the Delphi method reported on in the literature. Many of these were applications of Delphi in a wide variety of judgmental settings, but there was also a growing academic interest in Delphi and its effectiveness.

Critique

Sackman (1975), also of the RAND Corporation, published the first serious critique of the Delphi method. His book, *Delphi Critique*, was very critical of the technique — particularly its numerical aspects — and ultimately recommended (p. 74) "that … Delphi be dropped from institutional, corporate, and government use until its principles, methods, and fundamental applications can be experimentally established as scientifically tenable."

Sackman's critique spurred both the development of new techniques for obtaining group judgments and a variety of studies comparing Delphi with other such techniques. The primary alternatives can be categorized as statistical group methods (where the answers of the group are tabulated statistically without any interaction); unstructured, direct interaction (another name for traditional, face-to-face

discussions); and structured, direct interaction (such as the Nominal Group Technique of Gustafson et al. 1973). In his comprehensive review, Woudenberg (1991) found no clear evidence in studies done for the superiority of any of the four methods over the others. Even after discounting several of the studies for methodological difficulties, he concludes that the original formulation of the quantitative Delphi is in no way superior to other (simpler, faster, and cheaper) judgment methods.

Another comprehensive evaluation of Delphi (Rowe et al. 1991) comes to much the same conclusion that Sackman and Woudenberg did, but puts much of the blame on studies that stray from the original precepts. Most of the negative studies use non-experts with similar backgrounds (usually undergraduate or graduate students) in simple tests involving almanac-type questions or short-range forecasts. Rowe et al. (1991) point out that these are poor tests of the effects that occur when a variety of experts from different disciplines iterate and feed back their expertise to each other. They conclude that Delphi does have potential in its original intent as a judgment-aiding technique, but that improvements are needed and those improvements require a better understanding of the mechanics of judgment change within groups and of the factors that influence the validity of statistical and nominal groups.

Applications

In the meantime, it is generally conceded that Delphi is extremely efficient in achieving consensus and it is in this direction that many subsequent Delphi evaluations have been used. Variations of the Delphi method, such as the policy Delphi and the decision Delphi, generally retain the anonymity of participants and iteration of responses. Many retain specific feedback as well, but these more qualitative variations generally drop the statistical group response. Delphi has been used in a wide variety of applications from its original purpose of technology forecasting (one report says that Delphi has been adopted in approximately 90% of the technological forecasts and studies of technological development strategy in China) to studying the future of medicine, examining possible shortages of strategic materials, regional planning of water and natural resources, analyzing national drug abuse policies, and identifying corporate business opportunities.

In addition, variations of Delphi continue to be developed to accommodate the growing understanding of its shortcomings. For example, a local area network (LAN) was constructed, composed of lap-top computers connected to a more capable workstation. Each participant had a dedicated spreadsheet available on a lap-top computer. The summary spreadsheet maintained by the workstation was displayed using a large-screen projector, and included the mean, media, standard deviation, and histogram of all the participants scores. In real-time, the issues were discussed, the various participants presented their interpretation of the situation, presented their analytic arguments for the scores they believed to be appropriate, and changed their scoring as the discussion developed. Each participant knew their scores, but not those of the other participants. When someone was convinced by the discussions to change a score they could do so anonymously. The score was transmitted to the workstation where a new mean, median, standard deviation, and histogram were computed and then displayed using a large screen projector. This technique retained all the dimensions of the traditional Delphi method and at the same time facilitated group discussion and real-time change substantially shortening the time typically required to complete a Delphi round.

Density

The proportion of the coefficients of a constraint matrix that are nonzero. For a given $(m \times n)$ matrix $\boldsymbol{A} = (a_{ij})$, if k is the number of nonzero a_{ij}, then the density is given by $k/(m \times n)$. Most large-scale linear-programming problems have a low density of the order of 0.01.

See

- Sparse Matrix
- Super-Sparsity

Density Function

When the derivative $f(x)$ of a cumulative probability distribution function $F(x)$ exists, it is called the density or probability density function (PDF).

See

- Probability Density Function (PDF)

Departure Process

Usually refers to the random sequence of customers leaving a queueing service center. More generally, it is the random point process or marked point process with marks representing aspects of the departure stream and/or the service center or node from which they are leaving. For example, the marked point process $(\boldsymbol{X}^d, \boldsymbol{T}^d)$ for departures from an M/G/1 queue takes $\boldsymbol{X}^d$ as the Markov process for the queue length process immediately after the departure time and $\boldsymbol{T}^d$ is the actual time of departure.

Descriptive Model

A model that attempts to describe the actual relationships and behavior of a man/machine system. For a decision problem, such a model attempts to describe how individuals make decisions.

See

- Decision Problem
- Expert Systems
- Mathematical Model
- Model
- Normative Model
- Prescriptive Model

Design and Control

For a queueing system, design deals with the permanent, optimal setting of system parameters (such as service rate and/or number of servers), while control deals with adjusting system parameters as the system evolves to ensure certain performance levels are met. A typical example of a control rule is that a server is to be added when the queue size is greater than a certain number (say N_1) and when the queue size drops down to $N_2 < N_1$, the server goes to other duties.

See

- Dynamic Programming
- Markov Decision Processes
- Queueing Theory

Detailed Balance Equations

A set of equations balancing the expected, steady-state flow rates or probability flux between each pair of states or entities of a stochastic process (most typically a Markov chain or queueing problem), for example written as:

$$\pi_j q(j,k) = \pi_k q(k,j)$$

where π_m is the probability that the state is m and $q(m, n)$ is the flow rate from states m to n. The states may be broadly interpreted to be multi-dimensional, as in a network of queues, and the entities might be individual service centers or nodes. Contrast this with global balance equations, where the average flow into a single state is equated with the flow out.

Developing Countries

Roberto Diéguez Galvão[1] and Graham K. Rand[2]
[1]Federal University of Rio de Janeiro, Brazil
[2]Lancaster University, Lancaster, UK

Introduction

OR started to establish itself in the developing countries in the 1950s, approximately one decade after its post-war inception in Great Britain and the United States. The main organizational basis of OR in the developing world are the national OR societies. These are in some cases well established, in other cases incipient. A number of them are members of the International Federation of Operational Research Societies (IFORS) and belong to regional groups within IFORS. In particular, ALIO, the Association of Latin American OR Societies, has the majority of its member societies belonging to developing countries. APORS, the Association of Asian-Pacific OR Societies within IFORS, also represents OR societies from developing countries. In 1989 a Developing Countries Committee was established as part of the organizational structure of IFORS, with the objective of coordinating OR activities in the developing countries and promoting OR in these countries.

The Social, Political, and Technological Environment

To speak of developing countries in general may lead to erroneous conclusions, since the conditions vary enormously from one country to another. First of all, how to characterize a developing country? Which countries may be classified as developing? The United Nations has, for some years now, started to distinguish between more and less developed countries in the developing world. It has adopted the term "less developed countries" (LDCs) to address those developing countries that fall below some threshold levels measured by social and economic indicators. But these questions are clearly well beyond the scope here.

The view here is that developing countries are those in which large strata of the population live at or below the subsistence level, where social services are practically nonexistent for the majority of the population, where the educational and cultural levels are in general very low. The political consequence of this state of affairs is a high degree of instability for the institutions of these countries, at all levels.

The economy is generally very dependent on the industrialized nations. Bureaucracy, economic dependence and serious problems of infrastructure conspire against economic growth. In the technical sphere there is again a high level of dependency on the industrialized world, with very little technological innovation produced locally. It is against this difficult background that one must consider the role OR can play and how OR can be used as a tool for development.

The Use of OR

Here the existence of three different emphases in the development of OR is considered: (i) development of theory, which takes place mostly in the universities; (ii) development of methods for specific problems, which occurs both in the universities and in the practical world; (iii) applications, which occur mostly in the practical world. The problems of OR are therefore a continuum, and both developing and industrialized nations share in all these three aspects of the continuum. The more important aspect for the developing countries tends, however, to be applications due to the nature of problems these nations have to face and their social, political, and technological environment discussed above. According to Rosenhead (1995), another important aspect is that existing theory and methods, grown in the developed world, are in many cases a poor fit for the problems facing the developing countries. Work on novel applications will be likely to throw up new methods and techniques of general interest.

The use of OR in the developing world is often seen as disconnected from the socio-economic needs of the respective countries, see Galvão (1988). Valuable theoretical contributions originate in these countries, but little is seen in terms of new theory and methods developed for the problems facing them.

A common situation in developing countries is a highly uncertain environment, which leads to the notion of wicked problems. These are, for example, problems for which there is often little or no data available, or where the accuracy of data is very poor. Complex decisions must nevertheless be made, against a background of competing interests and decision makers. There are not many tools available for solving these wicked problems, which are quite common in developing countries.

One of the main characteristics of applied OR projects in developing countries is that a large majority of them have not been implemented, see Löss (1981). This is due to a high degree of instability in institutions in these countries, to a lack of management education in OR, and to a tendency by OR analysts to attempt to use sophisticated OR techniques without paying due attention to the local environment and to the human factor in applied OR projects. These issues arise both in developed and developing countries, but experience indicates that they are more often overlooked in the latter.

A Special Issue of the European Journal of Operational Research (Bornstein et al. 1990) was dedicated to OR in Developing Countries. A review paper (White et al. 2011) provides an overall picture of the state of OR in the developing countries. In particular, it examines coverage in terms of countries and methods and highlights the contribution which OR is making towards the theme of poverty, the reduction of which is regarded as the key focus of development policy interventions as reflected in the Millennium Development Goals. Jaiswal (1985) and Rosenhead and Tripathy (1996) contain important contributions to the subject of OR in developing countries.

ICORD '92: The Ahmedabad Conference

Since the 1950s, there has been a controversy on the role of OR in developing countries. The central issue in this controversy is the following: Is there a separate OR for developing countries? If so, what makes it different from traditional OR? What steps could be taken to further OR in developing countries?

This issue has been discussed in different venues and several published papers have addressed it, see, for example, Bornstein and Rosenhead (1990). At one end of the scale there are those who think that there is nothing special about OR in developing countries, perhaps only less resources are available in these

countries to conduct theoretical/applied work. They argue that the problem should resolve itself when each country reaches appropriate levels of development, and not much time should be dedicated to this issue. At the other end there are those who think that because of a different material basis and due to problems of infrastructure, OR does have a different role to play in these countries. In the latter case, steps should be taken to ensure that OR plays a positive role in the development of their economies and societies.

Much changed in the latter part of the 1990s with the demise of communism in Europe and the emphasis on the globalization of the economy. The viewpoint that there is a separate OR for developing countries lost strength as a consequence. It had its high moment during ICORD '92, the first International Conference on Operational Research for Development, which took place in December 1992, at the Indian Institute of Management (IIM) in Ahmedabad. It was supported by IFORS, The British OR Society and the OR Society of India. It was partly funded by IIM itself, The Tata Iron and Steel Company (India) and (indirectly) by the Commonwealth Secretariat. Participants at the Conference numbered more than 60 and countries represented included Australia, Brazil, Eire, Great Britain, Greece, India, Kenya, Malaysia, Mexico, Nigeria, Peru, South Africa, Sri Lanka, United States, and Venezuela. Some 40 contributed papers were delivered and plenary speakers included the President of IFORS, Professor Brian Haley, Professor Kirit Parikh, Director of the Indira Ghandi Institute for Development in Bombay, and Dr. Francisco Sagasti of Peru, who had just spent five years in senior positions at the World Bank (Rosenhead 1993).

A series of plenary sessions were held, which resulted in a statement which has come to be known as the Ahmedabad Declaration, a political document drafted with the intention of strengthening the OR for Development movement, that called for a range of actions from IFORS to support and strengthen OR in developing countries, including a call for more space for discussion of OR for Development issues in OR departments in developed countries, for IFORS support for successor conferences to ICORD '92, and for IFORS increased economic support of OR activities in developing countries. It relied mainly on IFORS for its implementation. Despite IFORS' continued support of some OR activities in the developing countries, few of the main recommendations of the declaration were implemented. ICORD '96, the second Conference in the series, which took place in Rio de Janeiro, Brazil, in August 1996, was a disappointing sequel to the Ahmedabad Conference and signaled the decline of the movement.

Despite the perceived lack of commitment on the part of IFORS to implement these proposals (Rosenhead 1998), IFORS support of development related OR activities have continued, including the support of successor ICORDs, held in Manila, The Philippines (1997), Berg-en-Dal, South Africa (2001), Jamshedpur, India (2005), Fortaleza, Brazil (2007) and Djerba Island, Tunisia (2012). The IFORS Prize for OR in Development (known as the Third World Prize until 1993) competition has been held at every triennial conference since 1987. The Prize recognizes exemplary work in the application of OR to address issues of development. More recently, a particular focus has been encouraging the development of an OR infrastructure in Africa, and, with EURO, IFORS has sponsored conferences and scholarships in the African continent.

A fuller account of IFORS initiatives in promoting the use of OR for development is described in by Rand (2000). See also del Rosario and Rand (2010).

Is it safe to conclude, therefore, that those who advocate that there is nothing special about OR in developing countries had the better insight on the controversy? The hard facts of life show that little has changed in the social, political and technological environment in the developing countries. The decline of the OR for Development movement is a consequence of the new balance of power in global affairs since the Soviet Union ceased to exist. This decline did not occur because conditions in the developing world improved, or because OR has failed to contribute to the development of the respective economies and societies.

Development Tool

Software used to facilitate the development of expert systems. The three types of tools are programming languages, shells, and integrated environments.

See

► Expert Systems

Devex Pricing

A criterion for selecting the variable entering the basis in the simplex method. Devex pricing chooses the incoming variable with the largest gradient in the space of the initial nonbasic variables. This is contrasted with the usual simplex method entering variable criterion that chooses the incoming variable based on the largest gradient in the space of the current nonbasic variables. The Devex criterion tends to reduce greatly the total number of simplex iteration on large problems.

Differential Games

Gary M. Erickson
University of Washington, Seattle, WA, USA

Introduction

Differential games offer a valuable modeling approach for problems in operations research (OR) and management science (MS). Differential game models are useful because they combine the key aspects of dynamic optimization and game theory. As such, differential game modeling allows the analysis of a broad set of problems that involve decisions by multiple players over a time horizon. After a discussion of the essential concepts of differential games, applications from the literature are reviewed as examples of how differential game methodology has been used to study problems of interest to OR and MS.

Discussion

A differential game is a game with continuous-time dynamics. Two types of variables are involved, state variables and control variables, both of which vary with time. Control variables are managed by the players. State variables are subject to the dynamic influence of the control variables, and evolve according to differential equations. Each player has an objective function that consists of a stream of instantaneous payoffs integrated over a horizon, plus, perhaps, a salvage value if the horizon is finite. The decision problem for each player is to determine a continuous path of control variable values that maximizes the player's objective function, while taking into account what the player knows or anticipates about the decisions of the other players in the game.

Complete information is assumed in a differential game, so that player outcomes given different combinations of player strategies are known to all players, and each player is able to infer correctly the best strategies for the other players. Also, an assumption is typically made that the players are unable to agree to cooperate, and so are engaged in a noncooperative differential game. Further, if the players choose their strategies simultaneously, the appropriate way to determine what strategies the players are likely to adopt is to identify a Nash equilibrium. A Nash equilibrium is a set of player strategies such that each player is unable to improve their outcome, given the strategies of the remaining players. In a Nash equilibrium, no individual player has an incentive to deviate to another strategy.

There are two types of Nash equilibrium that can be derived: open-loop and feedback. Alternative terms for feedback are closed-loop and Markovian (Dockner et al. 2000, p. 59). The two equilibrium types differ in terms of what information is used to develop the players' strategies. In an open-loop Nash equilibrium, the players' strategies are a function of time only, while feedback Nash equilibrium strategies depend on levels of the state variables as well as time. Further, for a differential game with an infinite horizon, and in which time is an explicit factor in the objective functions only through discount factors, it is appropriate to focus on stationary feedback strategies, which depend on levels of the state variables only (Jørgensen and Zaccour 2004, pp. 7–8).

Different methods are typically used to derive the different Nash equilibrium concepts. The maximum principle of optimal control, with Hamiltonians and costate variables, is used to determine open-loop Nash equilibria (Kamien and Schwartz 1991, p. 274). To derive an open-loop equilibrium, a Hamiltonian is created for each player, and necessary conditions produce a system of differential equations that can be solved numerically as a two-point boundary value problem.

In theory, a feedback Nash equilibrium can also be determined using optimal control methods, but the maximum principle is difficult to apply for feedback strategies, since the solution requires that the strategies of the players be known even as they need to be derived. An alternative way to develop feedback Nash equilibrium strategies is through a dynamic programming approach with value functions and Hamilton-Jacobi-Bellman equations (Kamien and Schwartz 1991, p. 276). The Hamilton-Jacobi-Bellman equations form a system of partial differential equations, which for many problems are inherently impossible to solve. For certain problems, though, it is possible to discern an appropriate functional form for the value functions that allows a solution. In particular, for infinite horizon games, it is often possible to derive stationary feedback equilibrium strategies analytically as closed-form functions of the state variables.

An alternative to simultaneous play of strategies is that of Stackelberg games (Dockner et al. 2000, ch.5; Jørgensen and Zaccour 2004, pp. 17–22). Stackelberg games have an alternative information structure, one in which one player takes on a leadership role and makes their strategy choice known before other players choose their strategies. Such a structure can be appropriate for certain problems, such as supply chain management, where coordination may be achieved to benefit of the supply chain overall through one of the members of the supply chain taking a leadership role.

As for Nash equilibria in games with simultaneous play, there are open-loop and feedback Stackelberg equilibria that can be derived. In an open-loop Stackelberg equilibrium with two players (Dockner et al. 2000, pp. 113–134; Jørgensen and Zaccour 2004, pp. 17–20), the Stackelberg leader announces a control path, and, if the Stackelberg follower believes that the leader will stay with the announced control path, the follower will determine their best response control path by solving an optimal control problem with the leader's control path as given. The leader then solves an optimal control problem that incorporates the follower's best response.

For a feedback Stackelberg equilibrium, Basar and Olsder (1995, pp. 416–420) present a feedback Stackelberg solution, which involves instantaneous stagewise Stackelberg leadership, where a stage is an arbitrary combination of time and state variable values. In the development of the feedback Stackelberg solution, stagewise Hamilton-Jacobi-Bellman equations are formed for the leader and the follower, the equation for the follower defining an optimal response and that for the leader incorporating the optimal response of the follower.

The open-loop and feedback equilibrium concepts for both Nash and Stackelberg games can be further examined on the basis of important credibility-related criteria. Dockner et al. (2000, pp. 98–105) and Jørgensen and Zaccour (2004, pp. 15-16) discuss two such criteria, time consistency and subgame perfectness.

A Nash equilibrium is time consistent if at some intermediate point in a differential game, the players choose not to depart from their equilibrium strategies. Dockner et al. (2000, p. 99) and Jørgensen and Zaccour (2004, p. 15) define a subgame that begins at an intermediate time point in the game, and has particular values for the state variables at the time. An equilibrium for the original game "...is time consistent if it is also an equilibrium for any subgame that starts out on the equilibrium state trajectory..." (Jørgensen and Zaccour 2004, p. 15). Both open-loop and feedback Nash equilibria are time consistent. The open-loop Stackelberg equilibrium is not always time consistent, however. As Dockner et al. (2000, pp. 113–134) discuss, an open-loop Stackelberg equilibrium fails to be time consistent in games in which the leader finds it to their benefit to reset its control path at a some point in time after the game has begun.

Subgame perfectness is a stronger condition than time consistency, requiring that an equilibrium also be an equilibrium for any possible subgame, "...not only along the equilibrium state trajectory, but also in any (feasible) position...off this trajectory." (Jørgensen and Zaccour 2004, p. 16). A feedback Nash equilibrium that satisfies the Hamilton-Jacobi-Bellman equations, is by construction subgame perfect. Also, the feedback Stackelberg solution is, according to Basar

and Olsder (1995, p. 417), "...strongly time consistent (by definition)", and strong time consistency coincides, at least essentially, with subgame perfectness (Dockner et al. 2000, pp. 106–107).

Differential Game Applications

The differential game framework is designed to model the decisions of multiple decision makers in a continuous-time dynamic context. This framework can be applied to a variety of problem areas of interest and relevance to OR and MS. Furthermore, modeling the passage of time as continuous, rather than discrete, allows the possibility of mathematical, and therefore generalizable, conclusions. This section discusses applications in advertising, pricing, production, and supply chain management.

Advertising

Competitive advertising in the context of dynamics has been especially a popular area of study. Erickson (2003) provides a review. Two particular models of demand evolution have acted as foundations for differential-game applications to advertising. Kimball (1957, pp. 201–202) presents four versions of Lanchester's formulation of the problem of combat, one of which, Model 4,

$$dn_1/dt = k_1 n_2 - k_2 n_1, dn_2/dt = k_2 n_1 - k_1 n_2$$

has become the foundation for what is known as the Lanchester model. Kimball (1957, p. 203) offers the following interpretation of Model 4: "The n_1 and n_2 are then to be interpreted as the numbers of customers for two similar products, while k_1 and k_2 are in essence the amounts of advertising." The Lanchester model in application is generally interpreted in terms of market shares rather than numbers of customers (Erickson 2003, p. 10), so that advertising for a competitor works to attract market share from the competitor's rival.

Vidale and Wolfe (1957) introduce a model of sales evolution for a monopolistic company

$$dS/dt = \beta A(t)(M - S)/M - \lambda S$$

in which $A(t)$ is the advertising rate, S the sales rate, M the maximum sales potential, β an advertising effectiveness coefficient, and λ a sales decay parameter. In the Vidale-Wolfe model, advertising attracts demand from the untapped sales potential, and the sales attracted are subject to decay. Although the Vidale-Wolfe model is defined for a monopolist, it has been adapted for the study of advertising competition.

Many differential-game applications using the Lanchester and Vidale-Wolfe models study open-loop Nash equilibria, since the two models do not readily allow the derivation of subgame-perfect feedback Nash equilibria. Sorger (1989) offers a modification of the Lanchester model that does allow a feedback equilibrium to be derived for duopolistic competitors. Sorger (1989, p. 58) develops a differential game with market-share dynamics

$$\dot{x}(t) = u_1(t)\sqrt{1 - x(t)} - u_2(t)\sqrt{x(t)}, x(0) = x_0.$$

where $\dot{x}(t) = dx/dt$, $x(t)$ is competitor 1's market share, and $u_1(t)$ and $u_2(t)$ are advertising rates for firm's 1 and 2, respectively. The square-root form in the market share equation in the model allows value functions that are linear in the market share state variable, which allows a solution to the Hamilton-Jacobi-Bellman equations for the differential game. Sorger derives both open-loop and feedback equilibria, and finds that the feedback and open-loop equilibria do not coincide.

The Sorger (1989) modification of the Lanchester model allows subgame-perfect feedback Nash equilibria for a duopoly. Feedback equilibria, however, are not achievable in an extension of the Lanchester model to a general oligopoly, in which the number of competitors may exceed two. For an oligopoly, Erickson (2009a, b) provides a modification of the Vidale-Wolfe model that allows the derivation of feedback equilibria. Erickson's (2009a) model has sales dynamics for each oligopolistic competitor i of $n > 2$ total competitors,

$$\dot{s}_i = \beta_i a_i \sqrt{N - \sum_{j=1}^{n} s_j} - \rho_i s_i.$$

In the model, a_i is the advertising rate, s_i the sales rate, N the maximum sales potential, β_i an advertising effectiveness parameter, and ρ_i a sales decay parameter. The expression under the square-root sign

represents untapped potential, that is, the maximum sales potential minus the total sales for all n competitors, including competitor i. An instantaneous change in the sales rate for a competitor comes from two sources: (1) the competitor's advertising attracting sales from the untapped potential in square-root form, (2) a decay from the competitor's current sales rate. Erickson (2009b) extends the model to allow multiple brands for each competitor. As for the Sorger (1989) model, the square-root form in the model allows value functions linear in the state variables, so that the Hamilton-Jacobi-Bellman equations can be solved. Both the Sorger (1989) and Erickson (2009a, b) models are related to a monopolistic modification of the Vidale-Wolfe model suggested by Sethi (1983). Erickson (2009a) uses the derived expressions for feedback Nash equilibrium advertising strategies in an empirical study of the U.S. beer market, and Erickson (2009b) empirically applies the multiple-brand model extension to the carbonated soft drink market.

Pricing

Pricing is a primary and challenging task for management. Prices are the source of revenue for the firm, but also affect demand for the firm's products, especially in a competitive setting. The challenge is compounded when dynamics are involved, and prices are expected not to stay at the same levels. This is the case for new products, in particular new durable products, for which demand tends to develop through a diffusion process that is influenced by the price strategies of competing firms.

Bass (1969) provides a diffusion model of first-time adoption of a new durable product that combines innovation and imitation on the part of customers

$$S(T) = (p + qY(T)/m)(m - Y(T)),$$

where $S(T)$ represents current sales at time T and $Y(T)$ cumulative sales, so that $S(T) = dY(T) / dT$. Further, p is an innovation coefficient, q is an imitation coefficient, and m is the total number of customers who will eventually adopt the new product. The Bass (1969) model has been accepted by much of the OR and MS literature as the primary model of new durable product diffusion.

The Bass (1969) model is for a single firm, and does not consider price explicitly. Dockner and Jørgensen (1988) develop a more general framework for new product diffusion, one that includes competition and prices, which they use to study new-product pricing strategies through differential-game analysis. Dockner and Jørgensen (1988, p. 320) offer the general diffusion model specification

$$\dot{x}_i = f^i(x_1, ..., x_M, p_1, ..., p_M), x_i(0) = x_{i0} \geq 0.$$

In the model, x_i is the cumulative sales volume of competitor $i = 1, 2,\ldots, M$, and the prices $p_1,\ldots, p_M$ of the competitors are assumed to vary with time. To determine their dynamic price strategies, each competitor is assumed to seek to maximize its objective function

$$J^i = \int_0^T e^{-r_i t}(p_i - c_i) f^i dt$$

where unit cost c_i is a nonincreasing function of cumulative sales x_i, as is often the case with new durable products, that unit cost declines with experience. For mathematical tractability reasons, Dockner and Jørgensen (1988) study open-loop Nash equilibria.

Dockner and Jørgensen (1988) derive the necessary conditions for an open-loop Nash equilibrium for their differential game involving the general diffusion model; for further insights, they analyze more specific functional forms. They consider three special cases, competition with price effects only, multiplicative separable price and adoption effects, and adoption effects only with a multiplicative own-price effect.

Production

The management of production quantities and timing is a critical operations function. Dynamics are involved, since production plans may imply that production does not equal customer demand at particular times. This can result in inventories, which need to be carried at a cost, or backlogs, which involve delay in delivery to customers, presumably at a cost to the firm.

Production management can be studied in a competitive context. Eliashberg and Steinberg (1991) consider the dynamic price and production strategies of two competing firms with asymmetric

cost structures. As Eliashberg and Steinberg (1991, p. 1453) explain: "The objective of this paper is to gain insight into the dynamic nature of the competitive aspects of the various policies of two firms, one operating at or near capacity, facing a convex production cost, and the other operating significantly below capacity, facing a linear cost structure. The firms are assumed to face a demand surge condition. We will refer to the firm operating at or near capacity as the 'Production-smoother' and the firm operating below capacity as the 'Order-taker.' "

Eliashberg and Steinberg (1991) define a differential game in which production levels and prices are control variables for the two competing firms, and pursue an open-loop Nash equilibrium. They derive several propositions regarding the equilibrium policies of the two competitors. A particular finding is that the Production-smoother follows a strategy of first building up inventory, then drawing the inventory down, and finishing a seasonal period by engaging in a policy of carrying zero inventory for a positive interval.

Supply Chain Management

A supply chain involves various independent players—e.g., supplier, manufacturer, wholesaler, retailer—as raw materials become products that are distributed to retail locations where final customers are able to buy them. All players have an economic stake in their position in the supply chain that is affected by the decisions of the other players. The interest of supply chain management is in coordination of the decisions of the players, given the players' strategic interdependence.

When dynamics are involved, the interdependence of the players in a supply chain can be interpreted as a differential game. A cooperative differential game would produce full coordination. However, since binding agreements among the supply chain players are difficult to establish and maintain, an alternative focus is to consider noncooperative games with coordinating mechanisms.

One mechanism for achieving coordination is through one of the players in the chain becoming the leader. If there are two players in a supply chain, the differential game becomes a leader-follower game in which a Stackelberg equilibrium provides the coordinating solution. A study that considers this approach is Jørgensen et al. (2001), who analyze the advertising and pricing strategies of two players in a marketing channel, a manufacturer and a retailer.

With the differential game that they develop, Jørgensen et al. (2001) derive four different equilibrium solutions: Markovian (feedback) Nash, feedback Stackelberg with the retailer as the Stackelberg leader, feedback Stackelberg with the manufacturer as the leader, and a coordinated channel solution. They give a detailed comparison of the outcomes for the four solutions.

Concluding Remarks

This article outlines the basic concepts of differential games, along with brief descriptions of relevant applications. More in-depth coverage is given in Dockner et al. (2000) and Jørgensen and Zaccour (2004). Differential games provide a powerful modeling framework for the study of the interaction of multiple decision makers in dynamic settings. As the applications illustrate, the understanding of dynamic and game-theoretic OR and MS problems has been advanced through the analysis of differential-game models.

► Queueing Theory

Diffusion Process

A continuous-time Markov process on $\mathbb{R}$ or $\mathbb{R}''$ which is analyzed similar to a continuous-time physical diffusion.

Digital Music

Elaine Chew
Queen Mary University of London, London, UK

Introduction

The advent of digital music has enabled scientific approaches to the systematic study, computational modeling, and explanation of human abilities in music perception and cognition, and in music making, which includes the activities of music performance, improvisation, and composition. The move from analog to digital music, and from music stored on a compact disc to music streamed live over the Internet, has brought new engineering challenges, innovation opportunities, and creative outlets. The pervasiveness of computing power and the Internet has changed the ways in which people interact with, and make, music. The research communities at the cusp of music science and engineering came about after the turn of the last millennium, and have been increasing exponentially since. A short list of the communities involved in scholarly pursuits in music science and engineering is provided in Chew (2008).

Impact of Digital Music Research

Science and technology has changed the face of arts and humanities scholarship. Advances in digital music technology have enabled new discoveries by harnessing the computational power of modern computers for music scholarship. For example, the Joyce Hatto scandal, documented in *The Economist* and elsewhere in 2007, in which over 100 CDs released in recent years under her name were in fact the work of other pianists, was unveiled in part because of the machinery available to automatically evaluate and compare recordings of musical works. The technology exists to begin mapping the myriad decisions involved in composing and performing music, and to start charting human creativity. The fact that mathematical models, and by extension operations research (OR) methods, are widely applied in digital music research and practice should come as

no surprise, given the historical connections between music, mathematics, and computing.

The music technology industry has emerged as a major economic force. The phenomenal explosion in digital music information has led to the need for new technologies to organize, retrieve, and navigate digital music databases. Examples of major advances in the organizing and retrieval of digital music include Pandora, a personalized Internet radio service that helps people discover new music according to their tastes, and Shazam, a service that helps people identify and locate the music they are hearing. Pandora generates a playlist based on an artist or song entered by the user, and refines future recommendations based on user preference ratings of the songs in that list. Shazam identifies the song and artist, and the precise recording, from a musical excerpt supplied by the user over a device such as an iPhone. In both Pandora and Shazam, the user is offered the opportunity to purchase the song that is playing, or that has been identified, from various vendors. As of 2010, Pandora had 50 million registered users, and more than 1 billion stations, covering 52% of the Internet radio market share. In December 2010, Shazam announced that it has surpassed 100 million users in 200 countries.

Any young or young-at-heart person may be familiar with the music video game, Guitar Hero®, which allows everyone to live the dream of being a rock star in their own living room by pushing colored buttons on the guitar interface in sync with approaching knobs in the video screen. In a few short years, Guitar Hero took over a significant share of the video game market, grossing over two billion dollars by 2009 and leading to it being featured in a South Park television episode. Bands featured in the game — owned and marketed by Activision — experience significant increases in song sales, so much so that major labels vie for their music to be included in new versions of it and in its successor, Rock Bandpt® vie for their music to be included in new versions.

Music Structure

The understanding of music structure is fundamental to computer analysis of music, and a precursor to digital music processing and manipulation. Music consists of organized sounds with perceptible structures in both time and frequency domains. Often, music can be considered to comprise of a sequence of tones, or several concurrent sequences of tones. Each tone has properties such as pitch (the perceived fundamental frequency of the tone), duration, timbre, and loudness. Much of the music that is heard consists of more than a single stream of tones. When hearing multi-tone textures, the ear can segregate the collection of sounds into streams. The most prominent of these streams is often considered to be the melody of the music piece. Structures relating to individual streams as they progress over time are sometimes referred to as horizontal structures. Like language, music streams can be segmented into phrases. Salient tone patterns in music phrases form motifs, short patterns that recur and vary throughout the piece. The varying of these patterns forms the surface structure of the music piece.

Overlapping pitches in the overlay of multiple tone sequences form chords; conversely, one could say that chords consist of the synchronous sounding of two or more pitches. Chords constitute mid-level structure in music. Structures, such as chords, that relate to synchronous sounds or chunks of music over overlapping streams are sometimes referred to as vertical structures. In Western tonal music, the pitches and durations and their ordering generates the perception of pitch stability relative to one another. This pattern of perceived stability is set up as soon as the ear hears as few as only three to four tones in the sequence. The most stable pitch is the name of the key of the tone sequence. The key, in turn, implies adherence to the pitch set of the scale. The pitches in a scale have varying levels of perceived stability, the result of the physics of sound, the physiology of the ear, or exposure to music. The varying of the most stable pitch over time forms the deep structure of the piece.

The structure of a musical piece can also be conceptualized as a sequence of section labels such as AB (binary form), ABA (ternary form), ABACAC′ADA (a sample rondo form), and intro-(verse-chorus)^n-outro (a common popular music form). While some composers, when writing in a particular genre, choose to adopt a particular form for a composition, structure can also emerge from choices made in composition or improvisation to manage a listener's attention.

Sequences of durations, or sequences of inter-onset-intervals, form rhythms. Periodic onsets

generate perceived beats, and accent and stress patterns in beat and in rhythm sequences. The periodic accent patterns in beat sequences, in turn, result in meter. For example, there are cyclic patterns of four beats in the march with a strongest-weak-strong-weak accent pattern, whereas each of the four beats in a tango is subdivided into two with a resulting strong-weak-weak-strong-weak-weak-strong-weak accent pattern. Conversely, the meter of a composition often implies a persistent periodic accent pattern. The beat rate charts the tempo of the music: a high beat rate results in fast music, and a low beat rate results in slow music. Like many things in art, it is deviations from the norm that form the core of artistic expression. Thus, a large part of expressive musical performance is the art of systematically varying the tempo, and deviating from an underlying time grid. For example, not playing the beats as notated is essential to playing a convincing swing rhythm. Other important parameters of variation in expressive performance include loudness and timbre.

Structure guides expressive decisions in performance, and expressive performance, in turn, influences structure. For example, a performer may choose to emphasize unusual key changes by slowing down the tempo and dramatically reducing the loudness of the sound produced at the juncture of change. Alternatively, by punctuating the playback of a tone stream with judicially placed accents and pauses, the performer can impute phrase and motivic structure on a music stream.

Music problems can be broadly categorized into the areas of analysis, performance, and composition and improvisation. When the problems are concerned with human abilities in music making and listening, they also touch upon the area of music perception and cognition. It is beyond the scope of this article to give a comprehensive survey of problem formulations and solutions in computational modeling of music. Rather, this article focuses on representative problems in each category and solutions, covering some essential background on music representation and computation.

Computational Music Analysis

The goal of computational music analysis is to automatically abstract structures, such as those described above, from digital music.

Key and Harmony

The determination of key is a problem in the detection of vertical pitch structure. Key finding (a.k.a. tonal induction) can be described as the problem of finding the note on which a music piece is expected to end. The most stable pitch in a key is also the one that is expected to end a piece of music in that key. Key finding is an important step preceding a number of music applications such as automatic music transcription, accompaniment, improvisation, and similarity assessment. While the focus here is key finding, it is worthwhile to mention chord tracking, a related problem for which the solution bears similarities to key finding. A survey of automatic chord analysis algorithms can be found in Mauch (2010).

Key Finding Using Correlation: Key is most often inferred from pitch information. Each pitch can be represented as an integer, according to pitch height. For example, in MIDI (musical instrument digital interface) notation, the pitches A, B♭, B, C in the middle range of the piano keyboard are represented as 57, 58, 59, 60. Pitches repeat on the keyboard, and the twelfth tone above C is C again, one octave higher. Sometimes only the pitch class is of interest, and pitch numbers can be collapsed into pitch classes using modulo arithmetic. If p is a pitch number, then the corresponding pitch class is $p \mod 12$.

Key-finding algorithms tend to match music data with templates representing the prototypical profile for the 24 major and minor keys. A key-finding algorithm by Krumhansl and Schmuckler (described in Krumhansl 1990) compares a vector, $\mathbf{d} = [d_i]$, summarizing total note duration for each of the twelve pitch classes, to experimentally obtained probe tone profiles for each of the major and minor keys, $\mathbf{v}_i = [v_{ij}]$ for $i = 1 \ldots 24$, by calculating their correlation coefficients, $\rho_{\mathbf{dv}_i}$. Each probe tone profile is generated by playing a short sequence of chords to establish the key context, then having listeners rate (on a scale of 1 to 7) how well a probe tone that is then played fit in the context. The best match key probe tone profile is the one having the highest correlation coefficient with the query vector, i.e.

$$\arg\max_i \rho_{\mathbf{dv}_i} = \arg\max_i \frac{\sigma_{\mathbf{dv}_i}}{\sigma_{\mathbf{d}}\sigma_{\mathbf{v}_i}}.$$

Creating Spatial Models: Having a spatial model that mirrors the mental representation of tonal space is

something that is of interest not only to cognitive scientists, but also to computational scientists who use these spaces to design algorithms for tonal induction. Kassakian and Wessel (2005) proposed a convex optimization solution for incrementally creating spatial representations of musical entities, such as key and melody, in Euclidean space in such a way as to satisfy a set of dissimilarity measures. Assuming the existing elements to be $\mathbf{r}_i \in \mathbb{R}^n$ and the vector of dissimilarity distances between the new element and existing ones to be $\mathbf{s} = [s_i] \geq 0$, where $i = 1, 2, \ldots, m$. The problem then becomes one of finding

$$\arg\min_{\mathbf{x},\gamma} \sum_{i=1}^{m} (||\mathbf{x} - \mathbf{r}_i|| - \gamma s_i)^2.$$

Using the geometric insight that each $(||\mathbf{x} - \mathbf{r}_i|| - \gamma s_i)$ is the optimal value of $\min_{\mathbf{b}_i} ||\mathbf{x} - \mathbf{b}_i||^2$ for some $\mathbf{b}_i \in \mathbb{R}^n$ inscribed on the ball of radius γs_i around the point $\mathbf{r}_i$, the problem can be re-written as:

$$\begin{aligned} \min_{\mathbf{x},\gamma,\mathbf{b}} \quad & ||\mathbf{J}\mathbf{x} - \mathbf{b}||^2 \\ \text{s.t.} \quad & ||\mathbf{r}_i - \mathbf{b}_i||^2 = \gamma^2 s_i^2, i = 1, 2, \ldots, m \\ \text{where} \quad & \mathbf{b} \equiv [b_1^T, b_2^T, \ldots, b_m^T]^T \in \mathbb{R}^{mn} \\ \text{and} \quad & \mathbf{J} \equiv [I, I, \ldots, I]^T \in \mathbb{R}^{mn \times n} \end{aligned}$$

While the primal problem is not convex, the dual obtained by Lagrangian relaxation is convex, as is the dual of the dual. The authors used a semi-definite programming solver to obtain a solution to the dual of the dual. Because the dual's dual is a relaxation of the primal, they computed a primal feasible solution from the relaxation using a randomized method reported by Goemans and Williamson, and generalized by Nesterov. The problem can also be solved using more conventional gradient descent methods.The resulting key space map generated in this fashion corresponds well to Krumhansl's map created using multi-dimensional scaling (Krumhansl 1990).

Key Finding Using Geometric Spaces: Starting from a model of tonal space that concurs with human perception can be an advantage in the design of computational algorithms for key finding. Observing that the pitch classes in a major key and in a minor key each occupy distinctly shaped compact spaces on the harmonic network or tonnetz, Longuet-Higgins, and Steedman (1971) proposed a shape matching algorithm to determine key from pitch class information.

The tonnetz is a network model for pitch classes where horizontal neighbors are pitch classes whose elements have a fundamental frequency ratio of approximately 2:3 (four major/minor scale steps apart), neighbors on the northeast diagonal have a ratio of approximately 4:5 (two major scale steps apart), and neighbors on the northwest diagonal have a ratio of approximately 5:6 (two minor scale steps apart). The dual graph of the harmonic network connects all triads (three-note chords) sharing two pitches, the transition between which has the property of smooth voice leading. Lewin (1987) lays the foundation for the theory underlying transformations on this space in his treatise on Generalized Intervals and Transformations. Callendar, Quinn, and Tymoczko (Tymoczko 2006; Callender et al. 2008) further generalized these chord transition principles to non-Euclidean space.

The tonnetz is inherently a toroid structure. By rolling up the planar network so that repeating pitch classes line up one on top of another, one gets the pitch class spiral configuration of the harmonic network. Inspired by interior point approaches, Chew (2000) proposed the spiral array model, which uses successive aggregation to generate higher level representations, inside this three-dimensional structure, from their lower level components. For example, if pitch classes were indexed by their positions on the line of fifths, then each pitch classes can be represented as:

$$\mathbf{P}_{k+1} \equiv \mathbf{R} \cdot \mathbf{P}_k + \mathbf{h},$$

$$\text{where } \mathbf{R} = \begin{bmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \mathbf{h} = \begin{bmatrix} 0 \\ 0 \\ h \end{bmatrix}, k \in \mathbb{Z}.$$

The positions of major and minor chords are computed as convex combinations of their component pitches:

$$\mathbf{C}_{M,k} \equiv \omega_1 \cdot \mathbf{P}_k + \omega_2 \cdot \mathbf{P}_{k+1} + \omega_3 \cdot \mathbf{P}_{k+4},$$

and

$$\mathbf{C}_{m,k} \equiv u_1 \cdot \mathbf{P}_k + u_2 \cdot \mathbf{P}_{k+1} + u_3 \cdot \mathbf{P}_{k-3},$$

respectively, where $\omega_1 \geq \omega_2 \geq \omega_3 > 0$, $u_1 \geq u_2 \geq u_3 > 0$, $\sum_{i=1}^{3} \omega_i = 1$, and $\sum_{i=1}^{3} u_i = 1$. Major and minor keys are generated from the weighted average of their defining chords:

$$\mathbf{T}_{M,k} \equiv \omega_1 \cdot \mathbf{C}_{M,k} + \omega_2 \cdot \mathbf{C}_{M,k+1} + \omega_3 \cdot \mathbf{C}_{M,k-1},$$
$$\mathbf{T}_{m,k} \equiv \upsilon_1 \cdot \mathbf{C}_{M,k} + \upsilon_2 \cdot [\alpha \cdot \mathbf{C}_{M,k+1} + (1-\alpha) \cdot \mathbf{C}_{m,k+1}] + \upsilon_3 \cdot [\beta \cdot \mathbf{C}_{m,k-1} + (1-\beta) \cdot \mathbf{C}_{M,k-1}],$$

where $\omega_1 \geq \omega_2 \geq \omega_3 > 0$, $\upsilon_1 \geq \upsilon_2 \geq \upsilon_3 > 0$, $\sum_{i=1}^{3} \omega_i = 1$, $\sum_{i=1}^{3} \upsilon_i = 1$, and $0 \geq \alpha \geq 1$, $0 \geq \beta \geq 1$. The calibration of the spiral array, finding solutions to the variables that satisfy perceived properties of pitch relations, is a nonlinear constraint satisfaction problem for which the author found near-feasible solutions using a gradient-inspired heuristic.

Given a music sequence of pitches that map to the pitch representations $\{\mathbf{P}_i\}$, with corresponding durations, $\mathbf{d} = [d_i]$, where $i = 1, \ldots, m$, the center of effect of the sequence, $\text{CE} \equiv \sum_{i=1}^{m} d_i \cdot \mathbf{P}_i$. The most plausible key for the sequence is given by the key representation nearest to the center of effect of the sequence:

$$\arg \min_{\mu \in \{M,m\},k} ||\text{CE} - \text{T}_{\mu,k}||.$$

Extensions: The descriptions of key-finding algorithms have focussed on discrete information. It is possible to apply probabilistic approaches using the same representations. For example, Temperley (2007) explores a Bayesian approach to the Krumhansl key-finding framework.

Both Krumhansl's probe tone profile method and Chew's spiral array center of effect generator algorithm have been extended from symbolic to audio key finding. The underlying methodology remains the same. However, when starting from audio, some pre-processing of the signal needs to be done to convert it to pitch class information. Similarly, the key templates may have to be adapted for audio input. Common techniques for extracting frequency information from the signal include the Fast Fourier Transform and the Constant-Q Transform. This step is followed by the mapping of spectral information to pitch class bins, then the key finding algorithm is applied accordingly. While signal-based information tends to be more noisy than discrete symbolic information, much of the noise results from the harmonics of the fundamental frequency of each tone, which tend to be frequencies in the key, and help reinforce and stabilize key identity.

Meter and Rhythm

While historically the modeling of meter and rhythm has not received as much attention as that of key and harmony, the feeling of pulse, and the grouping of events embedded in that pulse, are some of the most visceral responses humans have to music. An overview of symbolic and literal (signal) representations of rhythm can be found in Sethares (2007) and Smith and Honing (2008). In symbolic music, tone onsets are encoded explicitly in the representation. When analyzing audio, a pre-processing step of extracting onset information must first be performed. An overview of onset detection methods is given in Bello et al. (2003).

Meter Induction: The determining of meter can be described as the finding of the periodic accent patterns in the underlying pulse of music. Meter induction, like key finding, is an important step for numerous music applications such as automatic music transcription, generation, and accompaniment. Most algorithms for finding meter apply autocorrelation to find periodicity in the signal, see for example, Gouyon and Dixon (2006). A different computational model for extracting meter from onset information is described in Mazzola's extensive volume on mathematical music theory (Mazzola 2002), and expanded by Volk (2008) to investigate local versus global meters.

The solution method is restated here in a slightly different format. Suppose $\mathbb{N}$ indexes the smallest grid possible to capture all event onsets in a score. And suppose we are interested in pulse layers at onset times of all possible periodicities, $g \in \mathbb{N}$, and offsets, $f = 0, \ldots, i-1$, then a pulse layer might be indexed by $y = \frac{1}{2} \cdot g(g-1) + 1 + f$ and be represented as a vector $\mathbf{p}_y = [p_{yi}]$, where

$$p_{yi} = \begin{cases} 1 \text{ if } i \in \{gk - f : k \in \mathbb{N}\}, \\ 0 \text{ otherwise.} \end{cases}$$

Suppose the onsets in the music are represented as a vector, $\mathbf{o} = [o_i]$, where

$$o_i = \begin{cases} 1 \text{ if an onset occurs on that grid marking, and} \\ 0 \text{ otherwise,} \end{cases}$$

$$p^o_{yi} = \begin{cases} 1 \text{ if } (p_{yi} = 1) \cap (o_i = 1), \text{ and} \\ \text{otherwise.} \end{cases}$$

Effectively, $\mathbf{p}^o_y$ serves as an indicator function for when an onset in the music coincides with a pulse at layer y. Introducing one more variable, let ℓ_{yi} be the span of the longest chain of ones surrounding p^o_{yi}. ℓ_{yi} can be defined recursively as follows:

$$\ell_{yi} = \ell^R_{yi} + \ell^L_{yi},$$

$$\text{where } \ell^R_{yi} = \begin{cases} 0 & \text{if} \quad p^o_{yi} = 0, \\ 1 + \ell_{yi+1} & \text{if} \quad p^o_{yi+1} = 1, \end{cases}$$

$$\ell^L_{yi} = \begin{cases} 0 & \text{if} \quad p^o_{yi} = 0, \\ 1 + \ell_{yi-1} & \text{if} \quad p^o_{yi-1} = 1. \end{cases}$$

The metric weight of an onset at time i is then given by

$$w_i = \sum_y \ell^a_{yi}.$$

The resulting vector, $\mathbf{w}$ gives a profile of the accents and reveals the periodicity in the rhythm. Recall that $y = \frac{1}{2} \cdot g(g-1) + 1 + f$. A variation on this technique (Nestke and Noll 2001) assigns the weight ℓ_{yi} to all points on pulse layer y, i.e. $\forall i = gk - f, k \in \mathbb{N}$.

Genre Classification using Metric Patterns: Periodicity patterns are one of the defining characteristics of dance music, and this feature has been used to classify music into different genres such as tango, rumba, and cha cha (Dixon et al. 2003; Chew et al. 2005). Dixon et al. (2003) uses a set of rules, which can be implemented using decision trees, to categorize the music using tempo and periodicity features. Similar to the key-finding methods, (Chew et al. 2005) uses correlation to compare the metric weight profiles derived from the data to templates for each dance category.

Segmentation in Time

Few pieces of music stay entirely in one key or one rhythmic pattern. Composers generate interest by varying the tonal and rhythmic content of the music over time. Thus, it would be unrealistic to compute only one key or one meter based on available information. A common adaptation of key-finding or meter induction algorithms to allow for changing key or metric identity is to use a sliding window (Shmulevich and Yli-Harja 2000), or an exponential decay function (Chew and François 2005).

The determining of section boundaries is important in music structure analysis, the applications for which include music summarization. Using the key and meter representation frameworks introduced above, it is possible to create a dynamic programming formulation, with an appropriate penalty function for change between two adjacent windows, for assigning boundaries in a piece of music, for example for key as discussed in Temperley (2007). Another method for determining key change is described in Chew (2002), which borrows ideas from statistical quality control. In large structure analysis, it is often useful to be able to label sections (for example, as chorus or verse in popular songs). Toward this end, Levy and Sandler (2008) have applied a number of clustering techniques to audio features extracted from music signal.

Melody

Melody represents the horizontal structure of music. Apart from the straightforward event string representation of melody, melody can also be decomposed into building blocks and represented as grammar trees, as prescribed by Lerdahl and Jackendoff (1983).

Similarity Assessment: Quantifying the similarity between two melodies is important for music information retrieval. Typke et al. (2003) describe the use of the Earth Mover's Distance (EMD) to quantify melodic similarity. Represent each melody as weighted points in pitch-time space, for example, melody $\mathrm{A} = \{\mathbf{a}_1, \mathbf{a}_2, \ldots, \mathbf{a}_m\}$ and melody $\mathrm{B} = \{\mathbf{b}_1, \mathbf{b}_2, \ldots, \mathbf{b}_n\}$ with respective weights, $\omega_i, u_j \in \mathbb{R}^+ \cup \{0\}$, where $i = 1, \ldots m$ and $j = 1, \ldots n$. The similarity measure between the two melodies is the EMD, the minimum cost flow to transform one melody into another by moving weight from one point in A to one point in B, where the cost is the weight moved times the distance traveled.

Suppose $W = \sum_{i=1}^{m} w_i$ and $U = \sum_{i=1}^{n}$, and f_{ij} is the flow of weight from a_i to b_j over the distance d_{ij}. The problem can thus be stated as:

$$\begin{aligned} \min \quad & \sum_{i=1}^{m}\sum_{j=1}^{n} f_{ij}d_{ij} \\ \text{s.t.} \quad & \sum_{j=1}^{n} f_{ij} \le w_i, i = 1,\ldots,m, \\ & \sum_{i=1}^{m} f_{ij} \le u_j, j = 1,\ldots,n, \\ & \sum_{i=1}^{m}\sum_{j=1}^{n} f_{ij} = \min(W,U), \\ & f_{ij} \ge 0,\ i = 1,\ldots,m,\ j = 1,\ldots,n, \end{aligned}$$

which can be solved using linear programming, and

$$\mathrm{EMD}(\mathrm{A},\mathrm{B}) = \frac{\sum_{i=1}^{m}\sum_{j=1}^{n} f_{ij}^{*} d_{ij}}{\min(W,U)}.$$

Stream Segregation: A number of approaches have been proposed to tackle the problem of automatically separating a polyphonic (multi-line) music texture into its component voices. An example might be to separate a fugue by Johann Sebastian Bach into its four parts. A randomized local search method to optimize a parametric cost function that penalizes undesirable traits in a voice-separated solution was proposed by Kilian and Hoos (2002). Chew and Wu (2004) proposed a contig-mapping approach to first break a piece of music into contigs with overlapping fragments of music. Then, exploiting perceptual principles such as voices tend not to cross in maximal voice contigs, the algorithm re-connects the fragments in neighboring contigs using distance minimization.

Composition and Improvisation

The use of mathematical models in music composition has become an active area for musical innovation since Xenakis (2001), who used stochastic processes, probabilistic models, and game theory to guide his compositions. With widespread access to computing to help solve music composition mathematical problems, computer-assisted composition has emerged as a useful tool to help composers create new music, as well as an important area of digital music research.

Constraints

A number of music composition problems can be naturally described as constraint satisfaction problems (CSPs). Solution methods for CSPs include combinatorial optimization and local search techniques such as Tabu search, simulated annealing, and genetic algorithms.

Truchet and Codognet (2004) list fourteen examples of musical CSPs and propose to apply a heuristic adaptive search technique to solve the CSPs. An example of a compositional CSP is as follows: Given a sequence of chords, suppose the composer is interested in finding an ordering of the sequence such that two adjacent chords have the maximal number of common tones. If the chords were represented as nodes, and the distance between any two nodes is the number of common tones, then the problem of interest takes the form of the Traveling Salesman Problem. Every chord must be visited once, and the desired solution must minimize $(-1) \times$ distance.

Related to this is the classic problem of providing harmonization for a given melody. The most widely used solution method for generating a score from a melody is via constraints, and a variety of approaches and results are reviewed in Pachet and Roy (2004).

Markov Chains and Other Network Models

The use of Markov chains (MCs) forms another solution method that is commonly used in the generating of music. In the case of MCs, the probabilities are estimated from existing data, and used to generate music in the style of the training data set. Farbood and Schoner (2001) use MCs to generate music in the style of Palestrina. Using the tonnetz as scaffolding to reduce the search space, Chuan and Chew (2007a) use MCs to generate style-specific accompaniment for melodies given only a few examples. MCs are excellent models for imitating local structure, but lack high level structure knowledge to guide the shaping of a composition. To remedy this deficiency, researchers have considered computer systems that create the local surface structure while relegating higher level structural control to humans.

In Pachet's Continuator, the system builds prefix trees from music data, weights each possible continuation with a probability estimated from the data, and uses the resulting MC to generate music in dialog with a human musician. Extensions of the basic MC model consider hierarchical representations and ways of imputing rhythmic structure to the resulting music. Assayag and Dubnov (2004) describe an alternate approach using factor oracles. The suffix links in the resulting network model is assigned transition probabilities that causes the original music material to be recombined smoothly. Using the same factor oracle approach, François et al. (2010) created Mimi4x, an installation that allows users to make high-level structural improvisation decisions while the computer manages surface details on four improvising systems.

Expressive Music Performance

Music is rarely performed as notated. The score is an incomplete description of the experience of a music piece, and leaves much to interpretation by a performer. In expressive music performance, a performer manipulates parameters such as tempo, loudness, and articulation for expressive or interpretive ends, and to guide the listener's perception of groupings and meter. The expressive devices in the performance of music is sometimes called musical prosody. See Palmer and Hutchins (2006) for a definition and review of research on musical prosody. The extraction of performance parameters can be viewed as the continuous monitoring of expressive features such as tempo and loudness over time.

Representation

Tempo and loudness are two important features of music performance. Suppose the list of onsets in the performed music are $O = \{o_0, o_1, \ldots, o_n\}$. Then the inter-onset-interval at time i is $IOI_i = o_i - o_{i-1}$. If a listener sat and tapped along to the beat of the music, then the list of beat onsets might be $B = \{b_0, b_1, \ldots, b_n\}$. The interbeat-interval would be $IBI_i = b_i - b_{i-1}$, and the instantaneous tempo would be $T_i = \frac{1}{IBI_i}$. Often, some smoothing is desired, and one would report a moving average for the smoothed tempo. Sometimes, the acceleration is desired, where $a_i = \Delta T_i = T_i - T_{i-1}$. A number of models for deriving loudness from the signal exist, many of which have been implemented in Matlab. Timmers (2005) surveys some ways of measuring tempo and loudness in musical performance and of comparing them across performances.

Using the tempo-loudness representation proposed by Langner and Goebl, Dixon et al. (2002) created a computer system for for real-time visualization of performance parameters in the Performance Worm. The exploration of Langner's tempo-loudness space for performance analysis led to its use for performance synthesis in the Air Worm (Dixon et al. 2005).

In the spirit of annotations of speech prosody, Raphael proposed a series of markup symbols for expressing musical flow (Raphael 2009). The symbols consist of

$$\{l^-, l^\times, l^+, l^\rightarrow, l^\leftarrow, l^*\}.$$

$\{l^-, l^\times, l^+\}$ denote a sense of arrival, where l^- is a direct and assertive stress, $l^\times$ is a soft landing that relaxes upon arrival, and l^+ is an arrival whose momentum continues to carry forward into the future. $\{l^\rightarrow, l^*\}$ mark notes that continue to move forward toward a future goal, $l^\rightarrow$ is a passing tone and l^* is a passing stress, and $\{l^\leftarrow\}$ denotes a pulling back movement. Because it is hard to determine the exact sets of tempo and loudness parameters, and more locally, the exact amounts of delay or anticipating of an onset, that lead to these flow sensations, Raphael uses a hidden Markov model (HMM) to estimate the most likely hidden variables to have given rise to the observed prosodic annotation.

Phrases

In expressive performance, performers indicate phrase groupings by varying tempo (accelerate and decelerate at beginnings and ends of phrases) and/or loudness (crescendo and decrescendo at beginnings and ends of phrases). As a result, this aspect of a performer's interpretations can be directly inferred from tempo and loudness data. For example, Chuan and Chew (2007b) propose a dynamic programming (DP) method for automatic extraction of phrases. The authors test a model that fits a series of quadric curves (first modeled by polynomials of degree two, then by a series of quadratic splines) to the tempo time series. The best fit curve is found using quadratic programming, and the phrase boundaries are determined using DP.

Alignment

A common use of DP in music processing is in the alignment of music sequences that may be in the same or different format. Arifi et al. (2004) reviews the state of the art, and describes an algorithm for aligning music sequences in two of three possible formats – score, Musical Instrument Digital Interface (MIDI), and pulse-code modulation (PCM) audio format.

Assuming the two sequences are the score, $\mathbf{s} = [s_i]$, and a PCM representation of the audio performance, $\mathbf{p} = [p_j]$. The first task is to generate a cost matrix for aligning any point, s_i, in the score with any point, p_j, in the PCM audio. In Arifi et al. (2004), the distance minimization step is embedded in the cost matrix. Suppose the cost matrix is represented by $\mathbf{C} = [c_{ij}]$, each element of which expresses the cost minimizing SP-match for $[s_1, s_2, \ldots, s_i]$ and $[p_1, p_2, \ldots, p_j]$, i.e.

$$c_i j = \min\left\{c_{i,j-1}, c_{i-1,j}, c_{i-1,j-1}, d_{ij}^{SP}\right\}.$$

Then, the algorithm for synchronizing the two streams is as follows:

```
SCORE-PCM-SYNCHRONIZATION(C, s, p)
1    i = length(s), j = p, SP-Match = 0
2    while (i > 0) and (j > 0)
3        do if c[i, j] = c[i, j − 1]
4                then j = j − 1
5             else if c[i, j] = c[i − 1, j]
6                     then i = i − 1
7             else SP-Match = SP-Match ∪
                          {(i, j)}, i = i−1,  j = j−1
8    return SP-Match
```

Dixon and Widmer (2005) introduced MATCH, a tool chest for efficient alignment of two time series using variations on the classic dynamic time warping (DTW) algorithm. Niedermayer and Widmer (2010) proposed a multi-pass algorithm that uses anchor notes (notes for which the alignment confidence is high) to correct inexact matches.

Concluding Remarks

Digital music research has rapidly evolved with computing advances and the increasing possibilities for connections between music and computing. The latest advances in the field are reported in the annual *Proceedings of the International Conference on Music Information Retrieval*, *Proceedings of the Sound and Music Computing Conference*, and the *Proceedings of the International Symposium on Computer Music Modeling and Retrieval*, the biennial *Proceedings of the International Conference on Mathematics and Computation in Music*, and the occasional *Proceedings of the International Conference on Music and Artificial Intelligence*. They can also be found in the traditional conferences of the multimedia, databases, human computer interaction, and audio signal processing communities. The archival journals include the *Computer Music Journal*, the *Journal of New Music Research*, and the *Journal of Mathematics and Music*.

There exist close ties between digital music research and the fields of music perception and cognition and computer music (which places greater emphasis on the creating of music), and the community of researchers interested in interfaces for musical expression. Work that overlaps with these other areas can be found in the biennial *Proceedings of the International Conference on Music Perception and Cognition*, and the annual *Proceedings of the International Computer Music Conference* and *Proceedings of the International Conference on New Interfaces for Musical Expression*.

Dijkstra's Algorithm

A method for finding shortest paths (routes) in a network. The algorithm is a node labeling, greedy algorithm. It assumes that the distance c_{ij} between any pair of nodes i and j is nonnegative. The labels have two components $\{d(i), p\}$, where $d(i)$ is an upper bound on the shortest path length from the source (home) node s to node i, and p is the node preceding node i in the shortest path to node i. The algorithmic steps for finding the shortest paths from s to all other nodes in the network are as follows:

Step 1. Assign a number $d(i)$ to each node i to denote the tentative (upper bound) length of the shortest path from s to i that uses only labeled nodes as intermediate nodes. Initially, set $d(s) = 0$ and $d(i) = \infty$ for all $i \neq s$. Let y denote the last node labeled. Give node s the label $\{0, -)$ and let $y = s$.

Step 2. For each unlabeled node i, redefine $d(i)$ as follows:

$d(i) = \min\{d(i), d(y) + c_{yi})\}$. If $d(i) = \infty$ for all unlabeled vertices i, then stop, as no path exists from s to any unlabeled node i with the smallest value of $d(i)$. Also, in the label, let p denote the node from which the arc that determined the minimum $d(i)$ came from. Let $y = i$.

Step 3. If all nodes have been labeled, stop, as the unique path of labels $\{d(i), p\}$ from s to i is a shortest path from s to i for all vertices i. Otherwise, return to *Step 2*.

Direction of a Set

A vector $\boldsymbol{d}$ is a direction of a convex set if for every point $\boldsymbol{x}$ of the set, the ray $(\boldsymbol{x} + \lambda \boldsymbol{d})$, $\lambda \geq 0$, belongs to the set. If the set is bounded, it has no directions.

Disaster Management: Planning and Logistics

Gina M. Galindo Pacheco[1,2] and Rajan Batta[1]
[1]University at Buffalo, The State University of New York, Buffalo, NY, USA
[2]Universidad del Norte, Barranquilla, Colombia

Introduction

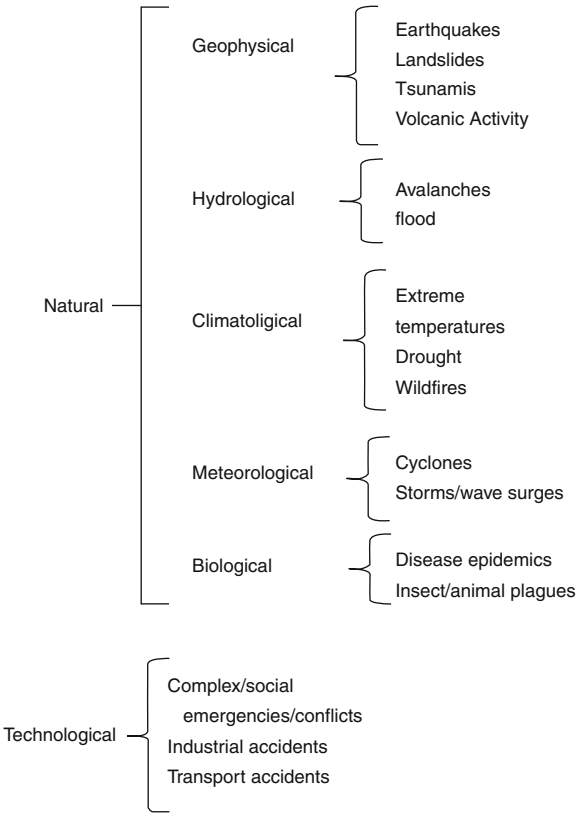
Due to significant losses of life, as well as extremely high economic costs, the prevention and improvement of disaster response has been a continuing area of research. OR analysts have been in the forefront of such work and have made significant contributions that have helped to mitigate the impact of disasters. This article reviews some of the basic concepts related to disaster management (DM) and summarizes many of the topics that have been addressed.

The presentation is as follows: section one reviews disaster definitions and types; section two focuses on the role of DM, the concepts associated, and the stages that are traditionally identified within DM; section three discusses the role of the planning process; section four reviews the related logistics issues; section five discusses DM topics based on a sample of work from the period 2005-2010; and the last section presents a summary and concluding remarks.

Definition of Disaster

According to the International Federation of Red Cross and Red Crescent Societies (IFRC), a disaster is a sudden event that causes disruption of the normal functioning of a community; causes human, economic, and environmental losses; and generates requirements that exceeds the capacity of response using available resources.

Losses due to disasters may be of the order of thousands of lives and billions of dollars. Kunkel, Pielke, and Changnon (1999) give some statistics about human and economic losses due to weather and climate extremes in the U.S. They estimate that between 1986 and 1995 there was an annual mean loss of 96 lives due to floods and 20 due to hurricanes. In the same period, the annual mean of economic losses was $6.2 billion for hurricanes. In 2005, the National Hurricane Center estimated that hurricane Katrina left a total of 1,200 reported casualties, with a total damage cost of $81 billion. Man-made disasters can also have drastic consequences if they are purposely planned. For example, according to the National Commission on Terrorist Attacks upon United States, more than 2,981 people died in the attacks of 9/11. Even though environmental disasters typically do not involve many human casualties, they do cause great ecological damages, e.g., the Gulf of Mexico oil spill that affected thousands of turtles, birds, and mammals, as reported by the International Disaster Database Web site (in addition to the considerable monetary loss for British Petroleum). The types of natural and man-made disasters are listed in Fig. 1.



Disaster Management: Planning and Logistics, Fig. 1 Types of disasters

This classification derives partly from IFRC, Alexander (2002), and Van Wassenhove (2006).

Criteria	Classification
Cause	Natural
	Technological
Onset	Sudden
	Slow
Detection	Predictable
	Unpredictable

Disaster Management: Planning and Logistics, Fig. 2 Disaster classification

Natural disasters may be grouped into predictable ones, such as hurricanes, and unpredictable events, such as earthquakes. Data about predictable disasters are not deterministic, but some information about the time and place of such disasters is available. Such disasters can also be classified with respect to their time of onset. Tornadoes happen suddenly and last for a short period of time, while events such as pandemics may go from a few days to several months. These classifications become important at the time of planning and responding: for predictable disasters actions like evacuation or prepositioning of supplies are possible, while for unpredictable ones, such actions are not possible alternatives; for very short-term disasters it is easier to estimate the amount of resources needed to overcome the situation, where for long-term disasters this is a more difficult task. Figure 2 summarizes these classifications.

Role of Disaster Management

According to the IFRC, the management of resources and responsibilities to respond to humanitarian needs after an emergency is known as Disaster Management (DM).

DM can be viewed as including the strategic, tactical, and operational activities, as well as the personnel and technologies involved at various stages of a disaster situation for the purpose of mitigating its possible consequences (Lettieri et al. 2009).

The different stages involved in DM are classified as mitigation, preparedness, response, and recovery (McLoughlin 1985). Miller, Engemann, and Yager (2006) provide a detailed explanation of the four DM stages. Each of these stages is briefly discussed below with respect to a flood disaster.

Mitigation consists of those activities that help to reduce the long-term risk of the occurrence of a disaster or its consequences. For a flood scenario, mitigation would involve not building on low lands, and creating barriers along rivers or ponds. Preparedness refers to planning operational activities to respond to a disaster—creating shelters, prepositioning supplies, and evacuating people from most dangerous locations is a way in which preparedness may be applied for a flood setting. The response stage includes actions that correspond to those performed upon the occurrence of the disaster to help affected people to overcome their needs of essential resources or getting them out from danger e.g., delivering supplies and rescuing people. The recovery phase involves short and long-term activities to restore normal functioning of the community, as well as repairing roads and buildings.

The recovery phase should be designed in such a way that it contributes to mitigation efforts. For the flood example, rebuilt houses should not be located in lands known to be highly exposed to floods. This is how DM could be viewed as a cycle created by the link of mitigation and recovery activities. In general, the different stages of DM require a previous planning process to coordinate all the ulterior actions that would be performed. In addition, a logistic process is involved mainly, but not exclusively, for the preparedness and response phases.

Disaster Management and Planning Process

The Oxford English Dictionary defines the verb "to plan" as meaning "to devise, contrive, or formulate (something to be done, or some action or proceeding to be carried out.)" For DM, Alexander (2002) distinguishes emergency planning in terms of long and short-term. The former gives the context for the latter. It involves forecasting, warning, educating, and training people for the event of a disaster. It includes the study of patterns to predict the possible time and place at which a disaster could occur. Seasonal natural disasters, such as tropical storms in the Caribbean, are examples. The concept of long-term planning is related

to the definition of emergency planning given by Perry and Lindell (2003) for whom emergency planning focuses on the two objectives of hazard assessment and risk reduction. The purpose of short-term planning is to guarantee the prompt deployment of resources where and when needed.

Alexander (2002) describes an outline of the methodological components of an emergency plan and includes a generic emergency planning model. The planning process may be summarized as gathering information, managing and analyzing it, extracting some conclusions and actions to be developed, and communicating the resulting plan to the staff involved.

Disaster Management and Logistics

Several definitions are used for the term logistics. Van Wassenhove (2006) gives a brief and illustrative review of some of these definitions as applied to business, military, and humanitarian DM logistics. In summary, logistics, when applied to DM, is referred to as the storage and deployment of resources and information, as well as the mobilization of people in an effective way to reduce the impact of the disaster. Kovács and Spens (2007) and Van Wassenhove (2006) reflect upon the comparison between business and humanitarian DM logistics. However, despite the differences, business and humanitarian logistics are intrinsically related and they both refer to a process that includes planning, distribution and transportation, storage, location and supply chain management (SCM).

In what follows, some common problems related to planning and logistics in DM and OR are discussed.

OR and DM

A survey of OR research related to DM since 2005 was conducted. A total of 222 items in journals, books, book chapters, and conference papers were reviewed. A finding was that topics of planning and logistics in DM attracted most of the attention. For planning, the most common topics were evacuation and risk analysis. General humanitarian logistics was a topic addressed in terms of (i) transportation, (ii) inventory, (iii) location analysis, and (iv) humanitarian logistics (in general). Material from (i) to (iii) are referred to as specific activities inside the concept of logistics, while that from (iv) considers logistics as a whole or that combines different aspects of humanitarian logistics. Other topics of logistics are reviewed separately because they constitute a widely studied topic as is the case for transportation that includes research on routing, traffic and network management.

Even though there were many other topics of OR interest in the reviewed research such as demand forecast, business continuity, and hospital capacity, the topics mentioned earlier represent the main streams that were studied. In the following sections, the topics will be discussed separately focusing on the relationship to DM phases, methodologies, objectives, and real-life applications.

Evacuation: The major way for reducing the potential population affected by a disaster is evacuation. An evacuation typically involves mobilizing people from endangered zones to safer ones, which includes routing strategies and preparation of shelters, among other activities. This process is mostly associated with the preparedness phase of DM, and, therefore, to the planning processes. However, some related work for real-time decisions may be linked to the response phase (Chiu and Zheng 2007). For predictable disasters, it is possible to develop evacuation plans to be performed before the disaster strikes; no pre-disaster-evacuation planning is possible for unpredictable disasters.

The most common objective in evacuation research was minimizing the evacuation time of the total affected population (Chen and Zhan 2008). Other objectives included maximizing the total number of evacuees during a given evacuation time (Miller-Hooks and Sorrel 2008), maximizing the minimum probability of reaching an exit for any evacuee (Opasanon and Miller-Hooks 2009), and minimizing total system travel time (Chiu et al. 2007). Some studies considered multiple objectives. In Saadatseresht, Mansourian, and Taleai (2009) the objectives were to minimize travel distance, evacuation time, and overload capacity of safe areas. Stepanov and Smith (2009) provide a critique of performance measures for evacuation that include clearance time, total traveled distance, and blocking probabilities.

Simulation was the most used method to solve evacuation problems. Bonabeau, (2002) and

Chen and Zhan, (2008) used agent-based simulation—the process in which entities termed autonomous agents assess their situations and make decisions according to a set of rules(say something about validation). Other studies developed multi-level models (Liu et al. 2006), queue analysis (Stepanov and Smith 2009), mixed integer linear programming (Sayyady and Eksioglu 2010); others used Cell Transmission Models (Chiu et al. 2007), and genetic algorithms (Miller-Hooks and Sorrel 2008).

Most of the studies employed real data to validate their results. For example, Chen, Meaker and Zhan (2006) developed a simulation model for evacuating the Florida Keys under a hurricane setting. They considered two questions: one related to the time for evacuating the total population, while the other considered how many residents would need to be accommodated if evacuation routes were impassable. The authors used a previous study as a reference for comparing the results of their model. However, no validation based on real evacuation times is reported.

Risk Analysis: DM risk analysis is mainly concerned with quantifying the risk of the occurrence of an undesirable event, as well as developing measures to diminish the impact of a disaster. Risk analysis is mainly a planning tool related to the mitigation. The objectives of the DM risk analysis studies were forecasting, infrastructure planning and design, vulnerability, and analysis of uncertainty, as discussed next.

In relation to forecasting, Hu (2010) uses a Bayesian approach to analyze flood frequencies. Infrastructure planning and design based on risk analysis refers in some cases to making the infrastructure (buildings, networks, supply chains, etc.) more resistant to disaster damages and disruptions, and to building physical barriers or diversions to diminish the impact of a disaster on an endangered community. Snyder et al. (2006) reviewed several models for designing supply chains resilient to disruptions. These models considered costs from the business point of view, with objectives, in most of the cases, being the minimization of the expected or the worst case cost. Li, Huang and Nie (2007) used a model for flood diversion planning under uncertainty where, among the objectives considered, was the minimization of risk of system disruption. Vulnerability relates to the way in which current systems are affected by damages. Matisziw and Murray (2009) maximized system flow for a disrupted network. Barker and Haimes (2009) focused on a sensitivity analysis of extreme consequences due to uncertainties on the parameters, and Xu, Booij and Tong (2010) analyzed the sources of uncertainty in statistical modeling.

Probability and statistics were the main methods used to analyze risk analysis. In the case of Li, Huang, and Nie (2007) the authors used a methodology that combines fuzzy sets and stochastic programming. Another example in which fuzzy sets have been incorporated into risk analysis is given by Huang and Ruan (2008). In this DM area, even though some researchers used real data to develop numerical examples, complete case studies were rare.

Transportation: Transportation problems typically deal with routing, vehicle schedule, traffic, and network management. The problems may be to transport goods to provide relief supplies, evacuate people from endangered areas, or movement of resources such as medical staff to areas where their services are required.

For transportation analyses, as applied to DM, there are a wide variety of objectives related to the efficiency of delivery times. Campbell, Vandenbussche, and Hermann (2008) considered two objectives for minimizing the arrival times of relief to demand points. Similarly, Yuan and Wang (2008) minimized the total travel time through a path selection methodology, while Jin and Ekşioğlu (2008) minimized vehicle delay.

Methods used included mathematical programming and its derivates, such as stochastic and integer programming, Campbell, Vandenbussche, and Hermann (2008) and Yuan and Wang (2009). Jotshi, Gong and Batta (2009) used the HAZUS program to develop a post-earthquake scenario in Los Angeles. [HAZUS is a computer-based system created and distributed via the Web by the Federal Emergency Management Agency (FEMA) for estimating potential losses caused by earthquakes, floods and hurricanes].

Inventory: Traditionally, in the commercial area, inventory analyses address a number of areas: materials, components, work-in-process, and finished goods (Nahmias 2009). But, businesses may use inventory theory to pre-analyze forecasted disasters, e.g., Taskin and Lodree (2011) developed an inventory

model for a manufacturing facility whose demand could be impacted by a potential storm. This might also be appropriate for DM in the case of items such as canned food, lamps, and coolers. In general, humanitarian logistics inventory concerns are mostly related to the prepositioning or early acquisition of relief goods. Decisions related to inventory problems fit better in the preparedness phase of DM, but they may affect directly the effectiveness of the response phase if a shortage of inventory occurs.

Most of the inventory-oriented papers shared one common objective: minimize expected cost. This cost may be expressed as a loss function (Taskin and Lodree 2011) or may be a composition of traditional inventory costs including the cost per order, holding inventory cost, and back-order cost (Beamon and Kotebla 2006). Salmerón and Apte (2010) developed a two-stage model for a humanitarian logistics for optimally allocating a budget for acquiring and positioning relief assets. Two objectives were pursued: minimization of the expected number of casualties, and minimization of the expected amount of unmet transfer population. Here, casualties were the result of seriously injured people who were not served promptly by medical staff, and people needing relief supplies who do not get them on time. On the other hand, transfer population represent people who are not in a critical condition, but still need to be evacuated to relief centers. Unmet transfer population applies when these people are not promptly evacuated.

DM inventory problems were analyzed using stochastic optimization combined with statistical tools such as Bayesian methods. Taskin and Lodree, (2011) present some numerical examples with simulated data, while other research used hypothetical data from previous studies.

Location: In general, location analysis deals with problems of siting facilities in a given area (ReVelle and Eiselt 2005). Such problems are commonly classified by businesses as strategic, i.e., a type of decision whose effects are expected to last for a long period due to the fixed cost of opening a facility, and/or changing the location of a facility may be a very expensive. In humanitarian logistics, however, location analysis may be best defined as a tactical decision, as most often it considers locating temporary shelters and warehouses where relief assets may be kept safe. These facilities generally consist of existing sites suitable, such as schools, stadiums, or churches.

Depending on the objectives pursued, results from location analysis may set the framework for ulterior decision problems such as: where to store prepositioned supplies; given the location of such relief supplies, how they would be distributed; where the evacuees will be directed to; and where to locate emergency vehicles or provisional health centers. Location analysis may be more accurately relate to the preparedness phase of DM. But, it could also be associated to the mitigation phase for locating facilities in low-risk areas, or, based on the disaster, in the response phase to improvise additional shelters or medical centers other than those that were planned.

Facility location applied in the preparedness phase is discussed by Balcik and Beamon (2008) who sought to locate distribution centers and determine the amount of supply to preposition at such centers to maximize the total expected demand covered. Lee et al. (2009) studied multiple dispensing points to service a large population searching for prophylaxis, with the objective to minimize the maximum expected traveled distance.

For the mitigation phase, Berman et al. (2009) analyzed where to locate p facilities to maximize coverage on a network whose links could be destroyed. Beraldi and Bruni (2009) studied the location of emergency vehicles under congested settings with the objective of minimizing cost.

Most of the DM location analysis research used mixed integer programming (MIP) and, in some cases, applied heuristic methods to help determine the solution of large problems (Berman et al. 2009). Other studies used stochastic programming models (Beraldi and Bruni 2009), or simulation to generate potential scenarios so as to compare the model results to actual data form a case study (Afshartous et al. 2009).

Logistics Models Overview

DM logistics involves several activities that include planning, warehousing, location, and distribution, among other elements. Some studies combined one or more of these activities, with others focused on an integrated and general concept of logistics.

Kovács and Spents (2007) and Van Wassenhoven (2006) describe humanitarian logistics as a whole. They sought a better understanding of planning and carrying out of logistics in disaster relief through a literature review. Van Wassenhoven presents a parallel between private and humanitarian logistics, and also proposes some guidelines for developing a better preparedness strategy for the latter.

Yi and Özdamar (2007) define an integrated capacitated location-routing model. Their model was designed to coordinate the distribution of relief material and the transportation of evacuees to emergency units selected through location analysis. The objective was to minimize the relationship between the weighted sum of unsatisfied demand and the weighted sum of wounded people at temporary and permanent emergency units using a two stage MIP model.

Chang, Tseng and Chen (2007) analyze a combination of location and transportation: the coordination activities related to rescue logistics efforts under a flood setting in an urban area. They consider the location of rescue resource inventory, allocation and distribution of rescue resources, and the structure of rescue organizations. Using two models, they first classified the rescue areas according to levels of emergency with the objective of minimizing the shipping cost of rescue equipments; the second model was a two stage stochastic-programming model that minimized set-up cost of storehouses and rescue equipment costs.

Yan and Shih (2009) developed a model for roadway repair scheduling and subsequent distribution of relief supplies. The objective was the minimizing the total expected time for repair and distribution using a MIP model. A related study in which a distribution system is modeled as a supply chain where the echelons are the relief suppliers, relief distribution centers, and relief demanding areas is described in Sheu (2007). Here, the objective was to minimize the expected cost of relief distribution during the three days following the onset of the disaster using a hybrid fuzzy-clustering method.

Balcik, Beamon and Smilowitz (2008) studied what is termed the last mile relief distribution, i.e., the distribution of relief assets from distribution centers to final demand. Their model dealt with the allocation of relief supplies to local distribution centers, and the delivery of schedules and routes for distributing vehicles. Their MIP model minimized the expected cost of distribution that included routing costs and a penalty for unmet demand.

Concluding Remarks

This article presented an overview of DM focused on planning and logistics. It is clear that planning and logistics are inseparable, intrinsically related, and both present in different phases of DM. These phases should be performed in a cyclic fashion so that the recovery efforts should also pursue mitigation objectives. Related research showed that many OR/MS-based studies have been directed at improving the effectiveness and efficiency of DM. The impetus for this is probably due to the catastrophic events of the Twin Towers attack in 2001, the 2004 tsunami in the Indian Ocean, and hurricane Katrina in 2005. These events have contributed to generating an increasing concern of reducing both the risk of such disasters happening and diminishing their consequences. A comparison between humanitarian and business logistics highlighted both their differences as well as their commonalities.

The main topics found from the review of OR/MS research, as related to DM, appear to be evacuation, risk analysis, and logistics. The following remarks with respect to these main topics are based on a review of a fraction of the available literature in this area; it is felt, however, that they do represent an accurate view of the state of the art in this growing field, circa 2011.

In general, the evacuation problems showed that the main concern was the minimization of evacuation time. Some researchers stated that one of the important limitations of such studies was predicting the behavior of evacuees—many variables would have to be considered, as well as social context of the evacuated population. Peacock, Morrow, and Gladwin (1997) analyzed how some people may not respond to evacuation measures before a disaster strikes as a function of their ethnic origin or their socio-economic level. The authors' main conclusion dealt with the perception the evacuee population may have about authorities who may stop them from following pre-disaster evacuation orders.

Risk analysis has proved to be a useful concept when planning for disasters, especially during the

mitigation phase. A problem is the difficulty of enumerating the possible risk scenarios. Moreover, many studies are based on statistical analyses to historical data, but in some occasions, the events being studied are so infrequent that no reliable analysis can be achieved.

For humanitarian logistics research, a distinction was made between transportation, location analysis, inventory, and humanitarian logistics, in general. A limitation that may arise in a transportation study is the inability to incorporate the presence of congestion, even though some studies do, see for example Beraldi and Bruni (2009). Inventory theory has been used by both business and humanitarian logistics to better prepare for disasters, including, as well, location analysis problems from business being applied in humanitarian location settings.

The research papers reviewed referred mainly to the preparedness phase of DM, followed by response and mitigation phases; no work was found related to the recovery phase. Altay and Green, (2006) noted the lack of OR studies related to recovery efforts in comparison to the other phases. Another aspect in which the findings obtained here agree with the ones presented by Altay and Green (2006) is that most of the studies reviewed consists of the development of models, rather than theoretical studies or application tools such as software. For the disasters most commonly studied, there was not a clear reference to man-made disasters such as terrorist attacks; the case studies always dealt with natural disasters.

For DM, an important challenge for the OR/MS community "is to develop a science of disaster logistics that builds upon, among others, private sector logistics and to transfer to private business the specific core capabilities of humanitarian logistics," (Van Wassenhove 2006).

Introduction

Advances in medical treatment have resulted in a patient population that is more complex, often with multiple diseases, competing risks of complications, and medication conflicts, rendering medical decisions harder because what helps one patient or condition may harm another. The use of Operations Research (OR) methods for the study of healthcare has a long history. Furthermore, there is a growing literature on emerging applications in this area. This article provides examples of contributions of OR methods, including mathematical programming, dynamic programming, and simulation, to the prevention, detection, and treatment of diseases. More extensive surveys of OR studies of health care delivery, including medical decision making, can be found in Pierskalla and Brailer (1994), Brandeau et al. (2004), and Rais and Viana (2010).

Advances in medical treatment have extended the average lifespan of individuals, and transformed many diseases from life threatening in the near term to chronic conditions in need of longterm management. Many new applications of OR are emerging as treatment options and population health evolve over time. For example, new treatments have become available for various forms of cancer, HIV, and heart disease. In some cases, patients are living decades with diseases that previously had low short-term survival rates. As a result, more patients are living with co-morbid conditions, and competing risks, creating challenging decisions that must balance the downside of treatment (e.g., medication side effects and long-term complications) with the benefits of treatment (e.g., longer life expectancy and better quality of life).

Diabetes is a good example of a chronic disease for which medical treatment is complex. With nearly 8% of the U.S. population estimated to have diabetes, it is recognized as a leading cause of mortality and morbidity. It is associated with long-term complications that affect almost every part of the body, including coronary heart disease (CHD), stroke, blindness, kidney failure, and neurological disorders. For many patients, diabetes might be prevented through improved diet and exercise. However, due to the slow development of symptoms in many patients, diabetes can go undetected for years. For patients that are diagnosed with diabetes, risk models exist to predict the probability of complications, but alone these models do not provide optimal treatment decisions. Rather, they provide raw data that can be used in OR models to make optimal treatment decisions. This general situation is true of many chronic diseases. As a result, there are many emerging opportunities for applications of OR to disease prevention, detection, and management.

This article is organized as follows. The section on Disease Prevention and Screening describes important contributions of OR to disease prevention, including vaccination and screening methods for detecting disease in a population of potentially infected people. The section on Treatment Choices focuses on applications to long-term management of chronic diseases, including selection among multiple treatment choices, and decisions about timing and dosage of treatment. The section on Emerging Applications reviews some emerging applications to real-time decision making at the point of care and patient decision aids. Finally, research opportunities are discussed in the Conclusions section.

Disease Prevention and Screening

Prevention and screening are important factors in determining overall population health. OR has been applied to help inform decisions related to prevention and screening for decades. Two major topics in this area, that are prominent in the OR literature, are vaccination and disease screening. Vaccination emphasizes the prevention of infectious diseases, while disease screening is common for both non-infectious and infectious diseases. Each of these topics will be discussed in detail in this section.

Vaccination

The biological and genetic sciences have greatly increased the knowledge of how viruses and bacteria operate within the body to create disease. This has led to the discovery of many new vaccines. However, the myriad interactions as well as controversy about their effects on individuals, and an overall population, have drawn considerable public attention. These interactions and effects present several challenges in the utilization of the vaccines for disease control. First, there are a large number of diseases for which effective vaccines are available. Some have specific requirements, such as multiple doses that must be administered within a minimum or maximum time window. Also, some have conflicts with other vaccines. Second, many new vaccines are coming on the market, including combination (multi-valent) vaccines that can cover multiple diseases. Third, for some diseases there is uncertainty about the future evolution of epidemic strains, leading to questions about optimal design of vaccines. Finally, there are challenges in the vaccine manufacturing process including uncertain yields, quality control, supply chain logistics, and the optimal storage location of vaccine supplies. OR models have been applied to address many of these challenges.

Pediatric Vaccination

Pediatric or childhood vaccination is the most common means of mass vaccination. OR researchers have developed models to aid in the selection of a vaccine formulary, pricing of vaccines, and design of vaccination schedules. Jacobson et al. (1999) proposed integer-programming models to determine the price of combination vaccines for childhood immunization. Their models considered all available vaccine products at their market prices and constraints based on the U.S. national recommended childhood immunization schedule. Their objective was to find the vaccine formularies with the lowest overall cost from the patient, provider, and societal perspectives. Their integer-programming models considered the first five years of the recommended childhood immunization schedule against six diseases. They used binary decision variables to denote whether a vaccine is scheduled for a particular month's visit.

In a later study, Jacobson et al. (2006) investigated a pediatric vaccine supply shortage problem to assess the impact of pediatric vaccine stockpile levels on vaccination coverage rates of the guidelines during supply interruption. Their model was similar to inventory models that consider stock-outs, as well as lot sizing problems with machine breakdowns. Objectives of their model included optimizing service level and minimizing a standard loss function. Using their model, they concluded that the guidelines are only sufficient to mitigate a vaccine production interruption of eight months.

Hall et al. (2008) considered a childhood vaccination formulary problem that allows for combination vaccines. They proposed an integer-programming model to minimize the cost of fully immunizing a child under the constraints of a recommended schedule. They proved their proposed model is NP-hard. They proposed exact algorithms using dynamic programming and heuristics for approximating near optimal solutions to their model. Engineer et al. (2009) further investigated an extension that involves catch-up scheduling for childhood vaccination. They provided details of a successful implementation of their model as a decision support system.

Flu Vaccination

Some diseases evolve rapidly over time, necessitating frequent vaccination on a regular basis. For example, the composition of seasonal flu vaccine changes every year. Wu et al. (2005) proposed a model for flu vaccine design. They used a continuous-state discrete-time dynamic-programming model to find the optimal vaccine-strain selection policy. In their dynamic program, the state was represented by the antigenic history, including previous vaccine and epidemic strains. The decision variable (action) was the vaccine strain to be selected, and the reward is the

cross-reactivity representing the efficacy of the vaccine. The objective was to maximize the expected discounted reward. Approximate solutions were obtained by state-space aggregation and compared to an easy to-implement myopic policy based on approximating the multi-stage problem by a series of single period problems. They compare policies suggested by their model to theWorld Health Organization (WHO) recommended policy. Based on their results, the authors suggested that the WHO policy is reasonably effective and should be continued.

Vaccination for Bio-defense

OR researchers have contributed to problems related to vaccination strategy for bio-defense. For instance, Kaplan et al. (2003) analyzed bio-terror response logistics using smallpox as an example. The authors proposed a trace vaccination model using a system of ordinary differential equations (ODEs) incorporating scarce vaccination resources and queueing of people for vaccination. An approximate analysis of the ODEs yields closed-form estimates of numbers of deaths and maximum queue length. They also obtained approximate closed-form expressions for the total number of deaths under mass vaccination. Using these results, approximate thresholds for controlling an epidemic were derived.

Kress (2006) also considered the problem of optimizing vaccination strategy in response to potential bio-terror events. The author developed a flexible, large-scale analytic model with discrete-time decisions. The author used a set of difference equations to describe the transition of the number of people at each epidemic stage and proposed a vaccination policy, which is a mixture of mass and trace vaccination policies.

Other Vaccination Related Problems

Several other vaccine-related problems have been investigated by OR researchers. For example, vaccine allocation problems must consider criteria and constraints related to vaccine manufacturing and supply chain logistics. Becker and Starczak (1997) formulated the optimal allocation of vaccine as a linear-programming problem. Their objective was to prevent epidemics with the minimum required vaccine coverage. Their linear-programming model considered heterogeneity among individuals and minimized the initial reproduction number for a given vaccination coverage. The optimal vaccine allocation strategy suggested more individuals need to be vaccinated in larger households.

Disease Screening

Disease screening is important in extending life expectancy and improving people's quality of life. Effective screening can also reduce costs to the healthcare system by avoiding the high costs associated with treatment of late-stage disease. However, when and how to screen for a specific disease is a complex decision. For instance, model formulation is often difficult due to unclear pathology and risk factors, uncertainty in disease staging and the relationship to symptoms and test results, and the trade-off between the benefit of early detection and the side effects and costs of screening and treatment. The types of OR methods employed depend on whether the disease is non-infectious or infectious. Following are several examples from each category of diseases.

Non-infectious Disease Screening

Modeling disease progression among different stages throughout a patient's lifetime, as well as the trade-off between pros (e.g., longer life expectancy and better quality of life) and cons (e.g., side effects and costs of over-diagnosis and over-treatment) of disease screening are central to non-infectious diseases. Shwartz (1978) proposed one of the first models for breast cancer screening to evaluate and compare alternative screening strategies. Their stochastic model consisted of a discrete set of breast cancer disease states and criteria including life expectancy and the probability of diagnosis. A significant amount of research on breast cancer screening has developed; see Mandelblatt et al. (2009) for a review of breast cancer screening models.

Eddy (1983) presented a general model of monitoring patients with repeated and imperfect medical tests. The model considered clinical and economic outcomes such as the probability of detecting a disease, the method and timing of detection, the stage at which the disease is detected, costs, and the benefit of screening based on the

willingness to pay. The model incorporated disease incidence, the natural history of disease progression, the effectiveness of tests and subsequent treatments, and the order and frequency of tests. The model was illustrated using a hypothetical example. The model had subsequently been applied in clinical practice to several cancer screening problems.

To capture uncertainty in identifying disease states, OR techniques such as partially observable Markov decision process (POMDP) have been applied. For example, Zhang et al. (2012) developed a POMDP model for prostate cancer screening. Due to the slow growing nature of prostate cancer, the imperfect nature of diagnostic tests, and the quality of life impact of treatment, whether and when to refer a patient for biopsy is controversial. The objective of their model was to maximize the quality adjusted life expectancy and minimize the costs of screening and treatments. They assumed that cancer states are not directly observable, but the probability a patient has cancer can be estimated from their PSA test history. A control-limit type policy of biopsy referral and the existence of stopping time of prostate cancer screening were proven. The authors compared policies suggested by their model, to commonly recommended screening policies, and concluded there may be substantial benefits from using prostate cancer risk to make screening decisions.

Screening for disease is greatly influenced by the diagnostic accuracy of the tests. An example of work done in this area is given by Rubin et al. (2004) in which the authors used a Bayesian network to assist mammography interpretation. Interpreting mammographic images and making correct diagnoses are challenging even to experienced radiologists. False-negative interpretations can cause delay in cancer treatment and lead to higher morbidity and mortality. False positives, on the other hand, result in unnecessary biopsy causing anxiety and increased medical costs. The American College of Radiology developed BI-RADS which is a lexicon of mammogram findings and the distinctions that describe them. The authors showed that their Bayesian network model may help to reduce variability and improve overall interpretive performance in mammography.

Many other diagnostic areas have been addressed including gastrointestinal diseases, neurological diseases, and others.

Infectious Disease Screening

In infectious diseases screening, one of the goals is to prevent an epidemic outbreak. Therefore, disease progression and communication throughout a population is an important consideration. Lee and Pierskalla (1988) proposed a mathematical-programming model for contagious diseases with little or no latent periods. The objective of their model was to minimize the average number of infected people in the population. Their model was converted to a knapsack problem. They considered both perfect and imperfect reliability of tests and showed the optimal screening policy has equally spaced screening intervals when the tests have perfect reliability.

Disease screening problems often involve multiple criteria, stemming from the patient, provider, and societal perspectives. For example, Brandeau et al. (1993) provided a cost-benefit analysis of HIV screening for women of childbearing age based on a dynamic compartmental model incorporating disease transmission and progression over time. The model was formulated as a set of simultaneous nonlinear differential equations. The authors found the primary benefit of screening is to prevent the infection of their adult contacts, and that screening of the medium to high risk groups may be cost-beneficial, but it is not likely to be cost-beneficial for low risk women.

Blood screening tests have been used to improve the quality of the blood supply. An early example to improve the performance of testing strategies in the 1980s was provided by Schwartz et al. (1990) for screening blood for the HIV antibody, and making decisions affecting blood donor acceptance. At the time the work was done, limited knowledge was available about the biology, epidemiology, and early blood manifestations of HIV. Furthermore, the initial and conditional sensitivities and specificities of enzyme immunoassays and Western blot tests had wide ranges of errors. A decision tree, with the decisions probabilistically based on which screening test to use, and in what sequence, was used to minimize the number of HIV infected units of blood and blood products entering the nation's blood supply subject to a budget constraint. The model was used at a meeting of an expert panel of the U.S. National Heart Lung and Blood Institute to inform the panelists who were deciding which blood screening protocol to

recommend. The model provided outputs including: expected number of infected units entering the blood supply per unit time, expected number of uninfected units discarded per unit time, expected number of uninfected donors falsely notified, and the incremental cost among screening regimens.

Efficiency of screening can be a defining factor in the success or failure of proposed screening methods. Wein and Zenios (1996) proposed models for pooled testing of blood products for HIV screening. Optimization of pooled testing involves decisions such as transfusion, discarding of samples in the pool, and division of the pool into sub-pools. Several models were proposed to minimize the expected costs. The outcome of an HIV test was measured by an optical density (OD) reading, a continuous measurement which is determined by the concentration of the antibodies. The states of the system were the previous history of the OD readings. A dynamic-programming model with a discretized state space and a heuristic solution algorithm were introduced to obtain near optimal solutions. The policy obtained by the heuristic algorithm was proposed as a cost-effective, accurate, and relatively simple alternative to the implemented HIV screening policies.

Treatment Choices

The following section focuses on treatment decisions for patients with chronic diseases such as diabetes, HIV, cancer, and end-stage renal disease. Treatment of patients with chronic diseases is often complex due to the long-term nature of the illness and the future uncertainty in patient health. Complicating matters, these patients may have other comorbidities that need to be taken into account when treatment decisions are made. In the following section, two areas related to choice of treatment are presented where OR is used to address challenges related to drug treatment decisions and organ transplantation for patients with chronic conditions.

Drug Treatment Decisions

Many diseases involve complex drug treatment decisions, particularly for chronic conditions. Decisions about which medications to initiate, when to initiate treatment, and the appropriate dosage are of primary importance. Additional challenges arise from the fact that there is uncertainty about the future health of the patient, adherence to treatment, and the efficacy of drugs for a particular patient. Treatment decisions must also take into account the often irreversible nature of treatment decisions. Many treatment optimization models employ the use of a natural history model of the disease and all-cause mortality, incorporating the influence of competing risks into the treatment decision.

Choice of Treatment

When there are multiple candidate treatments available, the choice of treatment may be unclear. OR techniques have been used to select treatments. For example, Pignone et al. (2006) presented a Markov model to select among aspirin, statins, and combination treatment, for the prevention of coronary heart disease (CHD). The model simulated the progression of middle-aged males with no history of CHD. The model was used to estimate cost per quality-adjusted life year (QALY) gained. The authors found that aspirin dominates no treatment when a patient's ten-year risk of CHD is at least 7.5%. If a patient's risk is greater than 10%, combination treatment is recommended.

Hazen (2004) used dynamic influence diagrams to analyze a chain of decisions as to whether a patient should proceed to total hip replacement surgery or not. The objective in making this decision was to calculate the optimal expected costs and QALYs under each choice. The use of QALYs for the objective was important because an older person undergoing hip replacement may not have more expected years of life relative to not doing surgery, but the quality of life improvement can be considerable and, quite possibly, worth the cost.

Timing of Treatment

With chronic conditions that can span many years, the optimal time to initiate particular treatments may be unknown. There have been several studies that researched the optimal timing of treatment. Two models relate to the optimal timing of HIV treatment. This question is of particular interest since patients that begin HIV treatment will only be able to use the drug for a limited amount of time, as the virus builds up resistance to the drug. Shechter et al. (2008) used a Markov decision process (MDP) model to find the optimal time to initiate HIV therapy, while

maximizing the patient's quality of life. At monthly decision epochs, the decision was made to initiate therapy or wait until the next month to decide. The health states were based on the number of CD4 white blood cells, the primary target of HIV, and the reward was the expected remaining lifetime in months. They assumed a stationary infinite horizon model and found that if it is optimal to initiate treatment at a given CD4 count, it is also optimal to initiate treatment for patients with higher CD4 counts. The model supported earlier treatment, despite trends toward later treatment. Braithwaite et al. (2008) analyzed the timing of initiation based on CD4 counts for varying viral loads. They used a simulation to compare different CD4 count treatment thresholds for initiation of therapy. The model compared life expectancy and QALYs for the different strategies of initiation. In agreement with Shechter et al.'s finding, the simulation suggested that the use of earlier initiation of treatment (higher CD4 count thresholds) results in greater life years and QALYs.

Agur et al. (2006) developed a method to create treatment schedules for chemotherapy patients using local search heuristics. The model simulated cell growth over time and finds two categories of drug protocols: one-time intensive treatment and a series of nonintensive treatments. Chemotherapy schedules were evaluated based on a patient's state at the end of a given time period, number of cancer and host cells, and the time to cure. Simulated annealing, threshold acceptance, and old bachelor acceptance—a variant of threshold acceptance in which the trial length is set by users—were used to obtain better treatment schedules. The authors reported good results with all three techniques, but they showed simulated annealing resulted in the greatest computational effort.

Denton et al. (2009) investigated the optimal timing of statin therapy for patients with type 2 diabetes. This problem was formulated as a discrete time, finite horizon, discounted MDP in which patients transition through health states corresponding to varying risks of future complications, their history of complications, and death from other causes unrelated to diabetes. The objective was to maximize reward for QALYs minus costs of treatment. The optimal timing of treatment for patients was determined using three published risk models for predicting cardiovascular risk. The earliest time to start statins was age 40 for men, regardless of which risk model was used. However, for female patients, the earliest optimal start time varied by 10 years, depending on the risk model. Mason et al. (2012) extended this work to account for poor medication adherence. The authors used a Markov model to represent uncertain future adherence after medication was initiated. They observed that the optimal timing of statins should be up to 11 years later for patients with uncertain future adherence. However, they also found that improving adherence has a much larger effect on QALYs than delaying the timing of initiation.

Paltiel et al. (2004) constructed a simulation model to treat asthma. The model forecasted asthma-related symptoms, acute exacerbations, quality adjusted life expectancy, health-care costs, and cost-effectiveness. Their intent was to reduce asthma manifestations, improve life quality, and reduce costs of care. The authors pointed out that similar models could be constructed for the control of other subpopulation-wide diseases such as obesity, smoking, and diabetes.

A great deal of work has also been done on modeling CHD interventions. Cooper et al. (2006) provided an excellent review of many models used for this disease. Most of the models reviewed by the authors are decision trees, Markov processes, or simulation models. Decisions included when and what types of interventions, and what types of drugs to employ, at various stages of disease.

Dosage of Treatment

Given a particular treatment has been selected, the appropriate dosage must be determined. He et al. (2010) provided a discrete-state MDP model for determining gonadotropin dosages for patients undergoing in vitro fertilization-embryo transfer therapy. This work focused on patients with the chronic condition of polycystic ovaries syndrome that tend to be more sensitive to the gonadotropin treatment. The resulting policies from the MDP model were evaluated through simulation to determine the impact of misclassifying patients. In general, the use of OR techniques can be used to provide a better starting dosage with less fine tuning needed after initiation of treatment.

Dosage decisions are also important in radiation treatment planning. Several studies have focused on radiotherapy for cancer using mathematical optimization techniques. Although the vast majority of these treatment plans are designed by clinicians through intelligent trial and error, it is becoming

essential to use optimization for extremely complicated and complex plans. Holder (2004) used linear programming for intensity modulated radiotherapy treatment (IMRT). Ferris et al. (2004) discussed various optimization tools for radiation treatment planning. In both of these papers, the objective was to deliver a specified dose to the target area (above a minimum and below a maximum level of dosage) and spare or minimize damage to surrounding healthy tissue and nearby critical body structures and organs.

Organ Transplants

End-stage liver disease (ESLD) and end-stage renal disease (ESRD) have received a great deal of study in the OR literature. They are chronic conditions that can result in patients eventually needing liver or kidney transplants, respectively. Chronic liver disease or liver failure can result from many causes, including liver cancer and chronic hepatitis. Often, initial treatment of liver failure attempts to manage the underlying cause, followed by intensive care and management of complications such as bleeding problems. If patients continue to deteriorate to ESLD, liver transplantation may be the only option. Patients with chronic kidney disease have a continuing loss of renal function, leading to ESRD. Once a patient has ESRD, renal replacement therapy in the form of dialysis or kidney transplantation is necessary.

While organ transplants are the best long-term solution for patients with chronic liver or kidney disease, there is a shortage of organs for transplant and a growing waiting list of patients. OR techniques have been applied to optimize the allocation of organs and timing of transplants for increasing quality and length of life of the recipients. The allocation of kidneys and livers for transplantation is challenging because both living and cadaveric donors are possible. With living donors, there is more flexibility in the timing of the transplant, allowing for the transplant timing decision to be optimized. For both kidney and liver transplantation, there are challenging decisions about whether to use a living or cadaveric donor (if both are available), and when the transplant should occur. OR techniques have also aided in finding the greatest number of donor-recipient matches, considering the challenges of blood and tissue type compatibilities.

Alagoz et al. (2004) studied the question of the optimal timing of liver transplantation. They developed an MDP model to find the optimal timing for a patient to have a transplant from a living donor. The patients transitioned through health states defined by a scoring system for ESLD. With the donor assumed to be available at any time, the MDP maximized the patient's quality adjusted lifetime—striking a balance between having the transplant before the patient becomes too sick and waiting long enough due to the limited amount of time a patient can live after a transplant.

Su and Zenios (2004) presented an M/M/1 queueing model to determine if incorporating patient choice into allocation will improve efficiency and reduce waste of organs offered to patients but not accepted. Their model incorporated uncertain arrival of patients and organs, with the service process being the kidney transplant. Since organs cannot be stored, the service time was given by the interarrival time of organs. In addition to the traditional M/M/1 assumptions, each organ had a reward corresponding to its quality, and patients may reject an organ they believe has poor quality. The authors found that a first-come-first-serve policy can lead patients to refuse organs of lesser quality, leading to waste of up to 15% of organs. They also found that last-come-first-serve (LCFS) allocation lowers the wasteful effect of patient preference. While LCFS was not a feasible rule to implement, their results highlighted the need for adjustment of incentives associated with patient choice to prevent wasting organs.

A common way for patients to find organ donors is to ask willing family members or friends to be tested for compatibility. Another area, where OR has contributed, considers patients with willing donors that are not matches. Segev et al. (2005) considered the problem of paired kidney donation, matching two incompatible pairs with each other resulting in two successful transplants. The study considered a graph theory representation of a large pool of incompatible patient-donor pairs where each pair was represented with a node and two compatible pairs were linked with an edge. An algorithm based on the Edmonds matching algorithm (Edmonds 1965) was used to find all feasible matching solutions, and the best solution was chosen based on some predefined criteria, including the number of total matches and the number of transplant patients alive five years after the operation.

This matching strategy was compared to the first-accept scheme, which only finds one feasible solution, that is used in practice. The authors found that their algorithm could increase the total number of matches and take into account patient priorities.

Emerging Applications

Rapid advances in medicine are driving new OR research opportunities. As evidence of this, over the period from 2000–2010 the total number of health care related presentations at the Institute for Operations Research and Management Science (INFORMS) annual meeting has grown from 35 in 2000 to 281 in 2009 (Denton and Verter 2010). This section provides some specific examples of emerging areas of research.

Personalized Medicine

With the sequencing of the human genome and many advances in biomarkers for certain diseases, the idea of personalized medicine has received a great deal of attention. There are some examples of successful applications of personalized medicine, such as breast cancer treatment. However, for most diseases even basic risk factors are not yet considered as part of the standard guidelines. For example, gender is a well known risk factor for heart disease and stroke. While this has been known for decades, in many countries, including the U.S., the published treatment guidelines for control of risk factors such as cholesterol and blood pressure are the same for men and women. These examples point to opportunities to improve the design of screening and treatment guidelines through consideration of individual patient risk factors.

Decision Aids

The use of OR techniques in the development of decision aids is not as wide as in other areas of treatment choices. This is an area of research that must expand if OR models are to be translated into practice. Researchers have attempted to use artificial intelligence and computer science/information systems to provide decision support to the physician and/or patient. However, many clinicians still hesitate to use models for diagnosis or treatment. There are many possible reasons for the slow diffusion into practice. An important goal is the study of the clinician-model interface. In spite of adoption difficulties, there are examples of where OR has contributed significantly to treatment decisions. Several examples follow.

White et al. (1982) developed a quantitative model for diagnosing medical complaints in an ambulatory setting with the goal of reducing costs and improving quality of diagnoses. The model structure was influenced by three methods: decision analysis, partially observed semi-Markov decision process models, and multi-objective optimization therapy (MOOT). The authors used Bayesian-based modeling of disease progression and heuristics (a single-stage decision tree that reduces the amount of computation time and storage space per patient) to consider individual patient and physician preferences. For the MOOT heuristic, suggested by White et al. (1982), the list of possible diagnosis tests were provided, highlighting nondominated tests. The authors described a detailed example of the decision aid to treat a patient in an ambulatory setting.

Policies related to health information exchanges assume patients want to explicitly decide who can have access to their medical records. Marquard and Brennan (2009) tested this assumption by questioning 31 patients from a neurology clinic about their willingness to share information about their medication with a primary care physician, a neurologist, and an emergency room physician. Almost all patients decided to share their current medication usage with all three doctors citing the potential clinical care benefits. However, not all patients understood the possible effects of sharing this information. The use of realistic decision scenarios and structured conversations used in this study are likely to reveal more true patient preferences than abstract opinion surveys that are commonly used in practice. In addition to correctly identifying patient preferences, it is important to assess patient understanding of the consequences of their choices. Understanding the true willingness of patients to share health information is an important step in the development of decision aids and the inclusion of patient choices in medical decisions.

Using multi-attribute utility theory, Simon (2009) considered the choice of treatments for prostate cancer including surgery, external beam radiation, brachytherapy, and no treatment. The model used data collected from the medical literature to compute

probabilities regarding the likelihood of death and other side effects for each of the choices. The model also incorporated the patient's individual preferences regarding length of life and quality of life in view of the possible side effects (impotence, incontinence, and toxicity). The model evaluated each treatment alternative and compared the results for the particular patient.

Real Time Decision Making

Many medical treatment decisions must be made in real time. Depending on the particular application, the definition of real time could be anything from a few seconds to several minutes. Such applications can be highly demanding, often trading off the need for high quality decisions with available time.

One area in which OR has contributed to real time decision making is blood glucose control in patients with diabetes. Patients with type 1 diabetes are insulin dependent, and careful control of blood glucose within defined physiological limits is necessary to avoid a potentially life threatening occurrence of hypoglycemia (very low blood glucose that can lead to coma and/or death if not treated immediately). Blood glucose levels can change significantly over very short periods of time (seconds) depending on a variety of factors, such as caloric intake. The most common treatment for patients with type 1 diabetes is to inject insulin. However, the need for regular injection has a serious impact on a patient's quality of life. Research has been conducted on the design of closed loop control algorithms that could enable an implantable device to optimize insulin delivery (Parker et al. 2001).

Outpatient procedures can also pose a series of challenging decisions that must be made in real time (minutes). For instance, radiation treatment for cancer patients involves a series of complex decisions that can influence the effectiveness of treatment. One example is brachytherapy for prostate cancer treatment, that involves the implantation of radioactive seeds in close proximity to a tumor. The method of brachytherapy is to place seeds in and around a tumor such that dual goals of maximizing dose to the tumor and minimizing dose to healthy tissue are balanced. Due to changes that occur in tumor size and shape and the physical movement of healthy tissue and organs in proximity to the tumor over short time periods, such decisions must be made in real time at the point of placement. This real time analysis selects the actual placements of the seeds in the prostate from the thousands of possible locations, millimeters apart. Lee and Zaider (2008) presented a nonlinear mathematical-programming model to make location decisions using real time imaging information. They demonstrated a practical application in which the clinical goals of reduced complications (e.g., impotence and incontinence) and reduced costs ($5,600 per patient) were achieved.

Concluding Remarks

The use of OR for the study of disease treatment and screening decisions has a long history. Furthermore, advances in medicine are creating new challenges which are in turn resulting in new applications of OR and new methods. This article surveyed some of the significant contributions of OR methods, including mathematical programming, dynamic programming, and simulation. Contributions of OR to disease prevention and screening, long term management of chronic conditions, and several emerging application areas for OR were discussed.

Many examples of successful OR applications were described, as well as many challenges. For example, the availability of data for analyzing medical decisions is often more complex compared to other real-world decision situations. This is true for a variety of reasons including confidentiality concerns, the fragmented nature of health care delivery, and the lack of the requisite information systems. There are also challenges related to the fundamental difficulty of measuring criteria related to medical decision making, such as the cost to the patient as a result of a burdensome treatment plan. Finally, there are significant challenges in the translation of OR models from theory to practice.

Distribution Selection for Stochastic Modeling

Donald Gross
George Mason University, Fairfax, VA, USA

Introduction

The choice of appropriate probability distributions is the most important step in any complete stochastic system analysis and hinges upon knowing as much as possible about the characteristics of the potential distribution and the physics of the situation to be modeled. Generally, the first thing that has to be decided is which probability distributions are appropriate to use for the relevant random phenomena describing the model. For example, the exponential distribution has the Markovian (memoryless) property. Is this a reasonable condition for the particular physical situation under study? Assume the problem is to describe the repair mechanism of a complex maintained system. If the service for all customers is fairly repetitive, then an assumption might be that the longer a failed item is in service for repair, the greater the probability that its service will be completed in the next interval of time (non-memoryless). In this case, the exponential distribution would not be a reasonable candidate for consideration. On the other hand, if the service is mostly diagnostic in nature (the trouble must be found and fixed), or there is a wide variation of service required from customer to customer so that the probability of service completion in the next instant of time is independent of how long the customer has been in service, the exponential with its memoryless property might indeed suffice.

The actual shape of the density function also gives quite a bit of information, as do its moments. One particularly useful measure is the ratio of the standard deviation to the mean, called the coefficient of variation (CV). The exponential distribution has a $CV = 1$, while the Erlang or convolution of exponentials has a $CV < 1$, and the hyperexponential or mixture of exponentials has a $CV > 1$. Hence, choosing the appropriate distribution is a combination of knowing as much as possible about distribution characteristics, the physics of the situation to be modeled, and statistical analyses when data are available.

Hazard Rate

An important concept that helps in characterizing probability distributions that is strongly associated with reliability modeling is the hazard-rate (also termed the failure-rate) function. This concept, however, can be useful in general when trying to decide upon the proper probability distribution to select. In the discussion that follows, the hazard rate will be related to the Markov property for the exponential distribution, and its use as a way to gain insight about probability distributions will be discussed.

Suppose it is desired to choose a probability distribution to describe a continuous lifetime random variable T with a cumulative distribution function (CDF) of $F(t)$. The density function, $f(t) = df(t)/dt$, can be interpreted as the approximate probability that the random time to failure will be in a neighborhood about a value t. The CDF is, of course, the probability that the time will be less than or equal to

the value t. Then the hazard rate $h(t)$ is defined as the conditional probability that the lifetime will be in a neighborhood about the value t, given that the time is already at least t. That is, if the situation deals with failure times, $h(t)dt$ is the approximate probability that the device fails in the interval $(t, t + dt)$, given it is working at time t.

From the laws of conditional probability, it can be shown that

$$h(t) = \frac{f(t)}{1 - F(t)}.$$

This hazard or failure-rate function can be increasing in t (called an increasing failure rate, or IFR), decreasing in t (called a decreasing failure rate, or DFR), constant (considered to be both IFR and DFR), or a combination. The constant case implies the memoryless or ageless property, and this holds for the exponential distribution, as will be shown. If, however, it is believed that the device ages and that the longer it has been operating the more likely it is that the device will fail in the next dt, then it is desired to have an $f(t)$ for which $h(t)$ is increasing in t; that is, an IFR distribution. This concept can be utilized for any stochastic modeling situation. For example, if instead of modeling lifetime of a device, the concern is with describing the service time of a customer at a bank, then, if service is fairly routine for each customer, then an IFR distribution would be desired. But if customers required a variety of needs (say a queue where both business and personal transactions were allowed), then a DFR or perhaps a CFR exponential might be the best choice.

Reversing the algebraic calculations, a unique $F(t)$ can be obtained from $h(t)$ by solving a simple linear, first-order differential equation, i.e.,

$$F(t) = -\exp\left(-\int_0^t h(u)\,du\right).$$

The hazard rate is another important information source (as is the shape of $f(t)$ itself) for obtaining knowledge concerning candidate probability distributions.

Consider the exponential distribution

$$f(t) = \theta \exp(-\theta t).$$

From the discussion above, it is easily shown that $h(t) = \theta$. Thus, the exponential distribution has a constant failure (hazard) rate and is memoryless. Suppose, for a particular situation, there is a need for an IFR distribution for describing some random times. It turns out that the Erlang has this property. The density function is

$$f(t) = \theta^k t^{k-1} \exp(-\theta t)/(k-1)!$$

(a special form for the gamma), with its CDF determined in terms of the incomplete gamma function or equivalently as a Poisson sum. From these, it is not too difficult to calculate the Erlang's hazard rate, that also has a Poisson sum term, but is somewhat complicated to ascertain the direction of $h(t)$ with t without doing some numerical work. It does turn out, however, that $h(t)$ increases with t and at a decelerating rate.

Suppose the opposite IFR condition is desired, that is, an accelerating rate of increase with t. The Weibull distribution can obtain this condition. In fact, depending on how the shape parameter of the Weibull is chosen, an IFR can be obtained with decreasing acceleration, constant acceleration (linear with t), or increasing acceleration, as well as even obtaining a DFR or the constant failure rate exponential. The CDF of the Weibull is given by

$$F(t) = 1 - \exp(-at^b)$$

and its hazard rate turns out to be the simple monomial $h(t) = abt^{b-1}$, with shape determined by the value of b (called the shape parameter).

As a further example in the process of choosing an appropriate candidate distribution for modeling, suppose, for an IFR that has a deceleration effect, such as the Erlang, there is a believe that the CV might be greater than one. This latter condition eliminates the Erlang from consideration. But, it is known that a mixture of (k) exponentials (often denoted by H_k) does have a CV > 1. It is also known that any mixture of exponentials is DFR. In fact, it can be shown that all IFR distributions have CV < 1, while all DFR distributions have CV > 1 (Barlow and Proschan 1975). Thus, if there is convincing evidence that the model requires an IFR, CV < 1 must be accepted. Intuitively, this can be explained as follows. Situations that have CV > 1

often are cases where the random variables are mixtures (say, of exponentials). Thus, for example, if a customer has been in service a long time, chances are that it is of a type requiring a lot of service, so the probability of completion in the next infinitesimal interval of width dt diminishes over time. Situations that have an IFR condition indicate a more consistent pattern among items, thus yielding a CV < 1.

Range of the Random Variable

Knowledge of the range of the random variable under study can also help narrow the possible choices in selecting an appropriate distribution. In many cases, there is a minimum value that the random variable can assume. For example, suppose the analysis concerns the interarrival times between subway trains, and it is given that there is a minimum time for safety of γ. The distributions discussed thus far (and, indeed, many distributions) have zero as their minimum value. Any such distribution, however, can be made to have a minimum other than zero by adding a location parameter, say γ. This is done by subtracting γ from the random variable in the density function expression. Suppose the exponential distribution is to be used, but we have a minimum value of γ. The density function would then become $f(t) = \theta \exp(-\theta[t - \gamma])$. It is not quite so easy to build in a maximum value if this should be the case. For this situation, a distribution with a finite range would have to be chosen, such as the uniform, the triangular or the more general beta distribution (Law and Kelton 1991).

Data

While much information can be gained from knowledge of the physical processes associated with the stochastic system under study, it is very advantageous to obtain data, if at all possible. For existing systems, data may already exist or can be obtained by observing the system. These data can then be used to gain further insight on the best distributions to choose for modeling the system. For example, the sample standard deviation and mean can be calculated, and it can be observed whether the sample CV is less than, greater than, or approximately equal to one. This would give an idea as to whether an IFR, DFR or the exponential distribution would be the more appropriate.

If enough data exist, just plotting a histogram can often provide a good idea of possible distributions from which to choose, since theoretical probability distributions have distinctive shapes (although some do closely resemble each other). The exponential shape of the exponential distribution is far different, for example, than the bell-shaped curve of the normal distribution.

There are rigorous statistical goodness of fit procedures to indicate if it is reasonable to assume that the data could come from a potential candidate distribution. These do, however, require a considerable amount of data and computation to yield satisfactory results. But, there are statistical packages, for example, Expert Fit (Law and Vincent 1995), which will analyze sets of data and recommend the theoretical distributions that are the most likely to yield the kind of data being studied.

Distribution selection (or input modeling, as it is sometimes called) is not a trivial procedure. But this is a most important aspect of stochastic analysis, since inaccuracies in the input can make the output meaningless. Fitting data to standard statistical distributions, which are mostly two-parameter distributions, limits focus on the first two moments only. There is evidence to suggest that this is not always sufficient (see Gross and Juttijudata 1997).

Finally, for emphasis, the point is made again that choosing an appropriate probability model is a combination of knowing as much as possible about the characteristics of the probability distribution being considered and as much as possible about the physical situation being modeled.

Documentation

Saul I. Gass
University of Maryland, College Park, MD, USA

Introduction

As many operations research studies involve a mathematical decision model that is quite complex in its form, it is incumbent upon those who developed the model and conducted the analysis to furnish documentation that describes the essentials of the model, its use, and its results. Of especial concern are those computer-based models that are represented by a computer program and its input data files. The most serious weakness in the majority of OR model applications, both those that are successful and those that fail, is the lack of documents that satisfy the minimal requirements of good documentation practices (Gass et al. 1981; Gass 1984). The reasons for requiring documentation are many-fold and include, among others, "to enable system analysts and programmers, other than the originators, to use the model and program," "to facilitate auditing and verification of the model and the program operations," and "to enable potential users to determine whether the model and programs will serve their needs" (Gass 1984).

The most acceptable view of model documentation is that which calls for documents that record and describe all aspects of the model development life-cycle. The life-cycle model documentation approach given in Gass (1979) calls for the production of 13 major documents. However, it is recognized that in terms of the basic needs of model users and analysts, these documents can be rewritten and combined into the following four manuals: *Analyst's Manual*, *User's Manual*, *Programmer's Manual, and Manager's Manual*. Brief descriptions of the contents of these manuals are given below; detailed tables of contents for each are given in Gass (1984).

Analyst's Manual

The analyst's manual combines information from the other project documents and is a source document for analysts who have been and will be involved in the development, revisions, and maintenance of the model. It should include those technical aspects that are essential for practical understanding and application of the model, such as a functional description, data requirements, verification and validation tests, and algorithmic descriptions.

User's Manual

The purpose of the user's manual is to provide (nonprogramming) users with an understanding of the model's purposes, capabilities, and limitations so they may use it accurately and effectively. This manual should enable a user to understand the overall structure and logic of the model, input requirements, output formats, and the interpretation and use of the results. This manual should also enable technicians to prepare the data and to set up and run the model.

Programmer's Manual

The purpose of the programmer's manual is to provide the current and future programming staff with the information necessary to maintain and modify the model's program. This manual should provide all the details necessary for a programmer to understand the operation of the software, to trace through it for debugging and error correction, for making modifications, and for determining if and how the programs can be transferred to other computer systems or other user installations.

Manager's Manual

The manager's manual is essential for computer-based models used in a decision environment. It is directed at executives of the organization who will have to interpret and use the results of the model, and support its continued use and maintenance. This manual should include a description of the problem setting and origins of the project; a general description of the model, including its purpose, objectives, capabilities, and limitations; the nature, interpretation, use, and restrictions of the results that are produced by the model; costs and benefits to be expected in using the model; the role of the computer-based model in the organization and decision structure; resources required; data needs; operational and transfer concerns; and basic explanatory material.

Dual Linear-Programming Problem

A companion problem defined by a linear-programming problem. Every linear-programming problem has an associated dual-programming program. When the linear-programming problem has the form

$$\begin{aligned} \text{Minimize} \quad & \boldsymbol{c}^T\boldsymbol{x} \\ \text{subject to} \quad & \boldsymbol{A}\boldsymbol{x} \geq \boldsymbol{b} \\ & \boldsymbol{x} \geq \boldsymbol{0} \end{aligned}$$

then its dual problem is also a linear-programming problem with the form

$$\begin{aligned} \text{Maximize} \quad & \boldsymbol{b}^T\boldsymbol{y} \\ \text{subject to} \quad & \boldsymbol{A}^T\boldsymbol{y} \leq \boldsymbol{c} \\ & \boldsymbol{y} \geq \boldsymbol{0} \end{aligned}$$

The original problem is called the primal problem. If the primal minimization problem is given as equations in nonnegative variables, then its dual is a maximization problem with less than or equal to constraints whose variables are unrestricted (free). The optimal solutions to primal and dual problems are strongly interrelated.

Duality Theorem

A theorem concerning the relationship between the solutions of primal and dual linear-programming problems. One form of the theorem is as follows: If either the primal or the dual has a finite optimal solution, then the other problem has a finite optimal solution, and the optimal values of their objective functions are equal. From this it can be shown that for any pair of primal and dual linear programs, the objective value of any feasible solution to the minimization problem is greater than or equal to the objective value of any feasible solution to the dual maximization problem. This implies that if one of the problems is feasible and unbounded, then the other problem is infeasible. Examples exist for which the primal and its dual are both infeasible. Another form of the theorem states: if both problems have feasible solutions, then both have finite optimal solutions, with the optimal values of their objective functions equal.

▶ Network Planning

Dynamic Programming

Chelsea C. White III
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Dynamic programming (DP) is both an approach to problem solving and a decomposition technique that can be effectively applied to mathematically describable problems having a sequence of interrelated decisions. Such decision-making problems are pervasive. Determining a route from an origin (e.g., home) to a destination (e.g., school) on a network of roads requires a sequence of turns. Managing a retail store (e.g., that sells, say, television sets) requires a sequence of wholesale purchasing decisions.

Such problems share important characteristics. Each is associated with a criterion to be optimized: choosing the shortest or most scenic route from home to school, and the buying and selling of television sets by the retail store manager to maximize expected profit. Also, each problem has a structure such that a currently determined decision has impact on the future decision-making environment. In going from home to school, the turn currently selected will determine the geographical location of the next turn decision; in managing the retail store, the number of items ordered today will affect the level of inventory next week.

Roots and Key References

In his 1957 book, Richard Bellman described the concept of DP and its broad potential for application. See Bellman's earlier publications that describe his initial developments of DP (Bellman 1954a, b); also see Bertsekas (1987); Denardo (1982); Heyman and Sobel (1984); Hillier and Lieberman (2004, Chapter 10), and Ross (1983) for in depth descriptions and applications of DP.

Central to the philosophy and methodology of DP is the Principle of Optimality, as related to the following multistage decision problem (Bellman 1957). Let $\{q_1, q_2, \ldots q_n\}$ be a sequence of allowable decisions called a policy; specifically, an n-stage policy. A policy that yields the maximum value of the related criterion function is called an optimal policy. Decisions are based on the state of the process, that is, the information available to make a decision. The basic property of optimal policies is expressed by the following:

> *Principle of Optimality*: An optimal policy has the property that whatever the initial state and the initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision (Bellman 1957).

The Principle of Optimality can be expressed as an optimization problem over the set of possible decisions by a recursive relationship, the application of which yields the optimal policy. This is illustrated next by two examples.

1. An itinerary selection problem. The problem is to find the shortest path from home to school. A map of the area describes the network of streets that includes home and school locations, intermediate intersections, connecting streets, and the distance from one intersection to any other intersection that is directly connected by a street. The DP model of this problem is as follows. Let N be the set composed of home, school, and all intersections. An element of N is termed a node. For simplicity, assume all of the streets are one-way. A street is described as an ordered pair of nodes; that is, (n, n') is the street going from node n to node n' (n' is an immediate successor of node n). Let $m(n, n')$ be the distance from node n to node n'; that is, $m(n, n')$ represents the length of street (n, n').

   The problem is examined recursively as follows. Let $f(n)$ equal the shortest distance from the node n to the goal node school. The objective is to find f (home), the minimum distance from home to school, and a path from home to school that has a distance equal to f (home), a minimum distance path.

Note that $f(n) \leq m(n, n') + f(n')$ for any node n' that is an immediate successor of node n. Assume that an immediate successor n'' of n such that $f(n) = m(n, n'') + f(n'')$ has been found. Then, if at node n, it seems reasonable that the street that takes us to node n'' is traversed. Thus, the evaluation of all of the values $f(n)$ determine both f (home) and a minimum distance path from home to school. Formally, determination of these values can proceed recursively from the equation $f(n) = \min\{m(n, n') + f(n')\}$, where the minimum is taken over all nodes n' that are immediate successors of node n and where f (school) $= 0$ is the initial condition.

2. An inventory problem. Let $x(t)$ be the number of items in stock at the end of week t, $d(t + 1)$ the number of customers wishing to make a purchase during week $t + 1$, and $u(t)$ the number of items ordered at the end of week t and delivered at the beginning of week $t + 1$. Although it is unlikely that $d(t)$ is known precisely, assume the probability that $d(t) = n$ is known for all $n = 0, 1, \ldots$. Keeping backorders, then $x(t + 1) = x(t) - d(t + 1) + u(t)$. A reasonable objective is to minimize the expected cost accrued over the period from $t = 0$ to $t = T$ $(T > 0)$ by choice of $u(0), \ldots, u(T - 1)$, assuming that ordering decisions are made on the basis of the current inventory level, that is, the mechanism that determines $u(t)$ (e.g., the store manager) is aware of $x(t)$, for all $t = 0, \ldots, T - 1$. Costs might include a shortage cost (a penalty if there is an insufficient amount of inventory in stock), a storage cost (a penalty if there is too much inventory in stock), an ordering cost (reflecting the cost necessary to purchase items wholesale), and a selling price (reflecting the income received when an item is sold; a negative cost). Let $c(x, u)$ represent the expected total cost to be accrued from the end of week t till the end of week $t + 1$, given that $x(t) = x$ and $u(t) = u$. Then the criterion to be minimized is

$$E\{c[x(0), u(0)] + \ldots + c[x(T-1), u(T-1)]\},$$

where E is the expectation operator associated with the random variables $d(1), \ldots, d(T)$.

This problem can be examined recursively. Let $f(x, t)$ be the minimum expected cost to be accrued from time t to time T, assuming that $x(t) = x$. Clearly, $f(x, T) = 0$. Note also that

$$f[x(t), t] \leq c[x(t), u(t)] + E\{f[x(t) - d(t+1) + u(t), t+1]\}$$

for any available $u(t)$. As was true for Example 1, an order number u'' which is such that

$$f[x(t), t] = c[x(t), u''] + E\{f[x(t) - d(t+1) + u'', t+1]\}$$

is an order to place at time t when the current inventory is $x(t)$. Thus, the recursive equation determines both $f(x, 0)$ for all x and the order number as a function of current inventory level.

Common Characteristics

Two key aspects of DP are the notion of a state and recursive equations. The state of the DP problem is the information that is currently available to the decision maker on which to base the current decision. For example, in the itinerary selection problem, the state is the current node; in the inventory problem, the state is the current number of items in stock. In both examples, how the system arrived at its current state is inconsequential from the perspective of decision making. For the itinerary selection problem, all that is needed is the current node and not the path that lead to that node to determine the best next street to traverse. The determination of the number of items to order this week depends only on the current inventory level equations (other names include functional equations and optimality equations) that can be used to determine the minimum expected value of the criterion and an optimal sequence of decisions that depend on the current node or current inventory level. In both cases, the recursive equations essentially decompose the problem into a series of subproblems, one for each node or current state value.

E

Earliest Finish Time

The earliest possible time an activity can be completed without reducing the duration of any of the preceding activities as described in a project network. It is simply the sum of the earliest start time for the activity and the duration of the activity.

Early British OR

Maurice W. Kirby and Graham K. Rand
Lancaster University, Lancaster, UK

The term operational research (OR) was first used in the later 1930s to describe the process of evaluation of radar as an essential aid to the air defense of Great Britain. Emanating from the work of Robert Watson-Watt of the National Physical Laboratory, the novel concept of controlled interception of enemy aircraft by electronic means could only be tested by practical experiment entailing the application of quantitative techniques of analysis. Under the auspices of the Committee for the Scientific Survey of Air Defence, the resulting research program was an outstanding success insofar as the home radar chain proved decisive in more than offsetting RAF Fighter Command's numerical inferiority during the Battle of Britain in 1940. With its credentials intact as a means of enhancing the effectiveness of an entire military command at a critical stage in the war, OR was thereafter diffused throughout the greater part of the British armed forces both at home and abroad.

At the end of the war, in conformity with the experience in Fighter Command, operational researchers, under the leadership of Blackett, regarded as the "father of Operational Research,"could congratulate themselves on their substantial and, on occasion, decisive contributions to the war effort in a number of theaters. In the RAF Coastal Command and the Admiralty, for example, operational

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

researchers were responsible for a sequence of tactical innovations which led to the defeat of the U-boats in the North Atlantic. For Operation Overlord, moreover, a detailed plan of targets in the French railway system was devised on the basis of quantitative assessment of their capacity for enemy logistical reinforcement, thereby enabling RAF Bomber Command to offer outstanding tactical support to the allied invading forces.

With achievement on this scale it is hardly surprising that the advocates of OR should have sought to secure its peacetime future via its diffusion beyond the military sector. In this respect, the period from 1945 to the mid-l970s may be viewed as the golden age of British OR, at least in methodological terms, when the new discipline was diffused into the nationalized industries, departments of civil government, and the corporate sector. Institutional developments were also notable, with the transformation of an informal OR Club, founded in 1948, created following the initiative of Sir Charles Goodeve, into the Operational Research Society in 1953, together with the establishment of that ultimate hallmark of professional status — a specialist journal: *The Operational Research Quarterly* first appeared in 1950, and continued in that form until 1978 when it was redesignated as the official *Journal of the Operational Research Society* with twelve annual issues. These developments may be viewed as a testament to the growing professionalization of the discipline, the subscription to common methodologies, and belief in its economic and social utility. Coincidentally, as OR was being recognized as a practically useful tool of analysis for executive decision makers, its public profile was further enhanced by formal academic recognition. By the early 1960s, several universities were making provision for OR taught courses for postgraduate students, and this served as a precursor to the expansion of the subject at undergraduate level after 1964.

A combination of acknowledged utilitarian value and formal academic recognition within thirty years of its foundation is consistent with an impressive trajectory of achievement for any human endeavor. Yet despite open acknowledgment of its wartime role, it is instructive to note that beyond the nationalized coal industry and the British Iron and Steel Research Association (BISRA), OR made little headway in civil government in the early postwar years. This is all the more surprising in view of the election in 1945 of Britain's first majority Labor Government ostensibly committed to centralized measures of economic and social planning. Indeed, the new government sought to alleviate resource constraints at the level of manufacturing industry by emphasizing the need for enhanced efficiency both in terms of managerial standards and the organization of work. In this respect, the official Committee on Industrial Productivity proclaimed the virtues of OR from the standpoint of "a scientific approach to running industry," and also as an aid to the machinery of government in planning the allocation of resources.

In any event, a combination of civil service conservatism and mounting political opposition to centralized measures of economic planning were sufficient to severely constrain the diffusion of OR in this particular context for a generation to come. Even within the coal and iron and steel industries it is evident that successful diffusion was heavily dependent on the efforts of specific individuals, in the former case, Sir Charles Ellis in his capacity as Scientific Member of the National Coal Board (NCB), and in the latter Sir Charles Goodeve, the first director of BISRA. Both men professed a firm appreciation of the wartime benefits of OR and were determined to apply quantitative methods of analysis as an aid to rational managerial decision making in their particular spheres. Goodeve, however, possessed a missionary zeal for the dissemination of OR beyond the iron and steel industry to embrace the manufacturing sector as a whole. From the late 1940s to the late 1970s, his advocacy was vigorous and persuasive and there is much documentary and anecdotal evidence to suggest that Goodeve, more than any other individual, was responsible for the adoption of OR in an increasing range of firms in the corporate sector.

Other key individuals in the dissemination process were Goodeve's colleagues at BISRA, Roger Eddison and Roger Collcutt, and in the private sector iron and steel firms, Steve Cook, Stafford Beer and Keith Tocher, and in the coal industry, Donald Hicks, Pat Rivett and Brian Houlden. It is significant that several of these key practitioners were instrumental in establishing OR as an academic discipline worthy of advanced study in the university sector. In this setting, the leading role was fulfilled by Pat Rivett who was appointed to the new University of Lancaster in 1964

as the first UK Professor of OR. This followed in the wake of his efforts to publicize the value of OR in higher education after his election as President of the OR Society in 1960.

The diffusion of OR was also facilitated powerfully by the development of analytical techniques and the innovation, during the course of the 1950s, of digital computers geared to the needs of commercial firms. In the former case, there were two outstanding developments. The first was linear programming emanating from the USA in the later 1940s. Although the foremost pioneer in the UK was Steven Vajda working at the Admiralty Research Laboratory in the early 1950s, the first significant use of linear programming in British industry took place in the NCB from the mid-1950s. Thereafter, it spread rapidly to the electricity, chemical and oil industries with British Petroleum (BP) developing a substantial OR effort in this area by the late 1960s. Complementing linear programming was the technique of simulation as an aid to rational decision making. The modeling of complex systems simulation, entailing the creation of a physical or mathematically-based analogue, was pioneered in the NCB and BISRA in the 1950s. In addition, an abstract approach could be adopted utilizing mathematical equations and logical relationships. However, such procedures were time consuming and repetitive and were thus ideally suited to digital computerization, a procedure which became increasingly commonplace in the coal and steel industries during the 1960s.

Innovative OR techniques, therefore, complemented by the development of the computer, had important roles to play in the diffusion of OR and in extending its practical scope. During the 1960s, the quantum leap in computer power through the use of the transistor, and the associated hype and mystique attached to computers, helped to ensure their commercial proliferation. Although there was a double-edged factor in this development — in the sense that the specialized needs of OR departments were rendered increasingly subordinate to overall company computing needs — the fact remains that by the mid-1960s computers were an essential tool for operational researchers, encouraging more powerful linear programming codes and new high-level simulation languages.

If the later 1950s and the 1960s witnessed methodological and technological developments conducive to the spread of OR, it remains to be said that the period also gave birth to corporate OR in a variety of business settings both in manufacturing and services. The precipitating factor was an upsurge in merger activity which entailed considerable changes in managerial styles and structures. Hitherto, the managerial organization of British business had reflected a continuing commitment to personal capitalism or family influence and control. This fact in itself had served to limit the extent of professionalism in British management, especially in an Anglo-American context.

The merger movement of the 1960s, however, in giving birth to a U.S.-style corporate economy, resulted in the recruitment of professional managerial hierarchies on the U.S. model, often on the advice of North American management consultants. In these circumstances, the Anglo-American corporate gap was closed, but in such a way as to encourage the adoption of OR as a management tool. As the structure of business became increasingly complex, the administration of larger scale enterprises was rendered more tractable by a combination of new instruments of control and decision making enshrined in the computer and OR. In a survey carried out on behalf of the Operational Research Society in 1967, 766 OR groups were identified in industrial sectors as wide ranging as printing and publishing, shoe manufacturing, textiles, glass, brewing, transport and banking. Although the figure embraced a large number of one-person teams, it remains true that by the end of the 1960s, corporate OR was an established fact with an impressive sectoral coverage.

Coincident with the revolution in the managerial structure of British business, the 1960s also witnessed a reforming movement at the level of central government which had major implications for the British OR community. This concerned the efforts of the post-1964 Labor government to reform the Civil Service in the wake of the recommendations of the Fulton Committee. The committee's terms of reference, embracing management as well as recruitment, provided the Operational Research Society with an excellent opportunity to advance the cause of OR as a solution to major policy problems. The formal evidence submitted by the Society fell on fertile ground in the Treasury, where the Permanent Secretary, Sir William Armstrong, proved entirely receptive to the Society's cause. Thus, following the publication of the Fulton Report, the Treasury was divided in 1968 with the Treasury retaining responsibility for economic policy and the

management of the Civil Service being taken over by a new Civil Service Department headed by Armstrong. It was the latter which provided a home for a central government OR facility and this served as a precursor to the establishment of OR groups in an increasing range of government departments after 1970.

In surveying the early history of British OR, a number of interrelated themes can be identified. In the first instance, there can be no doubting the vigor and enthusiasm of the discipline's postwar advocates, motivated by the conviction that the application of OR was conducive to the public good in a variety of settings, both economic and social. It is also true that the peacetime diffusion of OR was propelled, in part, by perceptions of its wartime role and status–the fact that operational researchers had outstanding achievements to their credit, both strategic and tactical, and had enjoyed privileged access to military commanders of the highest rank. But these war-induced relationships could not be replicated in peacetime. The organization of civil affairs was always unlikely to offer the same opportunities for high-level influence if only because the sheer urgency of wartime problem-solving was lacking. It is true that OR was adopted with some success by the postwar nationalized industries and penetrated into the corporate sector from the mid-1950s with a notable acceleration in diffusion during the 1960s. This was one consequence of the professionalization of decision-making, entirely consistent with the continuing demise of family influence and control in British business.

But although OR enjoyed substantial penetration into civil affairs, questions remained about its relative position in organizational structures. In the NCB, the high status of OR was underwritten from the outset by the presence on the board of a scientific member, and, in the case of BISRA, the long standing director was himself an ardent advocate of the discipline as a result of wartime experience. Elsewhere, however, the status of OR and the level at which advice was delivered was dependent upon the idiosyncratic enthusiasms of individual executives. This was exemplified by the rapid diffusion of OR within the civil service after 1967 as a result of the strong personal backing of Sir William Armstrong.

A second and related theme concerns the nature of peacetime OR. To the extent that it was outstandingly tactical it was but one element in the decision- making process and therefore vulnerable to slippage of status according to the perceived value of the work done. Even when OR had a powerful role to play in determining overall strategy, as in the case of the oil companies, it was dependent not only upon high-level backing, but also on a stable external environment. As the world became more turbulent after 1970, the limitations of linear programming became all too evident, especially for global corporations increasingly sensitive to prevailing economic and political conditions. Within Britain itself, the end of the long postwar boom — signaled by the economic recession of the early 1970s — underlined the still uncertain status of OR as a number of corporate OR groups were downsized, closed, or absorbed elsewhere. This was repeated in the early 1980s by which time the British OR community in the university sector was attempting to come to terms with Russell Ackoff's powerful and controversial attack on the extreme mathematization of the discipline in that particular context. It is clear, therefore, that British OR was entering a new phase of its evolution after 1970. The expansionary phase, as indicated by the rapid growth of membership of the Operational Research Society in the 1960s, was now to be followed by a period of introspection. This was most evident at the level of academic OR, but practitioners too began to modify their claims to the status of expert problem solvers by taking on a charge agent role conducive to the enhancement of decision-making processes in general.

Econometrics

Harry H. Kelejian and Ingmar R. Prucha
University of Maryland, College Park, MD, USA

Introduction

Literally speaking, econometrics stands for measurement in economics. Broadly speaking, econometrics is concerned with the empirical analysis of economic relationships. While early empirical work goes back at least to Sir William Petty's political arithmetic in the seventeenth century, econometrics as a field was firmly established through the foundation of the Econometric Society in 1930. Publication of its journal, *Econometrica*, started in 1933. The scope of the society is defined as follows: "The Econometric Society is an international society for the advancement of economic theory in its relation to statistics and mathematics . . ." Samuelson et al. (1954, p. 142) in a report on *Econometrica* defined econometrics

> . . . as the quantitative analysis of actual economic phenomena based on the concurrent development of theory and observation, related by appropriate methods of inference.

Similar definitions can be found in most econometric texts. For example, Goldberger (1964, p. 1) defined econometrics

> . . . as the social science in which the tools of economic theory, mathematics, and statistical inference are applied to the analysis of economic phenomena. Its main objective is to give empirical content to economic theory. . .

Single Equation Regression Models

Much of the early work in econometrics is related to the classical linear regression model

$$y_t = x_t\beta + u_t, \quad t = 1, \ldots, n, \tag{1}$$

where y_t is the tth observation on the dependent variable, x_t is the $1 \times k$ vector of observations on the explanatory variables, β is a $k \times 1$ vector of unknown parameters and u_t is the tth disturbance term. The assumptions of the classical model are: (i) $E(u_t) = 0$, (ii) $E(u^2_t) = \sigma^2$ and $E(u_t\, u_s) = 0$ for $t \neq s$, (iii) x_t is nonstochastic and (iv) $X = (x'_1, \ldots, x'_n)'$ has full column rank. Under these assumptions, the Gauss-Markov theorem implies that the ordinary least squares estimator is best (in the sense of having the smallest variance covariance matrix) within the class of linear unbiased estimators. If the disturbances are normally distributed, exact small sample inference is available. If normality is not maintained, then approximate inference is possible under additional assumptions on x_t and u_t.

The nature of economic data and models are such that the above assumptions are restrictive in certain applications, and hence, various extensions of the classical model have been considered. In particular, disturbances have been permitted to be autocorrelated and/or to have different variances, that is, to be heteroskedastic. Other extensions permit for the regressors to be stochastic. Stochastic regressors arise, for example, if the regressors are measured with error. They also arise in dynamic models in which one or several of the regressors depend on lagged values of the dependent variable. Models in which the parameters are permitted to vary deterministically or stochastically from observation to observation have also been considered. Still other extensions relate to sample selection issues. Text presentations of the issues discussed above are, for example, given in Amemiya (1985), Davidson and MacKinnon (1993), Judge et al. (1985), and Schmidt (1976).

Simultaneous Equation Models

The economy is a complex system of relationships. For this reason, economic models often involve more than one equation and so more than one dependent variable. To see the issues involved consider the following system of m equations:

$$y_t = y_t B + z_t C + u_t, \qquad t = 1, \ldots, n, \tag{2}$$

where y_t is a $1 \times m$ vector of the jointly dependent variables, $z_t = (y_{t-1}, \ldots, y_{t-h}, x_t)$ where x_t is a $1 \times k$ vector of nonstochastic variables, u_t is a $1 \times m$ vector of disturbances, and B and C are correspondingly defined matrices of parameters.

Basic assumptions for the model are: (i) u_t is i.i.d. with finite fourth moments and $\mathrm{E}(u_t) = 0$, $\mathrm{E}(u'_t u_t) = \Omega$ with Ω nonsingular, (ii) $(I - B)$ is nonsingular and the diagonal elements of B are zero, (iii) $n^{-1} \sum x'_t x_{t-\tau} \to Q(\tau)$ where the matrices $Q(\tau)$ are finite, and nonsingular for $\tau = 0$, (iv) the system is dynamically stable. Since $(I - B)$ is invertible the system can be solved as

$$\begin{aligned} &y_t = z_t \Pi + v_t, \\ &\Pi = C(I - B)^{-1} \text{ and } v_t = u_t (I - B)^{-1}. \end{aligned} \tag{3}$$

In the literature, equations (2) and (3) are called the structural and reduced form of the model, respectively. The parameters in B and C are generally not identified and hence, not consistently estimable without additional parameter restrictions. These parameter restrictions often take the form of exclusion restrictions based on economic theory; that is, theory may suggest that every variable does not appear in every equation and so certain elements of B and C are specified to be zero.

As is obvious from (3), the elements of y_t depend in general on all of the elements of u_t. As a consequence the structural equations in (2) cannot in general be estimated consistently by ordinary least squares. Fundamental work on estimation and identification of the model in (2) was done by the Cowles Foundation, which focused on the maximum likelihood technique based on the normal distribution; see Koopmans (1950) and Hood and Koopmans (1953). Estimation procedures developed later were typically based on instrumental variable techniques which do not require specific distributional assumptions; see Basmann (1957) and Theil (1953) for early fundamental contributions, and, for example, Amemiya (1985), Davidson and MacKinnon (1993), Judge et al. (1985) and Schmidt (1976) for later text presentations.

In recent years, the model in (2) has been generalized in ways that are similar to those mentioned above in reference to model (1). In addition, starting with the fundamental contributions of Jenrich (1969) and Malinvaud (1970), estimation theory has been developed for nonlinear counterparts to models (1) and (2); for recent presentations of estimation theory for dynamic nonlinear systems see, for example, Gallant and White (1988) and Pötscher and Prucha (1991a, b). Finally, Bayesian extensions of these models have been considered, see, for example, Zellner (1971) for early fundamental work and Judge et al. (1985) for a more recent text presentation.

Other Modeling Techniques

(a) *Time series models* — An important class of models used to describe economic data are autoregressive moving average (ARMA) models. These models have been popularized in economics by Box and Jenkins (1976); for a recent discussion of time series techniques see, for example, Brockwell and Davis (1991), and Harvey (1993).

A stationary stochastic process y_t (time series) that satisfies for every t

$$y_t = a_1 y_{t-1} + \cdots + a_p y_{t-p} + \varepsilon_t + b_1 \varepsilon_{t-1} + \cdots + b_q \varepsilon_{t-q} \quad (4)$$

where $\mathrm{E}(\varepsilon_t) = 0, E(\varepsilon^2{}_t) = \sigma^2 \varepsilon$ and $E(\varepsilon_t \varepsilon_s) = 0$ for $t \neq s$ is called an ARMA(p, q) process. If y_t was obtained by differencing some process z_t, then z_t is called an autoregressive integrated moving average (ARIMA) process. If the specification in (4) also permits nonstochastic regressors, then the corresponding processes are called ARMAX and ARIMAX, respectively. Clearly, the reduced form in (3) can be viewed as an ARMAX model. Although ARMAX models do not describe the structure of the system, they have been found, for example, to be useful for prediction purposes.

An important recent development in the time series literature is the introduction of the concept of cointegration as an equilibrium relationship between integrated variables. This development has particular appeal to economists because many economic variables appear to have random walk representations but yet certain linear combinations of them appear to be stationary. The basic ideas were proposed by Granger (1981); recent extensions and developments are discussed in Davidson and MacKinnon (1993), and Engle and Granger (1991).

(b) *Qualitative and limited dependent variable models* — Economists often formulate models to explain events which are at least partially qualitative in nature. For example, one might be interested in the factors determining whether or not a bank fails, a firm undertakes an investment, etc. More generally, such models could relate to events that are described by more than one category. Models relating to occupational choice, firm structure, and travel mode fall in this class.

Another class of models are limited dependent variable models. In these models the range of the dependent variable is constrained in some way. As one example, consider a model describing the selling price of a house. A limited dependent variable problem would arise if, for example, the only transactions that are recorded are those for which the selling price exceeds a certain dollar amount. The techniques involved for limited dependent variable models are similar to those in qualitative models. In recent years econometric models relating to qualitative and limited dependent variables have been generalized in ways that are similar to those described in the sections above. Excellent early reviews are given in McFadden (1974, 1976) and in Amemiya (1981). Later text presentations are given in Amemiya (1985), Maddala (1983), and Judge et al. (1985).

Concluding Remarks

This review has just touched upon a few of the major topics in econometrics. Many other topics were not covered, including model specification tests, rational expectations models, and model simulation.

Economic Order Quantity

The policy for a simple, deterministic inventory model that tells how much to order so that the sum of ordering and holding costs is minimized.

See

▶ Inventory Modeling
▶ Economic Order Quantity Model Extensions

Economic Order Quantity Model Extensions

Benjamin Lev
Drexel University, Philadelphia, PA, USA

The classical EOQ (Economic Order Quantity) model has a long list of assumptions. Begin by assuming that the horizon of the process is infinite and that all parameters stay the same over time. Then the solution to the classical EOQ problem is $\text{EOQ}(\infty) = Q = \sqrt{2AD/vr}$ where the parameters A, D, v, and r are the fixed cost of replenishment in \$/ order, (constant) annual demand in units/year, unit cost in \$/unit, and carrying charge in \$/unit/year, respectively. A typical picture of inventory level over time is displayed in Fig. 1.

A first possible extension to the classical model is to assume a finite horizon T; an example might be when a producer announces the discontinuation of an existing model at a future time T. The optimal solution is a series of n equal orders, each one of size DT/n, where n is the smallest integer such that

$$n(n+1) \geq \frac{Drv T^2}{2A}$$

(Schwartz 1972). The optimal solution is then either the integer

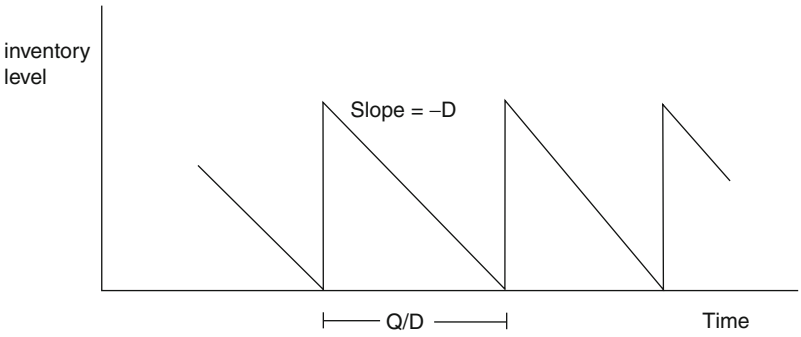
$$n = \left[T\sqrt{\frac{Drv}{2A}} \right]$$

or

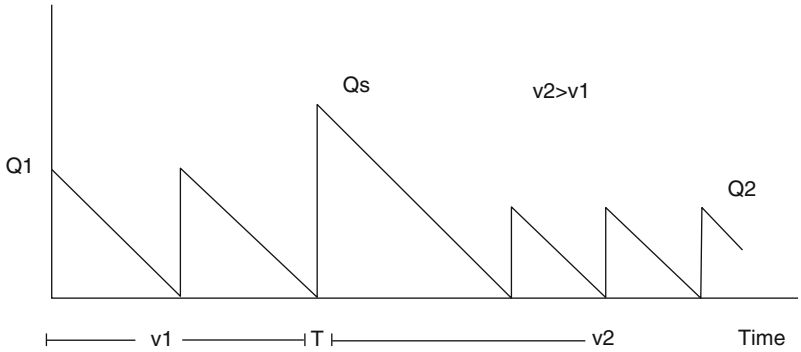
$$n = \left[T\sqrt{\frac{Drv}{2A}} \right] + 1.$$

Another extension is to relax the assumption that v is constant over time. An example is that the producer announces that in a future time T price will increase from v_1 to $v_2 (v_2 > v_1)$. The U.S. Postal Service increased the first class stamp rate on January 1999 from $v_1 = 32$ to $v_2 = 33$ cents (Fig. 2).

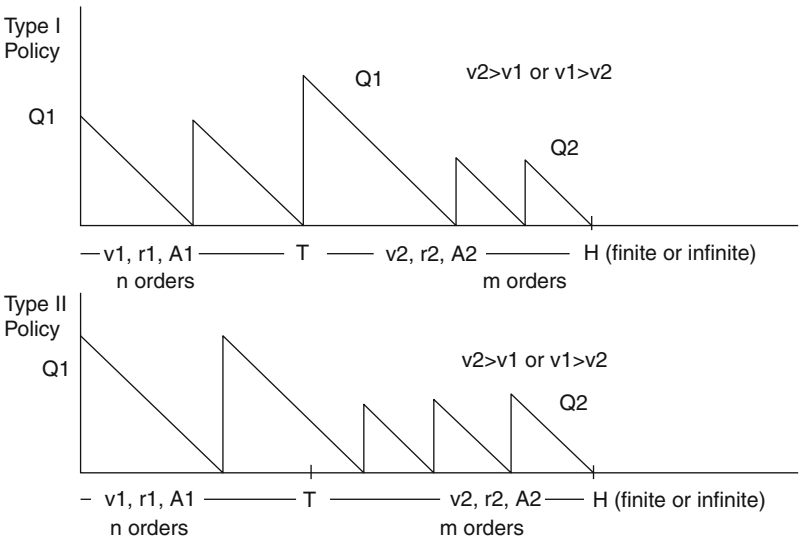
Naddor (1966) assumed that the inventory on hand is zero at the last opportunity to order at v_1 and suggested the solution of



Economic Order Quantity Model Extensions, Fig. 1 Classical EOQ model



Economic Order Quantity Model Extensions, Fig. 2 EOQ with price increases at time T



Economic Order Quantity Model Extensions, Fig. 3 EOQ with finite or infinite horizon H and parameters changing at time T

$$\text{EOQ}(\infty, v_1) = Q_1 = \sqrt{\frac{2AD}{v_1 r}}$$

(read this as the EOQ with infinite horizon and parameter v_1) followed by a single order size

$$Q_s = \frac{D(v_2 - v_1) + \sqrt{2AD/rv_2}}{rv_1}$$

followed by a series of order sizes

$$\mathrm{EOQ}(\infty, v_2) = Q_2 = \sqrt{\frac{2AD}{v_2 r}}.$$

This solution was later improved to include three possible solutions. The one suggested by Naddor where the inventory on hand is zero at time T, a solution when the inventory at time T is positive with either n orders during $(0, T)$, or $n + 1$ orders during $(0, T)$. A complete solution is presented in Lev and Soyster (1979).

The next extension is a combination of the previous two. Assume a finite horizon H, and at time T ($T < H$), some or all the parameters A, v, r might change (each one may increase or decrease, Fig. 3). There are two possible policies: Type I is used when the inventory on hand at time T is zero, and Type II is used when the inventory on hand at time T is positive. A procedure for finding n, Q_s, m for Type I and (n, m) for Type II is in Lev and Weiss (1990). See also Goyal (1992).

Economics and Operations Research

Frederic H. Murphy
Temple University, Philadelphia, PA, USA

Introduction

To understand the relationship between economics and operations research, one needs to understand some of the history of both fields. Operations research was developed prior to and during World War II with the pragmatic goal of improving military operations through the use of mathematics. The founders of the field of operations research came from diverse backgrounds, including physics, mathematics, engineering and economics. Operations research as a field has maintained its multidisciplinary character. Yet, the vast majority of the literature in the field has remained within the planning and operations areas of organizations and on algorithms to solve the models used for planning and operations. The textbooks on the subject contain a common set of subjects: stochastic modeling, simulation, optimization, inventory, and game theory.

Economics as a subject has been explored and developed for centuries. The field used to be called political economy, reflecting its public policy orientation, which carries through to today. The subject areas of economics can be defined broadly as follows: macroeconomics, the study of economic aggregates and the state of entire economies, and microeconomics, the study of economic agents, such as firms, and the market or organizational structures within which these agents operate to optimize their utility or profits. Examples of markets include monopolies, oligopolies, and perfect competition. Economists also develop tools such as the statistical techniques of econometrics, which are used for estimating the parameters of economic models. Despite strong connections between microeconomics and operations research, little overlap exists between macroeconomics and operations research.

While some early writers such as Adam Smith and Karl Marx were very influential as social philosophers, professional economists did not play an important role in day-to-day discussions of specific public policies and programs until well into the 20th century.

For example, the first tax cut based on macroeconomic theory and intended to stimulate the U.S. economy was implemented in the Eisenhower administration in the late 1950s, and regulatory reform based on microeconomic theory started to make headway in the 1970s, decades after the basics of the theory of workably competitive markets was understood. Economists drove many of the reforms in regulations around the world, most notably in the U.S., with Alfred Kahn leading the changes during the Carter administration. Economists played an even more central role in the restructuring of the British economy under Margaret Thatcher. The decisions of Competition Authority in the E.U. are based on modern economic theory and their work has led to new theory, such as understanding how electricity markets work. The European economies have also seen some restructuring reflecting the better understanding of markets. The remarkable rise of China is a result of the switch from a controlled economy to one that is more market based.

Economics developed contemporaneously with operations research and its broad impact in decision making is a post-World War II phenomenon as with operations research. The post-war development of economics and operations research was driven by the infusion of mathematics into areas beyond the hard sciences and engineering and the declining cost of computers and the greater reliance on analytics in making policy and operational decisions.

The Common History

Both fields apply mathematics to build and understand models that only approximate the reality being studied but improve decision making. Given this common starting point and the interest of operations researchers in finding the most economic solutions, the overlap in the fields has to be significant. The connections were most prominent in the early days of operations research and they involved such areas as optimization, inventory theory, and game theory.

Hitchcock (1941), a physicist, and Koopmans (1951), an economist, independently developed the first useful optimization model, the transportation model. Kantorovitch (1939), a mathematician in the Russian central planning agency, developed several linear programming (LP) models for production and distribution including the transshipment model. Stigler (1945), an economist, developed the diet/feed mix model. Dantzig (1951a and 1963), at the time, a mathematician in the US Air Force, invented the first generic linear programs and the simplex algorithm for solving them. The simplex algorithm has survived for 60 years as the primary method for solving linear programs. The collection of papers in Koopmans (1951) defined the beginning of the subjects of optimization, game theory, and the relationship between the two. It also devoted a substantial amount of space to generalizing the input–output model of an economy. Dantzig (1963) pointed to the work of Leontief in input–output models of the US economy as an important beginning for his ideas. The contributing authors to Koopmans' book were a mix of economists and mathematicians. Another important early book on linear programming, Dorfman et al. (1958), was written by economists. Indeed, Dorfman (1953) wrote the intuitive description of linear programming models that are found in all of the textbooks today. Current texts on microeconomics continue to include chapters on optimization and game theory.

Many of the first articles on optimization appeared in such journals as *Econometrica* (see the references in Dantzig 1963). Charnes and Cooper, the developers of many of the first linear programming models, also published in the economics journals (see, e.g., Charnes et al. 1952). Agricultural economists were quick to develop the feed-mix model for farmers. Mathematical programming has become a mainstay for agricultural economists (see Hazell 1986).

In the early days of inventory theory, the links between economists and operations researchers were equally strong. This area involved using such optimization techniques as dynamic programming and traditional, calculus-based methods to find optimal inventory policies (Arrow et al. 1958; Whitin 1957). However, the development of the field moved very quickly into the hands of operations researchers because the issues in inventory analysis evolved into the implementation of inventory systems and situation-specific models, away from the more broadly-based economic considerations.

Game theory was developed by von Neumann to study issues of conflict and cooperation at a theoretical level. He and Morgenstern applied game theory to economics (von Neumann and Morgenstern 1944).

The RAND Corporation became an early center for the development of game theory right after World War II, in good part to understand geopolitical and military strategy. The link between non-cooperative game theory and optimization was understood from very early on (see Dantzig 1951b; Gale et al. 1951). Game theory outside the military context plays a larger role in economics than it does in operations research, mainly because games are used for the qualitative analysis of interactions among players, which is appropriate for developing general policies, and few models are ever calibrated with numbers that reflect a specific situation.

The theory of auctions is an area of game theory with both qualitative and quantitative results and of interest to both economists and operations researchers. Auctions have been around for millennia, back to Babylonia. In one of the more notable auctions, Praetorian guards auctioned off the Roman Empire in A.D. 193, Shubik (1983). See Klemperer (1999) for a review of the literature. The economics literature focuses on single-item auctions whereas research on combinatorial auctions is in the operations research literature because of the emphasis on solution methods. Rothkopf et al. 1998 developed an approach to solve combinatorial auctions using integer programming. See de Vries and Vohra (2003) for a survey of combinatorial auctions.

The restructuring of electric utilities into a highly regulated market was driven by economics. However, the method for clearing the daily electricity markets is mainly linear programming, with integer programming coming in. Integer programming models for clearing the market take into account that there is a fixed cost to generating from the need to ramp power plants up and down. Some independent system operators such as PJM Interconnection are using integer programming. This has led to a literature on developing prices (see O'Neill et al. 2005, for one approach) using these models, as integer programs do not generate prices in the way linear programs do (see for example, Murphy et al. 2010).

Operations research techniques and operations researchers have contributed significantly to economics. Once Samuelson (1952) recognized the connection between mathematical programming and economic equilibrium models, mathematical programming became an important tool for economic analysis. In fact, the GAMS modeling language was developed by operations researchers at the World Bank for the purpose of solving computable general equilibrium models for evaluating national development plans (Brooke et al. 1993). An economist, Gustafson (1958), used dynamic programming, an operations research tool, to develop the first grain storage models to protect against famine. One of the most prominent microeconomic policy-analysis models of the 1970s, the Project Independence Evaluation System (PIES), was built by a team of operations researchers and economists led by William Hogan (1975), an operations researcher, who went on to organize the International Association of Energy Economists. Anyone working in electricity market restructuring has to be conversant in optimization, see Stoft (2002).

The Different Perspectives

Economics and operations research are distinct fields because the economists and operations researchers have different interests. Economists are primarily interested in qualitative analysis for policymaking and econometric modeling and estimation to understand the structure of an industry. Operations researchers are more interested in assisting decision making within the firm and have a strong computational orientation. For example, oil companies use the results of their mathematical programming models for operating their refineries and taking positions in forward markets. Even when economists are interested in numbers, they are looking to measure the impact of the sum of individual decisions rather than determining the decisions. This distinction between the fields is not absolute. Econometricians are interested in computational issues and the theoretical properties of their estimation methods. Scarf and Hansen (1973) has developed algorithms for computing economic equilibria. An emerging computationally intensive area of economics is agent-based modeling, which is a form of simulation where programmed agents act in their self interest and the simulations show how economies or ecologies evolve. The function of corporate planning and public policy studies produced by operations researchers is to provide insight rather than specific numbers. This is done through constructing multiple scenarios, examining alternative policies, and

analyzing the sensitivity of the results to the underlying parameters.

The different perspectives can be seen in the study of inventories. For the past few decades operations researchers and computer scientists have been implementing inventory systems, while the economists have been focusing on the effect of inventories on the business cycle rather than inventory policies per se and they gather data on inventories to measure aggregate inventory levels. The popularity of scientific inventory management in corporations and the desire to reduce inventories to free up capital and gain operational flexibility with just-in-time manufacturing has led to a significant decline in the inventory-to-sales ratio and rapid adjustments to inventories in response to changes in sales. That is, inventories turn over more quickly and companies are able to adapt to fluctuations in demand more rapidly with less draconian changes in production levels. The recession of 2008–2009 had a classic inventory reduction with the rebuilding of inventories contributing to the early recovery.

Inventory changes are known accelerators of business cycles. See Forrester (1961) for an illustration of this at the firm level. The smaller aggregate inventories are, relative to GNP, the less effect they have on business cycles. Economists measure this drop at the national level and factor this secular change into their macroeconomic models to explain the resultant dampening of business cycles. For example, the recession in the early 1990s was slow in coming and going but also shallow relative to past recessions because of the cumulative impact of individual improvements of inventory systems and production management. The 2000 recession did not have a strong inventory component to the decline or recovery, which made the recovery extremely sluggish, while recession of 2008–2009 is notable for the inventory movements that deepened the recession and provided an important component to growth in the first half of 2010. However, inventories were a secondary factor in that recession and not as important as they were in the recessions of the 1950's through the 1980's.

The different views of production functions taken by the two fields further illustrates the distinctions between the fields. When economists estimate production functions and are not building process models, they typically posit a differentiable functional form, gather data and estimate the parameters of the function using regression techniques. They do this to estimate output prices and understand the rates of substitution of inputs as a function of input prices. They are not looking inside the firm at the production process. Instead they are looking at market consequences. For example, from the rates of substitution, one can derive a demand curve for an input given the prices of the other inputs.

The operations research tool of data envelopment analysis (Charnes et al. 1978) estimates production functions using an alternative approach with different assumptions and goals. In data envelopment analysis the goal is to identify which decision-making units are efficient and which are not. That is, data envelopment analysis is a benchmarking tool for finding the best production practices with the ultimate goal of improving production processes. Unlike the econometric assumption that errors are in the data, data envelopment analysis assumes the data is error free and differences among decision-making units are due to different resource mixes and managerial effectiveness. The production function is the inputs and outputs of the decision-making units as activities in a linear program. A linear program is solved for each decision-making unit to see if it is on the efficient frontier. If it is, it represents best practices, given its mix of resources and products. If not, it is a candidate for improvement.

For every differentiator between operations research and economics, one can find an exception. Economists have focused on how agents interact in a framework and draw conclusions about the effect of changes in the framework, while operations researchers have been more interested in aiding the agents making the decisions. An exception to this is the study of traffic equilibria where the agents are travelers on a network of roads. The defining paper of this subject appeared in a civil engineering journal. Wardrop (1952) stated a set of equilibrium conditions based on trip times that are directly related to the equilibrium conditions for spatial economic equilibria based on cost. Although economists contributed to the early literature (e.g., Beckmann et al. 1956, established the relationship with economic equilibria), the bulk of the literature is in transportation journals with an operations research connection. See Nagurney (1993) for a description of different types of equilibrium models.

Agent-based modeling and OR-style simulation illustrate an area that has commonalities and differences between the economic and OR perspectives. In agent-based modeling one endows the agents with some knowledge of their environment and procedural rationality rather than a full understanding of how to optimize. The procedural rationality can be the steps of an optimization or search algorithm or a set of behavioral rules. See Epstein and Axtell (1996) and Tesfatsion and Judd (2006) for introductions to the subject. Usually, randomness in choices and/or outcomes is introduced. The agents interact in simulations and the equilibria or lack of equilibria are observed. This form of modeling is especially useful in exploring possible outcomes that can be later assessed using standard qualitative analysis methods or for observing markets that are too complicated for qualitative analysis. See Weidlich (2008) for a simulation of the German electricity market, a market that is too elaborate for standard qualitative analysis. The difference between agent-based modeling and the typical stochastic simulation built for operational purposes is that these simulations describe physical situations and look at material flows. When these simulations include people, the people are typically represented using probability distributions on some characteristic such as arrival patterns in a queueing simulation. Simulations can incorporate optimizations. However, the optimizations are for the system being studied and not the individual agents (see, for example, Andrews et al. 1996).

The Common Interests

The two fields overlap in several areas, including public policy analysis, finance, game theory, and decision analysis. There are others such as yield management that link both fields. The convergence of the fields in policy analysis comes about because politicians want quantitative analyses of programs. Economic models have a lot to say about how economic agents behave and operations researchers have the computational skills and modeling expertise to implement the economic theories and solve for the economic impacts of policy alternatives.

Examples here include the activity at the World Bank in building country and sector models. The close working relationships between economists and operations researchers have continued with the successor models to PIES, the Intermediate Future Forecasting System (Murphy et al. 1988) and the National Energy Modeling System (Energy Information Administration 2009). See Murphy and Shaw (1995) for a history of the energy models at the Energy Information Administration.

A key feature of these kinds of policy models is that in some sectors they model the decisions using optimization by representing the technology choices directly in the model. The main reason for using optimization is that the models need to have representations for policies and technologies that affect more than input and output prices and quantities and there is no history to assess the resulting decisions for some sectors. Other reasons include the need to link more than one sector and the existence of a convoluted data history that muddies the econometric analysis for estimating such things as a production function for electric utilities. The optimization models are usually simplified versions of the planning models used by the industry with coefficients based on industry aggregates and are process models as described by Manne and Markowitz (1961). They are treated as simulation models based on the result of Samuelson (1952) showing the connection between optimization and economic equilibrium models.

Markowitz (1954) proposed using process models almost 60 years ago as a way to model the whole economy, extending the input–output model to represent alternative production technologies. Henderson (1955) and Land (1956) successfully built models of coal markets using this approach. Only recently have databases, computers, and algorithms progressed to the point where these ideas can be realized for economy-wide models.

Policy models almost always include econometric components as well. For example, the above-mentioned energy models include econometrically estimated demand curves along with the process models for coal supply and transportation and electricity generation and transmission. In econometric models of production, one measures the inputs and outputs to statistically estimate the parameters of a production function. The model makes no statement about the actual decisions made by the agents. Instead, it models the outcomes of the decisions made by

the actors in the economic sector. Econometric approaches dominate optimization when there is too much heterogeneity among participants to specify the parameters of their decision environment, as in demand modeling or the behavior of producers when the industry has a large number of independent, small firms. In large-scale, capital-intensive industries, process models work well.

The finance literature is dominated by economic studies of financial markets and their efficiency. An example is the book *A Random Walk Down Wall Street* by Malkiel (1973). This book showed that movements in stock prices are a random walk, illustrating why stock pickers in general cannot beat the market. Also, Tobin's (1958) results on the relationship between risk and return were key to the development of decision models in finance. Equilibrium conditions lead to an efficient frontier in portfolio theory that simplifies the choices to a tradeoff between an index of risky assets and a risk-free asset, typically, government bonds. See Bodie et al. (2005) for an introduction to the subject. For a book that covers finance from an operations research perspective see Luenberger (1998).

Financial markets are not entirely efficient and the Black and Scholes (1973) model for pricing options created a whole new segment of the finance industry. Its basis is dynamic programming. The book by the economists Dixit and Pindyck (1994) emphasized the role of dynamic programming in properly valuing investments with uncertain returns.

Optimization models have come to play an important role in determining the mix of assets in a portfolio, the first one being the model by Markowitz (1952), which represents the beginning of computational finance. That model is a quadratic program that trades off expected return and portfolio variance. Because of the ability to solve far larger linear programs than in the past, stochastic programming models for building portfolios have made an important mark in the industry. For example, see Carino et al. (1994) for a description of the kind of operations research models used by the people known as "rocket scientists" in the financial press. Because of the difficulty of determining probability distributions and finding stable correlations among assets, an alternative approach known as robust optimization is gaining traction. Here random variables are captured in uncertainty sets. The model optimizes an objective function subject to satisfying all constraints for all parameter values in the uncertainty sets. In some sense this is a maximin optimization. See Bertsimas and Thiele (2006) for a tutorial on the subject.

Portfolio theory also uses the concepts of value at risk and conditional value at risk. Say a portfolio manager wants to limit the worst case outcomes by choosing a portfolio that maximizes the value of a cutoff point (minimizing the loss) on the left tail of a probability distribution where the left tale covers 5% of the possible outcomes. This is the value-at-risk optimization. Conditional value at risk minimizes the expected value of the losses below the value-at-risk loss. For readers with an inventory background, value at risk corresponds to setting reorder points and safety stocks at a level that targets a given probability of stock out. Conditional value at risk is the equivalent of setting reorder points at a target number of expected units short during lead time. There are convexity issues with value at risk. Rockafellar and Uryasev (2000) show how to formulate the conditional value at risk optimization as a linear program.

The interconnection between economics and operations research in game theory can be illustrated by the Averch-Johnson hypothesis (1962). This hypothesis states that regulated firms have a bias to overinvesting in capital rather than labor. They demonstrated their results by evaluating the Kuhn-Tucker conditions of an optimization model, where a firm with a monopoly maximizes profits subject to a rate-of-return constraint. With the deregulation of many industries, it is now known that these firms were not only overcapitalized, but they also had too much labor, in violation of the Averch-Johnson hypothesis.

The problem with the Averch-Johnson model was it presumed that the firm was a single entity and could optimize its behavior. However, one must not treat the firm as the atom. Instead, one must look at how the agents within the firm interact and look further into the nature of the behaviors of the agents who make up the firm. Figuring out the underlying incentives of the members of a firm and analyzing their behavior relative to the interests of stockholders is known as principal agent theory, an important area of microeconomics. For example, one could explain the behavior of regulated firms as follows: managers increase their importance by increasing the number of employees under them and buying labor peace by

paying high wages to unionized employees. Given the extent to which electric utilities were perceived as highly inefficient in the Averch-Johnson sense, it is interesting to see the differences in performance of investor-owned generators that were restructured, those that were not, and municipal utilities. Fabrizio et al. (2007) find only modest improvement.

Studying the behavior of economic agents and other individuals has a long tradition in economics and is the essence of game theory. Since little data exists for numerically evaluating game models, almost all studies examine the qualitative properties of the resulting games. Economists have focused mostly on markets (Shubik 1959). Indeed, outside of von Neumann's early work on parlor games, the book by von Neumann and Morgenstern (1944) was the first major treatment of the subject and focused on economics. Operations researchers have studied other types of games such as war games and invented some of what are now the classics like the prisoner's dilemma game (Poundstone 1992). The center for this work was RAND. An example of a strategic game that was studied was the stability of mutual assured destruction as a defense against nuclear war. Schelling (1980) presented an analysis of these strategic games. Both groups study the generic properties of games that abstract common situations. Shubik presented an interesting example of someone who does both strategic and economic games. As part of his examination of strategic issues, he used the dollar auction game to describe games of escalation such as war and lawsuits (Poundstone 1992).

Part of the reason for the common interest of economists and operations researchers in game theory is its universality in understanding conflict and cooperation. Political scientists and sociologists have become involved in game theory for the same reason. The link between political science and games is direct through the games already mentioned and the use of game theory concepts in negotiation. Sociologists use games to understand social interactions. The prisoner's dilemma game has been used repeatedly to explain the behavior of individuals in social situations and social structures. Thus, the notions of game theory have moved beyond the disciplines in which they were developed and influence important areas of the social sciences.

Rational decision making encompasses game theory. Indeed, a still invaluable work on the subject that treated both together is the book by Luce and Raiffa (1957). What is a rational decision is subject to debate. To explore the subject, von Neumann and Morgenstern developed the concept of expected utility. Utility is a simple concept in many situations when the goal can be clearly stated as with maximizing profits. However, in real life an individual faces many trade-offs. Examples include the willingness to bear risk, how to value income versus leisure, what value is in the products consumed, and how to value the future over the present. In the decision-making literature, Keeney and Raiffa (1976) explored the issues associated with multi-attribute utility in decision making. The notion of multi-attribute utility is central to the study of negotiation (Raiffa 1982), as the different parties in a negotiation generally value different aspects of the subject under discussion, creating an opportunity for joint gain.

As in other areas, economists have not focused on making actual decisions except in the general properties that can be understood from the decision-making process, as in Arrow (1951). In his seminal work on social choice, Arrow posits a set of axioms that define rationality and then shows how group interactions and voting processes lead to irrational decisions even though the original actors have rational utility functions. Another example of this is the economics literature on rational expectations. In its most basic form, the question addressed in the context of macroeconomic models is: "How do the consequences of macroeconomic policy change when the participants in the economy have rational expectations about the effect of macroeconomic policies and adjust their decisions?" See Redman (1992) or Sargent (1993) for a discussion of this area of economics.

In much economics theory the literature presumes the agents have full information and know their utility functions. These are questionable assumptions and one should treat the theorems of economics as hypotheses rather than foregone conclusions. Econometricians historically have done the testing. Smith (1994, 2005) developed the field of experimental economics by laboratory studies in which the subjects were rewarded based on their performance in economic situations. He verified results such as the effect of risk aversion on auction designs. This kind of work does not appear in the operations research literature because operations research is prescriptive rather than descriptive.

Operations research has come to dominate the subject so far as making actual decisions. For an example of a detailed decision analysis in a corporation see Borrison (1995). Some of the most important literature has come from psychologists trying to understand peoples' thought processes. The psychology literature is aimed squarely at the rational actor hypothesis of economics and finds it wanting. For a book that examines the approaches of all three disciplines see Bell et al. (1988). For a description of experiments that bring out cleverly human thought processes, see Ariely (2008). An area known as happiness research is moving economics from standard utility theory. Researchers do surveys to understand what makes people feel better. For example, rich people are happier than poor people. However, as a society gets richer, happiness does not increase. This has implications for the kinds of measures that should be used to determine the wellbeing of a society. See Graham (2005) for an overview. Again, a key difference between economics and operations research is that the goal of economics is to be descriptive, a science that discovers what is, and operations research, which comes from the engineering tradition of achieving organization-specific goals such as improved supply chains, looks to engineer better decisions.

An operations researcher cannot be an effective modeler and analyst without a good understanding of the basics of economic theory. Here is a simple example. The simplex algorithm represents the behavior of a set of independent economic agents (activities) making decisions to act or not based on a set of incentives in the form of objective coefficients and resource prices (dual variables). And if they choose to act based on profitability (reduced costs), they proceed until they reach a resource limit or drive a competitor out of business (the replaced activity reaches zero in the simplex pivot). By looking at a solution from the perspective of the simplex algorithm as an economic process, one gains the deeper insights into the story contained in the solution that takes analyst beyond just the value of the objective function and the level of activities.

The basic notions of substitutes and complements in production processes determines the character of optimization models. Network linear programs are models of pure substitution. Whereas, a product-mix model consists of activities that have inputs that are pure complements. The vast majority of the constraints in an LP can be classified as supply, demand or material-balance constraints. Greenberg (1981) used the notions of substitutes and complements to gain deeper insights into linear- programming models and their solutions.

Concluding Remarks

Economics and operations research have common roots. The fields often use the same tools, such as the Karush-Kuhn-Tucker conditions. In economics these conditions are used for pricing, marginal analysis, as with the search for institutional distortions of the marketplace in the Averch-Johnson hypothesis, and for such uses as the derivation of cost functions from production functions. Operations researchers exploit these conditions to improve algorithms and use the actual duals and ranges for evaluating the stability of the model results, estimating the effects of uncertainty in the coefficients on the solution, and determining the costs of constraints with an eye towards adding or reducing resources when making decisions within the firm.

Typically, the fields use these tools differently for different purposes. This reflects the different professional goals of the individuals involved in these fields. Operations researchers focus on making specific decisions and economists study the consequences of different organizational and market structures and policies through an assumption of rational decision making. Both groups are interested in understanding rational decision making and the consequences of rational decisions. This can be seen in the different views of the firm. The traditional economic theory of the firm is really a theory of the interactions of firms or constituencies within the firm. Whereas, operations research models provide a theory of decision making within the firm and are an important component of a theory of the internals of the firm. The operations research models do not provide a complete theory of decision making in the firm because operations researchers, although commenting on conflicts in the firm, tend to not focus on the incentives and structures that create these conflicts. This is where agency theory fits in and one of the places where game theory links both fields. The result is that operations research models tend to be most successful in capital intensive firms where the issues are managing those assets rather than large numbers of people.

The fields are now distinct because operations research takes an engineering perspective: the goal is to invent improved ways for making decisions, and in the process of doing this, inventing new models and algorithms as needed. In fact, the very success of operations research in building and using large computer-based models for planning and operations has led to the complaints of Ackoff (1987) that the field has abdicated its role in corporate strategy and public policy. Economics, instead, is a social science where the goal is to understand the existing world and study the consequences of policies that affect this world using the basic theme of exploring the consequences of rational self-interest. The two fields come together when there is the need to change the rules of the marketplace or when the marketplace creates opportunities to engineer new products that provide a profit as in finance and electricity markets. Both fields have their distinct niches, yet will always be connected by their tools and history. Each will continue to enhance the other field, an example of the economic notion of joint gain through comparative advantage.

Efficient Solution

For a maximizing multi-objective problem, a solution $\boldsymbol{x}^0$ is efficient if $\boldsymbol{x}^0$ is feasible and there exists no other feasible solution $\boldsymbol{x}$ such that $\boldsymbol{cx} \geq \boldsymbol{cx}^0$ and $\boldsymbol{cx} \neq \boldsymbol{cx}^0$. An alternative definition is that a feasible $\boldsymbol{x}^0$ is efficient if and only if there exists no other feasible $\boldsymbol{x}$ such that $\boldsymbol{c_k x} \geq \boldsymbol{c_k x}^0$ and $\boldsymbol{c_k x} > \boldsymbol{c_k x}^0$ for at least one $\boldsymbol{k}$. An efficient solution is a feasible solution for which an increase in value of one objective can be achieved only at the expense of a decrease in value of at least one other objective. Efficient solutions are also called nondominated solutions or Pareto-optimal solutions.

Electric Power Systems

Oliver S. Yu
Star Strategy Group, Los Altos Hills, CA, USA

Introduction

An electric power system is designed for reliable, economic, and socially acceptable production and delivery of electricity to individual customers. It involves many interrelated elements: generation stations, control centers, transmission lines, distribution substations, and distribution feeders. With an intricate system structure, complex economic and social objectives, and numerous reliability, safety, and resource constraints, power system planning and operation has long been an ideal field for the development and application of operations research and management science (OR/MS) techniques. These developments and applications continue to expand and evolve with the advancements in power technologies and changes in the utility industry. In the following sections, electric power generation system planning and operation is first used as a prototype example to present some basic concepts. This is then followed with a discussion of trends and challenges in the electricity industry to provide a glimpse of the enormous opportunity for OR/MS applications to power systems.

Overview

Electric power systems have been planned, constructed, and operated to supply electricity to the general public by regulated utilities. As regulated entities, these utilities are allowed to recover their capital investments and operating costs for supplying electricity, with an allowance for reasonable returns by collecting revenues from customers in the form of electric rates. To assure the economic efficiency of the utilities, regulatory commissions in general have required utilities to minimize their total revenues required for electricity supply. Therefore, electric power system planning and operation has been a classical OR/MS problem of minimizing utility revenue requirements to meet projected electric demand growth over a future time period at a given level of reliability.

An electric power systems have three major parts: generation, transmission, and distribution. Because power flows in transmission and distribution are still difficult to be estimated accurately and economically, most applications of optimization techniques have been in generation system planning and operation. Specifically, the generation system planning and operation problem is to select a combination of power plants and unit dispatch schedules to minimize the present worth of the total capital, fuel, and operations and maintenance expenditures for meeting future electric demand while satisfying generally agreed-upon generation system reliability standards.

Optimal Generation System Reliability

Setting generation system reliability standards is itself an optimization problem, because too low a standard would cause economic losses to the customers from frequent electric supply interruptions, while too high a standard would cause low capacity utilization of power plants and thus high electricity costs.

In the past, a commonly accepted empirical generation system reliability standard has been the one day in 10 year loss of load probability, that is, the daily electric peak load not to exceed available generating capacity of each day by more than one day in 10 years. However, with increasing technical capability, computationally efficient procedures have been developed to enable utilities to assess generation system reliability in detail (Yu 1978). Further-more, cost/benefit approaches have been used to derive the optimal reliability standard for a given socio-economic environment by determining the appropriate tradeoffs between the cost of power supply shortage and disruption and the cost of over-capacity to the customers (Kaufman 1975; Telson 1975; Keane and Woo 1992).

Optimal Dispatch of Generating Units

Because electric load varies by hour, day, and season in a year, the dispatching of generating plants to meet daily load requirements is also itself an optimization

problem. This so-called production costing problem strives to determine the plant dispatch schedule that will minimize the fuel as well as operations and maintenance costs for meeting the load. In a broader context, the production costing problem also involves power purchases from neighboring utilities for either low cost or backup capacity. Therefore, for optimal generation system planning, a solution to the operational sub-problem of production cost optimization must first be found.
