This equation can be analyzed by methods of functional analysis, which leads to many explicit matrix formulas for moments. In terms of the matrix $\tilde{\boldsymbol{G}}(z; s)$, the boundary behavior of the Markov renewal process can be studied in an elementary manner. In queueing applications, the analysis leads to equations for the busy period and the busy cycle. Waiting-time distributions under the first-come, first-served discipline are obtained as first passage time distributions. Extensive generalizations of the Pollaczek-Khinchin integral equation for the classical M/G/1 queue have been obtained (see Neuts 1986b).

Applications of Markov renewal theory lead to a matrix formula for the steady-state probability vector $\boldsymbol{x}_0$ for the states in level $\mathbf{0}$ in the imbedded Markov chain. Next, a stable numerical recurrence due to Ramaswami (1988) permits computation of the steady-state probability vector $\boldsymbol{x}_i$ of the other levels i, $i \geq 1$.

There is an interesting duality between the random walks on the infinite strip of states (i, j), $-\infty < i < \infty$, $1 \leq j \leq m$, that underlie the Markov renewal processes of M/G/1 type and those of GI/M/1-type (which lead to matrix-geometric solutions). That duality is investigated in Asmussen and Ramaswami (1990) and Ramaswami (1990a).

The class of models with an imbedded Markov renewal process of M/G/1-type is very rich. It is useful in the analysis of many queueing models in continuous or discrete time that arise in communications engineering and other applications. In queueing theory, results for a variety of classical models have been extended to versatile input processes and to semi-Markovian services. These generalizations often lead to natural matrix generalizations of familiar formulas. For a discussion of what happens to the M/G/1 model when the input is changed to a Markovian arrival process (MAP — as more precisely presented in a subsequent section), see Lucantoni (1993). A treatment of cycle maxima for the MAP/G/1 queue is found in Asmussen and Perry (1992). A mathematically rigorous discussion of the complex analysis aspects of the models of M/G/1-type is found in Gail, Hantler, and Taylor (1994). Asymptotic results on the tail probabilities of queue length and waiting time distributions are discussed in Abate, Choudhury and Whitt (1994), and Falkenberg (1994).

Matrix-Geometric Solutions

Under ergodicity conditions, discrete-time Markov chains with transition probability matrix $\boldsymbol{P}$ of the form

$$\boldsymbol{P} = \begin{bmatrix} \boldsymbol{B_0} & \boldsymbol{A_0} & \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots \\ \boldsymbol{B_1} & \boldsymbol{A_1} & \boldsymbol{A_0} & \mathbf{0} & \mathbf{0} & \cdots \\ \boldsymbol{B_2} & \boldsymbol{A_2} & \boldsymbol{A_1} & \boldsymbol{A_0} & \mathbf{0} & \cdots \\ \boldsymbol{B_3} & \boldsymbol{A_3} & \boldsymbol{A_2} & \boldsymbol{A_1} & \boldsymbol{A_0} & \cdots \\ . & . & . & . & . & \cdots \end{bmatrix},$$

where the $\boldsymbol{A}_k$ are $m \times m$ nonnegative matrices summing to a stochastic matrix $\boldsymbol{A}$, and the $\mathbf{B}_k$ are nonnegative matrices such that the row sums of $\boldsymbol{P}$ are one, have an invariant probability vector $\boldsymbol{x}$ of a matrix-geometric form. That is, the unique probability vector $\boldsymbol{x}$ which satisfies $\boldsymbol{xP} = \boldsymbol{x}$, can be partitioned into row vectors $\boldsymbol{x}_i$, $i \geq 0$, which satisfy $\boldsymbol{x}_i = \boldsymbol{x}_0 \boldsymbol{R}^i$. The matrix $\boldsymbol{R}$ is the unique minimal solution to the equation

$$\boldsymbol{R} = \sum_{k=0}^{\infty}\boldsymbol{R}^k\boldsymbol{A}_k,$$

in the set of nonnegative matrices. All eigenvalues of $\boldsymbol{R}$ lie inside the unit disk. The matrix,

$$\boldsymbol{B}[\boldsymbol{R}] = \sum_{k=0}^{\infty}\boldsymbol{R}^k\boldsymbol{B}_k,$$

is an irreducible stochastic matrix. The vector $\boldsymbol{x}_0$ is determined as the unique solution to the equations

$$\begin{cases} \boldsymbol{x_0} = \boldsymbol{x_0}\boldsymbol{B}[\boldsymbol{R}] \\ 1 = \boldsymbol{x_0}(\mathbf{1} - \boldsymbol{R})^{-1}\boldsymbol{e} \end{cases}$$

where $\boldsymbol{e}$ is the column m-vector with all components equal to one. If the matrix $\boldsymbol{A}$ is irreducible and has the invariant probability vector $\boldsymbol{\pi}$, the Markov chain is positive recurrent if and only if

$$\boldsymbol{\pi} \sum_{k=1}^{\infty} k\boldsymbol{A}_k \boldsymbol{e} > 1.$$

Analogous forms of the matrix-geometric theorem hold for Markov chains with a more complicated behavior at the boundary states and for continuous Markov chains with a generator $\boldsymbol{Q}$ of the same structural form. A comprehensive treatment of the basic properties of such Markov chains and a variety of applications is given in Neuts (1981).

This result has found many applications in queueing theory. The subclass where the matrix $\boldsymbol{P}$ or the generator $\boldsymbol{Q}$ are block-tridiagonal are called quasi-birth and death (QBD) processes. These arise naturally as models for many problems in communications engineering and computer performance. The matrix-geometric form of the steady-state probability vector of a suitable imbedded Markov chain leads to explicit matrix formulas for other descriptors of queues, such as the steady-state distributions of waiting times, the distribution of the busy period and others.

In addition to its immediate applications, this construct has also generated much theoretical interest. Its generalization to the operator case was established in Tweedie (1982).

The largest eigenvalue η of the matrix $\boldsymbol{R}$ is important in various asymptotic results. Graphs of η as a function of a parameter of the queue are caudal characteristic curves. Some interesting behavioral features of the queues can be inferred from them (Neuts and Takahashi 1981; Neuts 1986a; Asmussen and Perry 1992). A matrix-exponential form for waiting-time distributions in queueing models was obtained in Sengupta (1989). Its relation to the matrix-geometric theorem was discussed in Ramaswami (1990b). A matrix-analytic treatment, covering all cases of reducibility, of the equation for $\boldsymbol{R}$, is given in Gail, Hantler and Taylor (1994).

The matrix $\boldsymbol{R}$, which is crucial to all applications of the theorem, must be computed by an iterative numerical solution of the nonlinear matrix equation

$$\boldsymbol{R} = \sum_{k=0}^{\infty} \boldsymbol{R}^k \boldsymbol{A}_k$$

A major survey and comparisons of various computational methods is found in Latouche (1993). For the block tri-diagonal case (*QBD*-processes), a particularly efficient algorithm was developed by Latouche and Ramaswami (1993).

Markovian Arrival Processes

The analytic tractability of models with Poisson or Bernoulli input is due to the lack-of-memory property, an extreme case of Markovian simplification. At the expense of performing matrix calculations, more versatile arrival processes can be used in a variety of models. The Markovian arrival process (MAP) is a point process model in which only one of a finite number of phases must be remembered to preserve many of the simplifying Markovian properties. It can be incorporated in many models which remain highly tractable by matrix-analytic methods. The MAP has found many applications in queueing and tele-traffic models to represent bursty arrival streams. Many queueing models for which traditionally Poisson arrivals were assumed are also amenable to analysis with MAP input.

It was first introduced in Neuts (1979), but a more appropriate notation was proposed by David Lucantoni in conjunction with the queueing model discussed in Lucantoni, Meier-Hellstern, and Neuts (1990). Although discrete-time versions of the MAP, as well as processes with group arrivals have been defined, their discussion requires only more elaborate notation than the single-arrival MAP in continuous time described here. Expositions of the basic properties and many examples of the MAP are found in Neuts (1989, 1992) and Lucantoni (1991).

Consider an irreducible infinitesimal generator $\boldsymbol{D}$ of dimension m with stationary probability vector θ. Write $\boldsymbol{D}$ as the sum of matrices $\boldsymbol{D}_0$ and $\boldsymbol{D}_1$, where $\boldsymbol{D}_1$ is nonnegative and $\boldsymbol{D}_0$ has nonnegative off-diagonal elements. The diagonal elements of $\boldsymbol{D}_0$ are strictly negative and $\boldsymbol{D}_0$ is nonsingular. Consider an m-state Markov renewal process $\{(J_n, X_n), n \geq 0\}$ in which each transition epoch has an associated arrival. Its transition probability matrix $\boldsymbol{F}(\cdot)$ is given by

$$\boldsymbol{F}(x) = \int_0^x \exp(\boldsymbol{D}_0 u) du \boldsymbol{D}_1, \quad \text{for } x \geq 0.$$

The most familiar MAPs are the *PH*-renewal process and the Markov-modulated Poisson Process (MMPP). These, respectively, have the pairs of parameter matrices $\boldsymbol{D}_0 = \boldsymbol{T}$, $\boldsymbol{D}_1 = \boldsymbol{T}^{o}\alpha$, where $(\alpha, \boldsymbol{T})$ is the (irreducible) representation of a phase-type distribution and the column vector $\boldsymbol{T}^{o} = -\boldsymbol{T}\boldsymbol{e}$, and $\boldsymbol{D}_0 = \boldsymbol{D} - \boldsymbol{\Lambda}$, $\boldsymbol{D}_1 = \boldsymbol{\Lambda}$, where $\boldsymbol{\Lambda}$ is a diagonal matrix and $\boldsymbol{e}$ is the column m-vector with all components equal to one.

The matrix-analytic tractability of the MAP is a consequence of the matrix-exponential form of the transition probability matrix $\boldsymbol{F}(\cdot)$. It, in turn, follows from the Markov property of the underlying chain with generator $\boldsymbol{D}$, in which certain transitions are labeled as arrivals. A detailed description of that construction is found in Lucantoni (1991).

The initial conditions of the MAP are specified by the initial probability vector $\boldsymbol{\gamma}$ of the underlying Markov chain with generator $\boldsymbol{D}$. Taking $\boldsymbol{\gamma} = \boldsymbol{\theta}$, the stationary probability vector of $\boldsymbol{D}$, leads to the stationary version of the MAP. The rate γ^* of the stationary process is given by $\gamma^* = \boldsymbol{\theta}\boldsymbol{D}_1\boldsymbol{e}$. By choosing $\boldsymbol{\gamma} = (\gamma^*)^{-1}\boldsymbol{\theta}\boldsymbol{D}_1 = \theta_{\text{arr}}$, the time origin is an arbitrary arrival epoch.

Computationally tractable matrix expressions are available for various moments of the MAP. These require little more than the computation of the matrix $\exp(\boldsymbol{D}t)$. A comprehensive discussion of these formulas is found in Neuts and Narayana (1992). For example, the Palm measure, $H(t) = E[N(t) \mid \text{arrival at } t = 0]$, the expected number of arrivals in an interval $(0, t]$ starting from an arbitrary arrival epoch, is given by

$$\boldsymbol{H}(t) = \boldsymbol{\lambda} * t + \theta_{\text{arr}}[\boldsymbol{I} - \exp(\boldsymbol{D}t)](\boldsymbol{e}\boldsymbol{\theta} - \boldsymbol{D})^{-1}\boldsymbol{D}_1\boldsymbol{e}.$$

Other MAPs are constructed by considering selected transitions in Markov chains, by certain random time transformations or random thinning of a given MAP, and by superposition of independent MAPs. Statements and examples of these constructions are found in Neuts (1989, 1992). Specifically, the superposition of two (or more) independent MAPs is again an MAP. If two continuous-time MAPs have the parameter matrices $\{\boldsymbol{D}_k(i)\}$ for $i = 1, 2$, the parameter matrices for their superposition are given by $\boldsymbol{D}_k = \boldsymbol{D}_k(1) \bigotimes \boldsymbol{I} + \boldsymbol{I} \bigotimes \boldsymbol{D}_k(2) = \boldsymbol{D}_k(1) \bigotimes \boldsymbol{D}_k(2)$, for $k \geq 1, 2$, where $\bigotimes$ is the Kronecker pairwise matrix product.

MAUT

► Multi-Attribute Utility Theory

Max-Flow Min-Cut Theorem

For a maximum-flow network problem, it can be shown that the maximum flow through the network is equal to the minimum capacity of all the cuts that separate the source (origin) and the sink (destination) nodes, where the capacity of a cut is the sum of the capacities of the arcs in the cut.

Maximum

A function $f(x)$ is said to have a maximum on a set S when the least upper bound of $f(x)$ on S is assumed by $f(x)$ for some x^0 in S. Thus, $f(x^0) \geq f(x)$ for all x in S.

► Multiple Criteria Decision Making

Measure of Effectiveness (MOE)

In a decision problem, the single objective that is to be optimized is called the measure of effectiveness (MOE). In a linear-programming problem, the MOE is the objective function. In a queueing-theory problem, frequently used MOEs include the expected steady-state queue length and the mean delay in queue.

Memetic Algorithms

Hybrid metaheuristic evolutionary algorithms (EAs) that combine population-based approaches such as genetic algorithms with local search improvement procedures or individual learning. Also known as Baldwinian EAs, Lamarckian EAs, cultural algorithms or genetic local search. Derived from the word "meme" that was coined by the British scientist Richard Dawkins in his book, *The Selfish Gene* (1976), to represent an evolutionary unit for cultural transmission analagous to a gene in biological evolution.

Memoryless Property

For stochastic processes, lack-of-memory is synonymous with the Markov property. For a positive random variable T that models the duration of some phenomenon, lack-of-memory means that the time remaining is independent of the time already passed, i.e., $\Pr\{T > t + s \mid T > s\} = \Pr\{T > t\}$ for $s, t > 0$. The exponential distribution is the only continuous distribution with lack-of-memory, while the geometric distribution is the only discrete distribution with lack-of-memory.

[3]University of Colorado Boulder, Boulder, CO, USA

Introduction

A metaheuristic is a high-level problem-independent algorithmic framework that provides a set of guidelines or strategies to develop heuristic optimization algorithms. The term is also used to refer to a problem-specific implementation of a heuristic optimization algorithm according to the guidelines expressed in such a framework. It combines the Greek prefix meta- (μετά, beyond in the sense of high-level) with heuristic (from the Greek heuriskein or ευρισχειν, to search) and was coined by Fred Glover in 1986.

Most metaheuristic frameworks have their origin in the 1980s (although in some cases roots can be traced to the mid 1960s and 1970s) and were proposed as an alternative to classic methods of optimization such as branch-and-bound and dynamic programming. As a means for solving difficult optimization problems, metaheuristics have enjoyed a steady rise in both use and popularity since the early 1980s. EU/ME – the metaheuristics community – is the EURO-sponsored working group on metaheuristics and the largest platform for communication among metaheuristics researchers worldwide. Conferences and journals devoted to metaheuristics, along with some software, are described at the end of this article.

Different metaheuristics can vary significantly in their underlying foundations. Some metaheuristics mimick a process seemingly unrelated to optimization, such as natural evolution, the cooling of a crystalline solid, or the behavior of animal swarms. Attending such variation is also a striking similarity among some methods that rely on a common foundation. For example, many methods have been proposed (and given different names) that differ in not much more than the metaphor underlying them, which is often a close variant of an original method's metaphor. In this manner, the metaheuristic framework of ant colony optimization, for instance, has spawned a steady stream of different social insect-based methods (using bees, flies, termites, etc.). Most metaheuristic frameworks advise the use of randomness, although some propose completely deterministic strategies. In optimization, metaheuristics are most often used to solve combinatorial optimization problems, although metaheuristics for other problems exist (see below).

One of the defining characteristics of a metaheuristic framework is that the resulting methods are — as the name suggests — always heuristic in nature. Exact methods for combinatorial optimization, such as branch-and-bound or dynamic programming, are subject to combinatorial explosion, i.e., for NP-hard problems the computing time required by such methods increases as an exponential function of the problem size. By relaxing the demand that the optimal solution should be found in a finite (but often prohibitively large) amount of time, optimization methods can be built that attempt to find a solution that is good enough in a computing time that is small enough. However, there are important aspects of metaheuristics that link them more closely with exact methods and that give rise to a number of hybrids that unite these two types of methods. These aspects will be discussed later.

The required quality of a solution and the maximum allowable computing time can, of course, vary greatly across optimization problems and situations. Metaheuristic frameworks, being defined in very general terms, can be adapted to fit the needs of most real-life optimization problems, from the smallest and simplest to the largest and most complex. Additionally, metaheuristics do not put any demands on the formulation of the optimization problem (like requiring constraints or objective functions to be expressed as linear functions of the decision variables), in contrast, for example, to methods for mixed-integer programming. As a result, several

commercial software vendors have implemented metaheuristics as their primary optimization engines, both in specialized software packages for production scheduling, vehicle routing (Sörensen et al. 2008) and nurse rostering (Burke et al. 2004), as well as in general-purpose simulation packages (April et al. 2003; Fu 2002; Glover et al. 1999).

However, the research field of metaheuristics is not without its critics, most of whom attack the perceived lack of a universally applicable design methodology for metaheuristics and the lack of scientific rigor in testing and comparing different implementations. The no free lunch theorems (Wolpert and Macready 1997) state that, when averaged over all problems, all optimization methods perform equally well. This suggests that no single metaheuristic can be considered as a panacea for combinatorial optimization problems, but rather that a lot of problem-specific tuning is necessary to achieve acceptable performance. Moreover, metaheuristics often have a large number of parameters and tuning them is a notoriously difficult process. Consequently, computational testing to compare different metaheuristics is very difficult and often done in an ad-hoc way, rather than by established scientific standards (Barr et al. 1995; Hooker 1995; Rardin and Uzsoy 2001) This has motivated work on self-adaptive metaheuristics that automatically tune their parameters (Cotta et al. 2008; Kramer 2008; Nonobe and Ibaraki 2001, 2002) From an alternative perspective, if a research study identifies parameter values that work well for a selected class of applications — as most studies attempt to do — then for practical purposes other researchers can consider these parameters as being constants (Of course, this doesn't prevent future experimentation from seeking better parameter values.)

Another criticism sometimes levied at metaheuristics concerns the occasional tendency to create overly intricate methods (Michalewicz and Fogel 2004) with many different operators, where the contribution of these operators to the final quality of the solutions found may be poorly understood (Watson et al. 2006). Despite some theoretical results, such as proofs for the convergence of some metaheuristics under special assumptions – usually infinite running time (Eiben et al. 1991; Mitra et al. 1985) – or attempts to explain why genetic algorithms work (such as the heavily criticized Wright et al. (2003) building block hypothesis (Holland 1975)), research papers that attempt to capture the fundamental reasons why metaheuristics work are still few and far between.

Despite these criticisms, the ability to obtain good solutions where other methods fail has made metaheuristics the method of choice for solving a majority of large real-life optimization problems, both in academic research and in practical applications.

Metaheuristic Concepts

Like all optimization methods, metaheuristics attempt to find the best (feasible) solution out of all possible solutions of an optimization problem. In order to do this, they examine various solutions and perform a series of operations on them in order to find different, better solutions.

Metaheuristics operate on a representation or encoding of a solution, an object that can be stored in computer memory and can be conveniently manipulated by the different operators employed by the metaheuristic. Since metaheuristics are most often used to solve combinatorial optimization problems, representations too are generally combinatorial in nature (i.e., they are able to represent only a finite number of solutions). Representations used in the metaheuristics literature are quite diverse (see, e.g., Talbi (2009) for an overview) and range from vector-representations (binary, integer) over permutations to more complex representations such as trees and other graphs. Many metaheuristic algorithms use a combination of different representation types, such as a vector of permutations. Contrary to exact algorithms, metaheuristics do not require the encoding of solutions to be a bijection, i.e., several solutions may share the same encoding and a single solution may be encoded in different ways. Often, an encoding is chosen on the grounds of being convenient to manipulate, although sometimes a time-consuming decoding procedure may be required to obtain the actual solution (such as the encoding used in Prins (2004)).

Although many different metaheuristics have been proposed, their mechanisms for obtaining good solutions primarily operate by manipulating solutions in three ways: by iteratively making small changes to a current solution (local search metaheuristics), by

constructing solutions from their constituting parts (constructive metaheuristics), and by iteratively combining solutions into new ones (population-based metaheuristics). Each of these manipulation mechanisms gives rise to a class of metaheuristic frameworks that are discussed separately below. It is important to note that these classes are not mutually exclusive, and many metaheuristic algorithms combine ideas from each of them. Also, in some instances the transitions from one solution to another are achieved by solving specially generated subproblems.

Local Search Metaheuristics

Local search metaheuristics find good solutions by iteratively making small changes, called moves, to a single solution, called the current solution. The set of solutions that can be obtained by applying a single move to a given solution is called the neighborhood of that solution. In each iteration, a solution from the neighborhood of the current solution is selected to become the new current solution. The sequence of moves defines a trajectory through the search space. Hence, local search metaheuristics are also known under the names of neighborhood search methods or trajectory methods.

For almost all problem representations, different move types can be defined, resulting in different neighborhood structures. The rule used to select the new current solution is called the move strategy or search strategy and determines the aggressiveness of the search. Metaheuristics that use the steepest descent or steepest ascent strategy select the best move from the neighborhood and are often called hill-climbers. Other move strategies include selecting the first move that improves upon the current solution (called the mildest ascent/descent or first-improving strategy), as well as selecting a random improving solution.

In general, the set of allowable moves is restricted to those that result in solutions that are both feasible and improve upon the current solution. Some metaheuristics allow infeasible moves in a strategy that is called strategic oscillation. In this strategy, the search is usually only allowed to temporarily remain in the infeasible region of the search space. A striking example of the utility of this strategy is shown in Glover and Hao (2010).

A solution whose neighborhood does not contain any better solutions is called a local optimum (as opposed to a global optimum, i.e., a best possible solution to the optimization problem). When the current solution is a local optimum, the metaheuristic utilizes a strategy to escape to other regions of the search space. It is this strategy that distinguishes metaheuristics from simple heuristics and from each other. The metaheuristic's name therefore usually refers to the strategy to prevent the search from becoming ensnared within regions whose local optima may be substantially inferior to a global optimum.

The simplest strategy to escape to potentially more fertile regions is to either start the search again from a new, usually random, solution or to make a relatively large change (called a perturbation) to the current solution. These strategies are respectively called multi-start local search (MLS) and iterated local search (ILS) (Lourenco et al. 2003).

A number of metaheuristics define different move types and change the move type used once a local optimum has been reached. The rationale for this strategy is that a local optimum relative to a specific move type can often be improved by performing local search with a different move type. The global optimum on the other hand is a local optimum with respect to every possible move type. Metaheuristics that use this strategy are commonly called variable neighborhood search (VNS) (Mladenović and Hansen 1997) algorithms, but using more than one neighborhood is far more common in the metaheuristics literature and not restricted to algorithms labeled VNS (Sörensen et al. 2008).

Using memory structures is a third commonly encountered way for metaheuristics to avoid remaining trapped in a local optimum and to guide the search in general so as to find good solutions more quickly. Algorithms that use memory structures are commonly grouped under the umbrella term tabu search (Glover 1989, 1990, 1996) algorithms (sometimes also called adaptive memory programming algorithms). Different memory structures may be used to explicitly remember different aspects about the trajectory through the search space that the algorithm has previously undertaken and different strategies may be devised to use this information to direct the search (Glover and Laguna 1993) to promising areas of the search space. Often-used memory structures include the tabu list (from which the name of the metaheuristic

framework derives) that records the last encountered solutions (or some attributes of them) and forbids these solutions (or attributes) from being visited again as long as they are on the list. Some variants record move attributes rather than solution attributes on the tabu list, for the purpose of preventing moves from being reversed. The tabu list is usually organized in a first-in, first-out (FIFO) fashion, i.e., the current solution replaces the oldest one on the list. The length of the tabu list is called the tabu tenure. Frequency memory records how often certain attributes have been encountered in solutions on the search trajectory, which allows the search to avoid visiting solutions that display the most often encountered attributes or to visit solutions with attributes seldom encountered. Such memory can also include an evaluative component that allows moves to be influenced by the quality of solutions previously encountered that contain various attributes or attribute combinations. Other memory structures such as an elite set of the best solutions encountered so far are also common. Another example of the use of memory can be found in a metaheuristic called guided local search (GLS) (Voudouris and Tsang 1999). GLS introduces an augmented objective function that includes a penalty factor for each potential element. When trapped in a local optimum, GLS increases the penalty factor for all elements of the current solution, making other elements (and therefore other moves) more attractive and allowing the search to escape from the local optimum. Similarly, some variants of tabu search use penalties to determine the tabu status of moves, though drawing more strongly on memory.

Contrary to most other local search metaheuristics, simulated annealing uses a random move strategy, emulating the annealing process of a crystalline solid. At each iteration, this strategy selects a random solution x' from the neighborhood of the current solution x and accepts x' as the new current solution with probability $e^{-[f(x')-f(x)]/T}$, where $f(\cdot)$ is the objective function value (to be maximized) of the solution and T is an endogenous parameter called the temperature. The acceptance probability increases as the increase in solution quality is higher (or the decrease is lower). The temperature is initially set to a high value, which leads to higher acceptance probabilities, and then gradually lowered as the search progresses (although it may be increases again at certain moments during the search). The function that describes the evolution of T throughout the different iterations is called the cooling schedule. Simulated annealing was first described in Kirkpatrick et al. (1983), based upon an algorithm by Metropolis et al. (1953).

Relaxation induced local search (RINS) (Danna et al. 2005) is a metaheuristic that constructs a promising neighborhood using information contained in the continuous relaxation of the mixed integer programming (MIP) model of the optimization problem. Because it does not need problem-specific information to construct its neighborhood, RINS can be more easily built into general-purpose MIP solvers [11] and is currently available in the latest versions of LINDO/LINGO and CPLEX. Contrary to other metaheuristics, RINS requires the problem to be formulated as a MIP which makes it less general than other metaheuristics.

Constructive Metaheuristics

Constructive metaheuristics constitute a separate class from local search metaheuristics in that they do not operate on complete solutions, but rather construct solutions from their constituent elements, starting from an empty set and adding one element during each iteration, an operation that is also called a move. After each iteration except the last, the algorithm therefore operates on a partial solution (e.g., a traveling salesperson tour that does not visit all cities), of which it may not be possible to determine the objective function value or the feasibility status. Constructive metaheuristics are often adaptations of greedy algorithms, i.e., algorithms that add the best possible element at each iteration, a myopic strategy that may result in suboptimal solutions.

GRASP, the acronym for greedy randomized adaptive search procedure (Feo and Resende 1995), uses randomization to overcome this drawback of purely greedy algorithms by adding some randomness to the selection process. Several variants of GRASP have been proposed, founded on the following basic idea. At each iteration, a restricted candidate list, which contains the α best elements that can be added, is updated. From the restricted candidate list, a random element is selected for addition to the partial solution, after which the list is updated to reflect the new situation. The parameter α determines the greediness of the search: if α equals 1, the search is completely greedy, whereas if α is equal to the

number of elements that can be added, the search is completely random. A particularly useful advance in GRASP algorithms has occurred by blending them with the path relinking strategy of tabu search. Notable examples of this approach include Commander et al. (2008); Nascimento et al. (2010); Resende et al. (2010).

Rather that using randomness to outperform a greedy heuristic, more strategic ways of performing constructive (or destructive) moves, once again making use of memory, are examined in Fleurent and Glover (1999); Glover et al. (2000). Another approach is embodied in a look-ahead strategy (Pearl 1984), which evaluates the elements that can be added by considering not only the next move, but several moves into the future. The pilot method (Duin and Voß 1999), for example, uses a (usually greedy) constructive heuristic to determine a pilot solution for each potential move, i.e., the value of a potential element is evaluated by determining the objective function value of the solution that results from applying the heuristic to generate a complete solution from the current partial solution with this element added. The idea of looking ahead has a long history, having been proposed in probing strategies for integer programming in (Lemke and Spielberg 1967).

Ant colony optimization (ACO) (Dorigo et al. 1996, 2006) is an umbrella term for a set of related constructive metaheuristics that build solutions by imitating the foraging behavior of ants. Perhaps because of the appeal of its imagery, this class of approaches has received and continues to receive widespread attention in the popular press (e.g., Anonymous 2010). Ant colony optimization introduces an external parameter for each potential element called the pheromone level (a pheromone is a chemical factor that triggers a social response in the same species), initially set to zero for all elements. The metaheuristic uses multiple parallel artificial agents (called ants) that each construct a solution by an iterative constructive process in which elements are selected based on a combination of the value of that element and its pheromone level. Once all ants have constructed a solution, the pheromone level of all elements is updated in a way that reflects the quality of the solution found by that ant (the elements of better solutions receive more pheromone). Each ant then constructs a new solution, but elements that were present in high-quality solutions will now receive a higher probability of being selected by the ants. Periodically, the pheromone level of all elements is reduced to reflect evaporation. The process of constructing solutions in the way described above is repeated, and the best solution found is reported at the end.

To improve the quality of the final solutions, most constructive metaheuristics include a local search phase after the construction phase.

Population-Based Metaheuristics

The main mechanism that allows population-based metaheuristics to find good solutions is the combination of existing solutions from a set, usually called the population. The fundamental reasoning behind this class of metaheuristics is that good solutions can be found by exchanging solution attributes between two or more (usually high-quality) solutions. The most important members of this class are called evolutionary algorithms because they mimic the principles of natural evolution. Following Michalewicz and Fogel (2004), here the term evolutionary algorithms is used as an umbrella term to encompass the wide range names given to metaheuristics based on evolution. This includes genetic algorithms (Goldberg et al. 1989; Holland 1975), genetic/evolutionary programming (Koza 1992), evolutionary computation (Fogel 2006), evolution strategies (Beyer and Schwefel 2002), and many others. The literature on evolutionary algorithms is larger than that on other metaheuristics, and this field has spawned several dedicated journals and conferences.

Typical of the field of evolutionary algorithms is that its researchers tend to adopt the vocabulary of the metaphor on which the algorithms are based. The descriptions of these algorithms therefore are stated in terms of chromosomes (instead of solutions), fitness (instead of objective function value), genotype (instead of encoding), etc. The driving force behind most evolutionary algorithms is selection and recombination. Selection ensures that predominantly high-quality solutions in the population are selected for recombination, usually by biasing the probability of each solution in the population to be selected towards its objective function value. Recombination utilizes specialized operators to combine the attributes of two or more solutions into new ones. The new solutions are then added to the population by a process called

reinsertion, possibly subject to feasibility or minimum quality demands, to replace (usually low-quality) solutions. In a large majority of cases, all operators (selection, recombination and reinsertion) make heavy use of randomness. A large number of evolutionary algorithms additionally include a mutation operator that (again, randomly) changes a solution after it has been recombined. Most evolutionary algorithms iterate the selection, recombination, mutation, and reinsertion phases a number of times, and report the best solution in the population.

Scatter search and path relinking (Glover et al. 2000, 2003) are both population-based metaheuristics for continuous (or mixed-integer) and combinatorial optimization respectively, proposed as a deterministic alternative for the highly stochastic evolutionary algorithms. Scatter search encodes solutions as real-valued vectors (or rounded real-valued vectors for integer values) and generates new solutions by considering convex or concave linear combinations of these vectors. Path relinking, on the other hand, generalizes this idea, making it applicable to combinatorial optimization problems, by generating paths between high-quality solutions. Paths consist of elementary moves such as the ones used in local search metaheuristics and essentially link one solution (called the initiating solution) to a second solution (called the guiding solution) in the solution space. Contrary to local search metaheuristics, path relinking uses a move strategy that chooses the move to execute based on the fact that this move will bring the solution closer to the guiding solution. In both scatter search and path relinking, the selection of both initiating and guiding solution from a population (called the reference set) is done in a deterministic way, as are the mechanisms for updating the reference set once new solutions have been generated.

Hybrid Metaheuristics

Metaheuristics that combine aspects or operators from different metaheuristics paradigms are called hybrid metaheurstics. The term has lost much of its discriminatory power, however, since such combinations of operators from different metaheuristic frameworks have become the norm rather than the exception. Indeed, there is a tendency in the metaheuristics research field to look at metaheuristics frameworks as providing general ideas or components to build optimization algorithms, rather than to consider them as recipes that should be closely followed (Michalewicz and Fogel 2004). In this spirit, many metaheuristics use specialized heuristics to efficiently solve subproblems produced by the metaheuristic method (e.g., Gendreau et al. 1994). Also, a large number of local search metaheuristics use a construction phase to find an initial solution (or a set of initial solutions) from which to start the neighborhood search. In fact the original description of the GRASP metaheuristic (Feo and Resende 1995) prescribes a local search phase to follow the greedy randomized construction phase.

Memetic algorithms (Moscato 1989) are the only class of hybrid metaheuristics that has been given a specific name. Metaheuristics belonging to this class combine recombination operators from the class of evolutionary algorithms with local search (meta) heuristics. Although the name is commonly used, many evolutionary algorithms either replace or complement their mutation operator with a local search phase and can also be considered memetic.

Metaheuristics and Exact Methods

A more recent development has been a special focus on combining ideas from different metaheuristics, usually local search, with exact methods such as branch-and-bound or branch-and-cut. Sometimes called matheuristics, the resulting method usually integrates existing exact procedures to solve subproblems and guide the higher-level heuristic (Dumitrescu and Stützle 2009; Raidl and Puchinger 2008). In a similar way, ideas and operators from constraint programming techniques are integrated with metaheuristics (Van Hentenryck and Michel 2009). The links between metaheuristics and exact methods provide examples of additional forms of combinations:

1. There exist exact methods for solving various special classes of optimization problems, such as linear programming and certain graph (or matroid) problems, that can be incorporated to solve subproblems produced by a metaheuristic method. Such subproblems can be generated by a decomposition strategy, a restriction strategy or a relaxation strategy (see Glover and Klingman (1988); Rego (2005)).
2. Exact methods for more complex problems can sometimes solve small instances of these problems effectively. A metaheuristic may operate by constructing collections of such small instances as

a strategy for generating structured moves that transition from a given solution to a new one (see, e.g., Glover (2005)).
3. An exact method can be run for a very long time to obtain optimal solutions (to at least some instances of a problem class), and these optimal solutions can be used in the learning approach called target analysis (Glover 1990; Glover and Laguna 1997) as a way to produce improved decision rules for both metaheuristics and exact methods.
4. Metaheuristics can be integrated with exact methods to improve the performance of the exact methods (Friden et al. 1989; Glover 1990; Puchinger et al. 2009).
5. By not demanding that the optimal solution be found, metaheuristics can, for example, employ a truncated optimization method in place of (or in conjunction with) generating subproblems that are structured to be easier to solve.

Metaheuristics for Different Optimization Problems

Continuous Optimization

Although metaheuristics are predominantly used for combinatorial optimization, many of them have been adapted for continuous optimization. Some metaheuristics are very naturally defined over continuous search spaces. Notable examples include scatter search (Glover et al. 2000), particle swarm optimization (Kennedy et al. 1995) and an evolutionary approach called differential evolution (Storn and Price 1997). Other, especially constructive and local search approaches, require a considerable adaptation from their original formulation. Nonetheless, algorithms for continuous optimization based on tabu search (Chelouah and Siarry 2000; Glover 1994), GRASP (Hirsch et al. 2007), variable neighborhood search (Liberti and Drazič 2005), and others, have been proposed.

Multi-objective Optimization

Many real-life problems have multiple objectives, for which the notion of optimality is generally replaced with the notion of dominance. A solution is said to dominate another solution if its quality is at least as good on every objective and better on atleast one. In multi-objective optimization, the set of non-dominated solutions is called the Pareto set and the projection of this set onto the objective function space is called the Pareto front or Pareto frontier. The aim of multi-objective metaheuristics, i.e., metaheuristics specifically designed to solve multi-objective optimization problems, is to approximate the Pareto front as closely as possible (Zitzler et al. 2004). The outcome of any multi-objective algorithm is therefore generally a set of mutually non-dominated solutions, the Pareto set approximation. To measure the quality of such an approximation, many different measures exist (Jaszkiewicz 2004). Although adaptations to the multi-objective paradigm of both tabu search and simulated annealing exist (Czyżak et al. 1998; Hansen 1997), most multi-objective metaheuristics are of the evolutionary type (Jones et al. 2002), a fact generally attributed to the observation that these algorithms naturally operate on a set of solutions. Evolutionary multi-objective metaheuristics include the vector evaluated genetic algorithm (VEGA) (Schaffer 1985), the non-dominated sorting algorithm (NDSA) (Srinivas and Deb 1994), the multi-objective genetic algorithm (MOGA) (Fonseca and Fleming 1993) and the improved strength pareto evolutionary algorithm (SPEA2) (Zitzler and Thiele 1999).

Stochastic Optimization

Stochastic combinatorial optimization problems include uncertain, stochastic or dynamic information in their parameters. Metaheuristics for such problems therefore need to take into account that the objective function value is a random variable and that the constraints are violated with some probability. Evaluating a solution's objective function value and/or its feasibility can be done either exactly (if a closed-form expression is available), by approximation or by Monte Carlo simulation. Metaheuristicsusing each of these possibilities have been proposed to solve different stochastic problems (Bianchi et al. 2009; Ribeiro and Resende 2010).

Research in Metaheuristics

Conferences

The premier conference on metaheuristics is MIC, the Metaheuristics International Conference.

Other conferences on metaheuristics include the yearly EU/ME meeting on a specific metaheuristics-related topic, organized by EU/ME in collaboration with a local research group, and the Hybrid Metaheuristics conference series that focuses on combinations of different metaheuristics and the integration of AI/OR techniques. The Learning and Intelligent Optimization conferences aim at exploring the boundaries between machine learning, artificial intelligent, mathematical programming and algorithms for optimization.

A large number of conferences focus exclusively on evolutionary algorithms, including Parallel Problem Solving From Nature (PPSN), the Genetic and Evolutionary Computation Conference (GECCO), EvoStar (a multi-conference comprising EuroGP, EvoCOP, EvoBIO,and EvoApplications), Evolutionary Multi-Criterion Optimization (EMO), and the IEEE Congress on Evolutionary Computation (CEC).

The Ants conference series is dedicated to research in swarm intelligence methods.

Journals

The field of metaheuristics has several dedicated journals: the well-established *Journal of Heuristics* and the newer *International Journal of Metaheuristics* and *International Journal of Applied Metaheuristic Computing* (IJAMC). However, a large majority of articles on metaheuristics are published in general OR/MS journals.

Several journals are devoted exclusively to evolutionary algorithms: *Evolutionary Computation*, *IEEE Transactions on Evolutionary Computation*, *Genetic Programming and Evolvable Machines*, and the *Journal of Artificial Evolution and Applications*.

The journal *Swarm Intelligence* is currently the main journal for advances in the swarm intelligence area.

Metaheuristics Software

Several vendors of commercial optimization software have included (albeit to a limited extent) metaheuristics in their packages. Frontline Systems' Risk Solver Platform and its derivatives, an extension of the Microsoft Excel Solver, include a hybrid evolutionary solver. Tomlab/GENO is a package for static or dynamic, single- or multi-objective optimization based on a real-coded genetic algorithm. Both LINDO/LINGO and CPLEX include the relaxation induced neighborhood search (RINS) metaheuristic.

Open source metaheuristics software frameworks have recently appeared in the COIN-OR library. These include METSlib, an object oriented metaheuristics optimization framework, and Open Tabu Search (OTS), a framework for constructing tabu search algorithms.

Besides these solvers for combinatorial optimization, most commercial (stochastic) simulation packages today include an optimization tool (Fu 2002). Autostat, included in AutoMod, and Simrunner, included in ProModel, both use evolutionary algorithms. A variety of companies in the simulation industry, as well as general management service and consulting firms like Rockwell Software, Dassault Systemes, Flextronics, Halliburton, HP, Planview and CACI, employ OptQuest, which uses tabu search and scatter search.

Metamodeling

For simulation models, the objective is to provide an explicit input-output relationship through a fitted mathematical function, e.g., using statistical regression, splines, neural networks, or kriging. Differs from the use of the term in computer science.

► Simulation Metamodeling

Method of Stages

An analysis method that extends the birth-and-death-type analysis to queueing systems with Erlangian service or interarrival times. Since an Erlang random variable can be represented as the sum of independent and identically distributed exponential random variables, the method of stages increases the state space to coincide with the underlying exponential random variables and the resulting system of equations is generally solved using generating functions.

Military Operations Other Than War

Dean S. Hartley III
Oak Ridge National Laboratory, Oak Ridge, TN, USA

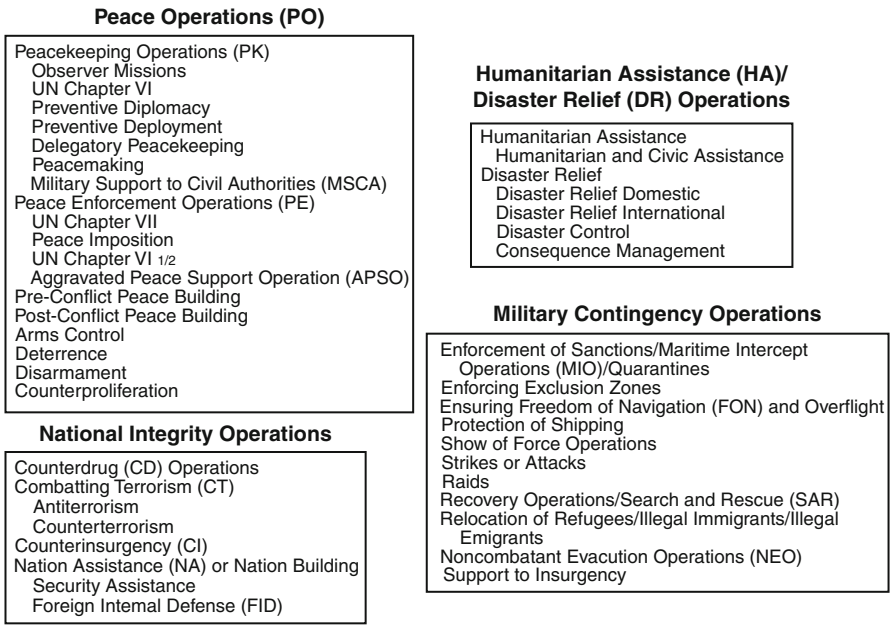
Introduction

Operations Other Than War (OOTW) suffer from an identity crisis. Sometimes called Military Operations Other Than War (MOOTW), sometimes known as Low Intensity Conflict (LIC), sometimes called Stability Support Operations (SSO), and sometimes designated as Small Scale Contingencies (SSC), these operations have caused both theoretical and practical problems for the military.

- These operations range in size from airlifting several fire trucks from Tennessee to Florida to fighting the 1998 Summer fires to the Bosnia Peacekeeping operation involving tens of thousands of U.S. military personnel and tens of thousands of other nations' military personnel, hardly a small-scale contingency.
- They include operations to provide stability to foreign countries, such as Haiti; however, they also include support to insurgencies, a "stability support operation" only in the negative.
- They include Non-combatant Evacuation Operations (NEOs) in which armed force may be needed to support the evacuation; they include operations such as Somalia that result in a number of U.S. military deaths in combat, low intensity conflict providing cold comfort to families of the dead; and they include operations such as fire-fighting that can be defined as conflict only by stretching the definition.

These operations cannot even be distinguished from other operations by time frame or geographic impact:

- Their time span ranges from the one-day cruise missile strike against Iraq to the 17-year peacekeeping operation in the Sinai (or the 45-year peacekeeping operation in Korea).
- Their geographic impact ranges from the purely local issues of disaster relief in Hawaii for Typhoon Iniki to the global geopolitical concerns stirred by peacekeeping in Bosnia.



Military Operations Other Than War, Fig. 1 Types of OOTW

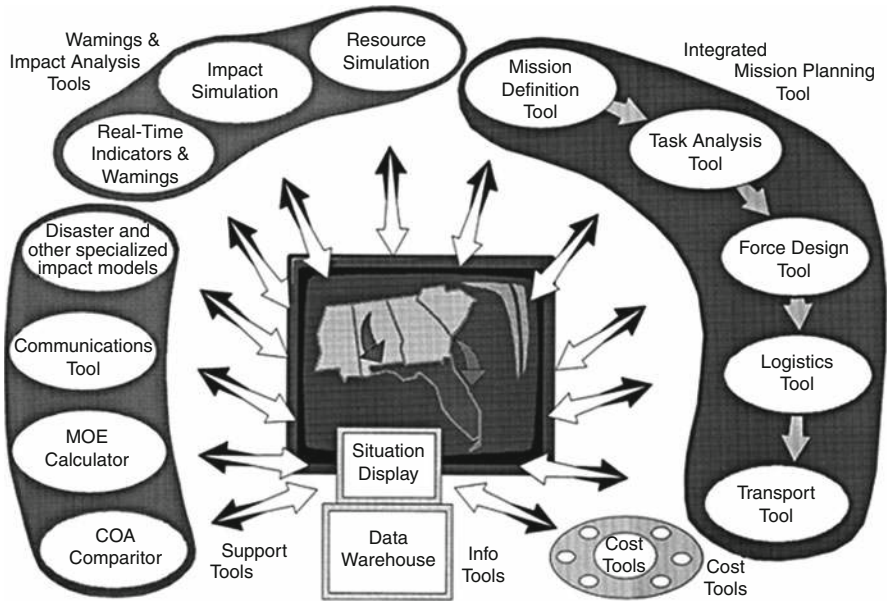
Clumsy as the OOTW designation may be, it is accurate: operations (as opposed to training activities) that are not war are included and operations that are part of a war are not included. Strictly speaking, the people who are using the designation are Department of Defense people and the operations so designated are military operations, leading to a preference for the term MOOTW; however, henceforth the shorter term OOTW will be used, because most of these operations are not led by the military, but by the State Department or some other agency. Figure 1 organizes OOTWs into categories.

The discussion of OOTWs suffering from an identity crisis is more than just a pleasant exercise in rhetoric. The underlying diversity of activities subsumed in the category creates a problem in defining standing operating procedures (SOPs) for dealing with them. The subordinate role of the military creates problems in planning for and executing them. The variability of participation of other federal agencies, other governments, the United Nations, non-governmental organizations (NGOs), and private volunteer organizations (PVOs) exacerbates the problem. Their ad hoc nature means that they are not included in the military's budget; the accounting systems are not designed to capture the costs; and recovering the resulting costs is problematic. These problems would be less troublesome if OOTWs were infrequent; however, since 1990 they have been undertaken at a rate of 20–35 per year! Over the past several years, there has been an increasing recognition of the need for analysis tools to support military planning and execution of OOTWs. Analysis tools to support decision making for large-scale military combat operations (such as major regional contingencies) are relatively mature (Battle Modeling). In contrast, OOTW analysis tools are embryonic or non-existent. The increasing U.S. military involvement in OOTWs during the post-Cold-War era has led to the need to develop OOTW analysis tools.

Questions

The analytical requirements are characterized by the questions that must be answered. The questions fall into five groups:

- Those that are non-mission-related (e.g., what force structure, equipment and plans are needed for the future?).
- Those that support a decision to engage (or not to engage) in a mission (e.g., what impacts will an OOTW have on other operations and how much will it cost?).



Military Operations Other Than War, Fig. 2 OOTW Analysis tool category

- Those needed to plan a mission (e.g., what is the right force structure and what transport support will we provide to reporters, NGO/PVOs, etc.?).
- Those that occur during a mission (e.g., which course of action will most quickly accomplish the mission?).
- Those related to the termination of a mission (e.g., how do we define success and what are its Measures of Effectiveness (MOEs)?).

The question groups are identical to the question groups for combat analysis. Most of the individual questions are also identical. In general, the analysis techniques required to answer the questions are the same. The problem lies in the application: standard applications make assumptions that are valid for combat analysis and invalid for OOTW analysis.

The question of force structure for a mission provides a simple example of the difference between combat analysis and OOTW analysis. For a combat mission, combat troops and equipment are determined first and the balance of the force structure is composed of the troops and materiel required to support them. Analysis procedures and tools are structured to support this situation. For an OOTW, however, the primary forces may be engineers for disaster reconstruction, medical personnel for disease control, some other support function, or combat troops, depending on the particulars of the mission. The implied force structure consists of the troops and materiel to support these forces and may (or may not) include combat troops to protect them. Not only are combat analysis procedures and tools set up backwards for OOTW analysis, but also OOTW analysis involves multiple possible permutations, requiring significantly more flexibility.

Nature of The Analysis Tools

Generally, the desirable tools are decision support tools, are simple (e.g., menu driven, point and click), are deployable, are joint (multi-service), are rigorous, use non-parochial data, have available data, and are capable of rapid turnaround. Analysis tools range from complex simulations of political, economic, sociological, military interactions to database tools, to spreadsheets, to checklists, with the emphasis on small tools. Figure 2 shows the categories of OOTW analysis tools.

Warnings and Impact Analysis Tools

These tools are among the most difficult (scientifically) to create, but are essential to the analysis of OOTWs. Three tools are included in this group.

- The real-time indicators and warnings tool serves to filter and interpret world news in the light of

possible future OOTWs: there are several attempts being made to create such a tool, such as the Protocol for the Assessment of Nonviolent Direct Action (PANDA) (Bond and Vogele 1995).

- The impact simulation models the significant relationships included in and surrounding an OOTW to permit prediction of the results of actions, whether human or environmental: the commercial computer game, Sim City™, is an example of an impact simulation. Unfortunately, the nature of social interactions is a matter for debate and consequently the proper mathematical expressions of these interactions and the best methods for modeling them are undecided. While at least two candidate simulations exist, Spectrum (National Simulation Center 1996) and the Deployable Exercise Support system/Civil Affairs Module (DEXES/CAM) (Woodcock 1996), these are regarded with some misgivings by working analysts, apparently because of lack of transparency or because they are used for training. The Situational Influence Assessment Module (SIAM) uses another technique to address social interactions. It is an influence diagram-based model, not a simulation model, but may be useful in this category.
- The resource simulation models the changes in resource consumption and sequestration over the course of an OOTW: this need may well be satisfied by the Joint Warfare Simulation (JWARS).

Integrated Mission Planning Tool

The five separate tools that comprise this group should ultimately be seamlessly integrated, although the initial integration may be loose. Each tool feeds its successor, while permitting reentry for iterative planning. These tools are relatively simple (scientifically); however, to be useful in an OOTW context, they require careful definition with respect to applicability to joint, coalition (multi-country) and non-military component analysis. The tools are a mission definition tool, a task analysis tool, a force design tool, a logistics tool, and a transportation tool.

- The mission definition tool should provide a reality check to ensure that the complete implications of the mission are fully understood. The Conceptual Model of Peace Operations (CMPO), a peace operations influence diagram-based checklist, is an example (Davis 1996).
- The object of the task analysis tool is to support an accurate and complete analysis of the mission tasks. The tool needed is a decision support tool that connects missions to strategies to tasks, both explicit and implied, in the OOTW domain. It should identify both those tasks that are central to the mission and any contingent tasks that might be implied by reasonable shifts in mission definition. It should also support replanning as the situation changes. Lidy (1998) has produced the data to support such a tool.
- The object of the force design tool is to support the designation of U.S. forces required for an operation in an OOTW context. The tool needed is a decision support tool that connects the tasks to generic resources and connects generic resources to actual available resources, including U.S. military, U.S. non-military, foreign government, NGO/PVO, and contractor resources. Data requirements include task capability for all resources (or the facility for user input of unique resources) and availability data (based on reserve commitments, etc.). It should provide for restrictions on choices based on cultural issues. Processing should include selection of military resources and substitution of other resources. The tool should also support replanning as the situation changes.
- The object of the logistics analysis tool is to support the logistics analysis of the mission in an OOTW context. The tool needed is a decision support tool that derives the logistics requirements from the total force structure. It should allow for supply from outside sources and provide for supply of non-military personnel. It should support replanning as the situation changes. Recent work has investigated the availability and utility of existing tools of this type (Brundage et al. 1998).
- The object of the transport analysis tool is to support the transportation analysis for mission arrival, sustainment, and departure in an OOTW context. The tool needed is a decision support tool that plans the transport requirements, based on all appropriate constraints. It must support replanning when the situation changes after some transport has been accomplished. The Joint

Flow and Analysis System for Transportation (JFAST) and the Model for Intertheater Deployment by Air and Sea (MIDAS) are examples of this type tool.

Support Tools

This group contains three specific tools and a cluster of several tools related by type. The *COA* comparitor permits the development of courses of action (COAs) through several levels of alternatives: an influence diagram/decision tree methodology would support this type analysis. The MOE calculator supports the calculation and tracking of MOE values. The communications tool supports planning the communications system within the complex context of OOTWs. The cluster of disaster impact tools (e.g., hurricanes, volcanoes, earthquakes, fires, and nuclear accident) supports the estimate of the situation in several technical areas, such as engineering and health. The Consequence Assessment Tool Set (CATS) supports some of these functions.

Cost Models

Seven tools make up this group. Their object is to calculate the cost information for various aspects of OOTWs: incremental costs of notional OOTWs, to support long-term analysis; probable incremental costs, to support the decision on engaging in a particular OOTW; relative (full) costs, to support the selection of the mission plan; costs incurred, to support cost recovery from other U.S. agencies and from foreign organizations and governments; incremental costs of a particular OOTW, to support the Congressional Budget process; costs of a particular OOTW, including equipment depreciation, readiness losses, increased reserve recruitment and training costs, and perhaps other costs, to support future acquisition, budgeting and training decisions; and actual costs of a completed OOTW, to support improved estimates of future operations and reports to Congress on actual costs. Work is underway to address analysis tools (Institute for Defense Analyses 1998; Hartley and Packard 1998b).

Information Tools

There are two tools in this category. The situation display presents the information concerning the situation in a manner designed to maximize understanding: the Virtual Information Center (VIC) project represents a first attempt at creating this type tool (Sovereign 1998). The data warehouse either stores or provides links to (as appropriate) all pertinent data. The data and their useability are critical to good analysis in the OOTW domain, as well as in the combat domain. However, the data required for OOTW analysis and the display requirements are in an embryonic state when compared to the state of affairs of combat analysis.

Tool Definition Process

Analysis of OOTWs is a new field and is in a state of flux. The first concerted effort to address the need for analytic tools is documented in Hartley (1996). Follow-on efforts are documented in Staniec (1998), Hartley and Packard (1998a), Brundage et al. (1998), Lidy (1998), Sovereign (1998), Hartley and Packard (1998b), and Hartley and Packard (1999).

Military Operations Research

Brian R. McEnany and Robert S. Sheldon
Military Operations Research Society (MORS), Alexandria, VA, USA

Introduction

To say that Military Operations Research (MOR) is the application to military operations of the methods of operations research (OR) is strictly correct, but gives only one clue to understanding the subject. The MOR accomplishments in World War II, sketched below, pioneered and greatly influenced the early development and institutionalization of operations research generally. Also, they led to the continuation of MOR after the war, in the governments of World War II participants, in academia, in industry, in not-for-profit think tanks, and its adoption in similar institutions of other nations. The emphasis in this article is on practice and trends in the United States, with particular emphasis on the Army.

The general methods of OR apply in particular to many aspects of military applications. Such differences as exist pertain mainly to the needs of military security and classification procedures, the nature of military operations and equipment, and the concerns of strategy, operational art, and tactics that relate to the use of military forces as instruments of national policy.

Current developments in the field are described in the quarterly bulletin *Phalanx* and the journal *Military Operations Research* published by the Military Operations Research Society (MORS) and the Military Applications Society (MAS) of INFORMS. MORS also conducts annual classified symposia, as well as smaller mini-symposia and workshops (some unclassified), from which they publish proceedings and monographs.

World War II MOR Accomplishments

Although there were individual contributions to the scientific study of military operations, ranging from Archimedes to the work of Thomas A. Edison in World War I, it was in World War II that MOR became widespread and institutionalized. Solandt (1955) recalled that MOR began in the services in England as operational research in the early days of the war. The British work centered about different subjects depending on the service: in the Air Force it was the problem of how to use radar, in the Navy it was the problem of anti-submarine warfare, and in the Army it was first limited to anti-aircraft problems and again centered around radar. Professor Blackett is sometimes said to have started the work in all three services, and his account in Blackett (1962) drew on earlier papers to describe both results and methods.

Schrader (2006) describes the organization and use of OR by the U.S. Army from WWII until 1995. His detailed account of how and where OR was used represents a definitive study of the U.S. Army's use of OR in peace and war, and much of what is summarized here is based on his writings.

Cooperation between the United States and Britain over the use of OR did not begin immediately during WW II. British liaison teams visited the U.S., but it was not until late in 1940, just after the fall of France, that President Roosevelt authorized the creation of the National Defense Research Committee (NRDC) and subsequently, the Office of Scientific Research and Development (OSRD) under Professor Vannevar Bush. This office helped recruit, manage and organize the military OR effort in the U.S defense establishment during the war.

While Britain fielded OR teams and detachments with its Army and Navy during the war, only the U.S. Navy and the U.S. Army Air Force (AAF) took full advantage of the new discipline after Pearl Harbor. OR teams of scientists and businessmen, recruited and organized through the OSRD, formed the initial groups. Small detachments were sent to AAF to conduct bombing accuracy studies and assessments of tactics. A useful account of World War II MOR, centering about the AAF, is Brothers (1954). In addition to illuminating examples such as aerial bombing accuracy improvement, it gives valuable guidance on the organization of MOR groups and operating procedures. In World War II, most of the MOR practitioners were civilians (though sometimes in uniform), and they had to earn the trust of military operators over time through useful work. This, of course, is by no means unique to MOR in World War II.

The U.S. Army's Technical Services – the scientific branches (Ordnance Department, the Medical Services, Signal Corps and Chemical Warfare Service) took advantage of the expertise offered by the new multi-disciplinary teams and detachments were deployed in Europe and in the U.S. The Army ground forces, on the other hand, were reluctant to begin using operational analysts (or "Op Annies" as they were called) until 1944. Teams were primarily used to support anti-aircraft weapons development and support to U.S. Army forces in the Pacific area.

The AAF was quick to emulate its British comrades and OR teams were soon supporting the various major Air Force operations in Europe and elsewhere. The Army's technical services were slower, but before the end of the war, studies in support of radar training, development, and organization, signal work load in message centers, transportation scheduling, loading, and handling, as well as some operational studies involving introduction of new equipment and technology to units were undertaken. The ground forces lagged well behind until late in 1944 when OR teams were sent to the Pacific.

At the end of the war, the rapid demobilization of the U.S. Army dissolved its existing teams and organizations as civilian scientists quickly returned to their academic or business careers. The national offices, NRDC and OSRD, were also demobilized, but the newly organized Department of Defense (DoD) created the Weapon Systems Evaluation Group (WSEG) to carry on work begun earlier. The limited use of OR in the Army's decision-making process during the war lagged well behind the other services. In the postwar period, the civilian leadership recognized the benefit provided by the studies and analysis of weapon systems and their development. The ground Army quickly closed the gap in the postwar period.

Early in the post-war period, Morse and Kimball (1946) drew on the work of many early MOR analysts of the Operations Research Group, U.S. Navy, to give results and methods. That work, once it was declassified and slightly modified, was republished in 1951 and was very influential, not only in introducing MOR to future analysts, but also in introducing the potential applications of OR generally to a wider audience. This Morse and Kimball classic was republished by MORS in 1998.

The above work quotes a letter from Admiral King that enumerated helpful MOR applications (suggestive also of the work in other services):

(a) The evaluation of new equipment to meet military requirements.
(b) The evaluation of specific phases of operations (e.g., gun support, anti-aircraft fire) from studies of action reports.
(c) The evaluation and analysis of tactical problems to measure the operational behavior of new material.
(d) The development of new tactical doctrine to meet specific requirements.
(e) The technical aspects of strategic planning.
(f) The liaison for the fleet with the development and research laboratories, naval and extra-naval.

Morse and Kimball also gave some reasons for the emergence in World War II of the practical value of the methods of MOR. As opposed to earlier wars there were the following:

(i) more repetitive operations susceptible to analysis — strategic bombing, submarine attacks on shipping, landing operations, etc.;
(ii) increased mechanization of warfare, in that "... a men-plus-machines operation can be studied statistically, experimented with, analyzed, and predicted by the use of known scientific techniques just as a machine operation can be."
(iii) increasing tempo of obsolescence in military equipment ... When we can no longer have the time to learn by lengthy trial and error on the battlefield, the advantages of quantitative appraisal and planning become more apparent."

Post-War MOR Developments

After World War II ended, a majority of the MOR practitioners returned to non-military pursuits: universities, laboratories, industry, etc. The military services wondered how much MOR would be needed in peacetime. Each decided to institutionalize its use of MOR. An early chapter of Tidman (1984) gives an interesting account of how the Navy chose to continue MOR by establishing the Center for Naval Analysis (CNA) after World War II and by 1948, each service had a different choice or mix of civil service groups, not-for-profit groups, use of industry, etc., and their emphases varied over time. The newly organized U.S. Air Force soon created Project RAND (later RAND Corporation) in 1948 to support its research and development efforts. The newly formed DoD followed suit with establishment of WSEG. Fairly soon, as the Cold War emerged, there was general recognition that it would be necessary to increase the use of MOR. Both Tidman and Schrader appropriately addressed this topic as periods of consolidation and growth in their respective histories.

The Army rapidly demobilized after the war, as stated above, the civilian scientists quickly returned to their jobs and homes. While the Army ground forces quickly inactivated its MOR organizations, the technical services (Ordnance and Signal) retained theirs. By 1948, the Army's leadership created a relationship with John Hopkins University under Dr. Ellis Johnson to form the Operations Research Office (ORO), a relationship that was to last for 13 years. World War II had seen the introduction of radar, atomic weapons, cruise missiles, and ballistic missiles, but each type was still improving rapidly at war's end. Their implications for, and fuller integration into, military forces needed more thought. The Cold War climate also provided a sense of urgency, and MOR offices took on these problems as important foci of effort. The growing Cold War with the Soviet Union forced the Army to address more than just weapons design and tactical doctrine. ORO soon began addressing areas well beyond weapons development – entering international politics, economics, national policy and global strategy while the technical services and newly organized field force boards maintained their focus on weapons development. Several key MOR organizations were created – ORO, Combat Operations Research Group (CORG), the Human Resources Research Organization (HumRRO), and Special Operations Research Office (SORO) dealing with psychological operations. Computer modeling of complex systems met increased need to process large quantities of data. At Headquarters, Department of the Army (HQ DA), the Strategic Tactics and Analysis Group (STAG) was formed to study force structure and future forces capability through gaming and simulation. The increasing use of MOR in the combat development process fostered a need for increased numbers of military officers with MOR training and a formal Operations Research/Systems Analysis (ORSA) specialty program was created in 1967 to satisfy the growing need to form in-house MOR capabilities as the Army moved toward a competitive contractual arrangement with various commercial and academic analytic groups. The Research Analysis Corporation (RAC) took over as the primary research arm of the Army staff in 1963 while primary research efforts were funneled into academia through the Army Research Office (ARO) at Duke University.

Some of the postwar applications of MOR resembled wartime MOR, with combat operations replaced by tests or exercises. With the rise of the Continental Army Command (CONARC), MOR organizations began efforts involving war gaming and field experimentation. As technology increased and problems became more complex, recommendations soon increased the amount of field

experimentation and testing, and by 1956, the first combat development and testing command was created. However, some of the OR (or operations analysis or operations evaluation, as it was often termed) *remained* devoted to operations of supply, logistics, recruiting, and training. Moreover, much of the post-war efforts went into thinking through the implications of new weapons for new types of combat operations. It fostered an atmosphere that led to increased use of digital computing capabilities in war gaming and simulation to help solve increasingly more sophisticated and complex problems.

The Emergence of Systems Analysis

MOR also took on problems at a level higher than that of individual weapon systems or engagements between two opposing weapon systems. Even in a Cold War climate, there were significant limits on national expenditures for armed forces. It was necessary for government to decide "how much is enough" and MOR sought to aid this decision.

Applications of OR at this high level, often termed systems analysis, face difficulties far greater than the difficulties of World War II MOR, significant as the latter were. Wartime combat analysis, sometimes without recognizing it, had already faced criterion problems of sub-optimization, as Hitch (1953) points out. These become still more significant when structuring forces for the future, seeking to be prepared to deal with contingencies still beset with great uncertainty.

Hitch (1955) gives an understanding of the relative difficulty of systems analysis by comparing the World War II problem of improving bomber accuracy with the postwar problems of weapon system development and force composition. In the former problem, difficult as it seemed at the time, known were the types of aircraft involved, how many there were, much about their characteristics, the kind of bombs available, and much about enemy targets and their defenses. These become variables when considering an uncertain future that may sometimes hold a multiplicity of potential opposing forces.

The difficulties are in the problems, as Hitch went on to point out. Despite these difficulties, governments must make decisions and systems analysis, with all of its limitations, has much to offer. MOR analysts developed judgment in cutting problems down to size, and Quade (1954) collected some of the helpful approaches in an influential volume. Quade and Boucher (1968) and Miser and Quade (1988) give refinements and extensions to non-defense analysis.

The Institutionalization and Impact of Systems Analysis

Hitch and McKean (1960) did much to introduce cost-effectiveness studies as instruments of defense systems analysis. In the Kennedy administration in 1961, Secretary of Defense McNamara brought Hitch into the Office of the Secretary of Defense (OSD) as Comptroller to install a system of planning-programming-budgeting (PPB), and Enthoven, as Hitch's assistant, started an office of systems analysis. Although the titles and organizational placement have changed over the years, OSD has continued both PPB and systems analysis.

These new offices had great impact. The government sought to create similar offices in other departments (Bureau of the Budget 1965). Within the DoD, the new OSD offices played an important role in departmental decisions. As its emphasis on, and requests for, quantitative analysis increased, the military services organized and enlarged their MOR offices to meet the demand.

The above developments came at a time when computer capabilities were rapidly increasing. Many MOR offices sought to use the new capabilities in producing cost-effectiveness studies required for systems analysis. Computer simulation models began to proliferate in the effort to understand what new or proposed weapon systems would contribute to the future battlefields. Because this effort contributed to studies with great impact on weapon systems acquisition, it has continued to grow.

Wartime Combat OR in Korea and Vietnam

Although its successes in World War II led service leadership to gradually incorporate MOR into its decision-making process, MOR efforts came to emphasize future weapon system acquisition as described above. For more details of what is summarized here, see Schrader (2008).

KOREA: Right from the beginning, the Army leadership was admonished to deploy MOR teams to Japan and Korea. As in WWII, the analysis of current operations, organizations and tactics were prominent. Increased interest in new organizations, counter-measures, winter operations, clothing, airborne operations, and psychological warfare were undertaken. By the end of 1953, the efforts of the deployed MOR teams had validated WWII experience and demonstrated that MOR could be successfully applied to land warfare. Between Korea and Vietnam, multiple MOR organizations provided analyses and supported the combat development process. Major war gaming and simulation centers were created to study the impact of new weapons, organizations, and future force structure and tactics. Centers grew within The U.S. Army Training and Doctrine Command (TRADOC) at Fort Leavenworth and White Sands to assist in defining new organizations, doctrine and tactics while HQ DA continued to rely upon the successor to STAG, the Concepts Analysis Agency (CAA), to evaluate future force structures. Individual weapons research and evaluation continued to expand at Aberdeen Proving Grounds where the Ballistics Research laboratory (BRL) studied, evaluated, assessed and developed new, improved weapons.

VIETNAM: While a shooting war was underway in Southeast Asia (SEA), the rise of PPB at the Pentagon split Army MOR activities. It developed additional in-house capability to support the centralization of decision-making begun under Secretary McNamara and the Office, Secretary of the Army (OSA). More MOR trained personnel were needed to support the PPB System (PPBS) and a formal specialty program was created in 1967 for military officers. This was coupled with use of civilian contractors and Federally Funded Research and Development Centers (FFRDCs). That is not to say that MOR activities were totally devoted to PPBS. Of particular interest was the lengthy analysis and assessment of the air mobility concept and organization of the air assault division prior to the war in SEA. Multiple organizations, field boards and MOR offices significantly supported the vast testing and experimentation of the air mobility concept.

The war in SEA renewed interest in the study of current operations, battlefield performance of weapons, equipment, organizations and tactics. RAC, the successor to ORO, deployed teams to to collect data along with HumRRO, SORO and Combat Development Command (CDC). HQ Military Assistance Command, Vietnam (MACV) established an in-theater analysis and assessment capability. Quantitative methods were employed extensively at Field Force and Division level. Manually assisted war games were run to help develop alternate strategies and think through potential issues. Efforts were focused upon counter-insurgency operations and suffered from lack of large amounts of quantitative data needed to adequately analyze it. Still, as one division commander noted, the "judicious use of operational analysis and analytic techniques when melded with military judgment were quite effective in improving performance of many activities."

In Chapter I of Hughes (1989), Thomas observed that combat OR both in Korea and later in Vietnam was very similar to that of World War II. Despite the postwar increase in modeling and computer capabilities, it did not make nearly as much contribution in Korea or Vietnam as might have been expected. "Though the menu of available techniques increased with time, much that had been learned in World War II was forgotten and relearned in later conflicts." The 1960s and 1970s were a time of great growth in the analytic community. MOR efforts greatly expanded force planning and management with a commensurate need to expand the number of MOR-trained officer personnel. A whole new set of challenges faced the Army after Vietnam as the MOR community assisted in helping the Army reorganize, revitalize, and reorient itself prior to the First Gulf War.

Contributions After Vietnam and the Gulf War

The period after Vietnam was a time of recovery and reorganization for the U.S. Army (see Schrader 2009 for more details). The multi-year conflict had severely damaged the Army's equipment modernization process and MOR efforts concentrated upon providing the analytic underpinning for major changes in weapon systems, equipment, organizations, doctrine and training. In light of two major studies affecting MOR organizations, competitive contracting was more formalized

(RAC was disestablished) and MOR assets became more concentrated into fewer organizations – CAA, TRADOC Analysis Command (TRAC), the Operational Test and Evaluation Command (OPTEC) and the Army's Material Systems Analysis Agency (AMSAA) ultimately concentrated the efforts of the majority of civilian and military MOR specialists and performed the majority of all studies. MOR became more integrated into the Army's decision-making process as new technology, better weapon systems, and improved organizations were developed. A pyramid of responsibility was formed with CAA at the apex studying force structure and strategy, TRAC focused on battalion to Corps level studies, and AMSAA dealing with individual weapon system analysis.

The end of the Cold War in 1989 presented the Army and the MOR community with entirely new issues – much more complex and demanding that ever before – and MOR support to the material acquisition process became more important. The ever-increasing improvements in technology and computing power brought with it an expanding use of models and simulations to solve the issues facing the Army. This expansion also created issues in validation, verification and accreditation of the analytic tools used to support the decision making process.

During the First Gulf War in 1991, the efforts of 20 years of MOR involvement in conjunction with new organizations, new equipment and weapon systems, new doctrinal, and training improvements, fielded the finest fighting force in the history of the United States. Each of the major organizations actively supported the collection of data. CAA was intimately involved in the evaluation of the forces involved during the planning phase of the operation. War games and separate assessments assisted Army planners and major headquarters in preparing for the deployment and employment of forces. Multiple rapid response assessments – some as short as 12 h – were provided during Operation Desert Shield. Ultimately, a small MOR cell was deployed to support HQ Central Command (CENTCOM), but most MOR efforts were conducted in the continental U.S. (CONUS). The successful military outcome underscored the need for rapid and flexible support to deployed forces with a full range of theater level analysis capabilities.

MOR Lessons from Desert Shield/Desert Storm

The new computer and modeling capabilities seemed to have more impact in MOR for the Gulf War combat of 1991. Vandiver et al. (1992) concluded that while some of its analytic lessons were reminiscent of World War II, and some lessons were probably peculiar to wars like the Gulf War, there were trends indicative of future combat analysis:

- Computer influence on analysis is increasingly varied and pervasive.
- Software analytical tools are increasingly available to all - including non-analysts.
- The demand for good databases is growing more rapidly than the supply.
- There is growing need for coalition and joint service analysis.
- There is increasing analytical interest in operational art and campaign focus.
- There is a need to have MOR teams ready to join, and planning models and simulations in place with deployed forces.
- Teams must be ready to improvise quickly to support ongoing and planned operations in the field.
- There is less danger of central misuse of field analysis and data than formerly. The lessons of better methods of data collection and selection of more accurate measures of effectiveness learned in earlier conflicts have been absorbed by the MOR community.

Concluding Remarks

Although MOR has been a flourishing enterprise with an expanding technological menu, there are still issues to resolve, some long standing. While it is clear that MOR tools and techniques improved the material acquisition process and the PPBS, a significant fraction of the issues relate to modeling and simulation, or are frequently so characterized. Some of the more serious concerns address scientific foundations (including verification and validation); DoD organization and management (including that for MOR); management; filling a perceived need; and taking suitable advantage of technological opportunities.

MIMD

Multiple instruction, multiple data. A class of parallel computer architectures in which each processing element fetches and decodes its own stream of instructions, possibly different from the instruction streams for other processors.

Minimum

A real-valued function $f(x)$ is said to have a minimum on a set S when the greatest lower bound of $f(x)$ on S is assumed by $f(x)$ for some x^0 in S. Thus, $f(x^0) \leq f(x)$ for all x in S.

- ▶ Global Maximum (Minimum)

Minimum (Maximum) Feasible Solution

In a mathematical-programming problem, the solution that both satisfies the constraints of the problem and minimizes (maximizes) the objective function is a minimum (maximum) feasible solution. Such solutions may not be unique.

Minimum Spanning Tree Problem

Given a connected network with n nodes and individual costs associated with all edges, the problem is to find the least-cost spanning trees.

See

- Network Optimization
- Spanning Tree

Minimum-Cost Network-Flow Problem

In a directed, capacitated network with supply and demand nodes, the problem is to determine the flows of a single, homogeneous commodity from the supply nodes to the demand nodes that minimize a linear cost function. In its general form, when the network contains transshipment or intermediate nodes – nodes that are neither supply nor demand nodes – the problem is called the transshipment problem. Conservation of flow through each node is assumed. Due to its special mathematical structure, this problem has a solution in integer flows, given that the data that define the network are integers. It is a linear-programming problem whose major constraints form a node-arc incidence matrix.

Model

An idealized — abstract and simplified — representation of a real-world situation that is to be studied and/or analyzed. Models can be classified in many ways. A mental model is an individual's conceptual, unstated, view of the situation under review; a verbal or written model is a description of one's mental model; an iconic model looks like what it is supposed to represent (e.g., an architectural model of

a building); an analogue model relates the properties of the entity being studied with other properties that are both descriptive and meaningful (e.g., the concept of time as described by the hands and markings of a clock); a symbolic or mathematical model represents a symbolic representation of the process under investigation, e.g., Einstein's equation $E = mc^2$, a linear-programming model, or a computer simulation model.

Model Accreditation

Saul I. Gass
University of Maryland, College Park, MD, USA

Model accreditation is an official determination that a model is acceptable for a specific purpose (Williams and Sikora 1991; Ritchie 1992). Accreditation certifies that the element being accredited meets given standards. For a model, accreditation must be done with respect to the model's explicit specifications and the demonstration that the computer-based model does or does not meet the specifications. This demonstration is the responsibility of the model developers, who must show that their work passes agreed-to user and developer acceptance tests. If the modeling process was done properly and was accompanied by appropriate documentation, accreditation of the model for its specified uses should follow.

Accreditation of a model must rely on a review and evaluation of its available documentation. Such an evaluation, usually done by an independent third-party, is made against various criteria to determine the levels of accomplishment of the criteria, in particular those of verification and validation. The review is made with a specific user and uses in mind. The review should produce a report that gives guidance to the user on whether or not the model in question can be used with confidence for the designated uses, that is, the model is or is not accredited for specific uses (Gass 1993).

The ideas, if not the general process behind model accreditation, have been accepted by modeling agencies within government and private industry, most notably by the U.S. Department of Defense (2009) in the context of modeling and simulation (see also Sargent 2005).

Model Evaluation

Saul I. Gass
University of Maryland, College Park, MD, USA

Model evaluation or assessment is a process by which interested parties, who were not involved in a model's origins, development and implementation, can assess the model's results in terms of its structure and data inputs so as to determine, with some level of confidence, whether or not the results can be used in decision making. Model evaluation encompasses: (1) verification, validation, and quality control of the usability of the model and its readiness for use, and (2) investigations into the assumptions and limitations of the model, its appropriate uses, and why it produces the results it does.

There are three reasons for advocating evaluation of models: (1) for many models, the ultimate decision maker is far removed from the modeling process and a basis for accepting the model's results by such a decision maker needs to be established; (2) for complex models, it is difficult to assess and to comprehend fully the interactions and impact of a model's assumptions, data availability, and other elements on the model structure and results without a formal, independent evaluation; and (3) users of a complex model that was developed for others must be able to obtain a clear statement of the applicability of the model to the new user problem area (Gass 1977a).

All procedures for evaluating a model are basically information gathering activities, with the detail and level of information being a function of the purposes of the assessment and the skills of the assessors. Specific evaluation approaches are given in Gass (1977a, b), Gass (1980), U.S GAO (1979), with an evaluation case study given in Fossett et al. (1991).

A model evaluation procedure and its objectives should be tailored to the scope and purposes of the model and will vary with the model, model developers, assessors, users, and available resources. Model assessment is an expensive and involved undertaking; all models need not be assessed. Model developers and users should recognize that by applying proper modeling management procedures, the burdens that evaluators of models have to contend with are alleviated greatly (Gass 1987).

Model Management

Ramayya Krishnan[1] and Kaushal Chari[2]
[1]Carnegie Mellon University, Pittsburgh, PA, USA
[2]University of South Florida, Tampa, FL, USA

Introduction

The term model management was coined in the mid-1970s in the context of work on decision support systems (DSS) (Sprague and Watson 1975; Will 1975). An important objective of the DSS concept was to provide an environment in which decision makers could gain materially useful insights by interactively exercising OR/MS models. However, developing such an environment required principled solutions to problems of specifying, representing and interacting with models. This focus on models, and in turn on modeling, led to the study of model management, defined broadly to encompass the study of model representation, the set of operations facilitated by such representation at various stages of the modeling life cycle, and computer-based environments that facilitate modeling.

What follows is a brief review of work in two areas that have been actively studied in model management. First, work on languages to specify models, and on the development of techniques to facilitate operations that support modelers in both the pre-solution and post-solution phases of the modeling life cycle. Second, work on the representation of a collection of models (e.g., a model library) and the development of techniques to enable model selection and configuration. As with other information technology-based fields, model management has benefitted from the growth of Internet technologies. A detailed review of the implications for model management of the growth in Internet, and in particular the World Wide Web technologies, is in Bhargava and Krishnan (1998), and Bhargava, Power, and Sun (2007).

Model Management-I

Modeling languages — The need to represent a model in a notation that is easy to validate, verify, debug, maintain and communicate motivated the development of modeling languages (Fourer 1983). Prior to their development, the only computer-executable representation of a model was in an arcane format optimized for efficient solution (e.g., the Mathematical Programming System MPS format).

Current modeling languages provide a high-level symbolic notation to specify models. Solution operations can also be declared and all the required details of binding the model instance to the data structures required by solver done transparently. Further, this has greatly increased the productivity of model-based work.

Four principles have been articulated as essential to modeling language design (Bhargava and Kimbrough 1993; Fourer 1983; Geoffrion 1992a; Krishnan and Chari 2000). These are:

- *Model data independence*: requires the mathematical structure of the model to be independent of the data used to instantiate it. This permits model data to be modified in format, dimension, units or values without any modification to the model representation.
- *Model solver independence*: requires the model representation to be independent of the representation required by the solver. This permits more than one solver to be used with a given model. Further, it recognizes the fundamental differences in the requirements placed on model representations and representations required by the solver.
- *Model paradigm independence*: requires that the modeling language allow the representation of models drawn from different paradigms (e.g., mathematical programming and discrete event simulation).
- *Meta level representation and reasoning*: requires that the modeling language represent information *about* model components and models, in addition to their mathematical structure in order to enable semantic consistency checking.

Modeling languages incorporate these principles to varying degrees. Examples of modeling languages include spreadsheet-based languages such as IFPS (Gray 1987), algebraic modeling languages such as GAMS (Bischop and Meeraus 1982), AMPL (Fourer et al. 1990), and MODLER (Greenberg 1992),

relational modeling languages such as SQLMP (Choobineh 1991), graphical modeling languages such as NETWORKS (Jones 1991), and Model Graphs (Chari and Sen 1997), typed modeling languages such as ASCEND (Piela et al. 1992), and XML-based languages such as OptML, SNOML, FML, and MathML. A survey of XML-based representations can be found in Valente and Mitra (2007). New developments in algebraic modeling languages include extensions for constraint programming (Fourer and Gay 2002), and extensions for stochastic programming (Valente et al. 2009). The formal analysis of the semantics of typed modeling languages is in Bhargava, Krishnan, and Piela (1997). There is also an active market in commercial modeling languages and systems. A survey of these systems can be found in Sharda and Rampal (1995).

Two developments have had a significant impact on modeling languages. One is the seminal work on Structured Modeling (SM) (Geoffrion 1987). Developments and research directions are described in a survey of structured modeling (Geoffrion 1999a), and an annotated bibliography is given in Geoffrion (1999b). While previous work on modeling languages had sought to provide a computer executable representation of the notation traditionally used by modelers, SM defines a theory that treats models as hierarchical collections of definitional dependencies. This enables structured modeling languages to satisfy all the four design principles discussed above. While several languages have implemented SM, the most completely developed of these is SML (Geoffrion 1992a, b). The other important development is the embedded languages technique, which can be used to define an architecture of considerable generality for modeling environments. This technique is used to specify modeling languages, as well as information about the terms and expressions stated in these languages. The TEFA modeling environment (Bhargava and Kimbrough 1993) has been implemented using this technique.

Operations — The early work on model management focused on model solution. The objective was to transparently bind solution algorithms to model instances. As noted above, modeling languages have realized this objective. Model management research has since focused on operations required to support both pre-solution and post-solution phases of the modeling life cycle. Next, research related to a pre-solution phase, model formulation, and a post-solution phase, model interpretation, are described.

Model Formulation — Model formulation is the task of converting a precise problem description into a mathematical model (Krishnan and Chari 2000). It is a complex task requiring diverse types of knowledge. The appropriateness of a model depends on a variety of factors such as accuracy, tractability, availability of relevant data, and understandability. Model formulation research has primarily focused on the development of theory, tools and techniques to support the formulation of deterministic mathematical programming models. Work by Gassmann and Ireland (1996) has studied the formulation of stochastic mathematical programming models.

Using protocol analysis, detailed studies of the expert modeling process have been conducted and process models have been developed (Krishnan et al. 1992; Raghunathan et al. 1994). Domain-independent and domain-specific model formulation strategies have been implemented in model formulation support systems (Krishnan 1990; Ma et al. 1989; Raghunathan et al. 1994) and a variety of representation and (deductive) reasoning schemes have been investigated. Liang and Konsynski (1993) have also investigated alternative approaches such as analogical reasoning and case-based reasoning to implement model formulation systems. A principled approach to formulating mathematical programming models is in Murphy, Stohr, and Asthana (1992). A survey of this research is given in Bhargava and Krishnan (1993).

Model Interpretation — Model interpretation consists of a variety of techniques to help a modeler comprehend a model. These include parametric analysis, structural analysis, and structure inspection.

Parametric analysis has long been supported in model management systems. Spreadsheets routinely support *what-if* analysis and goal seeking. Modeling languages for mathematical programming implement the theory of sensitivity analysis.

The pioneering work on structural analysis is due to Greenberg on the ANALYZE system (Greenberg 1987). ANALYZE extracts model structures that cause exceptions such as redundancy and infeasibility in linear programming models. The stream of work begun with ANALYZE has been considerably extended. Guieu and Chinneck (1999) described work and a toolkit called Mprobe that analyzes

infeasibility in mixed integer and integer linear programming models. Sharda and Steiger (1996) presented work on applying inductive learning techniques to facilitate model analysis. Kimbrough and Oliver (1994) examined the issue of post-solution analysis for models other than linear programs and have at-tempted to fashion a solution along the lines of ANALYZE. An important feature of their approach is the analysis of the impact on the solution to a model when changes are made to the parameters of a surrogate model.

Piela et al. (1992) described the use of a browser to inspect the structure of a model. Dhar and Jarke (1993) and Raghunathan et al. (1995) examined the usefulness of recording the rationale underlying a model. The documented rationale is used to aid comprehension as well as to correctly and consistently propagate the changes made to the structure of a model. Work on analyzing assumptions associated with models and visualizing the structure as a graph is reported in Basu and Blanning (1998). More recently, model ontology and model schema developed using OWL, a web ontology language based on XML, has been used for model representation and interpretation (Bhrammanee and Wuwongse 2008).

Model Management-II

Model libraries —In contrast to the work reviewed in the previous section, the focus of this stream of research assumes the existence of a library of debugged and validated models. This has led to the study of issues such as the representation of model libraries and operations such as model selection and configuration.

Model Representation — Predominantly, models are abstractly represented as black boxes, i.e., as a set of named inputs and outputs. This is in contrast to the detailed representation of the structure of the model in the previous section. A variety of representations, including virtual relations (Blanning 1982) and predicate logic (Bonczek et al. 1978) have been used to represent models. Additional structure has been imposed on these representations. Mannino, Greenberg, and Hong (1990) proposed the use of categories such as model type, model template, and model instance to organize the collection of models in a library. A model type is a general description of a model class such as linear programming. A model template is a refinement of a model type such as a production planning LP model, and a model instance is an instance of a model template in which the source of values for each parameter has been declared. Model templates have been represented using key-value pairs and filter lists in (Chari 2002), as Web Services Description Language (WSDL) service descriptors (Madhusudan 2007), and as OWL (XML-based) model profiles (Bhrammanee and Wuwongse 2008). Metagraphs (Basu and Blanning 1994a; Basu et al. 1997), a specialized type of graph structure, has been the significant development in this area.

Model Selection — Model selection leverages the existence of previously developed models to create a model for a new problem. In addition to the set of inputs and outputs associated with a model, additional information such as model assumptions need to be represented. Mannino et al. (1990) described model selection operators that match, either exactly or fuzzily, the assumptions associated with a model and those that are part of a problem statement. Work by Banerjee and Basu (1993) adopted the same framework as Mannino et al. (1990) but differed in its use of structuring technique called the Box Structure method (Mills et al. 1986), borrowed from the domain of systems analysis and design to develop its taxonomy of model types. Later, Guenther, Muller, Schmidt, Bhargava, and Krishnan (1997) studied the problem of selecting models and methods from web-based electronic catalogs. Chari (2002), implemented an approach based on matching filter spaces in selecting models. More recently, the work by Guntzer, Muller, Muller, and Schimkat (2007) have used a graph-matching procedure for selecting structured models represented as graphs. The problem of selecting and composing appropriate data mining models from a model library is now gaining attention (Liu and Tuzhilin 2008).

Model Configuration — Model configuration leverages previously developed models by either linking them together (referred to as model composition) or by integrating them (referred to as model integration). Model composition links together independent models such that the output of one model becomes an input to another. Model composition is often used in conjunction with model selection when no one model meets the requirements of a problem.

An example of model composition is the linking together of a demand forecasting model and a production scheduling model.

While the early work only permitted links between variables with the same name, later work of Muhanna (1992) and Krishnan, Piela, and Westerberg (1993) permitted linkages between objects (variables, arrays, instances of types, etc.) as long as certain semantic constraints are met. Muhanna (1992) also proposed methods that determine the order in which a collection of linked models should be solved. Representation methods and algorithms that can determine the set of models that need to be composed in order to obtain a set of outputs from a given set of inputs have been a major focus of model composition research. While the early work was based on virtual relations (Blanning 1982) and predicate logic (Bonczek et al. 1978), later work based on a construct called metagraphs (Basu and Blanning 1994a) has shown considerable promise. In addition to model composition (Basu and Blanning 1994b), the metagraph construct enables the representation of and reasoning with metadata such as assumptions associated with models (Basu, Blanning and Shtub, 1998). Work within the last ten years has focused on automating model composition and execution process, and combining partial solutions from multiple composite models and databases as in Chari (2002), leveraging XML in model composition (Bhrammanee and Wuwongse 2008) and implementing model composition through a sequence of web service invocations as in the WEBOPT project (Valente and Mitra 2007), and in (Madhusudan 2007).

Model integration differs from model composition in allowing modifications to be made to the models being integrated. Model integration involves both schema integration and solver integration (Dolk and Kotteman 1993). Schema integration is the task of merging the internal structure of two or more models to create a new model, while process integration is the task of interweaving associated solution processes in order to solve the integrated model.

Support for conflict resolution is a major focus of research in schema integration. This has involved the development of a variety of typing schemes that seek to integrate data typing (Muhanna 1992), and concepts such as quiddity and dimensions (Bhargava et al. 1991).

Detailed procedures for integrating models specified in the Structured Modeling Language (SML) (Geoffrion 1992a, b) have been proposed (Geoffrion 1989) and extended (Tsai 1998). The method uses to advantage the ability of structured modeling to trace the effects of changes and the formal definition of what constitutes a structured model. An update to structured modeling research is given in Geoffrion (1999a).

The pioneering work on solver integration is the work of Dolk and Kotteman (1993). They used the theory of communicating sequential processes (Hoare 1985) to address the problem of solver integration. A simplified version of the problem was addressed by Muhanna (1992) in the SYMMS system. As software components have emerged as a viable technology for web-based deployment of solvers on the Web, recent work has studied integration of solvers/methods on the Web (Guenther et al. 1997). Technology has made it possible to wrap a solver with a software layer that exposes standard interfaces thereby enabling multiple solvers to be invoked in a standard manner as in the case of Open Solver Interface (OSI) in the COIN-OR repository (Saltzman 2002).

Concluding Remarks

Research in the general area of model management since 2000 has contributed to (1) the extension of modeling languages to represent a variety of models; (2) the development of distributed model management systems using web technologies to support models as services; (3) the automation of model composition process; and (4) the integration of modeling languages and systems with databases. Among the numerous surveys that have been published on the subject, the model management chapter in the book on information systems and decision processes (Stohr and Konsynski 1992), the special issue of *Decision Support Systems* edited by Blanning (1993), and the special issue of the *Annals of Operations Research* edited by Shetty (1992) deserve special mention for their broad coverage of issues and their quality of exposition. A survey of the model management literature may be found in Krishnan and Chari (2000). A survey of model management issues pertaining to data mining models can be found in Liu and Tuzhilin (2008).

Model-based Search Methods

A class of global optimization methods that uses a probability distribution to generate candidate solutions, where in each iteration of the algorithm, the probability distribution is updated according to the performance of the population of candidate solutions. Examples include estimation of distribution algorithms, the cross-entropy method, and model reference adaptive search.

Moment Generating Function

For a random variable X, the moment generating function is given by $M_X(t) = E[e^{tX}]$, assuming the expectation exists. For non-negative continuous random variables, it is basically identical to the Laplace transform for the corresponding probability density function.

Monte Carlo Methods

General term used to refer to the use of random numbers in a particular methodology, e.g., evaluating a high-dimensional deterministic integral or carrying out a randomized algorithm or simulation of a stochastic system, all based on statistical sampling techniques. The term "Monte Carlo" signifies the random or uncertain component that characterizes the

method and was coined in the 1940s by physicists working on the Manhattan nuclear weapons project, an allusion to gambling in Monte Carlo casinos. One of the strengths of the Monte Carlo method is that in many applications its computational burden grows only linearly in the dimension of problems where other methods suffer from an exponential (geometric) growth in computation.

Monte Carlo Simulation

Simulation of systems modeled using random variables and/or stochastic processes. The underlying inputs are generally random numbers, sequences of independent and identically distributed random variables uniformly distributed on the unit interval. Sometimes called the Monte Carlo method, where the term "Monte Carlo" signifies the random or uncertain component that characterizes the method and was coined in the 1940s by physicists working on the Manhattan nuclear weapons project, an allusion to gambling in Monte Carlo casinos. Monte Carlo simulation is one of the most widely used tools in operations research and management science (OR/MS) and can be used to provide detailed models of complex systems arising in various OR/MS fields from manufacturing to transportation to computer/communications networks to financial engineering. One of the strengths of the Monte Carlo method is that in many applications its computational burden grows only linearly in the dimension of problems where other methods suffer from an exponential (geometric) growth in computation.

Moral Hazard

A term in economics describing a situation in which a decision maker's actions are taken without bearing full risk, responsibility, or consequences for the potential outcomes. For example, having a valuable item with full insurance coverage against theft might make the owner more lax in safeguarding it.

Economist Paul Krugman described moral hazard as: "...any situation in which one person makes the decision about how much risk to take, while someone else bears the cost if things go badly."

Multicommodity Network Flows

Bala Shetty
Texas A&M University, College Station, TX, USA

Introduction

The multicommodity minimal cost network flow problem may be described in terms of a distribution problem over a network $[V, E]$, where V is the node set with order n and E is the arc set with order m. The decision variable x^{jk} denotes the flow of commodity k through arc j, and the vector of all flows of commodity k is denoted by $\boldsymbol{x}^k = [x^{1k},\ldots, x^{mk}]$. The unit cost of flow of commodity k through arc j is denoted by c^{jk} and the corresponding vector of costs by $\boldsymbol{c}^k = [c^{1k},\ldots, c^{mk}]$. The total capacity of arc j is denoted by b^j with corresponding vector $\boldsymbol{b} = [b^1,\ldots, b^m]$. Mathematically, the multicommodity minimal cost network flow problem may be defined as follows:

$$\text{Minimize} \quad \sum_k \boldsymbol{c}^k \boldsymbol{x}^k$$

s.t.

$$\boldsymbol{A}\boldsymbol{x}^k = \boldsymbol{r}^k, \quad k = 1,\ldots, K$$

$$\sum_k \boldsymbol{x}^k \le \boldsymbol{b}$$

$$0 \le \boldsymbol{x}^k \le \boldsymbol{u}^k, \quad \text{for all } k,$$

where K denotes the number of commodities, $\boldsymbol{A}$ is a node-arc incidence matrix for $[V, E]$, $\boldsymbol{r}^k$ is the requirements vector for commodity k, and $\boldsymbol{u}^k$ is the vector of upper bounds for decision variable $\boldsymbol{x}^k$.

Multicommodity network flow problems are extensively studied because of their numerous applications and because of the intriguing network structure exhibited by these problems (Ahuja et al. 1993; Ali et al. 1984; Assad 1978; Castro and Nabona 1996; Kennington 1978; McBride 1998). Multicommodity models have been proposed for planning studies involving urban traffic systems (Chen and Meyer 1988; LeBlanc 1973; Potts and Oliver 1972) and communications systems (LeBlanc 1973; Naniwada 1969). Models for solving scheduling and routing problems have been proposed by Bellmore et al. (1971) and by Swoveland (1971). A multicommodity model for assigning students to achieve a desired ethnic composition was suggested by Clark and Surkis (1968). Multicommodity models have also been used for casualty evacuation of war time casualties, grain transportation, and aircraft routing for the USAF. A discussion of these applications can be found in Ali et al. (1984). Additional applications of multicommodity flows are given in Gautier and Granot (1995), and Popken (1994).

Solution Techniques

There are two basic approaches which have been employed to develop specialized techniques for multicommodity network flow problems: decomposition and partitioning. Decomposition approaches may be further characterized as price-directive or resource directive. A price-directive decomposition procedure directs the coordination between a master program and each of several subprograms by the changing the objective functions (prices) of the subprograms. The objective is to obtain a set of prices (dual variables) such that the combined solution for all subproblems yields an optimum for the original problem. A resource-directive decomposition procedure (Held et al. 1974; Kennington and Shalaby 1977), when applied to a multicommodity problem having K commodities, is to distribute the arc capacity among the individual commodities in such a way that solving K sub-programs yields an optimal flow for the coupled problem. At each iteration, an allocation is made and K single commodity flow problems are solved. The sum of capacities allocated to an arc over all commodities is equal to the arc capacity in the original problem. Hence, the combined flow from the solutions of the subproblems provides a feasible flow for the original problem. Optimality is tested and the procedure either terminates or a new arc capacity allocation is developed. Partitioning approaches are specializations of the simplex method where the current basis is partitioned to exploit its special structure. These techniques are specializations of primal, dual, or primal-dual simplex method. The papers of Hartman and Lasdon (1972), and Graves and McBride (1976) are primal techniques, while the work of Grigoriadis and White (1972) is a dual technique. An extensive discussion of these techniques can be found in Ahuja et al. (1993) and Kennington and Helgason (1980).

Several researchers have suggested algorithms for the multicommodity flow problem: Gersht and Shulman (1987), Barnhart (1993), Farvolden and Powell (1990), Farvolden et al. (1993), Liu (1997), and Schneur and Orlin (1998) all present alternative approaches for the multicommodity model. Parallel optimization has also been applied for the solution of multicommodity networks. Pinar and Zenios (1990) present a parallel decomposition algorithm for the multicommodity model using penalty functions. Shetty and Muthukrishnan (1990) develop a parallel projection which can be applied to resource-directive decomposition. Chen and Meyer (1988) decompose a nonlinear multicommodity problem arising in traffic assignment into single commodity network components that are independent by commodity. The difficulty of solving a multicommodity problem explodes when the decision variables are restricted to be integers. Very little work is available in the literature for the integer problem (Evans 1978; Evans and Jarvis 1978; Gendron and Crainic 1997).

Several computational studies involving multicommodity models have been reported in the literature. Ali et al. (1980) present a computational experience using the price-directive decomposition procedure (PPD), the resource directive-decomposition procedure (RDD), and the primal partitioning procedure (PP). They find the primal partitioning and price directive decomposition methods take approximately the same amount of computing time, while the resource directive decomposition runs in approximately one-half the time of the other two methods. Convergence to the optimal solution is guaranteed for PPD and PP, whereas RDD may experience convergence problems. Ali et al. (1984) present a comparison of the primal partitioning algorithm for solving the multicommodity model with a general purpose LP code. On a set of test problems, they find that the primal partitioning technique runs in approximately one-half the time required by the LP code. Farvolden et al. (1993) report very promising computational results for a class of multicommodity network problems using a primal partitioning code (PPLP). On these problems, they find PPLP to be two orders of magnitude faster than MINOS and about 50 times faster than OB1, a state-of-the-art LP solver.

Linear, nonlinear, and integer multicommodity models have numerous important applications in scheduling, routing, transportation, and communications. Real-world multicommodity models tend to be very large and there is a need for faster and more efficient algorithms for solving these models.

Thus, multicommodity models present unlimited opportunities for future research in large-scale optimization.

Multicommodity Network-Flow Problem

A minimum-cost network flow problem in which more than one commodity simultaneously flows from the supply nodes to the demand nodes. Unlike the single commodity problem, an optimal solution is not guaranteed to have integer flows. The problem takes on the block-angular matrix form that is suitable for solution by Dantzig-Wolfe decomposition. Applications areas include communications, traffic and logistics.

See

- ▶ Dantzig-Wolfe Decomposition Algorithm
- ▶ Minimum-Cost Network-Flow Problem
- ▶ Multicommodity Network Flows
- ▶ Network Optimization

Multidimensional Transportation Problem

Usually a transportation problem with a third index that refers to a product type available at the origins and demanded at the destinations. The variables x_{ijk} represent the amount of the kth product type shipped from the ith origin to the jth destination. The constraint set is a set of linear balance equations, with the usual linear cost objective function. It is also a special form of the multicommodity network-flow problem. Unlike the transportation problem, its optimal solution may not be integer-valued even if the network data are given as integers. The problem can also be defined with more than three indices.

Multiobjective Linear-Programming Problem

This problem has the usual set of linear-programming constraints ($\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$) but requires the simultaneous optimization of more than one linear objective function, say p of them. It can be written as "Maximize" $\boldsymbol{Cx}$ subject to $\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$, where $\boldsymbol{C}$ is a $p \times n$ matrix whose rows are the coefficients defined by the p objectives. Here "Maximize" represents the fact that it is usually impossible to find a solution to $\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$, that simultaneously optimizes all the objectives. If there is such an (extreme) point, the problem is thus readily solved. Special multiobjective computational procedures are required to select a solution that is in effect a compromise solution between the extreme point solutions that optimize individual objective functions. The possible compromise solutions are taken from the set of efficient (nondominated) solutions. This problem is also called the vector optimization problem.

Multiobjective Programming

Ralph E. Steuer
University of Georgia, Athens, GA, USA

Introduction

Related to linear, integer, and nonlinear programming, multiobjective programming addresses the extensions to theory and practice of mathematical programming

problems with more than one objective function. Single objective programming must settle on a single objective such as to maximize profit or minimize cost. However, many if not most real-world problems are in an environment of multiple conflicting criteria. A sample of problems modeled with multiple objectives:

Oil Refinery Scheduling

min {cost}
min {imported crude}
min {high sulfur crude}
min {deviations from demand slate}

Production Planning

max {total net revenue}
max {minimum net revenue in any period}
min {backorders}
min {overtime}
min {finished goods inventory}

Forest Management

max {timber production}
max {visitor days of recreation}
max {wildlife habitat}
min {overdeviations from budget}

Emerging as a new topic in the 1970s, multiobjective programming has grown to the extent that numerous books have been written on the subject (e.g., Zeleny 1982; Yu 1985; Steuer 1986; Miettinen 1999; Ehrgott 2005) and applications of multiobjective programming can now be found in virtually all areas of operational research.

Terminology

A multiobjective programming problem is the following:

$$\begin{aligned} &\text{maximize} \quad \{f_1(\boldsymbol{x}) = z_1\} \\ &\vdots \\ &\text{maximize} \quad \{f_k(\boldsymbol{x}) = z_k\} \\ &\text{subject to} \quad \boldsymbol{x} \in S \end{aligned}$$

where k is the number of objectives, the z_i are criterion values, and S is the feasible region in decision space. Let $Z \subset R^k$ be the feasible region in criterion space where $\boldsymbol{z} \in Z$ if and only if there exists an $\boldsymbol{x} \in S$ such that $\boldsymbol{z} = (f_1(\boldsymbol{x}),\ldots,f_k(\boldsymbol{x}))$. Let $K = \{1,\ldots,k\}$. Criterion vector $\overline{z} \in Z$ is nondominated if and only if there does not exist another $\boldsymbol{z} \in Z$ such that $z_i \geq \overline{z}_i$ for all $i \in K$ and $z_i > \overline{z}_i$ for at least one $i \in K$. The set of all nondominated criterion vectors is designated N and is called the nondominated set. A point $\overline{\mathbf{x}} \in S$ is efficient if and only if its criterion vector $\overline{z} = (f_1(\overline{\boldsymbol{x}}),\ldots,f_k(\overline{\boldsymbol{x}})$ is nondominated. The set of all efficient points is designated E and is called the efficient set.

Let $U: R^k \rightarrow R$ be the utility function of the decision maker (DM). A $\boldsymbol{z}^\circ \in Z$ that maximizes U over Z is an optimal criterion vector and any $\boldsymbol{x}^\circ \in S$ such that $(f_1(\boldsymbol{x}^\circ),\ldots, f_k(\boldsymbol{x}^\circ)) = \boldsymbol{z}^\circ$ is an optimal solution of the multiobjective program. The interest in the efficient set E and the nondominated set N stems from the fact that if U is coordinatewise increasing (i.e., more is always better than less of each objective), $\boldsymbol{x}^\circ \in E$ and $\boldsymbol{z}^\circ \in N$. In this way, a multiobjective program can be solved by finding the most preferred criterion vector in N.

One might think that the best way to solve a multiobjective program would be to assess the DM's utility function and then solve

$$\begin{aligned} &\text{maximize} \quad \{U(z_1,\ldots,z_k)\} \\ &\text{subject to} \quad f_i(\boldsymbol{x}) = z_i, \quad i \in K,\ x \in S \end{aligned}$$

because any solution that solves this program is an optimal solution of the multiobjective program. However, multiobjective programs are usually not solved in this way because (1) of the difficulty in assessing an accurate enough U, (2) U would almost certainly be nonlinear, and (3) the DM would not likely see other candidate solutions during the solution process from which to gain an appreciation of the tradeoffs inherent in the problem.

Consequently, multiobjective programming employs mostly interactive procedures that only require implicit, as opposed to explicit, knowledge about the DM's utility function. In interactive procedures, the goal is to search the nondominated set for the DM's most preferred criterion vector. Unfortunately, because of the size of N, finding the best criterion vector in N is not a trivial task. As a result, interactive procedures are carefully crafted and can generally only be expected to conclude with what is called a final solution, a solution that is either optimal or close enough to being optimal to satisfactorily terminate the decision process.

Background Concepts

Along with the basics of conventional mathematical programming, multiobjective programming requires additional concepts not widely employed elsewhere in operations research. The key ones are as follows.

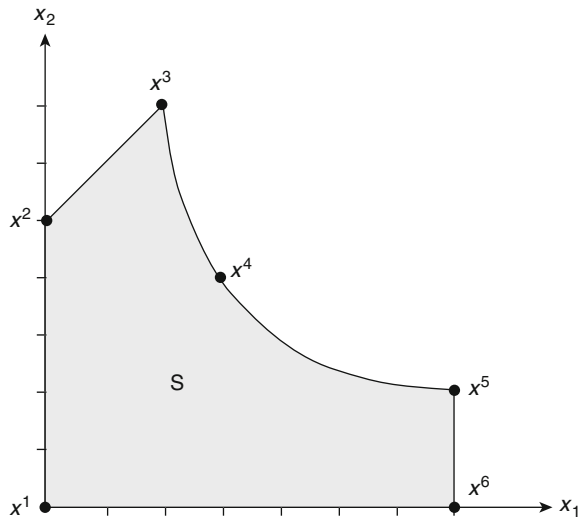
1. *Decision Space vs. Criterion Space*. Whereas single objective programming is typically studied in decision space, multiobjective programming is mostly studied in criterion space. To illustrate, consider

$$\begin{aligned} &\text{maximize} && \{x_1 - 1/2x_2 = z_1\} \\ &\text{maximize} && \{x_2 = z_2\} \\ &\text{subject to} && x \in S \end{aligned}$$

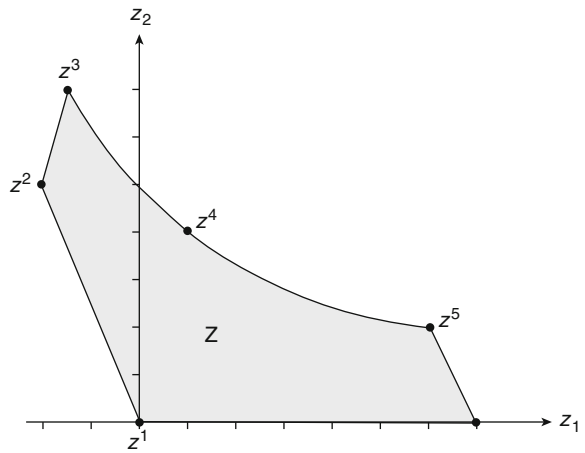
where S in decision space is in Fig. 1, and Z in criterion space is in Fig. 2. For instance z^4, which is the image of $\boldsymbol{x}^4 = (3, 4)$, is obtained by plugging the point (3, 4) into the objective functions to generate $z^4 = (1, 4)$. In Fig. 2, the nondominated set N is the set of boundary criterion vectors z^3 through z^4 to z^5 to z^6, inclusive. In Fig. 1, the efficient set E is the set of inverse images of the criterion vectors in N, namely the set of boundary points $\boldsymbol{x}^3$ through $\boldsymbol{x}^4$ to $\boldsymbol{x}^5$ to $\boldsymbol{x}^6$, inclusive. Note that Z is not necessarily confined to the nonnegative orthant.

2. *Unsupported Nondominated Criterion Vectors*. A $z \in N$ is unsupported if and only if it is possible to dominate it by a convex combination of other nondominated criterion vectors. In Fig. 2, the set of unsupported nondominated criterion vectors is the set of criterion vectors from z^3 through z^4 to z^5, exclusive of z^3 and z^5. The set of supported nondominated criterion vectors is the set that consists of z^3 plus the line segment z^5 to z^6, inclusive. Unsupported nondominated criterion vectors can only occur in problems that possess non-convex feasible regions; hence, they can easily be present in integer and nonlinear multiobjective programs.

3. *Identifying Nondominated Criterion Vectors*. To graphically determine whether a $\overline{z} \in Z$ is non-dominated or not, visualize the nonnegative orthant in R^k translated so that its origin is at $\overline{z}$. Note that, apart from $\overline{z}$, a vector dominates $\overline{z}$ if and only if the vector is in the translated nonnegative orthant. In other words, $\overline{z}$ is nondominated if and only if the translated nonnegative orthant is empty of feasible criterion vectors other than for $\overline{z}$. Visualizing in Fig. 2 the nonnegative orthant translated to z^4, it can be seen that z^4 is nondominated. Visualizing the nonnegative orthant translated to z^2, it can be seen that z^2 is dominated.



Multiobjective Programming, Fig. 1 Representation in decision space



Multiobjective Programming, Fig. 2 Representation in criterion space

4. *Payoff Tables*. Assuming that each objective is bounded over the feasible region, a payoff table is of the form

	z_1	z_2		z_k
z^1	z_1^*	z_{12}		z_{1k}
z^2	z_{21}	z_2^*		z_{2k}
z^k	z_{k1}	z_{k2}		z_k^*

where the rows are criterion vectors resulting from individually maximizing the objectives. For instance, z_{12} is the value of the second objective function at the point that maximizes the first objective. The z_i^* entries along the main diagonal of the payoff table are the maximum criterion values of the different objectives over the nondominated set. The minimum value in the ith column of the payoff table is often used as an estimate of the minimum criterion value of the ith objective over N because the true minimum criterion values over N (called nadir values) are typically difficult to obtain (Isermann and Steuer 1988; Alves and Costa 2009)

5. z^{**} *Reference Criterion Vectors*. A $z^{**} \in R^k$ *reference* criterion vector is a criterion vector that is suspended above the nondominated set. Its components are given by

$$z_i^{**} = z_i^* + \in_i$$

where the $\in_i$ are small computationally significant positive values.

6. *Weighting Vector Space*. Without loss of generality, let

$$\Lambda = \left\{ \lambda \in R^k | \lambda_i \in (0,1), \sum_{i \in k} \lambda_i = 1 \right\}$$

be weighting vector space. In an interactive environment, subsets of Λ called interval defined subsets are of the form

$$\Lambda^{(h)} = \left\{ \lambda \in R^k | \lambda_i \in \left(\ell_i^{(h)}, \mu_i^{(h)} \right), \sum_{i \in k} \lambda_i = 1 \right\}$$

where h is the iteration number and

$$0 \le l_i^{(h)} \le \mu_i^{(h)} \le 1 \quad i \in K$$
$$\mu_i^{(h)} - l_i^{(h)} = \mu_j^{(h)} - l_j^{(h)} \quad \text{for all } i \ne j$$

Sequences of successively smaller interval subsets can be defined by reducing the $\mu_i^{(h)} - l_i^{(h)}$ interval widths at each iteration.

7. *Sampling Programs*. The weighted-sums program

$$\max \left\{ \sum_{i \in K} \lambda_i f_i(x) | x \in S \right\}$$

can be used to sample the nondominated set because, as long as $\lambda \in \Lambda$, the program returns an efficient point. A disadvantage of the weighted-sums program is that it cannot generate unsupported points.

To make downward probes of the nondominated set from a z^{**} as required in many of the interactive procedures of multiobjective programming, the augmented Tchebycheff program is employed

$$\text{minimize} \left\{ \alpha - \rho \sum_{i \in K} z_i \right\}$$
$$\text{subject to}$$
$$\alpha \ge \lambda_i \left(z_i^{**} - z_i \right) \quad i \in K$$
$$f_i(\boldsymbol{x}) = \boldsymbol{z_i} \quad \boldsymbol{i \in K}$$
$$\boldsymbol{x} \in S$$
$$z \in R^k \text{ unrestricted}$$

where $\alpha \in R$, $\lambda \in \Lambda$, and ρ is a small computationally significant positive number. A disadvantage of the augmented Tchebycheff program is that, regardless of the value of ρ, there may still remain unsupported members of the nondominated set that the program is unable to compute (Steuer 1986).

A program that has better mathematical properties, although somewhat more difficult to implement, is the lexicographic Tchebycheff program

$$\text{lex}\ \min\left\{\alpha, -\sum_{i\in K} z_i\right\}$$
$$\text{subject to}$$
$$\alpha \geq \lambda_i\left(z_i^{**} - z_i\right) \quad i \in K$$
$$f_i(\boldsymbol{x}) = z_i \quad i \in K$$
$$\boldsymbol{x} \in S$$
$$z \in R^k \text{ unrestricted}$$

where $\lambda \in \Lambda$. At the first lexicographic level it is solved to minimize α. At the second lexicographic level, subject to only those solutions that minimize α, $-\sum_{i\in K} z_i$ is minimized. Not only does the lexicographic Tchebycheff program always return a nondominated criterion vector, but if $\boldsymbol{z}$ is nondominated, there then exists a $\overline{\lambda} \in \Lambda$ such that $\boldsymbol{z}$ uniquely solves the program (Steuer 1986).

8. *Aspiration Criterion Vectors*. An aspiration criterion vector $\boldsymbol{q} \in R^k$ is a criterion vector specified by a DM to reflect his or her hopes or expectations from a problem. An aspiration criterion vector, when specified, is typically projected onto N by an augmented or lexicographic Tchebycheff program in order to find the nondominated criterion vector closest to the aspiration criterion vector.
9. *T-vertex λ-vector Defined by* $\boldsymbol{q}$ *and* $\boldsymbol{z}^{**}$. The T-vertex (Tchebycheff-vertex) λ-vector defined by $\boldsymbol{q}$ and z^{**} is the $\lambda \in \Lambda$ whose components are given by

$$\lambda_i = \frac{1}{\left(z_i^{**} - q_i\right)}\left[\sum_{i\in K}\frac{1}{\left(z_j^{**} - q_j\right)}\right]^{-1}$$

The T-vertex λ-vector, when installed in an augmented or lexicographic Tchebycheff program, causes the program to probe the nondominated set along a line that goes through both z^{**} and $\boldsymbol{q}$ in the direction

$$-\left(\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_k}\right)$$

Vector-Maximum Algorithms

In the linear case, a multiple objective linear program (MOLP) is sometimes written in vector-maximum form

Multiobjective Programming, Table 1 Average numbers of MOLP efficient extreme points

MOLP size $k \times m \times n$	Efficient extreme points	Approximate times in seconds
$3 \times 50 \times 75$	1,798	2
$3 \times 100 \times 150$	11,897	40
$3 \times 200 \times 300$	128,237	1,600
$4 \times 50 \times 75$	9,921	30
$4 \times 100 \times 150$	682,920	3,500
$5 \times 50 \times 75$	141,444	300

$$\text{“ max ”}, \{\boldsymbol{Cx} = \boldsymbol{z} | \boldsymbol{x} \in \boldsymbol{S}\}$$

where $\boldsymbol{C}$ is the $k \times n$ matrix whose rows are the coefficient vectors of the k objectives. A point is a solution to a vector-maximum problem if and only if it is efficient. Algorithms for characterizing the efficient set E of an MOLP are called vector-maximum algorithms. In the 1970s, considerable effort was spent on the development of vector-maximum codes to compute all efficient extreme points. The thought was that, by reviewing the list of nondominated criterion vectors associated with the efficient extreme points, a DM would be able to identify his or her efficient extreme point of greatest utility in hopes of satisfactorily terminating the decision process.

Unfortunately, MOLPs have many efficient extreme points as indicted in Table 1 (sample size of ten for each problems size). Whereas the number of variables and the number of constraints play a role, the factor most dramatically affecting the number of efficient extreme points is the dimensionality of the criterion cone, the convex cone generated by the gradients of the k objective functions.

With nondominated sets of sizes indicated in Table 1, other approaches have been attempted such as by Klamroth, Tind and Wiecek 2002, but mostly, the figures have led to interactive procedures moving to the forefront of multiobjective programming.

Interactive Procedures

In interactive multiobjective programming, an exploration over the feasible region for the best point in the non-dominated set is conducted. Interactive

procedures are characterized by phases of decision making alternating with phases of computation. A pattern is generally established and kept repeating it until termination. At each iteration, a solution, or a group of solutions, is generated for examination. As a result of the examination, the DM inputs updated preference information to the solution procedure in the form of values of the controlling parameters (preference weights, aspiration criterion vectors, λ-vector interval widths, criterion vector components to be increased/decreased/held fixed, criterion vector lower bounds, etc., depending upon the particular interactive procedure).

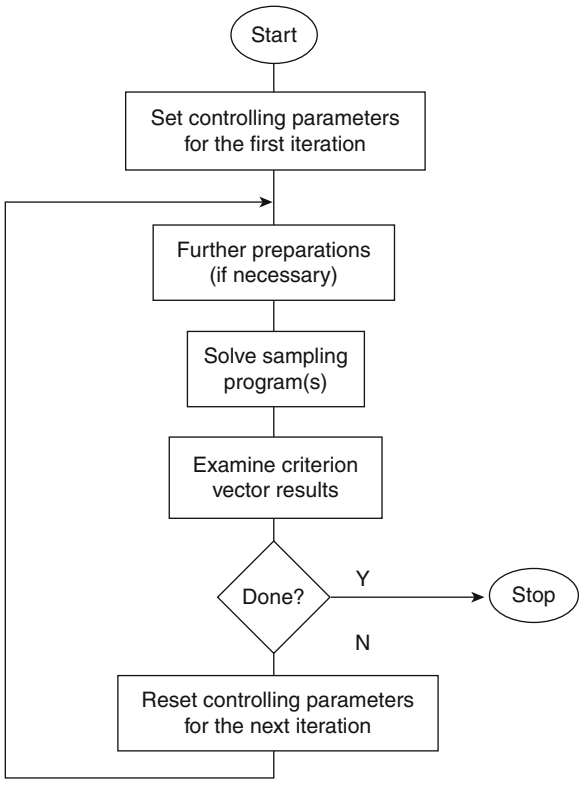
While many interactive procedures have been proposed, virtually all of them more or less follow the same general algorithmic outline. As portrayed in Fig. 3, the general algorithmic outline includes:

- an initial setting of the controlling parameters;
- optimization of one or more mathematical programming problems to probe (i.e., sample) the nondominated set;
- examination of the criterion vector results; and
- a resetting of the controlling parameters for the next iteration in the light of what was learned on the current iteration

With the consensus being that a range of interactive procedures is necessary because the most appropriate one to use is often application or user decision-making style dependent, ten of the most prominent interactive procedures, along with the dates of their original articles, are as follows:

1. ECON: e-Constraint Method, Traditional method
2. STEM: (Benayoun et al. 1971)
3. GDF: Geoffrion-Dyer-Feinberg Procedure (1972)
4. ZW: Zionts-Wallenius Procedure (1976)
5. IGP: Interactive Goal Programming (Spronk 1981)
6. WIERZ: Wierzbicki's Aspiration Criterion Vector Method (1982, 1986)
7. TCH: Tchebycheff Method (Steuer and Choo 1983)
8. RACE: Pareto Race (Korhonen and Laakso 1986; Korhonen and Wallenius 1988)
9. NIMBUS: (Miettinen 1999)
10. MICA: Modified Interactive Chebychev Algorithm (Luque et al. 2010)

Other interactive multiobjective programming procedures include those by Nakayama and Sawaragi (1984), Climaco and Antunes (1987), and Koksalan and Karasakal (2006).



Multiobjective Programming, Fig. 3 General algorithmic outline

Selected Interactive Procedures

The Aspiration Criterion Vector Method (WIERZ) begins by asking the DM to specify an aspiration criterion vector $\boldsymbol{q}^{(1)} < z^{**}$. Using the T-vertex λ-vector defined by $\boldsymbol{q}^{(1)}$ and z^{**}, the augmented Tchebycheff program is solved, thus projecting $\boldsymbol{q}^{(1)}$ onto N in order to produce $z^{(1)}$. In the light of $z^{(1)}$, the DM specifies a new aspiration criterion vector $\boldsymbol{q}^{(2)}$. Using the T-vertex λ-vector defined by $\boldsymbol{q}^{(2)}$ and z^{**}, the augmented Tchebycheff program is solved, thus projecting $\boldsymbol{q}^{(2)}$ onto N in order to produce $z^{(2)}$. In the light of $z^{(2)}$, the DM specifies a third aspiration criterion vector $\boldsymbol{q}^{(3)}$, and so forth. Algorithmically, the steps are as follows:

Step 1. $h = 0$. Construct a payoff table, form a z^{**} reference criterion vector, and specify $\rho > 0$ for use in the augmented Tchebycheff program. The DM specifies aspiration criterion vector $\boldsymbol{q}^{(1)}$.

Step 2. $h = h + 1$. Compute T-vertex λ-vector defined by $\boldsymbol{q}^{(h)}$ and z^{**}.

Step 3. Using the T-vertex λ-vector, solve the augmented Tchebycheff program for $z^{(h)}$.

Step 4. In the light of what the DM has been able to learn about the problem so far, the DM contemplates $z^{(h)}$.

Step 5. If the DM wishes to cease iterating, stop with $(z^{(h)}, x^{(h)})$ as the final solution. Otherwise, continue on to Step 6.

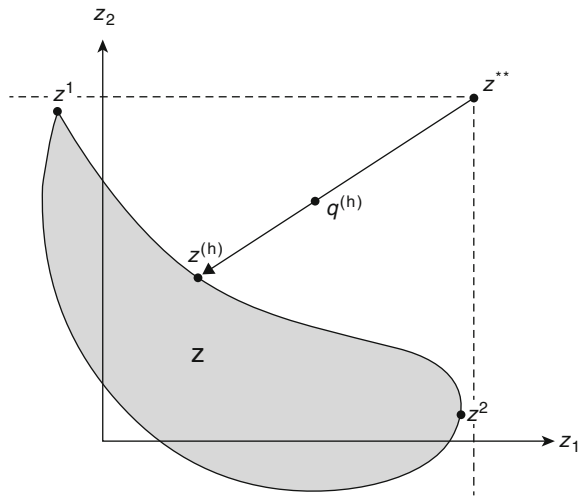
Step 6. The DM specifies another aspiration criterion vector, designated $q^{(h-1)}$. Go to Step 2.

Consider Fig. 4 in which N is the set of boundary criterion vectors z^1 through $z^{(h)}$ to z^2, inclusive. In the figure, it can be seen the way aspiration criterion vector $q^{(h)}$ is projected onto the nondominated set by means of the augmented Tchebycheff program. Note that the direction of the arrow emanating from z^{**} and going through $q^{(h)}$ is given by

$$-\left(\frac{1}{\lambda_1}, \ldots, \frac{1}{\lambda_k}\right)$$

where the λ_i are the components of the T-vertex λ-vector defined by $q^{(h)}$ and z^{**}. Thus changing $q^{(h)}$ changes the $z^{(h)}$ generated by the sampling program.

Instead of generating only one solution at each iteration, the Tchebycheff Method (TCH) generates groups of solutions by making multiple probes of each subset in a sequence of progressively smaller subsets of N. Letting P be the number of solutions to be presented to the DM at each iteration, TCH begins by generating P well-spaced λ-vectors from $\Lambda^{(1)} = \Lambda$. Then the lexicographic Tchebycheff program is solved for each of the λ-vectors. From the P resulting nondominated criterion vectors, the DM selects his or her most preferred, designating it $z^{(1)}$. At this point, the interval widths of $\Lambda^{(1)}$ are reduced and centered about the T-vertex λ-vector defined by $z^{(1)}$ and z^{**} to form an interval defined subset $\Lambda^{(2)}$. Then P well-spaced λ-vectors are generated from $\Lambda^{(2)}$ and the lexicographic Tchebycheff program is solved for each of the λ-vectors. From the P resulting non-dominated criterion vectors, the DM selects the most preferred, designating it $z^{(2)}$. Now the interval widths of $\Lambda^{(2)}$ are reduced and centered about the T-vertex λ-vector defined by $z^{(2)}$ and z^{**} to form an interval defined subset $\Lambda^{(3)}$. Then P well-spaced λ-vectors are generated from $\Lambda^{(3)}$ and the lexicographic Tchebycheff program is solved for each of them, and so forth.



Multiobjective Programming, Fig. 4 Projection of $q^{(h)}$ onto the nondominated set

Another procedure that also generates multiple solutions at each iteration, but employs the weighted-sums program, is the Geoffrion-Dyer-Feinberg (GDF) procedure. GDF begins with the specification of an initial feasible criterion vector $z^{(0)}$. Then the DM specifies a λ-vector that is to be reflective of the local marginal tradeoffs at $z^{(0)}$. Using this λ-vector, the weighted-sums program is solved for criterion vector $y^{(1)}$. Then the line through the feasible region in criterion space Z that starts at $z^{(0)}$ and ends at $y^{(1)}$ is divided into segments so as to create P equally spaced criterion vectors. The most preferred of the equally spaced criterion vectors becomes $z^{(1)}$. Then the DM specifies a new λ-vector that is to be reflective of the local marginal tradeoffs at $z^{(1)}$. Using this λ-vector, the weighted-sums program is solved for criterion vector $y^{(2)}$. Then the line segment through Z that starts at $z^{(1)}$ and ends at $y^{(2)}$ is divided into segments so as to create P new equally spaced criterion vectors. The most preferred of the new equally spaced criterion vectors becomes $z^{(2)}$, and so forth.

Features from different procedures can easily be combined. For instance, drawing from STEM, WIERZ and NIMBUS, one could have the following. After forming a z^{**} reference criterion vector, an initial aspiration criterion vector $q^{(1)}$ specified. Then one of the Tchebycheff programs is solved using the T-vertex λ-vector defined by $q^{(1)}$ and z^{**} to produce $z^{(1)}$. The DM then specifies the components of $z^{(1)}$ that are to be

increased, the amounts of each increase, the components that are to be relaxed, and the amounts of each relaxation in order to form a second aspiration criterion vector $\boldsymbol{q}^{(2)}$. Using the T-vertex λ-vector defined by $\boldsymbol{q}^{(2)}$ and z^{**}, one of the Tchebycheff programs is solved to produce $z^{(2)}$. The DM then specifies which components of $z^{(2)}$ are to be increased, the amounts of each increase, the components that are to be relaxed, and the amounts of each relaxation in order to form $\boldsymbol{q}^{(3)}$. Using the T-vertex λ-vector defined by $\boldsymbol{q}^{(3)}$ and z^{**}, one of the Tchebycheff programs is solved to produce $z^{(3)}$, and so forth.

Concluding Remarks

Because the weighted-sums, augmented Tchebycheff, and other variants of these programs that are used to sample the nondominated set are single criterion optimization problems, conventional mathematical programming software can in most cases be employed (Gardiner and Steuer 1994). In this way, interactive procedures can address multiobjective programming problems with as many constraints and variables as in single objective programming. Unfortunately, in multiobjective programming, there are limitations with regard to the number of objectives. Problems with up to about five objectives can generally be accommodated, but above this number, difficulties can arise because of the rate at which the nondominated set grows as the number of objectives increases.

Multi-armed Bandit Problem

Sequential decision-making problem under uncertainty involving a set of machines (arms) each offering random unknown rewards, in which the decision maker must decide each period which machine (arm) to play (pull), with the objective of maximizing the total reward received. The problem is analogous to playing slot machines in a gambling casino, but has many practical OR/MS applications involving dynamic stochastic resource allocation. One of the basic trade-offs in these types of problems is between exploitation (e.g., playing the machine that has given the best mean reward thus far) versus exploration (playing a machine that has not been tried or one that has been tried infrequently with highly variable rewards).

Multi-attribute Utility Theory

Rakesh K. Sarin
University of California, Los Angeles, CA, USA

Consider a decision problem such as selection of a job, choice of an automobile, or resource allocation in a public program (education, health, criminal justice, etc.). These problems share a common feature—decision alternatives impact multiple attributes. The attractiveness of an alternative therefore depends on how well it scores on each attribute of interest and the relative importance of these attributes. Multi-attribute utility theory (MAUT) is useful in quantifying relative attractiveness of multi-attribute alternatives.

The following notation will be used:

X_i the set of outcomes (scores, consequences) on the ith attribute
x_i a specific outcome in X_i
X $X_1 \times X_2 \times \ldots \times X_n$ (Cartesian product)
u_i a single attribute utility function $u_i : X_i \rightarrow \mathbb{R}$
u the overall utility function, u: $X \rightarrow \mathbb{R}$
$\gtrsim$ "is preferred to"

A decision maker uses the overall utility function, u, to choose among available alternatives. The major emphasis of the work on multi-attribute utility theory has been on questions involving u: on conditions for its decomposition into simple polynomials, on methods for its assessment, and on methods for obtaining sufficient information regarding u so that the evaluation can proceed without its explicit identification with full precision.

The primitive in the theory is the preference relation $\gtrsim$ defined over X. Luce et al. (1965) and Fishburn (1964) provide conditions on a decision maker's preferences that guarantee the existence of a utility function u such that

$$\begin{aligned} &(x_1, \ldots, x_n) \gtrsim (y_1, \ldots, y_n), \\ &\qquad x_i, y_i \in X_i, i = 1, \ldots n \\ &\text{if and only if} \\ &u(x_1, \ldots, x_n) \geq u(y_1, \ldots y_n) \end{aligned} \tag{1}$$

Additional conditions are needed to decompose the multi-attribute utility function u into simple parts. The most common approach for evaluating multi-attribute alternatives is to use an additive representation. For simplicity, assume that there exist the most preferred outcome x_i^* and the least preferred outcome x_i^0 on each attribute $i = 1$ to n. In the additive representation, a real value u is assigned to each outcome $(x_1, \ldots, x_n)$ by

$$u(x_i, \ldots, x_n) = \sum_{i=i}^{n} w_i u_i(x_i) \tag{2}$$

where the $\{u_i\}$ are single attribute utility functions over X_i that are scaled from 0 to 1, i.e., $u_i(x_i^*) = 1, u_i(x_i^0) = 0$ for $i = 1$ to n, and the $\{w_i\}$ are positive scaling constants reflecting relative importance of the attributes with $\sum_{j=1}^{n} w_j = 1$.

If the interest is in simply rank-ordering the available alternatives, then the key condition for the additive form in (2) is mutual preferential independence. The resulting utility function is called an ordinal value function. Attributes X_i and X_j are preferentially independent if the tradeoffs (substitution rates) between X_i and X_j are independent of all other attributes. Mutual preferential independence requires that preference independence holds for all pairs X_i and X_j. Essentially, mutual preferential independence implies that the indifference curves for any pair of attributes are unaffected by the fixed levels of the remaining

attributes. Debreu (1960), Luce and Tukey (1964), and Gorman (1968) provide axiom systems and analysis for the additive form (2).

If, in addition to rank order, one is also interested in the strength of preference between pairs of alternatives, then additional conditions are needed. The resulting utility function is called a measurable value function, and it may be used to order the preference differences between the alternatives.

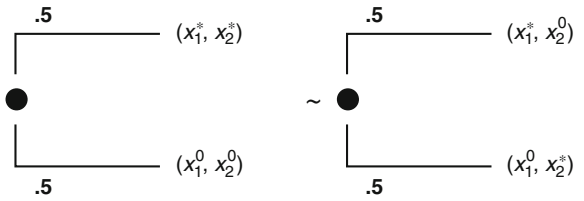
The key condition for an additive measurable value function is difference independence (see Dyer and Sarin 1979). This condition asserts that the preference difference between two alternatives that differ only in terms of one attribute does not depend on the common outcomes on the other $n-1$ attributes.

Finally, perhaps the most researched topic is the case of decisions under risk where the outcome of an alternative is characterized by a probability distribution over X. Denote $\tilde{X}$ as the set of all simple probability distributions over X. Assume that for any $p \in \tilde{X}$ there exists an alternative that can be identified with p, and thus p could be termed as a risky alternative. The outcome of an alternative $p \in \tilde{X}$ might be represented by the lottery which assigns probabilities $p_1, \ldots, p_l, \sum_{j=1}^{l} p_j = 1$, to the outcomes $x^1, \ldots, x^l \in X$, respectively. For the choice among risky alternatives $p, q \in \tilde{X}$, von Neumann and Morgenstern (1947) specified conditions on the decision maker's preference relation $\gtrsim$ over $\tilde{X}$ that imply:

$$\begin{aligned} &p \gtrsim q \\ &\text{if and only if} \\ &\sum_{x \in X} p(x)u(x) \geq \sum_{x \in X} q(x)u(x). \end{aligned} \tag{3}$$

Notice that the same symbol u has been used to denote ordinal value function, measurable value function, and now the von Neumann-Morgenstern utility function. The context, however, makes the interpretation clear.

A majority of the applied work in multi-attribute utility theory deals with the case when the von Neumann-Morgenstern utility function is decomposed into the additive form (2). Fishburn (1965a, b) derived necessary and sufficient conditions for a utility function to be additive. The key condition for additivity is the marginality condition, which states that the preferences for any lottery $p \in X$ should depend only on the marginal probability distributions over X_i and not on their joint probability distribution. Thus, for additivity to hold, the two lotteries below must be indifferent:



Notice that in either lottery, the marginal probability of receiving the most preferred outcome or the least preferred outcome on each attribute is identical. A decision maker may, however, prefer the right-hand side lottery over the left-hand side lottery if the decision maker wishes to avoid a 0.5 chance of the poor outcome (x_1^0, x_2^0) on both attributes.

The assessment of single attribute utility functions $\{u_i\}$ in (2) will require different methods depending on whether the overall utility represents an ordinal value function, a measurable value function, or a von Neumann-Morgenstern utility function. Keeney and Raiffa (1976) discuss methods for assessing multi-attribute ordinal value function and multi-attribute von Neumann-Morgenstern utility function. Dyer and Sarin (1979) and von Winterfeldt and Edwards (1986) discuss assessment of multi-attribute measurable value function.

Besides the additive form (2), a multiplicative form for the overall utility function has also found applications in a wide variety of contexts. In the multiplicative representation, a real value u is assigned to each outcome $(x_1, \ldots, x_n)$ by

$$1 + ku(x_1, \ldots, x_n) = \left[\prod_{i=1}^{n} [1 + kk_i u_i(x_i)]\right]$$

where the $\{u_i\}$ are single attribute utility functions over X_i that are scaled from zero to one, the $\{k_i\}$ are positive scaling constants, k is an additional scaling constant satisfying $k > -1$, and

$$1 + k = \prod_{i=1}^{n} [(1 + kk_i)].$$

If u is a measurable value function, then weak difference independence along with mutual

preference independence provides the desired result. An attribute is weak difference independent of the other attributes if preference difference between pairs of levels of that attribute do not depend on fixed levels of any of the other attributes. Thus, for $x_i, y_i, w_i, z_i \in X_i$, the ordering of preference difference between x_i and y_i, and w_i and z_i, remains unchanged whether one fixes the other attributes at their most preferred levels or at their least preferred levels.

If the overall utility function is used for ranking lotteries as in (3), then a utility independence condition, first introduced by Keeney (1969), is needed to provide the multiplicative representation (4). An attribute is said to be utility independent of the other attributes if the decision maker's preferences for lotteries over this attribute do not depend on the fixed levels of the remaining attributes. Mutual preferential independence and one attribute being utility independent of the others are sufficient to guarantee either the multiplicative form (4) or the additive form (2). The additive form results if in (4) $k = 0$ or $\sum_{j=1}^{n} k_j = 1$. Keeney and Raiffa (1976) discuss methods for calibrating the additive and multiplicative forms for the utility function. In the literature, other independence conditions have been identified that lead to more complex nonadditive decompositions of the utility function. These general conditions are reviewed in Farquhar (1977).

If utilities, importance weights, and probabilities are incompletely specified, then the approaches of Fishburn (1964) and Sarin (1975) can be used to obtain a partial ranking of alternatives.

The key feature of multi-attribute utility theory is to specify verifiable conditions on a decision maker's preferences. If these conditions are satisfied, then the multi-attribute utility function can be decomposed into simple parts. This approach of breaking the complex value problem (objective function) into manageable parts has found significant applications in decision and policy analysis. In broad terms, multi-attribute utility theory facilitates measurement of preferences or values. The axioms of the theory have been found to be useful in suggesting approaches for measurement of values. In physical measurements (e.g., length), the methods for measurement have been known for a long time and the theory of measurement has added little to suggesting new methods. In the measurement of values, however, several new methods have been developed as a direct result of the theory.

Multiple Criteria Decision Making

Ramaswamy Ramesh and Stanley Zionts
University at Buffalo, The State University of New York, Buffalo, NY, USA

Introduction

Multiple Criteria Decision Making (MCDM) refers to making decisions in the presence of multiple, usually conflicting, objectives. Multiple criteria decision problems pervade almost all decision situations ranging from common household decisions to complex strategic and policy level decisions in corporations and governments. Prior to the development of MCDM as a discipline, such problems have been traditionally addressed as single-criterion optimization problems by (i) deriving a composite measure of the objectives and optimizing it, or (ii) by choosing one of the objectives as the main decision objective for optimization and solving the problem by requiring an acceptable level of achievement in each of the other objectives. MCDM as a discipline was founded on two key concepts of human behavior, introduced and explored in detail by Herbert Simon in the 1950s: satisficing and bounded rationality (Simon 1957). The two are intertwined because satisficing involves finding solutions that satisfy constraints rather than optimizing the objectives, while bounded rationality involves setting the constraints and then searching for solutions satisfying the constraints, adjusting the constraints, and then continuing the process until a satisfactory solution is found. The rest of this article overviews important aspects of MCDM, including basic concepts, a taxonomy, modeling techniques, and algorithms.

Basic Concepts

An MCDM problem can be broadly described as follows. Let $D = \{d_1,\ldots, d_n\}$ denote the decision space, comprising the set of possible decision alternatives to a problem. Let $C = \{C_1,\ldots, C_p\}$ denote the objective space, comprising of a set of p mutually conflicting objectives. Without loss of generality, assume all objectives are to be maximized. Let E: $D \rightarrow C$ be a mapping of the decision space on to the objective space, where $E(d_i)$ is the vector $(C_1^i,\ldots, C_p^i)$. Each element of this vector is an assessment, or the value of the corresponding objective provided by the decision alternative d_i. A fundamental concept in MCDM is that of dominance, defined as follows.

***Definition* 1 (*Dominance*).** A decision alternative d_i said to be dominated by another alternative d_j if $C_k^i \leq C_k^j$, $k = 1,\ldots, p$ with at least one strict inequality.

In the above definition, if all the inequalities hold as strict inequalities, then the dominance is said to be strong; otherwise, it is called weak. The following concept is a logical extension of the dominance concept.

***Definition* 2 (Convex *Dominance*).** An alternative d_i is said to be convex dominated by a subset $\hat{D} \subset D$ if it

is dominated by a convex combination of the alternatives in $\hat{D}$

The above definitions lead to a central theme of all MCDM techniques as follows.

***Definition* 3 (*Efficiency*).** An alternative d_j is said to be efficient or nondominated in D if there is no other alternative in D that dominates it, even weakly.

The concept of efficiency can be extended to convex dominance as well. In this case, an efficient alternative is known as convex-efficient or convex-nondominated. The following theorem of Geoffrion (1968) shows how the efficiency of an alternative can be determined. Zionts and Wallenius (1980) introduced a different but equivalent methodology that solves a number of problems including that one.

***Theorem* 1.** Consider any decision alternative d_i and its mapping on the objective space $(C^i_1,\ldots, C^i_p)$. The decision d_i is efficient if only if the following linear program is unbounded:

$$\text{Maximize} \sum_{j=1}^{p} w_j C^i_j$$

$$\text{subject to} \sum_{j=1}^{p} w_j C^k_j \leq 0,\ k = 1,\ldots,n, k \neq i$$

$$w_j \geq 0,\ j = 1,\ldots,p.$$

A Taxonomy of MCDM Methods

The MCDM methods proposed in the literature cover a wide spectrum, and there are several alternative ways of organizing them into a taxonomy. The taxonomy described here is based on Chankong et al. (1984), which is one of the interpretations of the world of MCDM models. At the outset, MCDM methods can be classified into two broad classes: vector optimization methods and utility optimization methods. Vector optimization is primarily concerned with the generation of all efficient decision alternatives. These methods do not require intervention of a decision maker. These methods do generate a subset of nondominated solutions. Some of the well-known vector optimization methods include those of Geoffrion (1968), Villarreal and Karwan (1981), and Yu and Zeleny (1976).

Multiple Criteria Decision Making, Table 1 A taxonomy of MCDM approaches

Decision outcome	Decision space	
	Explicit	Implicit
Deterministic	Deterministic Multiattribute Decision Analysis	Deterministic Multiobjective Mathematical Programming
Stochastic	Stochastic Multiattribute Decision Analysis	Stochastic Multiobjective Mathematical Programming

The utility optimization methods can be broadly organized according to the following dimensions (see, for example, Zionts 1979):

1. Nature of decision space: Explicit or Implicit; and
2. Nature of decision outcomes: Stochastic or Deterministic.

In an explicit decision space, decision alternatives are stated explicitly. A classical example is the home buying problem, where a decision maker/home buyer is faced with a set of possible homes to consider purchasing. For an implicit decision, alternatives are stated using a set of constraints, such as in linear or nonlinear programming where a feasible alternative must satisfy the constraints. An implicit decision situation can be further categorized as continuous or discrete. The decision outcomes are stochastic or deterministic depending on whether the mapping function E: $D \rightarrow C$ is stochastic or deterministic. Table 1 classifies MCDM methods broadly along the two dimensions. There are many approaches in the various segments of this classification. Here, the discussion focuses on the best-known methods.

Methodological Approaches

Deterministic Decision Analysis — Deterministic decision analysis is concerned with finding the most preferred alternative in decision space by constructing a value function representing a decision maker's preference structure, and then using the value function to identify the most preferred solution. A value function $v(C_1, C_2,\ldots, C_p)$ is a scalar-valued

function defined with the property that $v(C_1, C_2,\ldots, C_p) > v(C',\ldots, C'_p)$ if and only if $(C_1, C_2,\ldots, C_p)$ is at least as preferred as $(C'_1,\ldots, C'_p)$ (Keeney and Raiffa 1976). The construction of the value function involves choice decisions made by the decision maker. Generating value functions is simplified if certain conditions hold, in which case it is possible to decompose the above functions into partial value functions $v_k(C_k)$ for each value of k.

The decomposition and certain simplifications of the value function may be carried out if certain underlying assumptions on the decision maker's preference structure hold. One of these is preferential independence, which is stated as follows: Consider a subset of objectives denoted as $\hat{C}$. If the decision maker's preferences in the space $C - \hat{C}$ are the same for any set of arbitrarily fixed levels of the objectives $\hat{C}$, then $\hat{C}$ is said to be preferentially independent of $C - \hat{C}$. The set C is said to be mutually preferentially independent if every subset of C is preferentially independent of its complement with respect to C. When mutual preferential independence holds, an additive value function of the form

$$v(d_i) = \sum_{k=1}^{p} \lambda_k v_k\left(C_k^i\right) \text{ where } \lambda_k \text{ is a scalar constant}$$

is appropriate. There are other nonlinear forms that can be used as well. Of course, an additive value function, if appropriate, is highly desirable. Once the value function has been determined, it can be used to evaluate and rank the alternatives.

Stochastic Decision Analysis — Stochastic decision analysis is similar to the deterministic case, except that the outcomes are stochastic, and utility functions are constructed instead of value functions. The ideas are similar. There is an analogous condition to that described for the discrete case above. It involves utility independence. A subset of objectives $\hat{C}$ is utility independent of its complement if the conditional preference order for lotteries involving changes in $\hat{C}$ does not depend on the levels at which the objectives in $\hat{C}$ are fixed. Since utility independence refers to lotteries and preferential independence refers to deterministic outcomes, utility independence implies preferential independence, but not vice versa. Analogous to mutual preferential independence, the set C is said to be mutually utility independent if every subset of C is utility independent of its complement with respect to C. Keeney and Raiffa (1976) show that if C is mutually utility independent, then a multiplicative utility function is appropriate. This function is of the form

$$u(d_i) = \prod_{k=1}^{p} \mu_k u_k\left(C_k^i\right),$$

where $u(d_i)$ is the overall utility of the decision alternative d_i, $u_k(C_k^i)$ is the utility of its kth objective component, and μ_k is a scalar constant. A more stringent set of assumptions must hold in order that the utility function be additive. In the stochastic case, not only must a utility function be estimated, but probabilities of various outcomes must also be estimated by the decision maker.

Multiobjective Mathematical Programming — Considerable work has been done in the multiobjective mathematical programming area. These include Multiobjective Linear Programming (MOLP) and Multiobjective Integer Programming (MOIP). Goal programming (Lee 1972), the method of Zionts and Wallenius (1976, 1983), the Step Method of Benayoun et al. (1971), and the method of Steuer (1976) are some of the better-known MOLP methods. Goal programming and the method of Zionts and Wallenius are now described in more detail.

Goal programming is an extension of linear programming and was proposed by Charnes and Cooper in 1961. A description of this technique is as follows. Consider the following MOLP problem:

$$\begin{aligned} &\text{Maximize } \boldsymbol{Cx} \\ &\text{subject to } \quad \boldsymbol{Ax} \le \boldsymbol{b} \qquad \text{(MOLP)} \\ &\boldsymbol{x} \ge \boldsymbol{0} \end{aligned}$$

where $\boldsymbol{C} = (c_{kj})$ is a $(p \times n)$ matrix, $\boldsymbol{A}$ is an $(m \times n)$ matrix and $\boldsymbol{x}$ is an $(n \times 1)$ vector. Let $(\alpha_1,\ldots, \alpha_p)$ denote the goals with respect to the desired levels of attainment in the objectives specified by a decision maker. Introduce over and under attainment variables y_k^+ and y_k^- for each objective and add the following constraints, where $\boldsymbol{c}_k$ is the kth row of $\boldsymbol{C}$:

$$\boldsymbol{c}_k\boldsymbol{x} - y_k^+ + y_k^- = \alpha_k, \quad k - 1,\ldots, p.$$

Let w_k denote the penalty for the net deviation from the goal of objective $k = 1,\ldots, p$. Then the goal programming problem is formulated as follows:

$$\text{Minimize} \quad \sum_{j=1}^{p} w_k\left(y_k^+ + y_k^-\right) \qquad \text{(GP)}$$

$$\text{subject to} \quad \sum_{j=1}^{n} c_{kj}x_j - y_k^+ + y_k^- = \alpha_k, \quad k = 1,\ldots, p$$

$$\boldsymbol{Ax} \leq \boldsymbol{b}$$

$$\boldsymbol{x}, \boldsymbol{y} \geq \boldsymbol{0}$$

The above problem minimizes a weighted sum of deviations from the desired goals, where weights are required from the decision maker. The goal programming formulation is an attempt to find a solution that is closest to the decision maker's desired goals, while also responding to his differential emphasis on the nonattainment of the various goals.

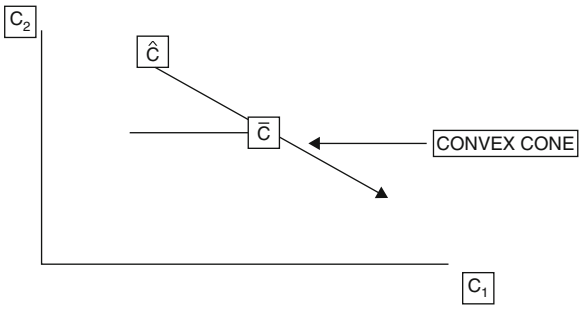
The Zionts and Wallenius method follows an interactive approach using pairwise evaluations of decision alternatives by a decision maker to solve problem MOLP. The method starts by choosing an initial set of weights $\lambda \in R^p$, and maximizing a linear composite objective $\lambda\boldsymbol{Cx}$. This generates a corner point of $\{\boldsymbol{Ax} \leq \boldsymbol{b}, \boldsymbol{x} \geq \boldsymbol{0}\}$ that is efficient. Call this solution $\boldsymbol{x}^0$. Next, the adjacent corner points of $\boldsymbol{x}^0$ that are also efficient (and whose edges leading to them are *also* efficient) are determined. Call this set S^0. The decision maker is asked to choose between $\boldsymbol{x}^0$ and a solution from S^0 until: (i) either he or she prefers $\boldsymbol{x}^0$ to all the points in S^0, or (ii) prefers some solution in S^0 to $\boldsymbol{x}^0$. If $\boldsymbol{x}^0$ is preferred to all the points in S^0, then the method stops with $\boldsymbol{x}^0$ as a "locally" best preferred corner-point solution. Otherwise, if some solution in S^0 is preferred to $\boldsymbol{x}^0$, then it is devoted as $\boldsymbol{x}'$. Linear constraints of the form $\lambda\,(\boldsymbol{Cx}' - \boldsymbol{Cx}'') \leq -\epsilon$ where $\boldsymbol{x}'$ is preferred to $\boldsymbol{x}''$ and ϵ is a small positive quantity are generated from the decision maker's pairwise preferences. A new set of weights that satisfy these constraints are then obtained. If these constraints are in conflict, then some of them are dropped in determining the new weights. Call the new set λ''. Maximizing the composite objective $\lambda''\boldsymbol{Cx}$, a new efficient corner point is generated, and the above steps are repeated until a corner point that is preferred to all its adjacent efficient corner points is obtained.

Compared to MOLP, research on MOIP is rather limited. Some of the earlier works on MOIP have been in the domain of vector optimization. Bitran and Rivera (1982) provided an implicit enumeration algorithm for determining the efficient set of 0-1 MOIP problems. Pasternak and Passy (1973) studied the vector optimization problem for two objectives. Klein and Hannan (1982) extended Pasternak and Passy's work to more than two objectives. Villarreal and Karwan (1981) generalized the classical dynamic programming recursions to a multicriteria framework. Ramesh et al. (1989) followed the utility optimization approach to find the most preferred solution to an MOIP problem.

The method of Ramesh et al. (1989) follows a branch-and-bound search strategy using the Zionts and Wallenius method for bounding. The decision maker's preference structure is assessed using pairwise evaluations and an internal representation of the preference structure is successively built during the course of the branch-and-bound search. This representation is used to deduce the decision maker's preferences wherever possible so that the cognitive load arising out of the pairwise judgments can be minimized. The internal representation is based on the concept of convex cones as described below (Korhonen et al. 1984).

Consider a two-dimensional objective space as shown in Fig. 1. Let $\bar{C}$ and $\hat{C}$ be two points in this space such that $\hat{C}$ is preferred to $\bar{C}$. Assuming a quasiconcave and nondecreasing utility function for the decision maker, it follows that every point falling on the ray $\left\{\hat{C} | \hat{C} = \hat{C} + \mu\,(\bar{C} - \hat{C}), \mu \geq 0\right\}$ is less preferred than $\hat{C}$ and no more preferred than $\bar{C}$. Consequently, every point in this ray and those dominated by it can be eliminated from consideration. This ray is called a convex cone, and is illustrated in Fig. 1. Every pairwise judgment of a decision maker yields a convex cone and the cones are ordered into a tree structured to eliminate search regions efficiently and minimize the need for the decision maker's pairwise evaluations throughout the search procedure.

Other Explicit Decision Space Methods — Several methods have been proposed for finding the most preferred alternative from an explicitly stated decision space without estimating a value function. These techniques are methods of deterministic decision analysis, and there is substantial interest in



Multiple Criteria Decision Making, Fig. 1 Illustration of convex cones

these problems. Three important methods in this category are the Multiple Criteria Decision Making (MCDM) Analytic Hierarchy Process (Saaty 1980), the method of Korhonen et al. (1984), and the AIM method (Lotfi et al. 1992).

The idea of Analytic Hierarchy Process (AHP) is that one can structure a problem hierarchically, and then make judgments regarding the relative importance of various aspects of the problem. As a result of these judgments, a ranking is produced. A simple decision problem would have a hierarchy that consists of three levels, from the top down: 1) the goal; 2) the criteria involved; and 3) the alternatives. The number of levels depends on the nature of the problem involved. In general, consider an n-alternative, p-criteria problem. Then the decision maker is asked to fill in entries in $p + 1$ reciprocal matrices as follows:

1. One $(p \times p)$ matrix relating each criterion to all others; and
2. P $(n \times n)$ matrices, each relating one criterion to all alternatives.

Each reciprocal matrix has all diagonal elements one, and off-diagonal elements reciprocal, that is, $a_{ij} = 1/a_{ji}$. Accordingly, the decision maker need only provide just less than half the entries, more specifically, the $[p(p-1)/2] + p[n(n-1)/2]$ off-diagonal (lower or upper) entries in the matrix. Though the amount can be reduced to as few as $(p-1) + p(n-1)$ entries (having no redundancy), the reduction in information required increases the cognitive load on the decision maker to provide entries, and does not provide the redundancy and cross checking that furnishing the complete input provides.

In filling in the matrices, the decision maker is asked to provide numbers between 1/9 and 9 reflecting the relative importance between the aspects involved. One of the matrices reflects the comparison among criteria and the p other matrices reflect evaluations of alternatives with respect to each criterion. AHP next solves for the right eigenvector, or characteristic vector, of each matrix. An eigenvector of a matrix may be estimated by taking the geometric mean of the elements of each row of the matrix (for a $p \times p$ matrix, the pth root of the product of the p elements of a row), and then normalizing the resulting vector so that the sum of the elements is unity. The consistency of the matrix (as differentiated from a matrix generated at random) may be tested using a calculation on the matrix. By the user furnishing fewer than all $p(p-1)/2$ entries required in the matrix, the test on consistency is compromised. The scaled eigenvectors are then used to score and rank each alternative.

Korhonen et al. (1984) presented an interactive method employing pairwise comparisons for solving the discrete, deterministic MCDM problem. Assuming a quasiconcave and nondecreasing utility function, they introduce the concept of convex cones. Choosing an arbitrary set of positive weights w_i, $i = 1,\ldots, p$, a composite linear utility function is initially generated. Using the composite as a proxy for the true utility function, the decision alternative maximizing the composite is generated. Call this solution d^0. Using the mapping E: $D \rightarrow C$, all adjacent efficient decision alternatives to d^0 (as in the Zionts-Wallenius method) are determined. This is done for the region that consists of all convex combinations of feasible solutions. Call the set of such solutions S^0. The decision maker is asked to choose between d^0 and some solution from S^0. Based on the response, a constraint on the weights is generated, as in the Zionts and Wallenius method for MOLP, and a convex cone is derived. Any solution in the set S^0 dominated by the cone is removed from S^0, and the above step is repeated until either d^0 is preferred to all solutions in S^0 or some solution in S^0 is preferred to d^0. The constraints on the weights and the convex cones generated at each iteration of this step are accumulated. The set of cones is used to deduce the decision maker's preferences wherever possible. This reduces the search space, while also minimizing the number of pairwise comparisons the decision maker has to perform.

Every solution in S^0 that is less preferred than d^0 is dropped from consideration. If d^0 is preferred to all the solutions in S^0, then it is denoted as d. If some solution in S^0 is preferred to d^0, then the preferred solution is denoted as d. If d is the only efficient solution remaining in the decision space, then the procedure stops with d as the most preferred decision. Otherwise, choosing a set of weights consistent with the weight constraints (after dropping any conflicting constraints), a new composite linear utility function is generated. Denoting the decision alternative maximizing this composite function as d, the decision maker chooses between d and d. Denoting the preferred solution as d^0, the above steps are repeated.

Lotfi et al. (1992) develop an eclectic method called the Aspiration-Level Interactive Method (AIM) for MCDM. It involves a philosophy that aspiration levels and feedback regarding the relative feasibility of the aspiration levels provide a powerful tool for decision making. The method is embodied in a computer program called AIM. The method provides the decision maker with various kinds of feedback as he explores the solutions. Several different kinds of objectives may be included: objectives to be maximized; objectives to be minimized; target objectives; any of the above kinds of objectives with thresholds, or levels beyond which the user is indifferent to further gains in the objective; and qualitative objectives. To further explain the idea of thresholds, suppose that in the purchase of a house, the age of the house is an attribute to be minimized. Suppose further that the buyer treats as equivalent, however, any houses ten years or less in age. In this case, there is a threshold of ten years, so that an eight-year-old house is considered to be no better than a ten-year-old house with respect to age.

To begin with, the decision maker has the following basic information:

1. A current goal or aspiration level for each objective, initially set to the median, together with the proportion of alternatives having values of the objective at least as good as that value.
2. Two other aspiration levels, the next better and the next worse than the current goal occurring in the data base.
3. The ideal and nadir solutions to the problem.
4. The proportion of alternatives that simultaneously satisfy aspiration levels given in 1 and 2.
5. A nearest nondominated solution to the current goal. The nearest solution is found by mapping the current goal to a solution on the efficient frontier or in the set of nondominated solutions.

The current goal may be (and should be) changed by the user, component by component, to any desired realizable level of any objective. The intention, however, is to keep the current goal near the efficient frontier and therefore nearly achievable. As the user changes the current goal, all but item(s) 3 above change.

The user can invoke various options to help in decision making. He or she can see which solutions, if any, satisfy his current goal. Second, he or she can obtain a ranking of solutions based on a function resulting from his choice of a current goal. Third, he or she can use a simplified version of a concept called outranking to identify neighbor solutions that are similar to his nearest solution. The decision maker may also review the weights implied by the current goal, see a quartile distribution of the problem by objective, and identify and possibly delete dominated solutions.

Concluding Remarks

The field of multiple criteria decision making has been an active since the 1960s. Many interesting approaches have been developed, explored, and implemented in solving problems. Implementation of MCDM methodologies include multiple criteria decision support systems (MCDSS) and negotiations, which may be regarded as multiple criteria problems involving multiple decision makers. MCDSS integrate the multiple criteria approaches in user-friendly microcomputer systems, such as the VIG/VIMDA system of Korhonen and Laakso (1986), the Expert Choice software that implements AHP, and the AIM package of Lotfi et al. (1992) implemented on the World Wide Web by Wang and Zionts (2005). An objective of most of the MCDSS is to provide inexpensive stand-alone software that is easy to use. A very useful set of computer MCDM method software may be found on the World Wide Web by a search on the word decisionarium; the software is housed at the

Helsinki University of Technology, now part of Aalto University.

Negotiations or multiperson MCDM is a natural extension of MCDM. Many decisions are made by groups, and negotiation theory involves using some of the MCDM concepts to simplify and assist negotiations; see for example, Wang and Zionts (2008).

In addition to the journals devoted to management science and operations research and behavioral science, there are two journals that contain articles more exclusively in this area: *Multi-Criteria Decision Analysis* and *Group Decision and Negotiation*. The paper by Wallenius et al. (2008) explores recent accomplishments and what lies ahead.

Multiple Optimal Solutions

In an optimization problem, when different feasible solutions yield the same optimal value for the objective function, the problem has multiple optimal solutions. If a linear-programming problem has multiple optimal solutions, then such solutions correspond to extreme point solutions and their convex combinations.

See

▶ Unique Solution

Multiple Pricing

When solving a linear-programming problem using the simplex method, it is computationally efficient to select a small number, say 5, possible candidate vectors from which one would be chosen to enter the basis. The candidate set consists of columns with large (most negative or most positive) reduced costs, and the vector in this set that yields the largest change in the objective function is selected. Succeeding iterations only consider candidate basis vectors from the vectors that remain in the set that have properly signed reduced costs. When all vectors in the set are chosen or none can serve to change the objective function in the proper direction, a new set is determined.

Multiplier Vector

For a given feasible basis $\boldsymbol{B}$ to a linear-programming problem, let the row vector $\boldsymbol{c_B}$ be the ordered set of cost coefficients for the vectors in $\boldsymbol{B}$. The multiplier vector is defined as $\boldsymbol{\pi} = \boldsymbol{c_B}\,\boldsymbol{B}^{-1}$. If $\boldsymbol{B}$ is an optimal basis, then the components of $\boldsymbol{\pi}$ are the dual variables associated with the corresponding primal constraints. The vector $\boldsymbol{\pi}$ is also called the simplex multiplier vector, with the components of $\boldsymbol{\pi}$ being the simplex multipliers.

Multivariate Quality Control

Francis B. Alt[1] and Scott D. Grimshaw[2]
[1]University of Maryland, College Park, MD, USA
[2]Brigham Young University, Provo, UT, USA

Introduction

A frequent quality control application in the chemical and process industries is the simultaneous monitoring of several correlated quality measurements. For example, González and Sánchez (2010) apply multivariate quality control to manufacturing the window frame for the door of a vehicle, where the five gaps on the window frame are measured at seven locations on the frame. Control charts that simultaneously evaluate all the information available on a process are based on the foundational work of Hotelling (1947) in a military application. While one could create univariate control charts for each measurement, ignoring the correlation between measurements impacts the statistical properties in many ways. Jackson (1956) showed that the use of univariate control charts can be misleading even when the measured characteristics are uncorrelated. Alt (1985) points out that not only is it statistically inefficient to monitor each measurement on its own control chart because the proper out-of-control region is elliptical, the process may exhibit frequent false out-of-control alarms.

Multivariate quality control procedures can be classified into two broad categories: (1) Shewhart procedures designed to quickly detect large out-of-control shifts from the in-control mean vector, and (2) Multivariate EWMA procedures that can be designed to efficiently detect persistent small

and moderate shifts. These are discussed in turn, followed by a discussion of other important methods for multivariate quality control.

Shewhart Charts

At regular time intervals, observe a rational subgroup of size n on p quality characteristics denoted by the vector $\mathbf{x}_i$. When the process is in-control, the quality characteristics will have mean $\boldsymbol{\mu}_0$ and variance-covariance matrix $\boldsymbol{\Sigma}_0$.

The Shewhart χ^2 chart produces an out-of-control signal when

$$\chi^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)'\boldsymbol{\Sigma}_0^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)$$

exceeds the upper control limit. The $\bar{\mathbf{x}}$ is the mean of each quality characteristic for the rational subgroup assembled as a $p \times 1$ vector.

The performance of a control chart is judged by its average run length (ARL), which is the average number of time periods taken before an out-of-control signal is given. A control chart is designed to have a large in-control ARL and a small out-of-control ARL. For multivariate Shewhart charts the upper control limit defines the in- and out-of-control ARL. The run length of Shewhart control charts follows a geometric distribution since each time interval is independent and the probability of an out-of-control signal is identical for each time interval. If ARL_0 denotes the in-control ARL, the upper control limit (UCL) is $\chi^2(1/ARL_0; p)$, the $100(1-(1/ARL_0))\%$ percentile of the χ^2 distribution with p degrees of freedom, if the $\bar{\mathbf{x}}$ is multivariate normal. The most frequent choice is $ARL_0 = 200$, so the upper control limit is the 95% percentile of the χ^2_p. When the process is out-of-control with mean $\boldsymbol{\mu}_1$, the multivariate Shewhart statistic has a non-central χ^2 distribution with p degrees of freedom and non-centrality parameter

$$\lambda = \sqrt{n(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0)'\boldsymbol{\Sigma}_0^{-1}(\boldsymbol{\mu}_1 - \boldsymbol{\mu}_0)},$$

and the out-of-control ARL, denoted by ARL_1, can be computed $ARL_1 = 1/[1 - F(UCL; p, \lambda)]$, where $F(\cdot; p, \lambda)$ is the cdf of a non-central χ^2.

A frequent obstacle to applying the Shewhart χ^2 control chart is the need for the in-control variance-covariance matrix $\boldsymbol{\Sigma}_0$. The Hotelling T^2 distribution, a generalization of the Student's t distribution, allows the estimated variance-covariance matrix $\mathbf{S}$ to replace $\boldsymbol{\Sigma}_0$. The Shewhart T^2 control chart compares the statistic

$$T^2 = n(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)'\mathbf{S}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0)$$

to the upper control limit

$$\text{UCL} = \frac{p(n-1)}{n-p} F(1/\text{ARL}_0; p, n-p)$$

which uses a well-known relationship between the Hotelling T^2 distribution and the F distribution.

In many applications, the in-control mean $\boldsymbol{\mu}_0$ and the in-control variance-covariance matrix $\boldsymbol{\Sigma}_0$ are unknown, but are estimated from data collected while the process is believed to be in-control. For this Phase I data of m time periods of rational subgroup size n, Alt (1982) proposed estimating $\boldsymbol{\mu}_0$ by the mean of the m sample mean vectors, denoted by $\bar{\bar{\mathbf{x}}}$, and estimating $\boldsymbol{\Sigma}_0$ by the pooled variance-covariance matrix which is the mean of the m sample variance-covariance matrices, denoted by $\mathbf{S}_p$. Because the in-control parameters are estimated, the upper control limit is inflated to

$$UCL = \frac{p(m-1)(n-1)}{mn-m-p+1} F(1/\text{ARL}_0; p, mn-m-p+1).$$

If any time period in Phase I has an out-of-control signal and an assignable cause is found, this time period is omitted and $\bar{\bar{\mathbf{x}}}$ and $\mathbf{S}_p$ are recomputed. This step is iterated until all $m^* < m$ time periods are considered in-control.

At this time, the monitoring of future time periods begins by using the statistic

$$T_f^2 = n\left(\bar{\mathbf{x}}_f - \bar{\bar{\mathbf{x}}}\right)'\mathbf{S}_\mathbf{p}^{-1}\left(\bar{\mathbf{x}}_f - \bar{\bar{\mathbf{x}}}\right)$$

with

$$\text{UCL} = \frac{p(m^*+1)(n-1)}{m^*n-m^*-p+1} F(1/\text{ARL}_0; p, m^*n-m^*-p+1)$$

where $\bar{\mathbf{x}}_f$ is a vector of sample means based on data for a time period after m^*. It is suggested that $\bar{\bar{\mathbf{x}}}$ and $\mathbf{S}_p$ be

updated fairly often in the beginning, as the number of future subgroups accumulates.

A common follow-up to a large T^2 statistic is to use standardized coefficients of the discriminant function (Rencher 2002, Chap. 5). That is, compute

$$\mathbf{a} = \text{sqrt}[\text{diag}(\mathbf{S})] \cdot \mathbf{S}^{-1}(\bar{\mathbf{x}} - \boldsymbol{\mu}_0),$$

where *sqrt* is the elementwise square root of the vector and diag($\mathbf{S}$) creates a diagonal matrix from the diagonal elements of the $\mathbf{S}$ matrix. The absolute values of the coefficients in $\mathbf{a}$ give relative contributions of each quality measurement to T^2. Another approach to interpreting a large T^2 value is a decomposition proposed by Mason et al. (1995, 1997). The T^2 can be written as p independent terms, each of which reflects the contribution of an individual quality characteristic. Runger et al. (1996) use this decomposition to improve diagnostics of an out-of-control signal.

MEWMA Charts

The multivariate exponentially weighted moving average (MEWMA) control charts are well suited to observing a single observation ($n = 1$) at each time period t and combining the information from a window of time to make a decision. The generalization from the univariate EWMA was formulated by Lowry et al. (1992). A weighted average of the observed $\mathbf{x}_t$ is formed by

$$\mathbf{Z}_t = \lambda(\mathbf{x}_t - \boldsymbol{\mu}_0) + (1 - \lambda)\mathbf{Z}_{t-1}$$

where the value λ is chosen in designing the control chart to represent the amount of smoothing ($0 < \lambda < 1$) and $\mathbf{Z}_0 = 0$. Small values of λ pool the data over a wide time interval and produce a control chart that effectively identifies small, persistent changes from the in-control mean, $\boldsymbol{\mu}_0$, or a gradual drift from $\boldsymbol{\mu}_0$. Large values of λ yield a $\mathbf{Z}_t$ with high weight on the current observation so the control chart is sensitive to immediate large shifts from $\boldsymbol{\mu}_0$.

The MEWMA chart signals a process is out-of-control at time t when

$$T_t^2 = \mathbf{Z}_t \boldsymbol{\Sigma}_{\mathbf{Z}}^{-1} \mathbf{Z}_t$$

exceeds an upper control limit. The variance-covariance matrix $\boldsymbol{\Sigma}_{\mathbf{Z}}$ depends on λ and t, and is given by

$$\boldsymbol{\Sigma}_{\mathbf{Z}} = \left(\frac{\lambda\left[1 - (1 - \lambda)^{2t}\right]}{2 - \lambda} \right) \boldsymbol{\Sigma}_0,$$

where $\boldsymbol{\Sigma}_0$ is the in-control variance-covariance matrix of $\mathbf{x}_t$. For a given λ, the upper control limit is chosen to provide an ARL for a specified out-of-control mean $\boldsymbol{\mu}_1$. Tables of the ARL for different p, λ, and upper control limit are given by Prabhu and Runger (1997) for in-control $ARL_0 = 200$.

In the univariate case, the CUSUM (cumulative sum) control charts are quite similar to the EWMA control charts. Although a number of multivariate CUSUM procedures have been proposed, an early suggestion by Woodall and Ncube (1985) was to monitor each of the p quality characteristics simultaneously with individual CUSUM charts. The ARL of this collection of p CUSUM control charts is the minimum of $\{ARL_1, ARL_2, \ldots, ARL_p\}$ if the quality characteristics are independent. If the quality characteristics are correlated, reduce the p dimensional space to the $p' < p$ largest principal components. An improvement to this collection of p CUSUMs is to update the CUSUM at each observation and shrink toward the zero vector as described in Crosier (1988).

Control Charts for Variance-Covariance

While monitoring the mean of p correlated quality characteristics has been well researched, less work has been performed on control charts for the variance-covariance matrix (the generalization from univariate control charts on process variability). The most common approach summarizes the $p(p + 1)/2$ variances and covariances in $\boldsymbol{\Sigma}$ into a scalar by defining the generalized variance $|\boldsymbol{\Sigma}|$, which is the determinant of $\boldsymbol{\Sigma}$. Montgomery and Wadsworth (1972) proposed control limits based on the asymptotic normality of $|\mathbf{S}|$, the determinant of the sample variance-covariance matrix based on the n observations in the rational subgroup. Control limits for the typical Shewhart control charts were proposed by Alt (1985) and are $E(|\mathbf{S}|) \pm 3\sqrt{Var(|\mathbf{S}|)}$ where $E(|\mathbf{S}|) = b_1|\boldsymbol{\Sigma}|$ and $Var(|\mathbf{S}|) = b_2|\boldsymbol{\Sigma}|^2$ with

$$b_1 = \frac{1}{(n-1)^p} \prod_{i=1}^{p} (n-i)$$

and

$$b_2 = \frac{1}{(n-1)^{2p}} \left[\prod_{i=1}^{p} (n-i) \right] \times \left[\prod_{j=1}^{p} (n-j+2) - \prod_{j=1}^{p} (n-j) \right].$$

Profile Monitoring

Many manufacturing processes in the chemical process and semiconductor industries have finite-duration processing periods under controlled conditions which result in the final product. With improved metrology these processes can be monitored during the processing time. In these applications the collection of measurements taken on each quality characteristic during processing when plotted over time creates a profile.

Nomikos and MacGregor (1995a) organized the large amount of profile data as a three-dimensional array whose n rows correspond to the different runs, t columns correspond to the measurements taken over processing time for a given run and the third dimension (depth) is the p different quality characteristics. While this is perhaps the organization of the data in a database, multivariate statistical methods require the expression of $\mathbf{Y}$ as a vector, and an 'unfolded' structure generates a tp vector of each quality characteristic at each processing time. Instead of monitoring this extremely large vector, one approach is to reduce the dimensionality to a set of summary scores $\mathbf{T}$. Nomikos and MacGregor (1995a) use principal components of $\mathbf{Y}$ to form $\mathbf{T}$, and Nomikos and MacGregor (1995b) use partial least squares to obtain linear combinations of $\mathbf{Y}$ which are highly correlated with a product's quality measurements taken after processing. Grimshaw et al. (1998) allow changing inputs that affect the profile and provide a real-time processing control chart statistic.

When there is a hypothesized relationship between the profile and an explanatory variable, the profile can be modeled using the parameters of the relationship. For example, if the relationship is linear the estimated regression coefficients are monitored using a Hotelling T^2 following Kang and Albin (2000). In a Phase II control chart where the profile has been estimated from historical data, Kim et al. (2003) address the linear case. The nonlinear profile case has been modeled by multiple regression and higher-order polynomials in Zou et al. (2007) and Kazemzadeh et al. (2008); nonparametric regression methods are used in Zou et al. (2008); and nonlinear profiles for dose–response applications are in Jensen and Birch (2009). Colosimo et al. (2008) monitor profiles of geometric specifications such as roundness, cylindricity, and flatness.

N

Nash Equilibrium

In (noncooperative) game theory, a set of (pure or mixed) strategies in which no player can gain by deviating unilaterally. In general, a game may have a unique, multiple, or no equilibrium. John Nash, who shared the 1994 Nobel Prize in Economic Sciences for his work in game theory, proved that there must exist as least one such mixed strategy equilibrium in a finite-action game.

Natural Resources

Andrés Weintraub
University of Chile, Santiago, Chile

Introduction

The field of natural resources covers various related areas: agriculture, fishing, forestry, mining. Though usually viewed separately, they share common problems, such as ecological concerns, use of scarce resources, and sustainability. There is also a common thread in what has happened since 1990. On the one hand, driven in part by population growth and economic development, many natural resources are beginning to reach or exceed sustainable levels of exploitation, or in the case of non-renewable resources there are limits on known reserves. A second main issue is the new awareness of the need to preserve natural habitats, protect endangered species, provide water and air quality, and promote biodiversity. This has often led to serious conflicts between production goals and ecological impacts, with increased public participation in decision processes. A third basic issue is the emergence of global, competitive markets with the need to derive efficient production processes. In this context, operations research and management science (OR/MS) have played a significant role in managing natural resources. It must be distinguished between methodological proposals through case studies and actual applications. This is an issue of importance. Typically, these problems are often complex, involve uncertainty and consider multiple objectives. Also, natural resources problems are often of large size and scope, with reliable data difficult to obtain. This partly explains the important gap that exists in some areas between modeling proposals shown through representative examples and actual use in planning and production processes. The introduction of personal computers, new information gathering systems, improved data processing, geographic information systems, satellite communication and algorithmic software plays a vital role in supporting

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

the used of OR/MS. A wide range of problems has been approached using typical OR/MS techniques in each area. In some cases, their solution has led to algorithmic developments. It is interesting to analyze the nature of the main problems in each area and the techniques proposed for their solutions, with linear programming, mixed integer programming and simulation being the techniques most commonly used across the areas. In the last decade the issue of integrating the supply chain has starting to emerge in some of the areas as important to improve productivity. Another emerging issue is the explicit introduction of uncertainty in some areas. In the last decade, climate change, carbon sequestration have become issues of increased research (Matthews et al. 2002). A state of the art in these four areas is presented in the Handbook of Operations Research in Natural Resources (Weintraub et al. 2007) and in Bjorndal et al. (2010).

Forestry

Most of the forestry issues are related to the management of forests. Native forests, often publicly owned, are viewed as multiple use entities, considering timber and range production, recreation, wildlife habitat preservation, water and soil quality. Plantations, such as pine or eucalyptus, are usually privately owned, sometimes integrated with pulp and sawmill processing plants, with timber production as their main objective within legal preservation regulations. Decisions in forestry management go from long-range planning to short-range operations.

Long-range planning, which, depending on the species under consideration, can go from 40 to more than 200 years to include up to two tree rotations, reflects basic silvicultural and economic options and in the case of plantations can include decisions on high-level investments in plants. Issues like sustainability of production, ecosystems, landscapes viewed in a strategic way are incorporated (Gunn 2007). A main objective is to maximize sustained long range production compatible with environmental preservation. Mathematical tools have been used successfully in this area. For the purpose of predicting tree growth under different management alternatives, simulation models based on regression techniques and sampling plots have proved reasonably accurate. Decision making has been supported mostly by linear programming models. Timber Ram (Navon 1971) was the first widely used LP model used for planning by the US Forest Service. FORPLAN, a multiple output linear programming model (Kent et al. 1991) and Spectrum (USDA 1995) were later introduced by the US Forest Service to incorporate increasingly environmental issues. Other LP models have been developed by private enterprises oriented towards managing plantations and are used in the USA, Canada, Europe, New Zealand, Chile, Brazil, and Australia.

Medium-range management decisions must consider spatial decisions, such as road building to access areas to be harvested. These decisions are the interface between strategic and operational decisions (Church 2007). One major spatial issue that has emerged during the last decades is that of spatial location of activities. Road building constitutes a major cost to reach areas to be harvested, in particular in native forests. Models have been proposed to integrate harvesting decisions and road building needed to reach harvest areas. These problems lead to mixed-integer programming (MIP) problems that have been successfully solved and used by forest enterprises (Kirby et al. 1986; Andalaft et al. 2003). Another spatial issue relates to the environment. To favor wildlife habitat or scenic beauty, adjacent blocks should be harvested in different periods to allow for new growth to establish itself. In this form, areas without tree growth have a maximum size. For example, some animals will graze only near cover provided by mature trees. These blocks were originally created manually by forests engineers clustering basic cells using a geographic information system (GIS). This problem adds considerable combinatorial complexity to the planning problems, particularly when combined with road building.) In the 1990s, meta-heuristic approaches, mainly Tabu search were used in practice. Exact approaches based on column generation techniques adding lifting constraints (Barahona et al. 1992), or strengthening of the formulation via cliques proved successful (Murray and Church 1996). In the late 1990s developments were proposed were the forming of the harvesting blocks were included into the problem. This approach led to better solutions, but to even more complex combinatorial problems. Again, meta-heuristic techniques were developed, mostly simulated annealing and tabu search (Murray 2007).

Exact algorithms have been proposed which can solve medium size problems (Goycoolea et al. 2009). Other applications consider problems as optimally locating wildlife habitat, selecting and locating vegetative seral stages to enhance faunal species diversity, (Hof and Bevers 1998). Wildlife protection can be incorporated through considering other spatial effects, such as the perimeter of forest areas where edge effects are important for some species, areas of old growth that allow wildlife to prosper, and corridors between old growth areas to let animals move between old growth areas. These problems lead to more difficult combinatorial models. (Hof and Haight 2007).

Short-term operations involve problems such as selection of units to cut, volumes to harvest, selection of bucking patterns, log allocation, selection of harvesting equipment and integration with downstream operations. (Epstein et al. 2007b) and transportation scheduling from forest sites to plants (Epstein et al. 2007a) A variety of models and algorithms have been proposed. Most used are linear programming based models for harvesting and allocation. For stem-bucking problems, dynamic programming and heuristic algorithms have been proposed. Scheduling of harvesting equipment such as towers, skidders or helicopters, decisions on road building, soil characterization and others related to locational aspects have been increasingly been carried out interacting with digital terrain models or geographic information systems. A successful application of OR/MS models to support operational decisions in transportation, machine harvesting scheduling and short term harvesting for Chilean forest firms was reported in Epstein et al. (1999). Since 2000, integrating the supply chain has started to be analyzed. Unlike other areas where sophisticated integration of supply chain activities has been successfully implemented, there have only been a few efforts in the forestry sector integrating forest harvesting, sawmills, pulp plants and secondary transformations such as panels (Carlsson and Ronnqvist 2005; D'Amours et al. 2008). In general at the operational level, OR has been most successful with multiple reported applications. Some of these problems are difficult to solve in exact formulations and heuristics have been necessary. For example, the problem of locating harvesting machinery and building access roads is a combination of a plant location problem and a network flow problem with fixed costs. A successful application solved using GIS-based data, a friendly graphical user interface and a heuristic algorithm is reported in Epstein et al. (2006).

Given the multiple uses of forests, it is only natural to view forest management as a multi-objective problem, considering diverse issues such as timber and range production, recreation, scenic beauty, preservation of endangered species, wildlife habitat, water quality, costs, income, carbon emissions and social impacts. The most common approaches to handle these problems have been through goal programming, or multi-objective linear programming. Multicriteria methods (Diaz-Balteiro and Romero 2007), where preferences are elicited from decision makers via comparisons, such as AHP have also been proposed. However, these developments have seldom been adopted by practitioners, mostly due to the difficulties in implementation.

The explicit treatment of risk and uncertainty has received increased attention of forest planners. The main issues related to uncertainty are in future timber markets, timber growth and yield projections and the possibility of catastrophes such as large fires or pests. Basic approaches proposed to handle uncertainty are : (a) parametric or scenario analysis (b) probability-based models such as stochastic dynamic programming, portfolio theory, chance-constrained linear programming, and simulation; and (c) fuzzy models, in which a certain ambiguity is assumed for restrictions or parameters. These efforts are still mostly at a developmental stage with few applications reported (Martell et al. 1998; Lohmander 2007).

Hierarchical Planning. Forestry problems range from decisions involving spatial concerns over 20 acres to entire forests of 2,000,000 acres, from short-term horizons of a few days or months to long-range planning over 150 or 200 years. Decision levels go from high-level management to operations on the ground. At first, large-scale monolithic models were proposed to solve global models. Given the difficulties in running and analyzing these models, several hierarchical decomposition approaches of global problems have been proposed to handle in a separate but linked way problems at different decision levels (Martell et al. 1998; Church 2007).

Consideration of fire effects in forests started in the 1980s (Martell 1982), where OR/MS was used in prevention of fires, fuel management, detection of

fires, resources acquisition, initial attack dispatching, extended attack management and training. In the last decade the concept of managing fires as system effort has become prevalent., with several systems in use in the US and Canada (Martell 2007).

Agriculture

Mathematical models have been proposed extensively to deal with agricultural problems (Hazell and Norton 1986). The main areas where quantitative approaches have been proposed are overviewed here.

Crop Production Problems at Farm Level. These include the determination of cropping patterns, planning of harvesting operations, design of harvesting equipment, and control of pests and diseases. These interrelated decisions include planting design, use of fertilizer, irrigation schemes and capital investment. The main techniques proposed to handle these problems are mainly linear programming and simulation, and also mixed integer programming, dynamic programming, and decision theory.

Uncertainty in crop yields and prices has also been introduced via portfolio theory, stochastic dominance, stochastic dynamic programming, and games against nature. Risk management considers how farmers perceive risk and act on it (Huirne et al. 2007). Another important issue is that of multiple criteria, relevant in most areas of agricultural decisions, handled mostly using goal programming and compromise programming (Romero and Rehman 1989; Hayashi 2007).

These proposed models have not been applied intensively. One main reason is the farming tradition of using judgment based on experience, rather than looking for technical optimality, which is also constrained by the lack of accurate information.

Regional Planning Problems. These are oriented toward centralized decisions such as the evaluation of development projects, determination of tax or price support policies, to analyze the trade-offs between economic returns and environmental impacts (Teague et al. 1995) or to determine and make operational the concept of sustainable agriculture (Pandey and Hardaker 1995). Spatial market equilibrium models serve for analysis of domestic or international trade. These approaches, however, have mostly had indirect influence on practice or are of research interest only (Campos et al. 2007).

Livestock Production. In this area, mathematical models have been widely and successfully used. In the classical diet and ration formulation problems, a variety of models, mostly linear programming and also quadratic programming, have been proposed for different animal stocks. Simulation has been used for modeling pasture-based livestock systems. The problem of livestock breeding and replacement has been approached through simulation, linear programming, deterministic and stochastic dynamic programming. Most applications are in the area of evaluation of replacement policies, particularly in large-scale dairy, egg production and poultry. Multi-objective considerations for diet problems include different nutrient requirements and costs (Peña et al. 2007).

Agriculture and the Environment. Since around 2000, environmental issues have become prevalent, as the negative aspects towards the environment due to agriculture became more evident. Crop simulation models as well as optimization models help quantify the environmental effects (such as soil erosion or pesticide use) of management practices. GIS systems have provided important support as decision systems integrated with OR models (Zekri and Boughanmi 2007).

Mining

Quantitative techniques have played a significant role in the mining industry (Lane 1988), accelerated since the 1980s. In particular, advances in computational power and OR software have resulted in an increased and successful use of mainly MIP models into mine planning (Newman et al. 2010). Mining is carried out as open pit or underground. In some cases lately, as in copper mines open pit and underground mining are integrated. Some major decision problems in mining are now described.

The optimal design of open-pit mines. The goal is to determine the feasibility of operations and the contours in mining extraction processes, where extraction is viewed as a series of nested blocks in three dimensions, so as to maximize the difference between sale value and extraction and processing costs within geological and mining restrictions.

Graph theory, linear programming, and heuristic methods have been used for this problem (Hochbaum and Chen 2000).

Optimization techniques have been used also for ore-body modeling and reserve estimations, optimal production schedules, capacity planning, machine scheduling, machine maintenance, production planning, and transportation. (Caccetta 2007).

Underground mine planning is more complex, as different extraction techniques are employed. The main problems approached are on how to plan the extraction of the mineral. MIP models have been successfully employed (Alford et al. 2007).

The introduction of large scale MIP models has led to increasingly consider the whole production chain, from mine extraction to plant processing (Caro et al. 2007).

Fishing

Fisheries Management present a different perspective from other natural resources in that since the resource is of free access, production is usually shared among different enterprises, and its allocation process is difficult and fuzzy. The long-term conservation of fish stocks is a high-priority issue, and a set of regulations to protect them has been developed worldwide. Fisheries systems are concerned mainly with two basic issues; biological analysis of fish stock behavior and the allocation and exploitation of the resources (Lane 1989; Bjorndal et al. 2004).

Biological issues include all aspects of population dynamics to understand how fish stock evolves (growth and mortality rates, reproductive properties) and fish stock assessment, given environmental impacts (pollution, warming or cooling trends), stock interactions, and exploitation.

The problem of resource allocation involves assigning and regulating fishing rights (quotas, licenses, capture taxes, area closures). Exploitation or management decisions include: fleet design and harvesting operations, determination of catching effort (the response of fishing captures to fishing effort provides important information for stock assessment), design of fish plants. (Arnason 2007).

Quantitative approaches have been widely proposed for all these problems: Descriptive mathematical modeling (in particular for the biological aspects), mathematical programming methods such as linear programming, nonlinear programming, optimal control and dynamic programming, statistical estimation and simulation. While the range of methodological proposals is wide, actual applications lag behind, mainly due to the lack of reliable data. Most applications are in the areas of exploitation and allocation. In this area there is also growing concern about explicit incorporation of uncertainty (Nostbakken and Conrad 2007) and multi-criteria decision making (Lane 2007).

Near-Optimal Solution

For an optimization problem, a near-optimal solution is a feasible solution with an objective function value within a specified range from the (usually unknown) optimal objective function value.

Neighboring Extreme Point

In a convex set of solutions to a linear-programming problem, two extreme points are neighbors if they are connected by an edge of the convex set. The path of solutions determined by the simplex method is one that moves from one neighboring extreme point to another.

See

► Simplex Method (Algorithm)

Nested Partitions Method

A metaheuristic search approach for discrete optimization that employs sampling and iterative partitioning and recombining of the feasible solution space.

Network

A network is a pair of sets (N, A), where N is a set of nodes (points, vertices) and A is a set of arcs (edges, lines, links). If i and j are nodes, then the arc joining them is denoted by the ordered pair (i, j). An arc may have a cost c_{ij} that denotes the cost per unit flow across that arc, and an upper bound flow capacity denoted by u_{ij}. For some applications, a node may be a supply (source) node in which goods enter the network, a demand (sink) node in which goods leave the network, or a transshipment node through which goods are shipped without a gain or a loss. In most network applications, it is assumed that the flow of goods that enter a node is equal to the flow that leaves the node. This is the conservation of flow assumption. However, in some applications, the amount of goods that enter a node can be more than the amount that leaves the node (e.g., due to the expansion of a liquid) or can be less than the amount that leaves a node (e.g., due to a leak or pilferage).

These latter situations are termed networks with gains or losses. In most instances, network problems are special forms of linear-programming problems.

Network Optimization

Thomas L. Magnanti
Massachusetts Institute of Technology,
Cambridge, MA, USA

Introduction

Networks are omnipresent in everyday life, e.g., highways, telephone lines, railways, electric power systems, airline route maps, computer and cable television networks. Networks also arise in other, perhaps less visible settings: manufacturing or distribution networks determine the flow of products through plants or between plants, warehouses, and retail outlets; and networks of interconnected components in integrated semiconductor chips and printed circuit boards provide electronic processing capabilities in thousands of commercial products.

In these settings, two sets of network optimization issues typically need to be addressed:

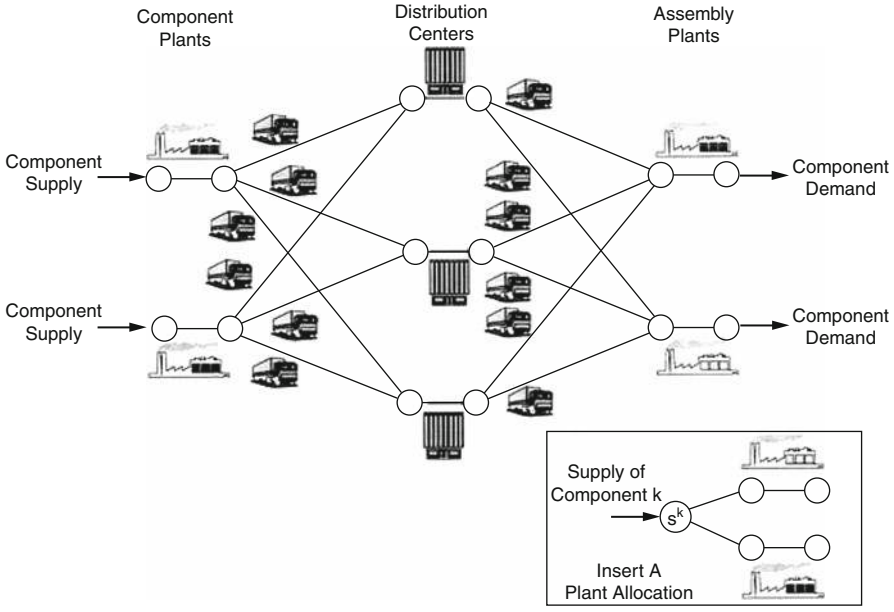
1. *Operational Planning* — How to use a given (distribution, telecommunication, or manufacturing) network as efficiently as possible? In this setting, the underlying network structure (topology and facilities) is known and the objective is to find the best way to route flow on it. For this reason, the set of optimization models for supporting these decisions have become known as network flow problems.
2. *System Design* — What is the best design of a network, one that will offer cost efficient and yet effective service to its users? In this setting, the objective is to simultaneously create the network structure and route flow on it. These models have become generally known as network design problems.

The OR/MS community has developed a rich array of network models and solution methods for operational planning and system design, applying these techniques in thousands of applications. Indeed, network optimization has served as one of the most active and fertile application, modeling, and theoretical domains within the fields of applied mathematics, computer science, engineering, and OR/MS.

Network Models

Figure 1 illustrates an application that contains the basic ingredients of network optimization. In this application context, which is typical of the automotive, computer and many other industries, a company produces product components in several plants/countries and assembles the products in other plants/countries. For convenience, any product component will be referred to as a commodity. One shipping option is to send all commodities directly from each component plant to each assembly plant. However, to achieve economies of scale, the firm uses a set of intermediate distribution centers (or warehouses). The distribution centers could also hold inventory and, thereby, permit the company to meet fluctuating demand requirements in the assembly plants.

To formulate this problem mathematically, first define an underlying network. In general, a network is (i) a set N of nodes, together with (ii) a set E of directed edges (i, j) that connect certain pairs i and j of the nodes. The application in Fig. 1 has a special network structure with one node corresponding to an



Network Optimization, Fig. 1 Network model of a production/distribution system

input and to an output for each plant and distribution center; the edges are of two types: those that connect plants and distribution centers and those that connect the input and the output node of each plant or distribution center. Each edge (i, j) has an associated per unit flow cost c_{ij}^k for each commodity $k = 1, 2, \ldots, K$, a flow capacity u_{ij}^k imposed upon commodity k, and flow capacity u_{ij} imposed upon the total flow of all commodities. For edges connecting plants and distribution centers, these quantities model the flow of commodities between the facilities. For edges joining the input and output nodes of each distribution center, these quantities model the throughput costs and capacities of the distribution center (similarly, for the plants). The use of two nodes to model the throughput at any node is a common modeling device for representing node costs and capacities as edges costs and capacities.

The arrows in Fig. 1 directed into the component plant input nodes specify the supplies of the commodities at the component plants. This model assumes that the production of each component in each component plant has already been determined. To use the network optimization model to allocate the production of each commodity among the component plants, one could introduce an additional component supply node s^k for each commodity k with the total supply of that commodity as the node's input. The flow on edges (s^k, q) connecting this node to the plants q would allocate the total supply of that component to the available plants (see Insert A in Fig. 1). The introduction of additional nodes and edges like this is another modeling device used frequently in practice.

To model a general network optimization problems (and thus various versions of the production and distribution planning problem), let f_{ij}^k denote the flow of commodity k from node i to node j (i.e., the flow on edge (i, j) in the direction i to j). Also let b_i^k denote the net supply of commodity k at node i; this quantity is positive at the input nodes of the network (component plants in the example), is negative (to model demand) at the output nodes of the network (the assembly plants in the example), and is zero at all the other nodes. The model has the following general form:

$$\text{minimize} \sum_{k=1}^{K} \sum_{(i,j)\in E} c_{ij}^k f_{ij}^k + \sum_{(i,j)\in E} F_{ij} y_{ij} \tag{1}$$

$$\text{subject to} \sum_{j:(i,j)\in E} f_{ij}^k - \sum_{j:(j,i)\in E} f_{ji}^k = b_i^k \quad \text{for all } i \in N \text{ and } k = 1, \ldots, K \tag{2}$$

$$\sum_{k=1}^{K} f_{ij}^k \le u_{ij} y_{ij} \text{ for all } (i,j) \in E \tag{3}$$

$$f_{ij}^k \le u_{ij}^k y_{ij} \text{ for all } (i,j) \in E \text{ and } k = 1, \ldots, K \quad (4)$$

$$f_{ij}^k \ge 0 \text{ for all} (i,j) \in E \text{ and } k = 1, \ldots, K \quad (5)$$

$$0 \le y_{ij} \le 1 \text{ and } y_{ij} \text{ integer for all } (i,j) \in E. \quad (6)$$

This model has the following interpretation. The flow conservation equation (2) for node i states the total flow out of that node minus the total flow into that node must equal the node's supply. The binary (0 or 1) decision variables y_{ij} model the network design decision, "should edge (i, j) be included in the network ($y_{ij} = 1$) or not ($y_{ij} = 0$)?" (In the application in Fig. 1, these variables model two types of decisions: (i) whether or not to locate a plant or a distribution center at one of the available locations and whether the network contains the corresponding throughput edge; and (ii) whether or not to use a particular transportation lane joining a plant to distribution center combination or distribution center to plant combination). The fixed cost F_{ij} associated with edge (i, j) is the cost for constructing/renting/ operating that edge (independent of its flow). The forcing constraints (3) and (4) force the flow on edges (i, j) for each commodity k to be zero if the network does not contain that edge ($y_{ij} = 0$). If $y_{ij} = 1$, constraint (3) states that the total flow on edge (i, j) cannot exceed the installed capacity u_{ij} of that edge, and constraint (4) states that the flow of commodity k on edge (i, j) cannot exceed the flow capacity u_{ij}^k for that commodity.

This model assumes that the edges are directed, i.e., flow on any edge goes in only one direction. But, in some applications, the edges will be undirected. To model these situations, impose the condition that $y_{ij} = y_{ji}$ and replace f_{ij}^k in constraints (3) and (4) with $f_{ij}^k + f_{ji}^k$, the total flow in both directions on edge (i, j).

The network optimization model (1)–(6) can be used to make facility location decisions (as in the example) and to make routing decisions (the choice of transportation lanes). Moreover, the model can be used in telecommunication and other applications to design a physical network, for example, to determine where to locate fiber optic cables in a telecommunication system.

The model (1)–(6) is a special type of mixed integer programming problem, i.e., it contains both continuous and integer/binary variables. In practice, solving this network optimization problem is a challenging (on the surface almost daunting) task. The model has a flow conservation equation for each node and commodity. Since networks with thousands of nodes arise frequently in practice, even for situations with a single commodity, the model often has thousands of equations. Many telecommunications and transportation applications require the flow of a commodity (message or freight) between every pair of nodes in the network. Therefore, with as few as one hundred nodes, the problem will have $100 * 99 = 9{,}900$ commodities and $9{,}900 * 100 \approx 1$ million flow conservation equations (one for each combination of commodity and node).

The problems become even more difficult when they have design variables. With as few as twenty nodes and a binary design variable y_{ij} for each of the $20(19)/2 = 190$ possible edges connecting these nodes, the model has 2,190 different design alternatives (since any design can include or exclude each of the 190 edges). This number is as large as the number of grains of sand needed to fill the solar system! Therefore, solving these problems requires considerable ingenuity. Since it is impossible to enumerate all possible solutions, the methods must consider them only implicitly.

Types of Models

The network optimization model (1)–(6) has many specializations and variants, each generating a considerable literature on its own (applications, solution methods, and underlying theory). Tables 1 and 2 show some of these models and indicates typical solution times for solving them (on a modern computer workstation).

The tables separate the models into two categories:

1. *Network flow models* — For these models, each binary variable y_{ij} is fixed at value 0 or 1 (and so the network topology is fixed) and the problem becomes a linear program. Notice that the problem has a very special structure since each flow variable f_{ij}^k appears in exactly two flow conservation equations, as an output of node i and an input of node j. Researchers have been able to use this feature to develop special purpose algorithms that solve the problems much more efficiently

Network Optimization, Table 1 Network flow models (each y_{ij} is fixed at value zero or one)

Model type	Problem description	Solution methods	Computational experience. Number of nodes: Solution time
Multicommodity flows	General flow model (1)–(6) with multiple commodities	Linear programming, decomposition methods	Hundreds: minutes
Minimum cost flows	Single commodity ($K = 1$)	Specialized path flow methods	Thousands: seconds
Maximum flows	Single commodity, no flow cost; send maximum flow between single source and destination node pair	Specialized node labeling (sequential search) methods	Thousands: seconds
Shortest paths	Single commodity, single origin, no flow capacities	Specialized node labeling (sequential search) methods	Tens of thousands: seconds

Network Optimization, Table 2 Network design models

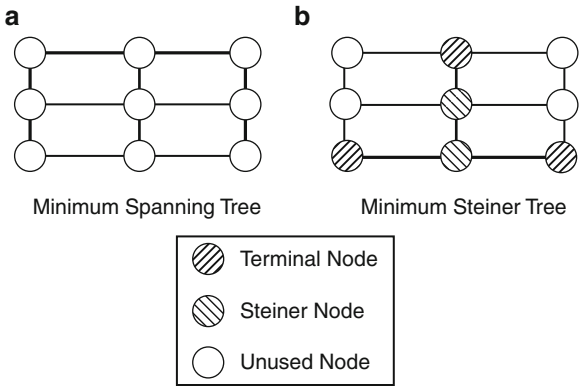
Model type	Problem description	Solution methods	Computational experience. Number of nodes: Solution time
Fixed cost network	General model (1)–(6)	Integer programming, heuristics	Tens: minutes or hours
Network loading	No flow costs, load network to meet required point-to-point demands (y_{ij} as integers, not binary)	Integer programming, heuristics	Tens: minutes or hours
Network connectivity	Find prescribed number of edge disjoint paths between various node pairs	Integer programming, heuristics, and linear programming dual ascent methods	Hundreds: minutes
Network synthesis	Given flow requirements, determine capacities on edges (at minimum cost) so that the network has the capability to meet prescribed demands between various node pairs	Minimum spanning tree if capacity on every edge costs the same	Thousands: seconds if all capacities have same cost
			Tens to hundreds: minutes (in general)
Minimum spanning trees	No flow costs, no capacities; find a network that connects all nodes	Specialized one-pass greedy algorithms	Thousands: seconds
Steiner trees	No flow costs, no capacities; find a network that connects prescribed set of nodes (and possibly others)	Heuristics and linear programming dual ascent methods	Thousands: seconds

For all network design problems, except the minimum spanning tree problem, the methods generally produce approximately optimal, not globally optimal solutions

than solving them using general purpose linear-programming software.

2. *Network design problems* –In these models, both design decisions and flow decisions are relevant. For some of these models, the flow costs are zero and the problems become that of finding a least cost network configuration that meets the required flow requirements.

Figure 2 gives examples of the minimum spanning tree and Steiner tree problems, assuming that the cost of each edge is proportional to its length. The underlying network in these examples is typical of those in printer circuit board applications that have East-west and North-south channels for making wiring connections (therefore, all the edges are in a rectangular pattern). Note that the minimum spanning tree needs to connect all the nodes and the Steiner tree needs to connect only a subset of the nodes (so called terminal nodes), but can optionally use some of the other nodes (so called Steiner nodes). In both cases, the goal is to find the least cost network configuration, as measured by the total cost of the



Network Optimization, Fig. 2 Minimum spanning tree and Steiner tree problems

chosen edges (flow costs are irrelevant). The other network design problems also want to find optimal network configurations, but might include flow costs as well.

The discussion has shown that the network optimization problem (1)–(6) has a wide range of applications and has shown how to introduce additional nodes and edges to enhance the model's ability to capture varied application features (e.g., to allocate production at the component plants or to represent the throughput of a node). Many other such modeling techniques have proven to be useful in practice. As indicated in Table 1, computer software is available for solving large-scale network flow problems very quickly. Except for spanning tree and Steiner trees, capabilities for solving network design problems is much more limited.

Solution Methods

Solving network optimization problems requires considerable ingenuity, in developing solution methods, implementing them efficiently on a computer, and analyzing them to determine their efficiency (in theory or practice). To illustrate these issues, consider one of the easiest network flow problems, the shortest path problem. After describing a basic algorithm for solving this problem, it will be shown how to organize the computations to implement the algorithm more efficiently and then how to improve on it even further when more is known about the underlying data (the edge lengths).

Suppose one is given a network with nonnegative lengths d_{ij} on the edges (i, j) and the goal is to find the shortest path between two designated nodes, a source node s and a terminal node t. To solve the problem, one could use the following algorithm (solution method). If node j is the node closest to the source node, then the shortest path distance $d(j)$ from the source node to this node is the direct path on the edge (s, j) whose distance is d_{sj}. Next consider the node k that is closest to node s either along the direct edge (s, k) or on the shortest path through node j, i.e., with the distance $d_{sj} + d_{jk} = d(j) + d_{jk}$. To choose the best of these two alternatives, compute $d(r) = \min\{d_{sr}, d(j) + d_{jr}\}$ for each node $r \neq s$ or j and select as the next node k, a node r with the smallest value of $d(r)$. It is easy to see that this choice gives the shortest distance along any path from node s to node k. In general, suppose that after several steps, the shortest path distances $d(j), d(k), \ldots, d(p)$ from the source node s to each of the nodes $j, k, \ldots, p$ have been found. Then to find the shortest path distance to the next node q, for all nodes $r \neq s, j, k, \ldots, p$, compute

$$d(r) = \min\{d_{sr}, d(j) + d_{jr}, d(k) + d_{kr}, \ldots, d(p) + d_{pr}\}. \tag{7}$$

Choose node q to be a node r with the smallest of the values $d(r)$. Once node t has been chosen in any of these steps, the problem is solved, i.e., the shortest path distance from node s to node t has been found. (See Ahuja et al. 1993, for a proof.)

This algorithm computes the shortest path distance to one more node at each step. If the network contains a total of n nodes and the shortest path distance to v of them have been found, then the computation (7) requires v additions and comparisons for each of $n - v$ nodes and so $v(n - v)$ computations. Therefore, to find the shortest path distance to all nodes, the algorithm requires $1(n-1) + 2(n-2) + 3(n-3) + \cdots + (n-1)(1) = n^2(n-1)/6$ computations. Can this be improved? Yes, by noticing that this algorithm performs many redundant computations. For example, after the first step, for each node r not yet chosen in one of the previous steps, the algorithm computes the quantity $d(j) + d_{jr}$. Note that after node q has been chosen, the computation (7) becomes

$$d^{\text{new}}(r) = \min\{d_{sr}, d(j) + d_{jr}, d(k) + d_{kr}, \ldots, d(p) + d_{pr}, d(q) + d_{qr}\}. \tag{8}$$

Comparing (7) and (8) shows that $d^{\text{new}}(r) \leftarrow \min\{d(r), d(q) + d_{qr}\}$. Therefore, if the values of $d(r)$ from one step to another are stored and one carries out the computation

$$d(r) \leftarrow \min\{d(r), d(q) + d_{qr}\}, \tag{9}$$

then at step v when there are $n - v$ nodes that are candidates to be chosen next, there are $v - r$ computations, and so overall the algorithm now requires only $(n-1) + (n-2) + \cdots + 1 = n(n-1)/2$ computations. As this simple example shows, by organizing the computations intelligently, one can often considerably reduce the computational requirements of an algorithm. Much of the literature of network flow algorithms involves the use of similar ideas for designing and analyzing algorithms (though, in general, the ideas are much more complex).

To illustrate further how researchers have used problem structure to design efficient algorithms, suppose that the cost structure for the shortest path problem were even simpler, such that each distance d_{ij} is limited to the values 1 or 2. Notice that in this case, the shortest path distance from the source node s to any node k is one of the integers 1, 2, …, $2(n-1)$. To obtain an improved algorithm, use this fact and implement the computations (9) in a more streamlined fashion by maintaining a collection of $2(n-1)$ buckets, storing all the nodes r whose distance $d(r)$ is k in the kth bucket. Then choose the buckets one at a time from smallest to largest, starting with bucket number 0. If the bucket is nonempty, select a node q from it and then any edge (q, r) incident to node r. Then use the expression (9) to update the distance $d(r)$ of node r and if the distance of node r increases, move it to a new bucket. Note that this algorithm considers each edge (i, j) only once and must search at most $2(n-1)$ buckets to see if they are empty or not and to extract their contents. Therefore, for a network with m edges, this implementation of the algorithm requires $m + 2(n-1)$ computations (assuming one can effectively transfer nodes between buckets, which is easy to do). Since m is often far less than its maximum possible value of n^2, this algorithm is typically much faster than the implementation embodied by the previous implementation of the computations (8). When the edge lengths are limited within some range $0 \leq d_{ij} \leq C$ for some constant C, a similar type of bucket implementation can be very efficient and produces some of the most effective algorithms for solving shortest path problems.

The design and analysis of network optimization algorithms has an enormous literature. This brief introduction to the topic has illustrated several important aspects of this field:

- Network algorithms often use simple computations, such as those invoked in expressions (7) and (9), for solving problems rather than the more sophisticated methods needed to solve other optimization problems such as general linear programs. Indeed, software based upon specialized methods like these are able to solve shortest path problems with thousands of nodes in just a few seconds of computational time (Table 1), even though these problems are linear programs with thousands of constraints (one conservation equation in the model (1)–(6) for each node).
- In solving a particular problem, it is often just as efficient to solve a broader class of problems (the algorithm described here finds the shortest paths from the source node to all other nodes, not just the terminal node).
- Organizing computations carefully can improve an algorithm's efficiency. In the shortest path example, the number of computations were reduced from $n^2(n-1)/6$ to $n(n-1)/2$ by merely avoiding redundant computations (see (8) and (9)).
- The creative use of data structures (buckets in the example) often leads to more efficient algorithms [$m + 2(n-1)$ instead of $n(n-1)/2$ computations in the example].
- Often one can design algorithms to exploit the nature of the data and not just the type of problem being solved. Two illustrations of this: (i) the algorithm described in the example here might not solve a shortest path problem when some the edge lengths are negative, so it has exploited the fact that all the edge lengths are nonnegative; and (ii) when the data have restricted ranges (e.g., the edge costs are between 0 and C in the example), one can frequently can devise more efficient algorithms.

- The shortest path algorithm described here is polynomial in the sense that the number of computations is a polynomial function of the number of nodes n and the number of edges m in the underlying network. One of the great challenges in network optimization is to discover polynomial algorithms with the lowest possible degree (or fastest running time). For most design problems, the research community has not been able to find polynomial algorithms (the minimal spanning tree problem is a notable exception). Indeed, most design problems are, in the parlance of computer science, *NP*-complete, implying that it is quite unlikely that a polynomial time algorithm exists. Nevertheless, the community has been able to design algorithms that are efficient in practice for many of these problems.

Further Readings

Several books amplify on the topics described here and introduce many other applied and theoretical aspects of network optimization. Ford and Fulkerson (1962) provide a seminal account of early developments in this field. Ahuja et al. (1993) offer a modern treatment of this subject covering both theory and applications. Glover et al. (1992) provide valuable insight into network modeling and applications. The handbooks edited by Ball et al. (1995a, b) contain comprehensive reviews by many leading researchers in network optimization. Lawler (1976) draws valuable connections between network flows and a related topic in combinatorial optimization known as matroids.

Network Planning

Willy S. Herroelen[1] and Graham K. Rand[2]
[1]Katholieke Universiteit Leuven, Leuven, Belgium
[2]Lancaster University, Lancaster, UK

Introduction

Network planning is a generic name for methods that study projects as a set of interconnected activities with the purpose of assisting in planning, scheduling and controlling projects. These methods are based on models describing projects as activity networks and include well-known techniques such as the Critical Path Method (CPM) and the Program Evaluation and Review Technique (PERT). CPM determines the critical path that includes the so-called critical activities (activities deserving maximal attention as any delay causes a delay of the project's completion date), whereas PERT estimates the probability distribution of the project's completion date. Essentially, network planning involves a planning phase, a scheduling phase and a project control phase. The planning process involves the identification of the project activities, the estimation of time and resources, the identification of the precedence relationship between the activities and the identification of the schedule and resource constraints.

Project scheduling involves the construction of a project base plan that specifies for each activity the precedence and resource feasible start and completion dates, the amounts of the various resource types that will be needed during each time period, and as a result the project budget. Once the project starts, the project must be monitored and controlled. Project control involves the difficult task of measuring actual progress and comparing it to planned progress. If this comparison reveals that the project is likely to run behind schedule, to overrun the budget, or to violate the original technical specification, corrective action must be taken to get the project back on track.

History

The need to improve planning techniques to help control major projects was recognized in the 1950s. CPM arose from a jointly sponsored venture of E.I. du Pont de Nemours and Company and the Sperry-Rand Corporation. By September 1957, an actual application was conducted on a pilot system using the UNIVAC I computer, and from this CPM evolved (Kelley and Walker 1959; Kelley 1961). At the same time, the U.S. Navy was developing a system to plan and coordinate the Polaris missile program. From this, PERT evolved, and was credited with helping to advance Polaris by at least two years (Malcolm et al. 1959). Further details of these early developments can be found in Moder et al. (1983) and Sculli (1989).

Since these early days, variations of these methods have been developed (VERT, GERT, SCERT), and continuing research has led to the development of new models and techniques allowing for more adequate procedures to deal with general types of precedence and resource constraints, new planning objectives, and better ways to cope with uncertainty. Excellent texts and surveys include Elmaghraby (1977); Slowinski and Węglarz (1989); Özdamar and Ulusoy (1995); Herroelen et al. (1998), Brucker et al. (1999); Klein (2000); Kolisch and Padman (2001), Demeulemeester and Herroelen (2002), Dorndorf (2002), Neumann et al. (2003); Herroelen and Leus (2004); Herroelen (2005); Schwindt (2005); Jozefowska and Węglarz (2006); Artigues et al. (2008); Hartmann and Briskorn (2010); Węglarz et al. (2011).

Planning

Construction of the project network — There are two possible modes of representation of a project network: the activity-on-arc representation (AoA), which uses a set of arcs to represent the activities and a set of nodes to represent events, and the mostly used activity-on-node representation (AoN). The AoN representation (Fondahl 1961; Roy 1964) allows for the representation of various types of precedence relations: finish-start precedence relations with zero time-lag (used in PERT and CPM), start-start, finish-start, start-finish and finish-finish relations with minimal and maximal time-lags. A minimal time-lag specifies that an activity can only start (finish) when its predecessor has already started (finished) for a certain time period, whereas a maximal time-lag specifies that an activity should be started (finished) at the latest a number of time periods beyond the start (finish) of another activity.

Time estimates — Deterministic project planning models assume that activity durations can be estimated with certainty, typically as a single-time estimate. It should be well understood that the use of a single duration estimate assumes an implicit choice of a particular execution mode for the activity corresponding with a particular resource allocation (single mode). Instead of working with single-time estimates, several possible execution scenarios (multiple execution modes) may be defined, each mode reflecting a feasible way to combine an activity duration and a resource allocation.

Dealing with uncertainty – The PERT approach — The originators of PERT proposed a stochastic approach to cope with probabilistic activity durations. The assumption made by PERT is that activity durations are beta-distributed. Three activity duration estimates are used: an optimistic estimate (t_o), an estimate of the most likely duration (t_m), and a pessimistic estimate (t_p). An approximation to the expected time can be found by taking a weighted average of the three estimates (in the ratio 1:4:1), $(t_o + 4t_m + t_p)/6$, which has a standard deviation $(t_p - t_o)/6$.

Resource estimates — Project activities require resources for their execution. Different resource categories have been defined in the literature (Węglarz et al. 2011), the most common ones being

renewable and non-renewable resources. Renewable resources (manpower, machines, equipment, tools) are available on a per-period basis; non-renewable resources (money, raw materials, energy) are available on a total project basis.

Generating a Feasible Baseline Schedule

The fundamental objective of network planning is the creation of a precedence and resource-feasible baseline schedule that establishes the planned start and finish times of the individual activities, meeting as much as possible the objectives set forward by project management. One of the most common time-based objectives is the minimization of the planned project duration.

In many real-world situations the time-oriented objectives may be replaced by resource-based or financial objectives. An important example of a resource-based objective occurs in the resource-availability cost problem, where the capacities of the renewable resources are to be determined such that a given project deadline is met and the resource availability costs are to be minimized. Another example is the resource leveling problem, which involves the generation of a time-feasible schedule for which the resource profiles for the various resources are as level as possible, without violating the project deadline. An important financial objective is related to the incoming and outgoing cash flows that are generated during the execution of a project. This results in models that aim at maximizing the net present value of a project. It should be clear that the construction of a baseline schedule should eventually be done under multiple objectives, using a multi-objective or multi-criteria approach.

Critical path analysis — Using the activity-duration estimates, and taking into account the precedence relations (PERT and CPM assume finish-start relations with zero time-lag), the longest path in the project network can be computed. This is the so-called critical path, which determines the planned project duration.

The PERT approach has been widely criticized on theoretical grounds (Elmaghraby 1977; Golenko-Ginzburg 1989; Sculli 1989). In the PERT system, the mean value for the project duration is taken as the sum of the mean values of the durations of the activities on the critical path. This assumption is only correct for a project that consists of a single chain of activities, but progressively underestimates the mean project duration as the complexity of the network increases. In the PERT system, the variance for the project duration is taken as the sum of the variances of the activities on the critical path. Again, this assumption is only correct for a project that consists of a single chain of (independent) activities, but progressively underestimates the variance as the complexity of the network increases. There have been serious doubts expressed as to the appropriateness of the beta distribution. The PERT approach does not take into account the probability of completion of sub-critical paths. This inability to take account of sub-critical paths is the most serious criticism of PERT. Because of this PERT typically underestimates the true statistical project mean duration and also seriously underestimates the probability of meeting a deadline.

Resource-constrained scheduling — The introduction of renewable resources into the analysis complicates matters considerably. Computing a precedence and resource-feasible deterministic schedule that minimizes the project duration, the infamous resource-constrained project scheduling problem (RCPSP), is *NP*-hard in the strong sense. Both exact and suboptimal procedures have been presented in the literature (Özdamar and Ulusoy 1995; Herroelen et al. 1998; Brucker et al. 1999; Kolisch and Padman 2001).

Exact procedures for solving the RCPSP typically rely on branch-and-bound (see e.g. Demeulemeester and Herroelen 1992, 1997). At the time of writing, the best exact results have been reported by so-called hybrid approaches, combining for example constraint programming and satisfiability testing. Constraint programming techniques learn about logical implications between variable settings, which are used to strengthen the bounds on variables. Satisfiability testing draws from unsatisfiable or conflicting structures, which helps to quickly find reasons for and excluding infeasible parts of the search space (Schutt et al. 2009; Berthold et al. 2010).

The complexity of the RCPSP has motivated numerous research efforts on the design of heuristic scheduling procedures (Hartmann and Kolisch (2000) and Kolisch and Hartmann (2006)), which have demonstrated that the best results are obtained by hybrid metaheuristics, yielding a 25–30% deviation from the critical path-based lower bound.

Robust project scheduling — The probability of a precomputed baseline schedule being executed exactly as planned is low: activities may take more or less time than originally anticipated, resources may become unavailable, material may arrive behind schedule, new activities may have to be incorporated or activities may have to be dropped due to changes in the project scope, ready times and due dates may be modified, etc.

The aim of proactive project baseline scheduling is to generate stable baseline schedules that are protected against the disruptions that may occur during project execution. Most commonly this is achieved by inserting buffers in the baseline schedule (Herroelen and Leus 2004).

The critical chain scheduling methodology, introduced by Goldratt (1997), uses aggressive duration estimates and computes the critical chain in the generated precedence and resource feasible baseline schedule. The critical chain is the chain of precedence and resource dependent activities that determines the overall duration of the project. The safety in the durations of the activities that are on the critical chain, which was cut away by selecting aggressive duration estimates, is shifted to the end of the critical chain in the form of a project buffer to protect the project due date against variability in the critical chain activities. Feeding buffers are inserted whenever a non-critical chain activity joins the critical chain. The working principles of critical chain have been evaluated by Herroelen and Leus (2001) and Herroelen et al. (2002).

Research efforts on the development of reliable proactive scheduling procedures include Herroelen and Leus (2004), Herroelen (2007).

Project Control

Once the project has started, control is maintained by a system of status reporting. Some activities will take longer than estimated and some shorter. Sometimes estimates for activities not yet completed require revision. At regular intervals the network must be updated, reanalyzed and new schedules prepared, taking into account all this new information.

The corrective actions needed when the schedule lags behind or the built-in protection breaks may involve activity crashing, giving rise to the so-called time/cost trade-off problems. The importance of time/cost trade-offs was recognized from the very start of CPM, when the developers of CPM recognized that the majority of activities encountered in real-life project settings can be performed in shorter or longer durations by increasing or decreasing the resources available to them. Most often the acceleration in the execution of activities comes at a cost.

It is usually assumed that the cost/duration relationship is linear between a normal and a crash duration, and that any intervening duration may be attained. The objective is, by selection of activity durations and their corresponding costs, to minimize total activity costs for a given project duration. A related problem is concerned with detecting the shortest project duration available within a given budget. The problem may be formulated as a linear program and solved by the simplex method, but a more efficient network flow algorithm was developed by Fulkerson (1961). Other approaches are described by Ritchie (1985). In most practical cases, resources are available in discrete units, such as number of machines, number of workers, etc. The resulting discrete time/cost trade-off problem is a hard nut to crack (De et al. 1995).

Computer Software Packages

A wide range of commercial project planning software packages is available on the market (Wasil and Assad 1988; De Wit and Herroelen 1990): among them Microsoft Office Project is probably the best known. The software relies on simple priority rules for resolving resource conflicts. As far as can be determined (the scheduling methodology incorporated in commercial software is generally proprietary and hence unavailable), the software computes the earliest start schedule and checks for resource overloads, which are resolved by delaying some of the involved activities. In some of the packages, the user may select one of the alternative priority rules (Maroto and Tormos (1994).

Network Simplex Algorithm

For the minimum-cost network-flow problem, a special adaptation of the simplex method that takes advantage of the mathematical structure of the network constraints to produce a computationally fast and efficient solution algorithm. The main idea behind this algorithm is the recognition that a basic feasible solution to the network problem, treated as a linear-programming problem, corresponds to a spanning tree of the defining network.

Networks of Queues

Richard F. Serfozo
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Many important operational issues in communication and manufacturing systems concern random movements of discrete units called customers in networks of service stations with queueing. Examples of such queueing networks are:

- Computer and telecommunications networks — data packets, read/write transactions, files, or telephone calls move among computers, buffers, operators or switching stations;
- Manufacturing networks — parts, orders, or material move among workstations, inspection points, automated guided vehicles or storage areas;
- Equipment maintenance networks — parts or subsystems move among usage sites and repair facilities;
- Logistics and supply-chain networks — parts, material, personnel, trucks or equipment move among sources, storage depots and production facilities; and
- Parallel simulation and distributed processing systems — messages, data packets and signals move among buffers and processors.

Other areas in which queueing networks arise include biology (movements of animals, fish or diseases) and economics (movements of labor, people, capital or shopping centers).

Common questions about a queueing network are as follows. Where are its bottlenecks or major delays? How does one network design compare with another? What is a good set of rules for operating the network (e.g., customer priorities or routings)? What is a least-cost network (e.g., numbers of machines, tools or workers)? Typical aims or performance objectives include the following: the probability of a busy signal in a telecommunications network should be less than 1%; the expected waiting times in a computer system should be less than certain values; the probability of meeting manufacturing deadlines should be above 90%.

To address such issues requires an understanding of the behavior of the network in terms of the equilibrium (or stationary) probability distribution of the numbers of customers at the queueing stations, which will usually be referred to as the nodes of the network. These distributions are used to evaluate a variety of performance measures such as throughputs, expected costs, and percentage of time a station is overloaded. The equilibrium distribution is a basic ingredient for constructing objective functions or constraints used in mathematical programming algorithms to select optimal network designs and protocols. The quality of a network is also determined by the duration of travel and sojourn times in it, such as the time for a customer to travel from one sector to another or the amount of time it takes for a customer to visit a certain set of nodes. Equilibrium distributions are used in describing the means or distributions of such travel times.

Many queueing network models have been developed using the theories of multi-dimensional Markov processes, point processes, and stationary processes. By their nature, stochastic networks have myriad dependencies that are analytically intractable. There are several types of network models, however, that have closed-form equilibrium distributions, some of which are described in the following sections, with pointers provided to others.

Jackson Networks

Consider an m-node network, where discrete units called customers move among the nodes where they are processed or served. The evolution of the network is represented by a continuous-time Markov process $\{X_t : t \geq 0\}$ whose states are vectors $\boldsymbol{x} = (x_1,\ldots, x_m)$, where x_j denotes the number of customers at node j (in service or waiting in queue). The network is a closed Jackson network if it contains a fixed number of customers that move as follows. Whenever there are x_j customers at node j, the time to the next departure from that node is exponentially distributed with rate $\phi_j(x_j)$, independent of the rest of the network. A standard service rate is $\phi_j(x_j) = \mu_j \max\{x_j, s_j\}$, which represents s_j independent servers whose service times are exponentially distributed with mean $1/\mu_j$. When a customer departs from node j, it moves immediately to node k with probability p_{jk}. In other words, the sequence of states that each customer visits forms a discrete-time Markov chain with transition probabilities $\{p_{jk}\}$. Without loss of generality, assume this routing chain is irreducible.

Under these assumptions, whenever the network process $\boldsymbol{X}$ is in state $\boldsymbol{x}$, a transition is triggered by a customer moving from some node j to another node k, and the time to such a transition is exponentially distributed with rate $\phi_j(x_j)p_{jk}$. Thus, $\boldsymbol{X}$ is a Markov process. It is positive recurrent because its state space is finite and the routing chain is irreducible. Its equilibrium distribution is

$$\pi(\boldsymbol{x}) = c \prod_{j=1}^{m} \alpha_j^{x_j} \prod_{n=1}^{x_j} \phi_j(n)^{-1}, \tag{1}$$

where $\{\alpha_j\}$ is the stationary distribution of the routing probabilities $\{p_{jk}\}$. The factor c is the normalization constant under which these terms sum to 1, and $\prod_{n=1}^{k} a_n = 1$ when $k = 0$.

Next, consider an open version of the network in which customers enter certain nodes in the network from outside (called node 0) according to independent Poisson processes, where λ_{0j} is the arrival rate for an entry node j. Then the probability that an arbitrary arrival enters node j from the outside is $p_{0j} = \lambda_{0j}/\Sigma_k \lambda_{0k}$. Assume the service and routing is done as above, and that there is a probability p_{j0} that a customer departing from j exits the network. Assume the Markov routing probabilities $\{p_{jk}\}$ are irreducible on $\{0, 1,\ldots, m\}$. The network is now an open Jackson network with unlimited capacity. In this case, the equilibrium distribution of the network process $\boldsymbol{X}$ is

$$\pi(\boldsymbol{x}) = \prod_{j=1}^{m} c_j \alpha_j^{x_j} \prod_{n=1}^{x_j} \phi_j(n)^{-1},$$

where

$$c_j^{-1} \equiv \sum_{k=0}^{\infty} \alpha_j^k \prod_{n=1}^{k} \phi_j(n)^{-1},$$

which is assumed to be finite, and α_j is the solution to the traffic equations

$$\alpha_j = \lambda_{0j} + \sum_{k=1}^{m} \alpha_j p_{jk}, j = 1, \ldots, m, \tag{2}$$

i.e., $\alpha_j = p_j/p_0$, where $p_0, p_1, \ldots, p_m$ is the stationary distribution of the Markov routing probabilities $\{p_{jk}\}$.

Another variation of this network is an open Jackson network with capacity v. This network operates like the open network described above except that when there are v customers in the network, the Poisson arrival streams are turned off (arrivals are turned away) — the total number of customers in the network may be from 0 to v. The equilibrium distribution of this network is given by (1), where α_j is the solution to (2) and the normalizing constant c is different.

Example: Single-Server Stations. Suppose each node is a single-server queue with service rate $\phi(x_j) = \mu_j$. If the network is closed with v customers, then

$$\pi(\boldsymbol{x}) = c\rho_1^{x_1} \ldots \rho_m^{x_m}, \tag{3}$$

where $\rho_j = \alpha_j/\mu_j$. In case the $\{\rho_j\}$ are distinct, $c = c_v^{-1}$, where

$$c_v = \sum_{j=1}^{m} \rho_j^{n+m-1} \prod_{k \neq j} (\rho_j - \rho_k)^{-1}.$$

There is a more complicated formula for c for non-distinct $\{\rho_j\}$. If the network is open with finite capacity v, then the equilibrium distribution is as in (3) with $c^{-1} = \sum_{n=0}^{v} c_n$ for distinct $\{\rho_j\}$. If the network is open with unlimited capacity and $\rho_j < 1$ for each j, then $\pi(\boldsymbol{x}) = \prod_{j=1}^{m}(1-\rho_j)\rho_j^{x_j}$. This is a product of equilibrium distributions of individual birth-death processes with birth rates α_j and death rates μ_j, and thus is called a product-form solution.

One can compute various quantities of interest from the equilibrium distribution π such as the marginal distributions, means and variances of quantities of customers at a node or in a sector of the network (a subset of nodes) and expected costs associated with network loads and movements. For closed or finite-capacity open networks, there are algorithms for computing these quantities (the unlimited-capacity open network is simpler because of its underlying product-form decomposition). Another approach is to estimate the quantities by a Monte Carlo simulation of a Markov chain (e.g., a Metropolis Markov chain) that has the same equilibrium distribution as the network; this is useful for large networks.

Important performance measures for a network are its throughputs. The throughput from node j to node k is the average number of network transitions per unit time in which a customer moves from j to k. This quantity is also the expected number of these transitions per unit time when the system is in equilibrium. The throughput from j to k is $\lambda_{jk} = \alpha_j p_{jk}$ when the Jackson network is open with unlimited capacity, and it is $\lambda_{jk} = c(v)c\,(v-1)^{-1}\alpha_j p_{jk}$ when the network is closed with v customers (or open with capacity v). Here $c(n)$ is the normalizing constant for a closed network with n customers (or an open network with capacity n). The throughput of node j is $\lambda_j = \Sigma_{k \neq j}\lambda_{jk}$. Then $\lambda_j = \alpha_j$ in case the network is open with unlimited capacity, and $\lambda_j = c(v)c\,(v-1)^{-1}\alpha_j$ for the other two cases. Similarly, the throughput of a sector J is $\lambda_J = \Sigma_{j \in J}\lambda_j$.

The main customer performance measures are sojourn times at the nodes, when the network is in equilibrium. The sojourn time T_j of a customer at node j is its service time plus time waiting for service. The expected sojourn time $W_j = E[T_j]$ is obtained by Little's law $L_j = \lambda_j W_j$, where L_j is the expected number of customers at node j, which is computed from the equilibrium distribution π. Similarly, the expected sojourn time W_J in a sector J can be obtained via Little's Law applied to the sector: $L_J = \lambda_J W_J$. Also, in an open network with unlimited capacity, the expected time a customer spends in a sector (in all of its visits) is $\overline{W}_J = L_J/\Sigma_{j \in J}\lambda_{0j}$

What is known about travel times in Jackson networks? Consider an open Jackson network with unlimited capacity in equilibrium. A simple route in the network is a set of nodes $1, \ldots, l$ such that a customer is able to traverse them in that order. Assume this is an overtake-free route in the sense that each node consists of a single server with a first-come-first-serve discipline, and once a customer is on the route, it cannot be overtaken by another customer. Then the sojourn times $T_1, \ldots, T_l$ at the respective nodes for an arbitrary customer that traverses the nodes in that order are independent exponential random variables and $E[T_j] = (\mu_j - \alpha_j)^{-1}$, where μ_j is the service rate at node j. When the network is closed or open with finite capacity, then $T_1, \ldots, T_l$ are dependent, but they have a known closed-form, multi-dimensional generating function. There are no comparable results for non-overtake-free routes.

In addition, there are closed-form expressions for a customer's expected travel time on a variety of very complicated routes. Examples include the time to travel from one sector J to another sector K, the time it takes to make n visits to a node j, and the time a customer spends in an open network while avoiding a sector J.

The preceding results for travel times are based on the MUSTA property that a "moving unit sees a time average." That is, suppose the Jackson network is open with unlimited capacity and is in equilibrium. Then at a transition in which a customer moves from one node to another, the probability distribution of the "other" customers in the network is the same as the equilibrium distribution of the network. Similarly, if the network is closed or open with finite capacity, then when a customer moves, the distribution of the other customers is the same as the equilibrium distribution of the network with one less customer. This MUSTA property is analogous to the PASTA property that Poisson arrivals to a single service queueing station see a time average.

Although the flow of customers over time from one node to another is generally not a Poisson process, there are some exceptions. Suppose the Jackson network is open with unlimited capacity and it is in equilibrium. Then the flow of customers departing the network from node j is a Poisson process with rate $\alpha_j p_{j0}$ (provided the rate is positive), and these Poisson departure processes are independent. Such a result might be of use for production planning for a manufacturing network, where the departures are customers of a finished product. Some internal flows are also Poisson processes. Suppose that customer j is such that a departure from it can never return. Then the flow of customers from node j to node k is a Poisson process with rate $\alpha_j p_{jk}$, and all these Poisson flows out of j are independent. There are no Poisson flows in closed or finite-capacity open networks, because the total number of customers is constrained.

Other Network Models

The following is a summary of other types of Markovian network models that have closed-form equilibrium distributions.

Whittle Networks

These networks operate like the Jackson network described above with the generalization that the service rate at node j is a function $\phi_j(\boldsymbol{x})$ of the entire network state $\boldsymbol{x}$ that satisfies a certain balance condition. Such system-dependent service rates are useful for modeling congestion dependent services.

Reversible Networks

Suppose the m-node network process $\boldsymbol{X}$ discussed above is a positive recurrent Markov process with transition rates $q(\boldsymbol{x}, \boldsymbol{y})$ from state $\boldsymbol{x}$ to state $\mathbf{y}$. The state x_j at node j may contain more information than just the quantity at the node, and the transitions can be very general (not necessarily like the single-customer movement in Jackson networks). The process is reversible if there is a probability measure π that satisfies the detailed balance equations $\pi(\boldsymbol{x})\, q(\boldsymbol{x}, \boldsymbol{y}) = \pi(\boldsymbol{y})\, q(\boldsymbol{y}, \boldsymbol{x})$ for each $(\boldsymbol{x}, \boldsymbol{y})$. In this case, π is the equilibrium distribution of the process, and there is a closed-form expression for π in terms of the transition rates. Such reversible processes can model dependent stations and batch movements, as well as single-customer movements of customers, provided the entire system is reversible.

Multi-Class Networks

Jackson, Whittle and reversible networks described above with homogeneous customers have analogues with multiple types of customers. In these networks, the state is a vector with components x_{γ_j} that represent the number of customers of class γ at node j. The network dynamics are the same, but the single subscript j is simply changed to a double subscript γj. For instance, in a Jackson network, a transition consists of a type γ customer at node j moving to node k and arriving there as an η customer — the rate of this transition is $\phi_{\gamma_j}(x_{\gamma_j}) p_{\alpha_j \eta_k}$. These models can represent fixed routes of customers fed by Poisson arrivals; a customer's type is $\gamma = rs$, where r is the route it is traversing and s is the stage (or node) on the route.

Networks with Batch or Concurrent Customer Movements

Multiple-customer movements in a network are represented by transitions from a state $\boldsymbol{x}$ to a state $\boldsymbol{x} + \boldsymbol{a} - \boldsymbol{d}$, where $\boldsymbol{a}$ and $\boldsymbol{d}$ are vectors that are added

and subtracted from the state $\boldsymbol{x}$. The models described above have analogues with certain types of multiple-customer movements that still lead to tractable stationary distributions.

Quasi-reversible Networks and Product-Form Equilibrium Distributions

Loosely speaking, a service station is quasi-reversible if its input and output processes in equilibrium are Poisson. Such stations can be connected with certain types of routings to produce a quasi-reversible network process whose equilibrium distribution is a product form $\pi(\boldsymbol{x}) = c\pi_1(x_1)\cdots\pi_m(x_m)$. The state x_j may contain more information than the number of customers at node j. This product-form distribution is a generalization of the Jackson product-form distributions above. There are also more general network models with product-form equilibrium distributions, where the $\{\pi_j\}$ are equilibrium distributions of the stations in isolation whose parameters are linked by certain traffic equations.

Networks with String Transitions

In this type of network, a transition is determined by a string of vectors representing multi-stage subtractions or additions of vector quantities at the nodes, and all of this is done instantaneously in a transition. The strings are randomly selected from an arbitrary family of variable-length strings. The equilibrium distributions contain parameters, like the $\{\alpha_j\}$ in the Jackson network, that are determined by nonlinear traffic equations.

Concluding Remarks

Jackson networks and some of the other models are discussed in Kelly (1979), Walrand (1988), Whittle (1986), Wolff (1989), and Boucherie and van Dijk (2011), and all of the models are discussed in Serfozo (1999). Disney and Kiessler (1987) study traffic flows in networks, and van Dijk (1993) discusses modeling by a systems approach.

Topics related to networks of queues that were not discussed include Brownian motion models for approximating networks in heavy traffic, fluid models of (discrete or continuous) flows in networks, polling systems in which servers move among stations, stochastic PERT networks, interacting particle systems, Petri net formulations of networks, space-time Poisson processes for modeling networks with no queueing, and spatial queueing systems. Some of these can be found in Boucherie and van Dijk (2011). Another excellent source for reading about developments in queueing networks is the journal *Queueing Systems: Theory and Applications*. For example, a special issue of the journal in 1998 reviews the state-of-the-art of Brownian queueing network models.

Neural Networks

Alice E. Smith[1] and Sarah S. Lam[2]
[1]Auburn University, Auburn, AL, USA
[2]Binghamton University, Binghamton, NY, USA

Introduction

A field that was started in the 1940s, when McCulloch and Pitts (1943) designed the first neural networks where artificial neurons are combined into a network structure, has attracted researchers from diverse disciplines. Inspired by biological neural networks, artificial neural networks crudely imitate human brains in processing information, recognizing patterns and retrieving stored information. For simplicity, artificial neural networks will be referred to as neural networks.

The first learning law for neural networks was designed by Hebb (1949), and later expanded by McClelland and Rumelhart (1988). The field of neural networks has gone through several stages since its beginnings, including some quiet years in the 1970s (Fausett 1994). A large number of neural network paradigms have appeared in the literature, including the Hopfield networks, multilayer perceptrons (also known as the backpropagation networks), self-organizing maps, adaptive resonance theory networks, radial basis function networks and general regression neural networks.

Neural networks are largely empirical models whose robustness and flexibility are prime advantages. On the debit side, neural networks generally require substantial amounts of data, require considerable expertise to properly construct and validate, and offer little in the way of discernible model structure to better understand the relationship modeled. Neural networks have been successfully applied to prediction, forecasting, process modeling, financial and business applications, combinatorial optimization, classification and control.

After describing several of the most popular neural networks, namely, backpropagation networks, self-organizing maps, and general regression neural networks, recent applications of neural networks to operations research type of problems will be discussed in the following sections.

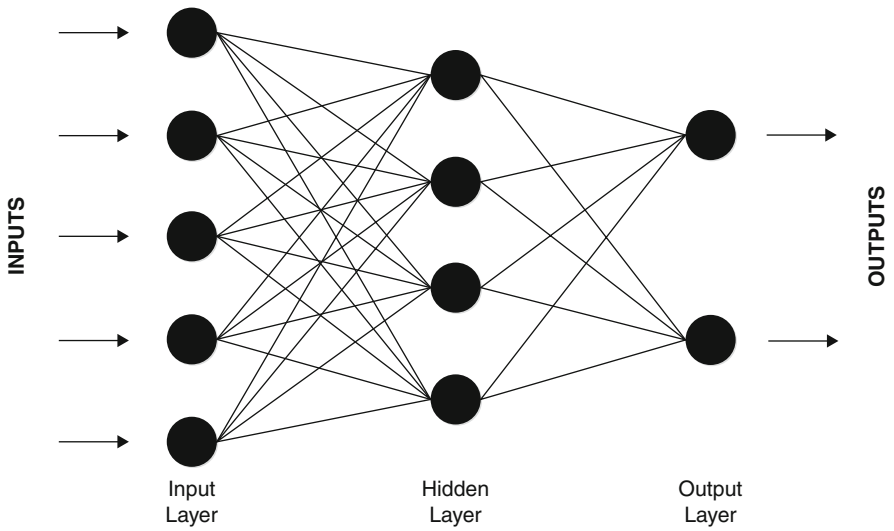
Neural Network Basics

An example of a network structure is shown in Fig. 1. External information is used as inputs (i.e., independent variables) to the network. The interconnections (in the form of real valued, or occasionally binary valued, weights) between the nodes in the input layer and the nodes in the hidden layer, and that between the hidden nodes and nodes in the output layer, represent the knowledge acquired or learned during the iterative training process of the network. The training algorithm for adjusting the connected weights is dependent on the specific network paradigm. During the training process, the interconnections or weights are adjusted according to some algorithm(s). Once the network is trained, it is then able to produce an output (or a set of outputs) for a given input set.

If the training set contains the target information (i.e., known values of the dependent variables), the learning algorithm is a supervised learning algorithm. Examples of supervised networks are backpropagation networks, radial basis function networks and general regression neural networks. On the other hand, if the training set does not contain the target information, the learning algorithm is an unsupervised learning algorithm. Examples of unsupervised networks are self-organizing maps and some versions of the adaptive resonance theory networks. Human and animal learning incorporates both supervised and unsupervised learning but in neural networks, a given paradigm will use one form of learning or the other.

Building and Validating a Neural Network

The process of constructing a neural network for an application generally involves three steps: data-preprocessing, model design and model validation. The first step is to determine which variables are to be modeled and these are generally divided into input variables and output variables. It is usually preferred to use the minimum number of variables that provide adequate characterization of the relationship to be modeled. Neural networks depend on data to establish the model. In fact, they normally require greater amounts of data than traditional statistical methods such as least squares



Neural Networks, Fig. 1 Network structure

regression or kriging. The dataset may require investigation on the characteristics of outliers, and may require preprocessing to extract the important features for the problem at hand. The dataset is normally divided into a training set and a validation set, though there are approaches which use all data for both training and testing (see for example, the resampling techniques used in Twomey and Smith (1998)).

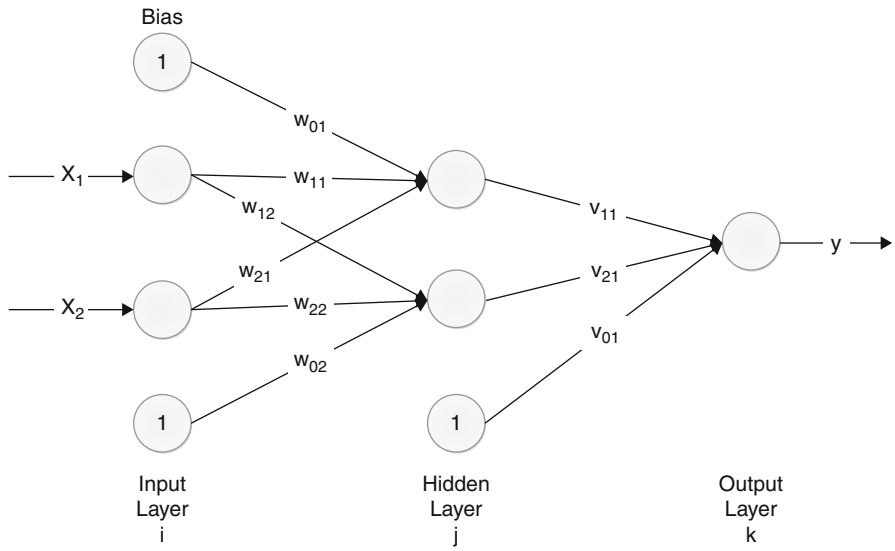
Once the data has been pre-processed, one or multiple networks may be selected for model building. This step often depends on the network modeler's experience and the network paradigms that have been successfully utilized for the application considered. Designing a network includes selection of the network paradigm, network size and structure, learning method and parameters, and stopping criteria for learning. A design of experiments could be used to fine-tune the network parameters. Designing and building a neural network is normally an artful and iterative task. There is little in the way of useful general guidelines and it is often difficult to choose a priori a superior set of network structures and parameters.

After the network has been trained using a training-set, the trained network is usually validated using a separate set of data (i.e., a validation set). The performance on the validation set is often used as an estimate of the network's generalization ability. Achieving a low error on the training set but a substantially high error on the validation set generally indicates overtraining and/or over specification of the network model. This often implies that the network memorizes the training set too well, and its ability to generalize on the validation set has significantly degraded.

After the neural network has been trained and validated, its structure and parameters are then fixed and it can be used for the task intended. Some neural network paradigms have the ability to continue learning even while in the operational state (see, for example, the adaptive resonance theory network). From a usage perspective, neural networks have the disadvantage of being a "black box" technology. That is, little useful insight can be gained by examining its parameters. This is unlike a regression model where intercept and slopes have a readily identifiable interpretation. There are also few statistical properties that can be calculated from neural networks.

Common Neural Network Paradigms

The so-called backpropagation network (the training method is actually backpropagation and it is generally used on the network structure termed multi-layer perceptrons), one of the most popular network paradigms, has been applied in many different areas in the literature. A simple 2-2-1 network that consists of 2 input nodes in the input layer, 2 hidden nodes in

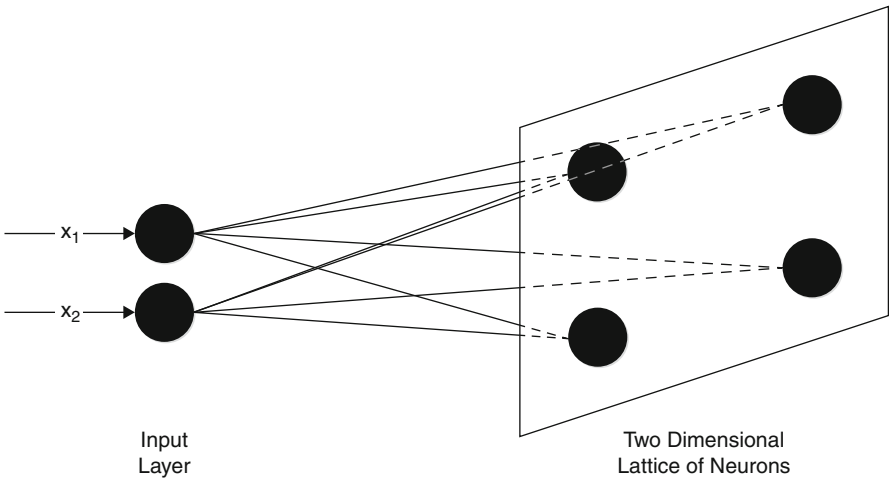


Neural Networks, Fig. 2 A 2-2-1 network

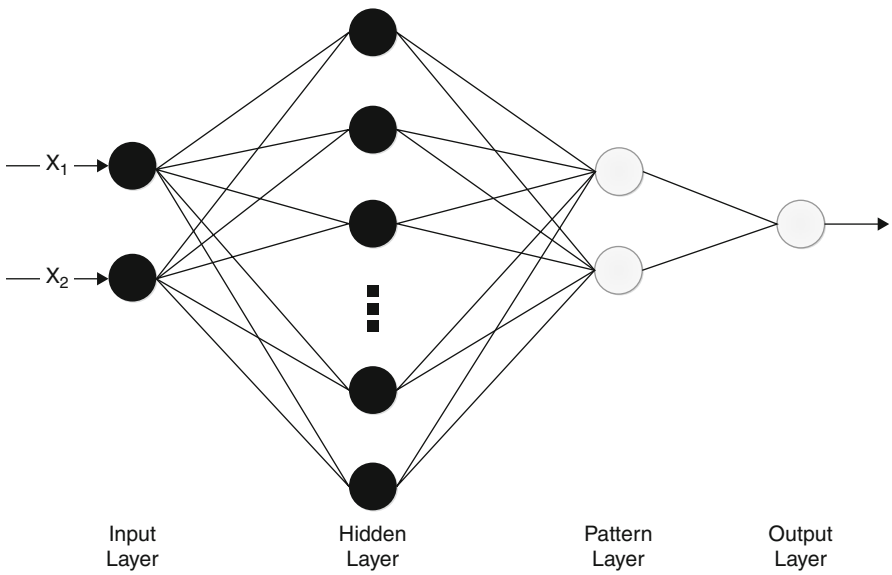
the hidden layer, and 1 output node in the output layer, is shown in Fig. 2. During the training process, each training vector is fed to the input layer. The inputs, weighted by the connected weights w_{ij} along with the bias are fed forward to the hidden nodes in the hidden layer. An activation function is then applied to the input signal to each hidden node to produce an output (outgoing) signal to the following layer. Common activation functions are the hyperbolic tangent and sigmoid. The output signals, weighted by v_{jk} along with the bias term are fed forward to the output node in the output layer. The received signal at the output node undergoes a transformation, via an activation function, to produce a network output in the output layer. The difference between the network output and the target output is then propagated backward to adjust the connected weights in the network. The adjustment is dependent on the squared error in the output layer, and a learning factor chosen for the backpropagation learning algorithm. The training process of the network continues until the weight adjustments become negligible or a predetermined number of iterations of training have been completed. The training process is equivalent to the determination of optimal weights that minimize the error between the network output and the target output. A mathematical formulation of the backpropagation learning algorithm is provided by Fausett (1994). These types of networks are multi-purpose and are usually used for prediction, classification and control.

The **self-organizing map**, also known as the Kohonen's self-organizing map, is based on a competitive learning algorithm (Kohonen 1982, 1997). The neurons in the self-organizing map (shown in a two-dimensional lattice in Fig. 3) are selectively tuned or adjusted according to the input information received during training. According to a distance metric (e.g., Euclidean distance), the neuron that is closest to the input vector wins the competition and is allowed to update its connected weights to the input nodes in the input layer. Over the course of the training process, the neurons are topologically ordered and their weight vectors represent an approximation of the input space. This approximation is also known as the feature map. One of the basic ideas of the self-organizing map is to extract the features from the input space and represent the features using a smaller set of neurons in the output space. Variations on the neighborhood structure of the neurons in the lattice allow for the winning neuron along with its nearest neighbors to "learn" from the input vector. The adjustment of the weight vectors gradually diminishes over time, which would signify that the training of the network has been completed. These types of networks are generally used for classification or clustering tasks.

The general regression neural network, developed by Specht (1991), is a probabilistic neural network. This network requires only a fraction of the training samples that a backpropagation network would



Neural Networks, Fig. 3 Kohonen's self-organizing map



Neural Networks, Fig. 4 General regression neural network

normally require (Specht 1991) (Fig. 4). Each neuron in the hidden layer uses a Gaussian probability distribution, centered at one of the training samples. Hence the connected weights between the input and the hidden layers are encoded as the input vectors (i.e., $\vec{x}$) in the training set. A training set of size n would require a total of n neurons in the hidden layer. One of neurons in the pattern layer, the numerator neuron, has its connected weights between the hidden and the pattern layers encoded as the target values of the input vectors (i.e., $\vec{y}$) in the training set. The vector $\vec{y}$ is a one-dimensional vector that has the same number of elements as the size of the training set. In the event that the original training samples have more than one output variable, each output variable would require a separate general regression neural network. The other neuron in the pattern layer, the denominator neuron, has its weights between the hidden and the pattern layers encoded as unit weights. The final output of the network (in the output layer) is the ratio of the weighted sum of inputs received at the numerator neuron in the pattern layer and the sum of inputs received at the denominator neuron in the pattern layer. Each hidden neuron contributes to the final output of the network. These types of networks are usually used for prediction and forecasting.

Prediction Applications

Probably the preponderance of applications of neural networks can be classified as prediction. Often these neural networks are used when a comparable statistical model (such as regression) proves to be too restrictive. These applications also have the property of ample data with which to train and validate the network model.

Brockett et al. (1997) discuss the possible advantages and feasibility of using neural networks to predict insurer insolvency (inability to pay debts). Their research examines a backpropagation network with a goal of obtaining early warnings (early being up to 3 years before) for both insolvency predictions, and priority ranking of insurance firms for potential auditing. The case study is constrained to insurance companies only located in Texas, and also insurance companies that only offer property and casualty insurance (as opposed to life and health insurance). Their model is designed having an input vector of eight financial variables to differentiate between healthy and weak insurers, with an output of the solvency results. The optimal number of iterations was based on the process of stopping the training once peak network performance is achieved. The results showed that the network was able to learn patterns corresponding to financial distresses of the companies, had a 95.45% accuracy rate in the 44 companies evaluated in determining the insolvency rate. Their research concluded with the benefits of using neural networks, specifically the ability to update without training the network from the beginning, using the current weights as a starting point for future iterations when more data becomes available, and the ability to adapt to changing economic influences.

Condition based maintenance is the act of keeping equipment maintained properly so that it does not fail. Remaining useful life (RUL) prediction of the equipment is instrumental in condition based maintenance. There exists two forms of RUL prediction: model-based (or physics-based), which relies on calculations involving the mechanics of the equipment, and data-based, which aims at predicting RUL based on a model of the relationship between RUL and equipment age, condition monitoring data, and equipment degradation. The adaptability, nonlinearity, and arbitrary function approximation ability of neural networks have been considered to be promising tools for RUL prediction. Tian et al. (2010) propose an approach for predicting RUL of equipment using a neural network with age and condition monitoring data as inputs and life percentage (1 - RUL) as the output. In this case, condition monitoring data includes some available failure history, as well as suspension history. Suspension history is information about a piece of equipment that has been suspended (removed) from use in its respective system. It provides useful insight into degradation of the piece of equipment and can lead to more accurate RUL predictions. The optimal predicted life is determined for each suspension history. The trained network was validated by using real-world vibration monitoring data collected from pump bearings. Their results showed that the neural network devised in their research can produce accurate RUL predictions. Another neural network application to condition-based maintenance can be found in Smith et al. (2010). This group developed hardware and software to estimate degradation of the door mechanism on airport people mover vehicles using a backpropagation neural network. This neural-based system was field tested at an airport and resulted in multiple patents issued.

Neural nets are known for their ability to estimate continuous functions well but the model is of a "black box" approach where the end-user does not know precisely how the model came to its conclusion. Setiono and Thong (2004) demonstrate the extraction of the knowledge that the neural network has learned in order to achieve better system understanding. The first step is to estimate the hyperbolic tangent activation function for each hidden unit of the hidden layer from a trained and pruned neural net by means of a three-piece linear function. Then the input region is divided and a linear function is estimated for each sub-region. Since the estimated linear function obtained for each region has inputs that are weighted, i.e., the weights from the input layer to the hidden layer, Setiono and Thong (2004) propose optionally the use of the C4.5 decision tree to get a set of rules independent of the weights.

According to Ladstatter et al. (2010), organizational research problems are seldom studied via neural networks and burnout has never been studied with neural networks, thus making their research unique. If burnout could be predicted accurately

then preventative measures could be used in an attempt to alleviate the problem. Burnout is described as being three dimensional, namely, emotional exhaustion, depersonalization and lack of personal accomplishment. The radial basis function neural network in this case uses seven input variables (conflictive interaction, workload, experience with pain and death, role ambiguity, age, job status and hardy personality) to predict the level of each of the three dimensions of burnout. Three types of neural networks, namely backpropagation and radial basis function networks with traditional and hybrid training algorithms, were constructed to see which model was the best. A hierarchical stepwise regression model was also developed from the same data for comparison purposes. The results were modest in that the radial basis function neural network, being the best neural network in this research, slightly outperformed the regression model in two of three dimensions of burnout.

A backpropagation network was used to predict internet traffic over internet-protocol (IP) networks in Chabaa et al. (2010). Multiple learning algorithms were implemented for comparison, namely, gradient descent, conjugate gradient, one step secant, Levenberg-Marquardt and resilient backpropagation. Additionally four variants of the conjugate gradient algorithm were used, namely, Fletcher-Reeves updates, Polak-Ribiere updates, Powell-Beale restarts and scaled. All conjugate gradient algorithms start searching in the area of steepest descent followed by combining the next (new) search direction with previous search direction. The four conjugate gradient variants differ in how they combine the new with the previous search direction. The multiple learning algorithms were then compared by using the following statistical measures: root mean square error, scatter index, relative error and mean absolute percentage error. The results showed that the Levenberg-Marquardt and resilient backpropagation performed the best for the prediction task based on the above statistical measures.

Forecasting Applications

Similar to prediction problems, forecasting applications are most specific to a series of data where the ordering is important. There have been a number of papers in which neural networks have been used effectively for this task. There are also reports of applications of neural networks managing time series data to make investment decisions (see, for example, Evensky (1997)).

Hansen and Nelson (2003) show the use of neural networks to improve forecasts of time-series components that are not effectively forecasted using classical decomposition of the forecast components (trend, seasonality, irregularity (error or residuals)). Traditional forecasts do not work as well when the trend/cycle component is not linear, there is variation in cycles, the seasonality component evolves over time, or when the irregularity component (residuals) does not appear to be from white noise. Hansen and Nelson (2003) noted that it could be possible to apply neural networks to extract information from the seemingly noisy or irregularity component of the forecast. Their framework was based on a "stacked generalization" model. First classical decomposition was conducted providing estimates for trend, seasonality, and irregularity. Then each estimated component was input into a separate neural network for each of the forecast components (i.e., a trend neural network, seasonality neural network, irregularity neural network). The result of the stacked generalization model is a non-linear combination/forecast of the time-series components. Their stacked generalization model was tested and compared to results obtained for classical decomposition and ARIMA models.

Tiwari and Chatterjee (2010) used bootstrap-based neural networks to predict flooding at multiple time intervals based on hourly water-level data taken from five different locations. The authors used statistical techniques to reduce the dimensionality of the data set and then a log transformation followed by linear scaling to achieve inputs ranging from 0 to 1. The network design consisted of the input and output layers defined by the problem and one hidden layer with the number of nodes in the hidden layer determined by cross-validation. The initial network model showed good results in its ability to predict water levels at different lead times (0, 1, . . ., 10 hrs into the future). Furthermore, Tiwari and Chatterjee (2010) also introduced a method to incorporate confidence intervals for the output obtained from the bootstrap ensembles which helped reduce the model uncertainty.

Process Modeling

Process modeling is an active area of neural network applications. A great variety of neural network paradigms and approaches have been used on a variety of industrial processes.

Maksoud et al. (2003) established a system of two backpropagation networks for monitoring and controlling grinding operations. The first network is used for the grinding process design to achieve the required workplace surface roughness, with an output of suitable values of machine variables. The second network is used for the grinding process control, with an output of modifying the cutting variables or flagging for automatic dressing activation. Tests were run to evaluate response to change variables in order to keep the surface roughness within the desired tolerance. It was found that the network model kept the surface roughness within the desired tolerance, and the model also alerted the machine when it needed to stop the process and flag it for automatic dressing activation. The research work could potentially be implemented in other grinding operations with different sets of variables.

Coit et al. (2002) developed a neural network system for process modeling and control of a wave soldering line in the production of printed circuit boards. They developed a hierarchy of neural networks each with a specialized task. The ultimate network predicted quality of solder connection based on both printed circuit board design characteristics and on solder process parameters. Lam and Smith (2001) discuss three diverse applications in manufacturing and how systems of neural network models were successful in improving process control. These are ceramic casting of sanitary ware (Lam et al. 2000), abrasive flow machining for automotive engine parts, and chemical oxidation of cyclohexane in a reactor (Lam et al. 2001).

Gupta (2010) devised empirical models for the prediction of surface roughness, tool wear, and power required using response surface methodology, neural networks and support vector regression. Descriptive statistics and hypothesis testing were used to compare and evaluate the model building methods. The results showed that neural network and support vector regression models were superior to regression and response surface methodology in the prediction of surface roughness, tool wear, and power required.

Financial and Business Applications

While some of the application areas cited above can span this sector, a good review article is followed by sample applications specific to finance. Smith and Gupta (2000) review neural network applications in the business domain and indicate that they are really a tool for the operations researcher. The authors identify five stages of neural network research development, with the first stage being related to computing paradigms and the last stage being the research of neural networks in business applications. An overview of business application areas (non-exhaustive) are given as marketing, retail, banking and finance, insurance, telecommunications and operations management. Interesting and successful examples in each of these industry sectors are given to show the diversity of neural network applications.

West et al. (2005) investigated neural network ensembles to produce better decision support mechanism for financial decisions. The argument for "ensembles" is that predictions from multiple experts (models) can produce results with less error than when only using the best fitting model. The ensemble methods discussed include cross-validation, bootstrap aggregation (or bagging), and adaptive boosting (or boosting). Cross-validation is where multiple, similar neural networks are trained on the same data. Bagging and boosting methods involve perturbing the training data such that the different neural networks in the ensemble are each trained on unique training data sets that are subsets of the original training set. Bagging creates the training data by randomly selecting data with replacement from the original training data set, whereas boosting creates multiple, unique training data sets that each contain multiple examples of hard-to-classify examples that a single neural network could not learn itself from the original training data. After the ensemble member networks are trained, the outputs are combined, or aggregated in a single decision. The research of this paper included creating different ensemble neural networks for three different financial data sets and comparing the results of the ensembles with each other and the single "best fitting" model. The results of their research show that cross-validation and bagging outperform the single "best fitting" model in all three data sets while the boosting method did not always outperform

the "best fitting" model, most likely due to outliers and possibly the need for better boosting algorithms. In all cases the reduction in generalization error was modest (~3%), but it was argued that in the case of financial decisions in a trillion dollar annual industry can mean significant savings.

Grznar et al. (2007) use neural networks to model complex, organization systems where statistical models have proved inadequate. In particular the authors use multilayered feedforward neural networks with backpropagation learning to model the relationship between inter & intra team processes, organizational context, and team size to team effectiveness. The basic argument that statistical procedures are not suited for this problem is due to outliers in the data and the non-linear relationships in complex systems. Grznar et al. (2007) created the training data by means of a survey that included 102 different teams from different organizations. The data was modeled by the neural network and also with traditional and robust regression (robust regression uses least median of squares to make the model less susceptible to outliers) in order to compare the results. The traditional and robust regression models each found the intra-team processes to be significant and the regression models had R^2 values of 0.247 and 0.313, respectively, which apparently are good R^2 values for organizational models. It is suspected that low R^2 values of organizational models are due to non-linear behavior that cannot be explained with these models. The neural network model resulted in a R^2 of 0.414, which was significantly better than the previous models. The authors were also able to experiment with multiple data streams on the validated model and found some interesting non-linear relationships. Among these relationships is that as team size increases it initially decreases team effectiveness but then as the team size becomes even larger team effectiveness begins to increase again.

Classification Applications

Fisch et al. (2010) made use of radial basis function neural networks to classify system behaviors, in particular to detect network intrusion. The radial basis function neural network is very similar to that of a backpropagation network except that the activation of the hidden neurons is calculated by radial basis functions instead of sigmoid or hyperbolic tangent functions. The training and test data for this research were from a DARPA project conducted in 1998, which contained over 300 examples of 38 different types of intrusions. This paper used a subset of the DARPA dataset which had a higher proportion of intrusions versus safe actions in order to make classification easier. Fisch et al. (2010) compared multiple methods including the two neural networks, neuro-fuzzy, decision trees, fuzzy-k-means, support vector machines, Bayesian networks and k-nearest-neighbor to report on which performs the best. The results showed that the radial basis function neural network performed slightly better than the k-nearest-neighbor approach but that there was no clear winner among the classification approaches.

Zhang (2000a) compared backpropagation networks with statistical classification and showed the superiority of neural networks when the model is non-linear or when the underlying distribution function is unknown. Additionally it was shown that with appropriate architectures one can essentially mimic the most widely used statistical classifiers with a neural network, which further shows their utility. The discussion addresses learning and generalization for future predictions and how they are related to model bias and variance. Overall, Zhang's paper is a good review of backpropagation networks' application to classification problems.

Control and Optimization

Sensor fault detection and isolation is an integral part of flight control systems, especially for an unmanned aircraft. The most common solution for sensor failure is using redundant hardware and output limit checks to see which sensors are operating as expected. Due to high cost and additional weight loads of redundant hardware it is preferred to use a model based approach. The majority of model-based senor fault detection and isolation use linear models which obviously have drawbacks when the system is not linear. Samy et al. (2010) used an extended minimum resource allocation network radial basis function neural network for sensor fault detection and accommodation. Their neural network was implemented in a simulated environment and only one type of fault (pitch gyro) was considered. The neural network model has six inputs including:

angle of attack, normal acceleration, airspeed, altitude, elevator angle, and throttle. There was a single output node corresponding to pitch rate. The model had to be able to detect eight different fault types corresponding to the output (pitch rate) exceeding certain thresholds. The neural network model was trained through batch learning to find all model parameters. Once the model was batch trained it was connected in parallel with a simulated model of an unmanned air vehicle. Sensor readings (six inputs) entered the unmanned air vehicle and neural network model, which is now switched to online learning, to obtain actual and estimated outputs, respectively. A residual was then generated from comparison that is used for fault detection, i.e., if this residual exceeds a certain threshold. The results indicate that the neural network was able to detect faults adequately. This work has shown the potential to use neural networks for unmanned air vehicle flight control, although it is not expected to replace hardware redundancy in the near future.

In optimization, neural networks were first noted as possibilities in the seminal paper by Hopfield and Tank (1985). Since that time there have been various approaches made and these are summarized and presented in the book by X. S. Zhang (2000b). It seems that other computational methods, however, are more well suited to optimization and the research community has largely moved on to those, such as the nature-based metaheuristics of genetic algorithms and ant colonies.

Neuro Dynamic Programming

Another name for approximate dynamic programming or reinforcement learning, where the "neuro" comes from the fact that a neural network might be used to approximate the value function.

- ▶ Approximate Dynamic Programming

Newsboy Problem

Items, here newspapers, have to be procured at the beginning of a time period and are discarded (or sold at a discounted price) at the end of the time period. The demand is assumed to be a random variable with known distribution. The problem is to determine how many items to stock at the beginning of the time period to minimize expected cost. This leads to a closed-form, single-period inventory model with stochastic demand. The problem statement also applies to items such as Christmas trees, time-dependent fashions, and items that can be stored until the next season like snow tires and Chanukah candles.

NLP

► Nonlinear Programming

Node

An element of a graph or network, pairs of which are connected by arcs or edges. Nodes are sometimes referred to as points or vertices. In queueing networks, a node is also called a station and represents a simple queueing subsystem consisting of a service center with one or more servers, a queueing capacity (infinite or finite), and a queue discipline. In a project network plan, a node is shown graphically as a circle depicting the beginning or end of an activity, and represents an instantaneous point in time at the junction of arrows.

Node-Arc Incidence Matrix

For the minimum-cost network-flow problem, this is a matrix in which the rows i correspond to the nodes and the columns j correspond to the arcs. For an arc (i, j), with its flow directed from i to j, the entry in matrix location (i, j) is $a + 1$ and the entry in location (j, i) is $a - 1$. All other entries are zero. Thus, every column has only two nonzero entries. Such matrices are unimodular.

Nonactive (Nonbinding) Constraint

An inactive constraint.

See

► Active Constraint
► Inactive Constraint

Nonbasic Variable

Given a feasible basis to a linear-programming problem, a variable is nonbasic if it does not correspond to one of the vectors in the basis.

See

► Basic Variables

Nondegenerate Basic Feasible Solution

A feasible basis to a linear-programming problem is nondegenerate if all basic variables are strictly positive.

► Goal Programming

Nonlinear Programming

Anthony V. Fiacco
The George Washington University,
Washington, DC, USA

Introduction

Nonlinear programming, a term coined by Kuhn and Tucker (Kuhn 1991), has come to mean the collection of methodologies associated with any optimization problem where nonlinear relationships may be present in the objective function or the constraints. Since maximization and minimization are mathematically equivalent, without loss of generality the nonlinear programming problem discussed throughout will be the problem of finding a solution point or optimal value of

$$\text{minimize } f(\boldsymbol{x}) \text{ subject to } g_i(\boldsymbol{x}) \geq 0 \quad (i = 1, \ldots, m)$$
$$\text{and } h_j(\boldsymbol{x}) = 0 \quad (j = 1, \ldots, p) \qquad (P)$$

where all problem functions are real valued. The underlying space can be more general but is here assumed $\boldsymbol{x} \in R^n$. In this terminology and context, problem (P) is a linear program (LP) if f, g_i and h_j are linear (technically linear-affine, i.e., linear plus a constant) for all i and j.

Another very important instance of problem (P) is where the constraints g_i and h_j are not present or where every point in the domain of f is feasible (i.e., satisfies the constraints). This is called an unconstrained problem and goes back to the very early days of mathematics.

Simple Examples

Finding the highest point of a pyramid may be viewed as a linear programming problem. Assuming that equations of the planes that contain the sides and base of the pyramid can be found, the pyramid is essentially the feasible region, the set of points in the volume contained by these planes, and the problem is to find the point in the region that yields the greatest height.

A somewhat analogous example is that of finding the deepest point in a lake, where the shoreline is the constraint, the surface of the water is the feasible region, and the depth is the objective function. This example would generally be highly nonlinear.

Another readily understandable example is that of finding a point where the maximum or minimum altitude is attained in a given area, e.g., find the highest point in the state of Virginia. The constraints are determined by the state boundaries. Lines of equal altitude are often displayed on a map and correspond to isovalue contours or level curves of the objective function (altitude), in mathematical programming terminology. Thus, the goal is to find the latitude and longitude of a location in Virginia (the feasible region) on a level curve of maximum value, a problem that is (logically) equivalent to a realization of a nonlinear problem of the form of problem (P). There are many local maxima (i.e., hills and peaks) in this problem that are not global, a formidable challenge to solving (P).

Mathematical Examples

Obtaining a solution to a system of equations $h_1(\boldsymbol{x}) = 0, \ldots, h_p(\boldsymbol{x}) = 0$ where $\boldsymbol{x} \in R^n$ may be posed as the unconstrained NLP, P: min $\Sigma_{j=1}^{q} h_j(x)^2$ s.t. $x \in R^n$, or equivalently, P: min $\|\boldsymbol{h}(\boldsymbol{x})\|^2$, where $\boldsymbol{h} = (h_1, \ldots, h_p)^{\mathrm{T}}$ and the norm is the usual Euclidian norm. Alternatively, one could choose to solve min $\|\boldsymbol{h}(\boldsymbol{x})\|^2$ or min $\|\boldsymbol{h}(\boldsymbol{x})\|$ for any suitable choice of norm. There may be no solution to the system of equations, but the indicated NLP problems can still be addressed, and their solutions would yield points that minimize the residual error, i.e., the deviation of $\boldsymbol{h}(\boldsymbol{x})$ from $\mathbf{0}$, in the sense of the given norm. The choice Σh_j^2 leads to a so-called least-squares solution and is undoubtedly the most popular, yielding a smooth (i.e., differentiable) problem if $\boldsymbol{h}$ is differentiable (the other

measures usually being nonsmooth). If the solutions are underdetermined, one could use the degrees of freedom to seek to determine a solution having a desired quality such as minimum norm, i.e., a solution of the constrained NLP, min $\|\boldsymbol{x}\|$ s.t. $\boldsymbol{h}(\boldsymbol{x}) = \boldsymbol{0}$.

The minimum norm-residual idea turns out to be extremely fruitful and is a driving mechanism for several important classes of NLP problems, including regression, also known as parameter estimation or data fitting and essentially a type of curve-fitting, minimum distance problems, and eigenvalue problems. The idea of regression is to assume a functional form, say $y = F(\alpha,\ x) + \varepsilon$ that relates observation $\boldsymbol{y}$ to the input data vector $\boldsymbol{x}$, parameter vector α, and a random experimental error ε. If y_i $(i = 1,\ldots, r)$ is observed, respectively, when x_i $(i = 1,\ldots, r)$ occurs, then, under suitable assumptions, a least-squares regression problem can be formulated. The goal is to find a parameter vector $\bar{\alpha}$ that solves the unconstrained NLP, $\min_\alpha \Sigma_{i=1}^{r}[y_i - F(\alpha, x_i)]^2$. If F is linear, then this is called linear regression and is well known, heavily used, and has a rich statistical basis and interpretation. Other norms could be used. A similar approach, so called curve-fitting, could be used to fit a function F to a given set of points or to approximate another function, possibly introducing constraints on F, for example, requiring bounds on F or its derivatives, without necessarily being supported by the attendant statistical rationale and utilizing a variety of norms.

The problem of finding the minimum eigenvalue and associated eigenvector of a real symmetric $n \times n$ matrix $\boldsymbol{A}$ can be posed as that of determining the optimal value and solution vector, respectively, of the constrained NLP problem, min $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{A}\boldsymbol{x}$ s.t. $\|\boldsymbol{x}\|^2 = 1$, again a minimum-norm-type problem. The problem of finding the shortest distance between one point and another, or a point and a line, or a point and a set or, more generally, between one set S_1 and another set S_2 takes on the rather natural NLP-constrained form, min $\|\boldsymbol{x} - \boldsymbol{y}\|^2$ s.t. $\boldsymbol{x} \in S_1$ and $\boldsymbol{y} \in S_2$. Many extensions and ramifications of this idea can be envisioned.

Practical Applications

Hancock (1960, p. 151) stated that "by means of Gauss's principle all problems of mechanics may be reduced to problems of maxima and minima." Principles in optics, wave mechanics, quantum physics, astronomy, chemistry, biology, etc., can usually be formulated in terms of extremal (i.e., maximum or minimum) principles, for example, a path of least resistance, minimum energy, maximum entropy, etc.

The practical applications of nonlinear programming are incredibly vast. Regression and curve-fitting applications abound in mathematics and physics, the natural and applied sciences, econometrics, and engineering statistics. Generalizations include possible constraints on the parameters and extensions to higher dimensions (surface fitting), with applications in pattern recognition, geography, agriculture and quantum physics, for example (Hobson and Weinkam 1979). As early as 1980, Hillier and Lieberman (1980, Ch. 1) reported that the most widely used operations research techniques were statistical techniques (mainly those involving regression analysis), simulation, and linear programming. They noted that the most important applications of mathematical programming were those in production management (e.g., in allocation of resources to maximize some measure of profit, quality, efficiency, effectiveness, etc.), followed next by financial and investment planning, and they reported that about 25% of all scientific computation on computers was devoted to linear programming and related techniques. It seems clear that these trends have sustained. Winston (1991, p. 51) noted that 85% of the respondents of a survey of Fortune 500 firms report use of LP, and that about 40% of his book is devoted to related optimization techniques.

Practically every research and textbook in NLP discusses important current applications. Fletcher (1987, p. 4) noted important applications in structural design, scheduling, and blending, as well as numerical analysis and differential equations. McCormick (1983) analyzed problems in chemical equilibrium, inventory control, engineering design and water pollution control. Bazaraa and Shetty (1979) discussed problems in discrete and continuous optimal control, mechanical and structural design, electrical networks, and location of facilities.

A methodology for NLP started coming together around 1960. This was largely motivated by applications, for example, to petroleum refinery problems which inspired algorithmic work by Rosen in 1960–61 and a paper-pulp manufacturing process that led to a technique proposed by Carrol in 1959

and 1961. A collection of case studies in such diverse areas as bid evaluation, stratified sampling, launch vehicle design and alkylation process optimization was given by Bracken and McCormick (1968). The algorithms used were based on Carrol's interior barrier function and Courant's exterior quadratic penalty function proposed in 1943, developed and extended by Fiacco and McCormick in 1963, and implemented via the SUMT computer program by McCormick, Mylander and Fiacco in 1965 (Fiacco and McCormick 1968; Fiacco and Ishizuka 1990).

Basic Theory

Problem types can be differentiated in many ways: (i) one dimensional or many dimensional, (ii) finite-dimensional (e.g., in R^n) or infinite-dimensional (e.g., as in variational calculus and optimal control), (iii) a finite number of constraints or an infinite number (as in semi-infinite programming), (iv) unconstrained or constrained, (v) involving real numbers (standard NLP) or integers (integer programming), (vi) convex or nonconvex, (vii) smooth (i.e., differentiable) or nonsmooth (nondifferentiable), and (viii) deterministic or stochastic.

A local minimizer of (P) is a feasible point $\bar{\boldsymbol{x}}$ such that $f(\bar{\boldsymbol{x}}) \leq f(\boldsymbol{x})$ for all $\boldsymbol{x}$ in a feasible neighborhood of $\bar{\boldsymbol{x}}$. If $f(\bar{\boldsymbol{x}}) \leq f(\boldsymbol{x})$ for *all* feasible $\boldsymbol{x}$, then is called a global minimizer. If $\bar{\boldsymbol{x}}$ is a local minimizer and $f(\bar{\boldsymbol{x}}) < f(\boldsymbol{x})$ for all $\bar{\boldsymbol{x}} \neq \boldsymbol{x}$ in a feasible neighborhood of $\boldsymbol{x}$, then $\bar{\boldsymbol{x}}$ is called a strict local minimizer. If $\bar{\boldsymbol{x}}$ is the only local minimizer in some feasible neighborhood of $\bar{\boldsymbol{x}}$, it is called an isolated local minimizer.

A fundamental result of great importance is the fact that a feasible global minimizer of a continuous function f exists in the feasible region R if R is nonempty and compact, a result attributed to Weierstrass. If f is once continuously differentiable and $\bar{\boldsymbol{x}}$ is a local unconstrained minimizer, then the gradient, $\nabla f(\bar{\boldsymbol{x}}) = 0$. If f is twice continuously differentiable, then $\nabla f(\bar{\boldsymbol{x}}) = 0$ and the Hessian (matrix of second partial derivatives) $\nabla f^2(\bar{\boldsymbol{x}}) = 0$ is positive-semi-definite (p.s.d.) at a local minimizer $\bar{\boldsymbol{x}}$ and $\nabla f(\bar{\boldsymbol{x}}) = 0$ is positive definite (p.d.), then $\nabla^2 f(\bar{\boldsymbol{x}}) = 0$ is an isolated (hence, also strict) local minimizer.

The usual Lagrangian of problem P is defined as

$$L(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}) = f(\boldsymbol{x}) - \sum_{i=1}^{m} u_i g_i(\boldsymbol{x}) + \sum_{j=1}^{p} w_j h_j(\boldsymbol{x})$$

where the $\{u_i\}$ and $\{w_j\}$ are the Lagrange multipliers. John in 1948, Karush in 1939, and Kuhn and Tucker in 1951 (Fiacco and McCormick 1968; Fiacco and Ishizuka 1990) independently generalized and extended the classical Lagrange multiplier rule (Lagrange 1762) for equalities to include inequalities, arriving at the following first-order conditions called the Karush-Kuhn-Tucker conditions and abbreviated as KKT $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$: there exist $\bar{u}_i \geq 0\,(i = 1, \ldots, m)$ and $\bar{w}_j (j = 1, \ldots, p)$ such that $\nabla_x L(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}}) = 0$ and $\bar{u}_i g_i(\bar{\boldsymbol{x}}) = 0\,(i = 1, \ldots, m)$, for $\bar{x}$ feasible. If a suitable constraint qualification (CQ) holds at a local minimizer $\bar{x}$, then KKT $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ holds. Though a more general CQ was given in Kuhn and Tucker (1951), it turns out that this holds if the binding constraint gradients are linearly independent, i.e., if $\{\nabla g_i(\bar{\boldsymbol{x}}), i \in B(\bar{\boldsymbol{x}}); \nabla h_j(\bar{\boldsymbol{x}}), j = 1, \ldots, p\}$ are linearly independent, where $B = \{i : g_i(\bar{\boldsymbol{x}}) = 0\}$. Denote this CQ by LI $(\bar{\boldsymbol{x}})$. The KKT $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ are sufficient for $\bar{x}$ to be a minimizer if (P) is a convex program, i.e., if f is convex, the $\{g_i\}$ concave and the $\{h_j\}$ affine. Convex programs have additional attributes: local solutions are global, they have associated with them a rich duality theory, and they are among the easiest to analyze and solve. Second-order optimality conditions are now also well known and heavily used.

When P is convex, a dual problem is the following:

$$\max_{(x,u,w)} L(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}) \text{ s.t. } \quad \nabla_x L(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}) = \boldsymbol{0},\ \boldsymbol{u} \geq \boldsymbol{0}, \quad (\mathbf{D})$$

where $\boldsymbol{u} = (u_1, \ldots, u_m)$ and $\boldsymbol{u} \geq \boldsymbol{0}$ means that $u_i \geq 0$ for all $i = 1, \ldots, m$. This simple but remarkably useful formulation was first proposed and developed by Wolfe in 1961 (Fiacco and McCormick 1968; Fiacco and Ishizuka 1990). It turns out that the optimal value of **P** is bounded below by the optimal value of **D**. Further, if $L(\bar{\boldsymbol{x}})$ holds, or one of several other well known CQs, then if $(\bar{\boldsymbol{x}})$ solves **P**, it follows that KKT $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ holds, $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ solves the dual **D**, and $f(\bar{\boldsymbol{x}}) = (\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$. Duality has significant computational applications; for example, algorithms that generate dual-feasible points also yield lower bounds on the primal optimal value.

Other duals have been developed, most notably the Fenchel Dual, significantly extended and utilized by Rockafellar (1970) and others. Not surprisingly, a rich and finely tuned duality theory has been developed for LP.

Algorithms

An algorithm is a numerical procedure that starting with given initial conditions, calculates a sequence of steps or iterations until some stopping rule is satisfied. Up until the emergence of interior-point methods, the uncontested winner for LP has been some version of Dantzig's Simplex Method, a technique based on the idea of moving from one vertex of the feasible region to an adjacent vertex while reducing the objective function with each move. The elegance of the mathematics, industrialization and economic planning needs, and the advent of the electronic digital computer in the 1940s, and a host of important practical applications that followed, all resulted in making LP widely accepted and heavily utilized.

The same forces that stimulated the development of LP in the latter 1940s were encouraging research on theory and algorithms for NLP. The 1930s and 1940s saw a flurry of theoretical activity in variational calculus and optimization at the University of Chicago and other mathematical centers by mathematicians like Valentine, Reid, McShane, Karush, Bliss, Graves, Hestenes, Courant, John and others. The early 1950s brought a sharper focus to first-order and second-order optimality conditions for inequality constrained NLP by Kuhn and Tucker in 1951 and Pennisi in 1953, respectively, and others. As early as 1951, for example, a paper by Arrow in 1951 on a gradient method for solving constrained saddle-point problems, there is evidence of serious algorithmic work. Two key results during this period were the conjugate direction method, an iterative procedure for solving a system of linear equations, by Hestenes and Stiefel in 1952, and a variable-metric method (a quasi-Newton algorithm wherein the required Hessian inverse is calculated iteratively) by Davidon in 1959. Such developments significantly enhanced the steepest-descent and Newton tools for solving equations, the heart of solving NLP problems, and were followed by an intense period of activity in the 1960s, with a rapid solidification of the theory and computational and methodological breakthroughs such as cutting plane algorithms by Kelley in 1960, methods of feasible directions by Zoutendijk in 1960, gradient projection methods by Rosen in 1960–61, and SUMT by Fiacco and McCormick in 1963 (Fiacco and McCormick 1968; Fiacco and Ishizuka 1990).

Many algorithms were subsequently developed for both unconstrained and constrained problems. The most popular prototype starts with a merit function (e.g., the objective function) and initial conditions, determines a search direction vector, then calculates a step in the given direction based on a line search, some one-dimensional curve fitting scheme aimed at both reducing the value of the merit function and maintaining feasibility. The process is repeated until some convergence criteria are satisfied. An algorithm for a well-posed problem generally attempts to satisfy first-order necessary optimality conditions for a local minimizer. More sophisticated algorithms satisfy second-order necessary conditions and others even seek out global minimizers, though techniques for the latter continue to be under intense development. Algorithms may be deterministic or stochastic, continuous or discrete-step, accumulate information or not, etc. A host of special-purpose algorithms have been developed for one-dimensional optimization, for example, variations of successive bisection, Newton's method, the secant method, false position, Fibonacci search and golden section (McCormick 1983).

Some of the most effective contemporary algorithms for smooth unconstrained problems are generally some variant or mixture of a quasi-Newton (approximate Newton) or conjugate direction algorithm. The survivors in the competition must fare well overall in meeting several demanding and sometimes opposing criteria: computational effort, speed of convergence, accuracy, robustness, ease of implementation, accessibility, and so on. Developing rigorous computational and theoretical standards for measuring these attributes are important, e.g., a rate of convergence theory is in place that establishes that steepest descent converges at least at a linear rate (as in a geometric series) and Newton's method at a quadratic rate (exponentially, at least quadratic), under rather ideal circumstances. Hybrid methods, conjugate directions and variable metric methods, are thought to perform adequately when they converge superlinearly (more or less, the best linear rate possible, a compromise between linear and quadratic).

Another important criterion is that an unconstrained algorithm be able to calculate the minimizer of a positive definite quadratic form in n variables, in at most n iterations. A key driving principle is exploitation of problem structure.

Some important algorithms for constrained problems are sequential linear programming (SLP), e.g., separating or cutting plane algorithms; sequential quadratic programming (SQP), e.g., constrained Newton approaches; generalized reduced gradient (GRG) methods, essentially, variable elimination simplex-type algorithms; feasible direction (constrained steepest descent) methods; projected gradient methods; and auxiliary function methods, e.g., augmented Lagrangian function (i.e., Lagrangian plus penalty term) techniques, penalty function (objective function plus constraint violation cost) and barrier function (objective function plus feasibility enforcing) methods. Algorithms and software are given in the references.

Additional important topics and suggested references are the following: global optimization, (Kan et al. 1989); parametric programming, sensitivity and stability analysis (Fiacco 1983; Fiacco 1990), discussed next; stochastic programming (Wets 1989); semi-infinite programming (SIP) (Fiacco and Kortanek 1983); multi-objective programming (Sawaragi et al. 1985); multi-level programming (Anandalingam 1992); control theory (Hocking 1991); numerical methods and implementation (Gill et al. 1981); software evaluation and comparison of algorithms (Waren et al. 1987) and (Moré and Wright 1993); parallel and large-scale programming (Rosen 1990); integer programming (Schrijver 1986); basic barrier and penalty function methodology (Fiacco and McCormick 1968; Fiacco and Ishizuka 1990); and nonsmooth optimization (Neittaanmaki 1992).

Intense activity in devising polynomial-complexity interior point methods for LP and NLP was sparked by a theoretical breakthrough with Khachian's ellipsoid method (Khachian 1979) and a theoretical-computational breakthrough with Karmarker's potential method (Karmakar 1984). The reader is referred to the excellent surveys by Gonzaga (1992) and Wright (1992) for a good introduction to this important development and for many good references, and to the books of Megiddo (1989) and Nesterov and Nemirovski (1993) for technical advances.

Software exists to implement variations of all the methods described here. As to computational capability, problems in thousand of variables and constraints can now be solved on a PC. Large problems may require parallel processors. However, a meaningful measure of computational difficulty is elusive in NLP. For example, consider that a high-degree polynomial in one variable may have many local minima and may be much more difficult to solve globally than a large convex program with hundreds of variables and constraints.

Sensitivity Analysis

The question motivating this topic can be raised in connection with almost any method of inquiry that results in a conclusion: How does the answer change when the assumptions change? The assumptions can be any conditions or data that are given and the changes can be qualitative or quantitative, controlled or uncontrolled, deterministic or stochastic, small or large, known or estimated, immediate or staged over time. The issue is inevitable and universal, since there are ever-present errors and ranges in approximation and interpretation, whether it be in carrying on a conversation, steering a car, hitting a tennis ball, or calculating expected return on investment.

In the early days of mathematics and physics, a related issue was apparently frequently raised: When is a problem well posed, i.e., when does a solution change continuously with continuous changes in the problem data? Variations on this theme must have quickly followed: When are the solution changes well behaved in some sense, e.g., when are they finite or bounded or smooth, and when are they not? Can the solution be calculated in closed form as a function of the changes in the data, or can at least bounds on the changes or rate of growth of the changes be calculated? Can any useful properties of perturbed solutions be identified or measured, e.g., whether a unique solution remains unique, whether a solution function or set is convex as a function of the changes, if a solution trajectory is differentiable, whether an assumption persists under given perturbations, etc.? At a slightly more sophisticated level, can some of these properties be calculated from information available at a solution ... without resolving the problem with new data?

A brief summary of a collection of such results is presented in the context of nonlinear programming (NLP) where there are parameters (e.g., data) present that are subject to perturbations. Here, the focus is on characterizations involving small specified changes in the parameters, the study of which is termed sensitivity analysis.

Very simple problems can be stable or unstable, for different parameter values. Consider the linear problem, minimize x_1 s.t. $x_1 \geq -1$, $x_2 \leq \varepsilon x_1$, and $x_2 \geq 0$, where $x \in R^2$ and $\varepsilon \geq 0$. If $\varepsilon > 0$, then the solution is $x(\varepsilon) = (0, 0)$ and does not change with small enough changes in ε. However, if $\varepsilon = 0$, then the solution is $\boldsymbol{x}(0) = (-1, 0)$ and this changes to $x(\varepsilon) = (0, 0)$ for arbitrarily small positive changes of ε, an extremely erratic change. The desire is to understand the causes and implications associated with such stability or instability.

Preliminaries — The parametric NLP is defined as

$$\begin{array}{l}\text{minimize} \quad f(\boldsymbol{x}, \varepsilon) \text{ subject to} \\ \{\boldsymbol{x} \in E^n : g_i(\boldsymbol{x}, \varepsilon) \geq 0,\ i = 1, \ldots, m; \\ h_j(\boldsymbol{x}, \varepsilon) = \boldsymbol{0},\ j = 1, \ldots, p)\}\end{array} \qquad \mathbf{P}(\varepsilon)$$

where $\boldsymbol{x} \in R^n$ and ε is a perturbation parameter in T, a nonempty subset of R^k. If ε is held constant, then problem $P(\varepsilon)$ is simply a realization of a standard NLP problem of the form P that was discussed at the outset. The Lagrangian associated with $P(\varepsilon)$ is defined as $L(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}, \varepsilon) = f(\boldsymbol{x}, \varepsilon) - \Sigma_{i=1}^m u_i g_i(\boldsymbol{x}, \varepsilon) + \Sigma_{j=1}^p w_j h_j(\boldsymbol{x}, \varepsilon)$. The optimal-value function f^* and the optimal-solution map S if $P(\varepsilon)$ are defined as

$$f^*(\varepsilon) = \begin{cases} \inf_{R(\varepsilon)} f(\boldsymbol{x}, \varepsilon) & (\text{if } R(\varepsilon) \neq \oslash) \\ +\infty & (\text{if } R(\varepsilon) = \oslash) \end{cases}$$

and $S(\varepsilon) = \{\boldsymbol{x} \in R(\varepsilon) : f(\boldsymbol{x}, \varepsilon) = f^*(\varepsilon)\}$. The set of optimal Lagrange multipliers for a given solution $\boldsymbol{x} \in S(\varepsilon)$ is the set $\{(\boldsymbol{u}, \boldsymbol{w})$: KKT$(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w})$ holds$\}$.

The directional derivative of the function f^* at the point ε in the direction z is defined as

$$D_z f^*(\varepsilon) = \lim_{\alpha \to 0^+} \frac{f^*(\varepsilon + \alpha z) - f^*(\varepsilon)}{\alpha}$$

if the limit exits.

The problem $P(\varepsilon)$ is said to be convex in $\boldsymbol{x}$ if f and the $-g_i$ are convex in $\boldsymbol{x}$ and the h_j are affine in $\boldsymbol{x}$ for each fixed $\varepsilon \in T$, and jointly convex if these functions have the respective properties in $(\boldsymbol{x}, \varepsilon)$ and T is a convex set. Assume that the functions defining problem $P(\varepsilon)$ are continuous jointly in $(\boldsymbol{x}, \varepsilon)$ in the sequel.

Some Basic Theoretical Results — The following conditions are used, which may hold at a feasible point x for some parameter value ε. Differentiability is assumed as needed, at $(\boldsymbol{x}, \varepsilon)$.

(a) The Karush-Kuhn-Tucker conditions, as before, designated KKT($\boldsymbol{x}$, $\boldsymbol{u}$, $\boldsymbol{w}$): there exist $u_i \geq 0$ ($i = 1, \ldots, m$) and w_j ($j = 1, \ldots, p$) such that $\nabla_x L(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}, \varepsilon) = 0$, $u_i g_i(\mathbf{x}, \varepsilon) = 0 (i = 1, \ldots, m)$, and $h_j(\boldsymbol{x}, \varepsilon) = 0 (j = 1, \ldots, p)$;

(b) Linear Independence, as before, designated LI(x) : $\nabla_x g_i(\boldsymbol{x}, \varepsilon) (i \in B(x, \varepsilon))$, $\nabla_x h_j(\mathbf{x}, \varepsilon)$ $(j = 1, \ldots, p)$ are linearly independent, where $B(\mathbf{x}, \varepsilon) = \{i : g_j(\boldsymbol{x}, \varepsilon) = 0\}$;

(c) Strict Complementary Slackness, designated SCS$(x) : u_i > 0 (i \in B(\boldsymbol{x}, \varepsilon))$;

(d) The Mangasarian-Fromovitz Constraint Qualification, designated MFCQ(x) : (i) $\nabla_x h_j(\boldsymbol{x}, \varepsilon) (j = 1, \ldots, p)$ are linearly independent and there exists z such that $\nabla_x g_i(\boldsymbol{x}, \varepsilon) z > 0 (i \in B(\boldsymbol{x}, \varepsilon))$ and $\nabla_x h_j(\boldsymbol{x}, \varepsilon) z = 0 (j = 1, \ldots, p)$;

(e) The Second-Order Sufficient Condition, designated SOSC$(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}) : z^{\mathrm{T}} \nabla_{x^2} \mathrm{L}(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w}, \varepsilon) z > 0$ for all $z \neq 0$ such that $\nabla_x g_i(\boldsymbol{x}, \varepsilon) z \geq 0$ $(i \in B(\boldsymbol{x}, \varepsilon)), \nabla_x g_i(\mathbf{x}, \varepsilon) z = 0 (i \in D(\boldsymbol{x}, \varepsilon) = \{i \in B(\mathbf{x}, \varepsilon) : u_i > 0\})$, and $\nabla_x h_j(\boldsymbol{x}, \varepsilon) z = 0 (j = 1, \ldots, p)$, for some $(\boldsymbol{u}, \boldsymbol{w})$ such that KKT$(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w})$ holds;

Known facts relevant to this brief overview are the following. The SOSC $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ implies that $\bar{\boldsymbol{x}}$ is a strict local minimizer (i.e., the unique global minimizer in some feasible neighborhood of $\bar{\boldsymbol{x}}$) of P with optimal Lagrange multipliers $(\bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$. The condition MFCQ$(\bar{\boldsymbol{x}})$ holds at a local solution $\bar{x}$ if and only if the set of $(\boldsymbol{u}, \boldsymbol{w})$ satisfying KKT $(\bar{\boldsymbol{x}}, \boldsymbol{u}, \boldsymbol{w})$ is nonempty, compact and convex. If $LI(\bar{\boldsymbol{x}})$ holds at a local solution $\bar{\boldsymbol{x}}$, then there exists a unique $(\bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$ satisfying KKT $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$.

Using these and other well-known facts, some of the important results that hold for problem $P(\varepsilon)$:

(i) If all f, g_i, h_j are once differentiable in $(\boldsymbol{x}, \varepsilon)$, $R(\bar{\varepsilon}) \neq \emptyset$, $R(\varepsilon)$ is contained in a compact set for ε

near $\bar{\varepsilon}$, and $MFCQ(\bar{\boldsymbol{x}})$ holds for some $\bar{\boldsymbol{x}} \in S(\bar{\varepsilon})$, then $f^* \in C$ it $\varepsilon = \bar{\varepsilon}$.

(ii) If problem $P(\varepsilon)$ is jointly convex, then f^* is convex on T. If f is concave in ε and R does not depend on ε, then $f^*>$ is concave on T. Global parametric optimal value bounds can readily be calculated at a solution point when f^* is convex or concave and optimal Lagrange multipliers exist and are known. Also, when f^* is convex or concave, it follows from well-known results that f^* is continuous in the interior of T.

(iii) If $R(\varepsilon) \neq \emptyset$ and is compact and independent of ε and f and $\nabla_\varepsilon f$ are jointly continuous in $(\boldsymbol{x}, \varepsilon)$, then $D_z f^*(\varepsilon) = \min \nabla_\varepsilon f(\boldsymbol{x}, \varepsilon) z \,\text{s.t.}\, \boldsymbol{x} \in \mathrm{S}(\varepsilon)$.

(iv) If f, g_i, h_j are twice continuously differentiable in $(\boldsymbol{x}, \varepsilon)$ and KKT, SOSC $(\bar{\boldsymbol{x}}, \bar{\boldsymbol{u}}, \bar{\boldsymbol{w}})$, $\mathrm{LI}(\boldsymbol{x})$ and $\mathrm{SCS}(\bar{\boldsymbol{x}})$ hold at $\varepsilon = \bar{\varepsilon}$, then $(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w})$ is locally unique and once continuously differentiable as a function of ε, such that the assumptions persist to hold at $(\boldsymbol{x}(\varepsilon), \boldsymbol{u}(\varepsilon), \boldsymbol{w}(\varepsilon))$, near $\bar{\varepsilon}, f^*$ is twice continuously differentiable where $f^*(\varepsilon) = f[\boldsymbol{x}(\varepsilon), \varepsilon]$ and $\nabla_\varepsilon f^*(\varepsilon) = \nabla_\varepsilon L[\boldsymbol{x}(\varepsilon), \boldsymbol{u}(\varepsilon), \boldsymbol{w}(\varepsilon), \varepsilon]$ near $\varepsilon = \bar{\varepsilon}$. Thus, $\mathbf{x}(\varepsilon)$ is an isolated (i.e., locally unique) and hence also strict local minimizer and $[\boldsymbol{u}(\varepsilon), \boldsymbol{w}(\varepsilon)]$ is unique. Strengthening SOSC by relaxing the restriction that $\nabla_x g_i(\boldsymbol{x}, \varepsilon) z \geq 0 (i \in B(\boldsymbol{x}, \varepsilon))$ and dropping SCS, $\boldsymbol{x}(\varepsilon)$ is an isolated local minimizer with unique $[\boldsymbol{u}(\varepsilon), \boldsymbol{w}(\varepsilon)]$ since the assumptions again persist near $\varepsilon = \bar{\varepsilon}$ at $[\boldsymbol{x}(\varepsilon), \boldsymbol{u}(\varepsilon), \boldsymbol{w}(\varepsilon)]$ locally unique, but now $(\boldsymbol{x}, \boldsymbol{u}, \boldsymbol{w})$ is not once continuously differentiable in ε but only directionally differentiable, with f^* once continuously differentiable and $\nabla_\varepsilon f^* = \nabla_\varepsilon L$ is before. Relaxing LI to MFCQ and further strengthening SOSC as above and assuming this holds for all $(\boldsymbol{u}, \boldsymbol{w})$ in the set of optimal multipliers, the assumptions again locally persist, although now the Lagrange multipliers are not unique but are known to form a nonempty compact convex set, $\boldsymbol{x}(\varepsilon)$ is a locally isolated minimizer as before and is known to be at least continuous and f^* is only directionally differentiable. It may also interest the reader to know that KKT, SOSC, LI and SCS are satisfied at the (unique vertex) solution of a nondegenerate LP problem.

Extensions and Future Research — With additional problem structure, more analytic results follow. For example, a fairly highly developed post-optimality sensitivity analysis is known and extensively used in linear programming, including parametric expressions for local solution changes and error bounds. Likewise, more can be said about unconstrained minimization, right-hand-side perturbations in the constraints, separable programs, geometric programs, etc. Closed-form formulas or detailed characterizations have been given for optimal value, solution point and Lagrange multiplier parameter derivatives or directional derivatives when these exist, in addition to those noted in the last section.

Extensions of the kind of results indicated have been developed for problems in more general spaces or with less structure, for example, utilizing weaker constraint qualifications, involving an infinite number of variables or constraints such as in control theory and semi-infinite programming, multiobjective optimization, integer programming, and stochastic programming. Further generalization of structure leads to variational inequalities, equilibrium problems and, at a more abstract level, generalized equations, for which a sophisticated parameter perturbation theory exists, specializations of which yield deep results for NLP. Qualitative extensions include significant additional more general convexity and concavity characterizations of the optimal value function for generalized convexity or concavity assumptions on the problem functions, more general optimal value derivative measures such as the Clarke generalized derivative, and other solution continuity concepts such as Holder continuity. Other significant extensions are those involving other (than parametric) classes of perturbations, for example, functional perturbations or abstract set-theoretic perturbations. A considerable literature exists on variations of all these ideas.

Two more research directions must be mentioned: the approximation of sensitivity information from information available as an algorithm makes progress towards a solution; and measurement of the effect of perturbations on the convergence and rate of convergence of solution algorithms. A solid basis for algorithmic approximation, the first topic, has been developed for barrier and penalty methods, but little

else. Some results on the latter topic are known for a few standard algorithms.

Applications — All the results mentioned have significant theoretical and practical applications. Perhaps one of the most obvious is in extrapolating from a solution with given data to a solution with perturbed data. Another is the approximation of the change in the optimal value resulting from perturbations of the constraints, a measure directly related to the associated optimal Lagrange multipliers (shadow prices in linear programming) which in turn are involved in duality relationships. Applications exist in decomposition, min-max problems, bilevel and multilevel programming, semi-infinite programming, implicit function optimization and other areas where optimal value functions of subproblems are encountered and certain variables are viewed as a function of others that are treated as parameters during a given iteration. Sensitivity analysis results provide valuable inputs to parametric programming, where one endeavors to approximate a solution over a finite range or given set of parameter values.

Post-optimality sensitivity analysis for linear programming is a standard option in many commercial packages and is heavily used in practice. The potential applications of NLP sensitivity analysis are even more vast. NLP computational implementations on practical problems have been extremely limited, sporadic and ad hoc, largely experimental, and applied only to a few well-structured models. A number of experiments have been conducted on geometric programs, for example. Some of the other models and parameters for which a variety of sensitivity results have been generated are stream water pollution with maximum allowable dissolved oxygen deficit and on the order of 70 other parameters perturbed, a continuous review multi-item inventory model with several parameters such as item unit cost and the standard deviation of the lead-time demand, the structural design of a vertically corrugated transverse bulkhead of an oil tanker with many design parameters, portfolio analysis with parameters affecting risk and expected return on investments, and a power system energy model requiring the development of a turbine exhaust annulus and condenser system design with objective and constraint function parameter changes. Sensitivity information was calculated by SENSUMT, a computer code developed in 1973 by Fiacco, Armacost and Mylander (see Fiacco 1983), using barrier function approximations. SENSUMT is apparently the first code to offer sensitivity analysis for NLP as a user option.

Notes and Literature — Most of the theoretical results presented here on SA can be found in Fiacco (1983), particularly in the survey given in Chapter 2. Much has been done elsewhere and since 1983, but the focus here has been on a nucleus of early basic results that provides a good profile of the variety of qualitative and quantitative sensitivity measurements. Other directly relevant surveys are Fiacco and Hutzler (1982), Fiacco and Kyparisis (1992), and Fiacco and Ishizuka (1990). For a compendium on the state of the art of sensitivity and stability analysis in variational inequalities, and stochastic, semi-infinite, integer, non-linear, geometric, linear and multi-objective programming with parameters, including results on continuity, differentiability, bounds, algorithmic perturbation results and continuation and parametric methods, the reader is referred to the collection of tutorials edited by Fiacco (1990). Hundreds of references are given to significant current work, including numerous references to other important areas such as generalized equations, curve-following techniques, multi-level programming and other topics mentioned in this article and beyond. Recent books in sensitivity analysis and related topics are those by Jongen et al. (1986) on parametric results; Brosowski (1982) on semi-infinite optimization; Brosowski and Deutsch (1985) on approximation; Guddat et al. (1987) on parametric optimization; Fiacco (1984) on a wide variety of topics; Bank et al. (1982) on continuity results in particular and nonlinear parametric optimization in general; Dontchev and Zolezzi (1993) on well-posed optimization; and Levitin (1993) for a unified general perturbation theory.

Nonnegative Solution

A solution to a problem in which all variables $x_j \geq 0$.

Nonnegativity Conditions

A restriction that limits a variable or a set of variables to be either zero or positive. The set of conditions $x_j \geq 0$ ($j = 1,\ldots, n$) are the usual nonnegativity conditions that apply to the variables of a linear-programming problem.

Nonsingular Matrix

A square matrix that has an inverse. A nonsingular matrix has a nonzero value for its determinant.

See

► Matrices and Matrix Algebra

Nontrivial Solution

For the set of homogeneous linear equations $\boldsymbol{Ax} = \boldsymbol{0}$, a solution $\boldsymbol{x} \neq \boldsymbol{0}$.

See

► Null Space
► Trivial Solution

Nonzero-Sum Game

A game in which the payoffs p_i to the players do not sum to zero. Here the payoff to player i is positive if it is a win and negative if it is a loss.

See

► Game Theory
► Payoff Matrix
► Zero-Sum Game

Non-Archimedean Number

A number that does not satisfy the Archimedean axiom. Such numbers arise in setting preemptive (lexicographic) priorities in goal programming, the "Big M" for finding a feasible basis to a linear-programming problem, and in selecting an infintesimal in data envelopment analysis.

See

► Archimedean Axiom
► Big M Method
► Data Envelopment Analysis
► Goal Programming

Non-Compensatory Choice Strategies

Not employing trade-offs between the dimensions of choice alternatives but, using thresholds (or cutoffs) that need to be achieved for choice of an alternative.

See

► Choice Theory

Non-Preemptive

Concept having to do with how priorities are treated. In queueing models, it refers to a queue discipline that does not allow a customer who has already started

service to be interrupted (preempted) when a customer with higher priority arrives. In goal programming, it has to do with a priority ranking that orders the systematic optimization of the deviation variables.

Normative Model

A model that attempts to describe standards of behavior of a man/machine system; the "what ought to be." Normative models identify feasible and desirable configurations of the system to serve as goals or norms. For a decision problem, such a model specifies logically consistent decision procedures that indicate how an individual should decide. Normative models are often based on an axiomatic foundation.

Northwest-Corner Solution

A procedure for finding a basic feasible solution to a transportation problem. For a problem with m origins and n destinations, the approach is to form a matrix with m rows and n columns, where a cell (i, j) of the matrix represents the shipment of goods from origin i to destination j. The algorithm starts with all shipments zero and first assigns the maximum shipment possible to the most northwest cell $(i = 1, j = 1)$. Each time an allocation is made, either a row or column of the matrix is crossed out. The algorithm continues to make the maximum possible shipments in the northwest corners of the reduced matrices, until the shipment is made in cell $i = m$ and $j = n$. The resulting shipments form a basic feasible solution to the underlying linear-programming problem. A degeneracy-avoiding procedure may have to be used in determining whether a row or column is to be crossed out in the intermediate steps.

Numerical Analysis

Stephen G. Nash
George Mason University, Fairfax, VA, USA

Introduction

Numerical analysis uses computation as a tool to investigate mathematical models. At its most basic, this might mean computing an answer, such as the optimal value of a linear program. Beyond this, one might want error estimates (how accurate is the optimal value computed by the algorithm) or sensitivity information (how sensitive is the optimal value to changes in the data). It might be desirable to visualize the results of the computation as a static image or – in the case of a dynamic model – as an animation. One might even wish to analyze the effects of randomness in the data. Numerical analysis can also be used as an experimental tool to reveal properties of models that may be inaccessible by analytic means.

The techniques of numerical analysis have been widely adopted. It is rare for someone to solve a linear program by hand — except perhaps in a classroom. Large-scale simulations would be all but impossible without the aid of a computer. For many people, numerical techniques have superseded analytic techniques as a tool for solving mathematical problems. There are many cases (such as when optimizing nonlinear models or solving differential equations) where no closed form analytic solution exists, but where a numerical solution is reasonable to compute. There are also cases where, even when an analytic solution is available, it is preferable to use a numerical method because it can compute the solution more efficiently and more accurately. In many areas of application, numerical analysis offers a routine, reliable, and often automated way of solving mathematical problems.

It is possible to solve many problems on standard computers, but the most challenging computational problems require high-performance computing. In moving to such highly parallel machines, it is typically necessary to use specially-adapted algorithms and software. This effort may be worthwhile in cases where no other approach is feasible.

The Impact of Computers

It makes sense to speak of numerical analysis together with the computer. Numerical analysis only developed as a separate discipline after the invention of the computer. Although computation was an important subject at earlier times, it is only with the invention of the computer that the full range of numerical analysis techniques becomes necessary. Pencil and paper calculations tend to be small scale, and are carefully supervised. There is less opportunity for accumulation of error. In addition, the precision of the calculations can be adjusted during a calculation, if that becomes necessary. On a computer, however, it is easy to perform a sequence of millions of calculations. These calculations will normally be performed at a fixed precision, without supervision. Further, algorithms that are satisfactory for small problems may not scale well to larger problems. Automatic computation carries with it both opportunities and risks. The techniques of numerical analysis attempt to exploit these opportunities while understanding and minimizing the risks involved.

There are some central questions in the study of numerical analysis. Is there an efficient algorithm to solve the given mathematical problem? How sensitive is the solution of the problem to errors in the data? How accurate is the computed solution? Can the algorithm provide an error estimate?

The most important and immediate question is whether there exists any algorithm to solve a particular problem. Currently a wide variety of numerical software is available, so for many classes of problems good methods are available. (Some sources are listed in the references.) These methods are capable of solving a great many problems that lack closed-form solutions. Even when closed-form solutions exist, the methods used in the software may be unrelated, for reasons of efficiency and accuracy. For example, the eigenvalues of a matrix will generally be calculated without forming the characteristic polynomial.

Good numerical methods, together with powerful modern computers, have made possible the routine solution of many large and difficult computational problems. Linear programs with thousands of variables pose no great challenge, for example. Although there still exist problems that strain the

most powerful computers (such as optimization models constrained by complicated partial differential equations), off-the-shelf software and desk-top computers are capable of serving many people's needs.

As software and computers have improved, the expectations of numerical software have expanded. Models have become more elaborate, and visualization of results is expected. More and more, modelers would like to incorporate uncertainty in their models. Doing this requires more sophisticated software and more powerful computers. It is now routine for computers to have multiple processors, and if software is to exploit the full capabilities of the computer, some degree of parallelism must be incorporated. In the realm of high-performance computing, computers may have more than 100,000 processors. There are significant research challenges in using these powerful machines, but they make it possible to simulate complex real-world phenomena with high fidelity.

Linear Equations

The ideas of numerical analysis are perhaps most clearly expressed in the context of solving systems of linear equations. Such a system can be written as $\boldsymbol{Ax} = \boldsymbol{b}$, where $\boldsymbol{A}$ is an $n \times n$ invertible matrix and $\boldsymbol{b}$ is the vector of right-hand side coefficients.

Methods for solving linear equations are central to numerical analysis. In particular, they form an essential component of algorithms for linear programming and other optimization problems.

The most commonly used technique for solving linear equations is Gaussian elimination. Gaussian elimination requires about n^3 arithmetic operations to solve a linear system, where n is the number of variables. On many current computers, a linear system with a few thousand variables can be solved in several seconds, and high-performance computers can solve problems with a million variables in well under a second. If the number of variables doubles, the number of arithmetic operations increases by a factor of eight.

Gaussian elimination does not compute $\boldsymbol{A}^{-1}$, and in fact there are a number of reasons why computing $\boldsymbol{A}^{-1}$ is undesirable in many circumstances (Golub and Van Loan 1996). This is especially true for large sparse problems, problems where many of the entries in the matrix $\boldsymbol{A}$ are 0. Gaussian elimination can take advantage of the presence of these zeros. Often the number of arithmetic operations required to solve such a system will be proportional to the number of nonzeros in the matrix, which in turn will often be proportional to the number of variables n. In contrast, $\boldsymbol{A}^{-1}$ may have virtually no zero entries, even when $\boldsymbol{A}$ is sparse, and computing and applying the inverse will require between $O(n^2)$ and $O(n^3)$ operations. This is one case, among many, where the mathematical solution $\boldsymbol{x} = \boldsymbol{A}^{-1}\boldsymbol{b}$ and the computer solution are calculated in different ways.

Gaussian elimination is not the only algorithm available for solving linear equations. There exist algorithms with costs proportional to n^{α} with $\alpha < 3$, but these are not widely used. There are also techniques called iterative methods that are especially effective on large sparse problems (Golub and Van Loan 1996).

Error Analysis

Suppose that one of these algorithms is applied to a system of linear equations. How accurately can the solution $\boldsymbol{x}$ be computed? It is useful to phrase this question in another way: How sensitive is the solution $\boldsymbol{x}$ to errors in the data $\boldsymbol{A}$ and $\boldsymbol{b}$? It is worrisome if small errors in the data are magnified into large errors in the solution. Such magnification can occur for two reasons. It may be because of a "bad" problem (the solution is poorly determined by the data) or because of a "bad" algorithm (an algorithm that magnifies errors in the data). If the problem is bad, it is called ill conditioned; if the algorithm is bad, it is called unstable.

If the data – either the matrix $\boldsymbol{A}$ or the right-hand side $\boldsymbol{b}$ – are subject to errors of order ε, then the relative errors in the solution $\boldsymbol{x}$ will in general be proportional to $cond\,(\boldsymbol{A})\,\varepsilon$, where $cond\,(\boldsymbol{A})$, the condition number of $\boldsymbol{A}$, is a measure of how close $\boldsymbol{A}$ is to being singular. These errors in the solution are due solely to the errors in the data; for now it is assumed that the system of equations is solved exactly. If $\boldsymbol{A}$ is singular, then $cond\,(\boldsymbol{A}) = \infty$; otherwise,

$$cond(\boldsymbol{A}) = \|\boldsymbol{A}\| \cdot \left\|\boldsymbol{A}^{-1}\right\|$$

in terms of some matrix norm $\|\cdot\|$. If, say, the Euclidean norm is used, then $cond(\boldsymbol{A}) \geq 1$ for all matrices $\boldsymbol{A}$. To illustrate this result, suppose that the data were accurate to $\varepsilon = 10^{-6}$ and that $cond\,(\boldsymbol{A}) = 10^4$; then it is expected that the relative errors in $\boldsymbol{x}$ to be proportional to 10^{-2}, that is, $\boldsymbol{x}$ would be accurate to two decimal digits. Thus, the condition number can be used as a quantitative tool to predict the accuracy of the solution to a linear system.

Even though $\boldsymbol{A}^{-1}$ is not computed by Gaussian elimination, it is still possible to estimate $cond\,(\boldsymbol{A})$ as a byproduct of the algorithm. Some additional calculations are required (about n^2 arithmetic operations), but this is much less than the n^3 operations required to solve the linear system. Thus, not only can the solution be computed, but an error estimate can be provided as well.

For most computational problems it will be possible to determine the sensitivity of the solution to errors in the data. This sensitivity can be considered as a "condition number" for that problem. If this condition number is large, it can be expected that the errors in the solution will be large, regardless of what algorithm is used to solve the problem. Of course, it will be desirable to use an algorithm that does not further magnify errors.

Computers only store numbers to a finite number of digits, often using binary arithmetic, so that just storing numbers in a computer can introduce errors in the data. For example, $1/3 = 0.333\ldots$ cannot be represented exactly with a finite number of binary digits. The precision of computer arithmetic – referred to as machine epsilon $\varepsilon_{\text{mach}}$ or unit round-off – limits the accuracy of computer calculations. Even if the data in a linear system are otherwise known exactly, when they are stored in the computer and computer arithmetic is use, the solution of the linear system can be expected to have errors proportional to $\varepsilon_{\text{mach}}$ times $cond\,(\boldsymbol{A})$. If $cond\,(\boldsymbol{A}) \approx 1/\varepsilon_{\text{mach}}$ then, from the point of view of computer arithmetic, the matrix might as well be singular.

Mathematically, a matrix is either singular or non-singular, and there are sharp differences between the two cases. Computationally it makes more sense to refer to the condition number of a matrix, and use this to measure how close a matrix is to being singular. Whether a matrix is sufficiently nonsingular to be useful will depend on the accuracy of the data and the desired accuracy of the solution. For many sorts of computational problems, the meaning of singularity or degeneracy will be blurred, with the accuracy of the solution deteriorating as the problem becomes closer to being degenerate.

So far, only errors arising from the data in the problem have been considered. The algorithm used to solve the linear system will also introduce errors. Assume that Gaussian elimination is used to solve the linear system. Gaussian elimination is unstable in its raw form, and can fail even when $\boldsymbol{A}$ is nonsingular. With minor modifications (such as the use of partial pivoting) it becomes a stable algorithm that can be applied to any nonsingular system. It can be proved that Gaussian elimination with partial pivoting computes the exact solution to a perturbed system of the form $(\boldsymbol{A} + \boldsymbol{E})\boldsymbol{x} = \boldsymbol{b}$, where $\|\boldsymbol{E}\|$ is proportional to machine epsilon times $\|\boldsymbol{A}\|$. Thus $(\boldsymbol{A} + \boldsymbol{E})$ can be interpreted as a perturbation of $\boldsymbol{A}$ where the relative errors are proportional to machine epsilon. As has been mentioned, just storing $\boldsymbol{A}$ in the computer can introduce relative errors of this magnitude. Thus the errors introduced by Gaussian elimination are comparable to the errors introduced by storing the problem on the computer. Thus Gaussian elimination is considered to be a benign algorithm.

Saying that the computed solution from Gaussian elimination is the exact solution to a perturbed problem $(\boldsymbol{A} + \boldsymbol{E})\boldsymbol{x} = \boldsymbol{b}$ represents the adoption of a distinctive point of view. For many, it will be more common to ask about the error in the computed solution. Instead the concern is how much Gaussian elimination distorts the original problem. This is a property of the algorithm. The error in the solution (or the amount by which this distortion is magnified in the solution) is a property of the data, and depends on the condition number of the matrix. This point of view isolates the effect of the algorithm on the accuracy of the solution. In this case, it shows that Gaussian elimination computes the exact solution to a "nearby" problem. This point of view is referred to as a backward error analysis.

The error analysis for linear systems is particularly elegant. For other computational problems the error analysis may not be so favorable (the computed solution may exactly solve a perturbed problem where the perturbations are large), or a backward error analysis may not be possible. In the latter case, other techniques must be used to assess the stability of an algorithm.

Concluding Remarks

The above comments illustrate some of the major questions of numerical analysis. In some settings additional questions arise. For example, the linear system might be obtained by discretizing a differential equation, i.e., by approximating a continuous function using its values at finitely many points. Then it is natural to ask how accurately the solution of the linear system approximates the solution of the original continuous problem. In addition, it is desirable that the discrete solution converge to the continuous solution as the size of the finite-dimensional problem increases.

When implementing an algorithm in software, the ultimate goal is to try to produce software that can efficiently compute a solution to full accuracy whenever the data and the solution consist of numbers that can be stored on the computer, and to design the software so that it works reliably on as large a collection of computers as possible. This goal can be difficult to achieve. Even seemingly innocuous tasks, such as computing the Euclidean norm of a vector, can require great care when the components of the vector are pathologically large or small, near the limits of computer arithmetic.

Numerical analysts continually try to solve ever larger and more difficult computational problems. This has often meant turning to parallel computers, computers capable of carrying on multiple computations simultaneously. This has led to further questions. Can an efficient parallel algorithm be found to solve the problem? Is the algorithm scalable, i.e., does it continue to perform well as the problem size and the number of processors increase? How does the parallel algorithm compare to the best scalar, or non-parallel, algorithm? Because of the variety of parallel computers available, the answers to these questions can vary from machine to machine, making it ever more difficult to design effective algorithms and software.

There is a vast literature on numerical analysis. General introductions to the topic can be found in Heath (2002); O'Leary (2009); Press et al. (2007), and Sauer (2006). An extensive discussion of numerical linear algebra is given in Golub and Van Loan (1996). A large online collection of software is described in Grosse (1994), the repository is available online at the Netliib Web site. Reviews of software for operations research are regularly published in *OR/MS Today*; the latest reviews are available online at the INFORMS Web site. The issues involved in developing software for linear algebra computations are mentioned in Anderson et al. (1999). An extensive discussion of parallel computing can be found in Dongarra et al. (2003). Examples of projects that use high-performance computing can be found, for example, at the Web site for the National Center for Supercomputer Applications.

O

O, o Notation

O means "order of" and o means "of lower order than." If $\{u_n\}$ and $\{v_n\}$ are two sequences such that $|u_n/v_n| < K$ for sufficiently large n, where K is a constant independent of n, then $u_n = O(v_n)$; for example, $(2n - 1)/(n^2 + 1) = O(1/n)$. The symbol O (colloquially called "big O") also extends to the case of functions of a continuous variable; for example, $(x + 1) = O(x)$. $O(1)$ denotes any function that is defined for all values of x sufficiently large, and which either has a finite limit as x tends to infinity, or at least for all sufficiently large values of x remains less in absolute value than some fixed bound; for example, $\sin x = O(1)$.

If $\lim_{n->\infty} u_n/v_n = 0$, then $u_n = o(v_n)$ (colloquially called "little o"); for example, $\log n = o(n)$, where again the notation extends to functions of a continuous variable; for example, $\sin x = o(x)$. Furthermore, $u_n = o(1)$ means that u_n tends to 0 as n tends to infinity; for example, $(\log n)/n = o(1)$. In probability modeling (e.g., Markov chains and queueing theory), it is common to see $o(\Delta t)$ used to represent functions going to 0 faster than a small increment of time Δt, i.e., $\lim_{\Delta t->0}[o(\Delta t)/\Delta t] = 0$.

Objective Function

The mathematical expression that is to be optimized (maximized or minimized) in an optimization problem.

Open-Source Software and the Computational Infrastructure for Operations Research (COIN-OR)

Matthew J. Saltzman
Clemson University, Clemson, SC, USA
The COIN–OR Foundation, Inc., Towson, MD, USA

Introduction

Algorithms are methods developed by mathematicians, scientists, and engineers for manipulating data to provide insight and solutions to problems in theoretical and applied fields. Computer software is a vehicle for realizing algorithmic ideas. Open-source software is a vehicle for sharing those ideas that complements archival journal publications and other means of knowledge transfer.

This article explains the ideas and principles behind open-source software, how it works in practice, and its benefits and costs. It also describes a number of open-source tools and resources available for operations research and management science researchers and practitioners. The premier publisher of open-source software for operations research is the COIN-OR initiative. This article describes the COIN-OR initiative, its history, and the impact of open-source software and COIN-OR on the field of operations research.

Section "Open Source: What and Why" describes the concept of open-source software, how it started, and how its impact has grown. It also discusses the relationship between open-source software and academic research. Section "How Open Source Works" describes open source licenses and the legal framework that supports them. The broad classes of open source licenses are described along with features of licenses that are common in operations research software. Section "Open Source in Operations Research" lists a wide variety of open-source tools available for operations researchers. The largest collection is the Computational Infrastructure for Operations Research (COIN-OR). The COIN-OR initiative is described and the available projects are enumerated. In addition, several other open-source resources for OR are listed.

A note on references. Several of the documents and resources referred to in this article are available only on the World Wide Web. The associated URLs are not cited in the *Encyclopedia of ORMS* because they are subject to uncontrolled change. The URLs can be located via most Internet search engines by searching on relevant terms, such as author, title, organization, or keywords.

Open Source: What and Why

Computers and software are indispensable tools for operations researchers, whether in academia, government, the military, or industry. Aside from standard software such as operating systems, office tools, and business management tools, OR practitioners need software to run simulations, solve optimization problems, and manage and analyze data. The technology inside those tools is developed by those same practitioners, by industrial software houses, and by academic researchers. Those developers need tools to create and manage their software libraries.

Proprietary software to fill these needs may be of high quality, but it is often costly to industrial customers and may come with restrictions on its use and redistribution that can be problematic. For researchers and developers, software created in the course of research may be abandoned after the project is completed. Researchers trying to follow up on computational work by others may have to redo the

earlier work from scratch, based only on sketchy descriptions of implementation details in articles or monographs. A principal tenet of scientific research—reproducibility of results—is undermined and extension of results of computational research is impeded by lack of access to the original source code.

The concepts of free and open-source software bear on these concerns. Free and open-source software leverages intellectual property law to support:

- software source code as a publication medium for algorithmic ideas,
- an environment for collaborative research and development of software, and
- a cooperative community of developers and users of software.

Users and developers of open-source software are guaranteed access to the source code. They are granted the right to read the code, modify it, and distribute their modifications. As a result, user and developer communities often grow around open-source packages, improving and extending them to better meet the communities' needs.

In the Beginning

The advent of commercially available digital computers in the 1950s began a fundamental transformation of the way research and business are done. Data collection and manipulation that was previously impossible to accomplish by hand became routine. As a result, the sophistication of simulations, data analyses, and decision making increased markedly. Computing power has increased and cost decreased exponentially over the intervening decades.

The availability of these machines sparked a strong interest in the development of algorithms that could efficiently carry out the needed analyses and software systems (including programming languages) that could express those algorithms precisely and translate them into instructions that the machines could carry out. Significant parts of computer science and operations research are devoted principally to developing new, more efficient, more powerful algorithms that take advantage of high-powered computing systems.

It is a part of folk history that, in the early days of computing, the knowledge being developed was widely and freely shared, both in literature and in code. Sharing helped to advance rapidly the limits of knowledge in the field. But as the commercial computing industry grew, vendors saw value in keeping their software proprietary and began selling it as add-ons to the computer systems they were marketing. An open letter to members of the microcomputer programming community (then primarily the province of hobbyists) by Microsoft founder Bill Gates 1976 famously criticized the culture of sharing that had dominated the computing community up to that point. Over time, the industry transitioned to the model familiar to those who lived and worked through the early days of the personal computer, where operating systems, compilers, office tools, and other software were primarily available only at a (sometimes significant) cost. Vendors of large systems and peripheral devices adopted the same proprietary conventions.

In the meantime, the academic research culture in operations research and computer science evolved into the familiar culture of today, where the primary means of disseminating knowledge are archival journal articles, peer-reviewed conference proceedings, and research monographs.

GNU and Linux

In the mid-1980s, Richard Stallman, a researcher at MIT's Lincoln Laboratories, became frustrated with one vendor's lack of response to a bug in a printer driver and the vendor's restrictions on access to the software. His response was to launch an effort to create software that could be freely shared and rules for distributing the software that would ensure that recipients of the shared code could not lock up the code in proprietary systems. The result of Stallman's efforts was the Free Software Foundation and the GNU (GNU's Not Unix) project to create a freely sharable version of the Unix operating system and accompanying software development toolchain. Stallman referred to code distributed under these rules as "free software." He was careful, however, to distinguish the idea of "freely sharable" from "free of charge." (Stallman describes the distinction as, "free as in 'free speech,' not as in 'free beer' (Stallman and Gay 2002).") The distinction between "free" and "open source" is addressed in Section "Open Source: What and Why."

The GNU project's efforts through the 1980s resulted in a software development toolchain including the Emacs editor, the GCC compiler suite, and most of the utilities associated with the Unix

operating system, all of which were distributed under rules that kept them open and sharable. In 1991, Linus Torvalds began the Linux project to implement an operating system kernel (the layer of the OS that communicates with the hardware and manages the scheduling of software tasks) for personal computers using the Intel 80386 CPU. The Linux kernel was distributed under the same rules as the GNU software.

The Spread of Free and Open Source Software

An important consequence of the GNU and Linux efforts was that they attracted large numbers of independent programmers to work on them. The developer communities came to include hobbyists, academics, and professionals, distributed over many countries around the world. Contributors to the Linux kernel now number in the tens of thousands. Individuals and academic, government, and commercial organizations devote significant resources to open source development. Currently, one can find multiple open-source operating systems, office tools, Web browsers, database systems, games, and all manner of specialized tools and systems.

Several factors are key to the spread of open source, including:

- *Participatory communities*. The open source model encourages the evolution of participatory communities of users and developers. The Linux kernel effort boasts contributions by tens of thousands of programmers distributed all over the world. Other projects have smaller but similarly diverse communities. The contrast between this development model and the common, centralized development model of proprietary software is outlined by Raymond (2001a).
- *Rapid evolution*. A consequence of this "community development" model and a "release early, release often" strategy common in open source projects is that bugs are found and fixed and features are added quickly. Users are encouraged to interact with developers to report bugs and test fixes, and users with programming skills can fix the bugs they find and submit their patches back to the authors for incorporation into the official releases. "Given enough eyeballs, all bugs are shallow (Raymond 2001a)."
- *Low cost*. Open-source software is often available at little or no cost. Because recipients are free to redistribute copies without paying royalties, the price of copies tends to fall toward the marginal cost of distributing them.
- *Associated business models*. Perhaps counterintuitively, there are viable business models built around open-source software (see, for example, Raymond 2001b; Young and Rohm 1999). Device manufacturers distribute open-source drivers or use open-source operating systems. Experts train or consult with users of systems and packages. Companies sell systems built around open-source tools or support contracts for those tools. Companies distribute code under dual licenses, selling a proprietary license for incorporation in proprietary products and giving away a version that cannot be made proprietary.

Open Source and Academic Research

The essential mission of the university is to create and disseminate knowledge. Traditional vehicles for dissemination are journal articles and research monographs, as well as integration of knowledge into courses and textbooks. But articles and monographs have significant drawbacks as outlets for computational research, because they do not generally include the code that the authors used to generate their results. The verbal descriptions of algorithms in articles cannot include all the details necessary for another developer to exactly reproduce the original implementation. As a result (Lougee-Hiemer 2003):

- *Results are irreproducible*. Without access to the original code, other researchers cannot reproduce or verify reported results of computational experiments.
- *Comparisons are unfair*. When investigators engaged in follow-on research attempt to compare their results to earlier work, they must re-implement the earlier work. Their re-implementations can (however unintentionally) be biased in favor of the new work.
- *Models and implementations are lost*. As researchers move on to new projects, they may neglect or even discard the codes they developed for their earlier work.
- *Evolution is stunted*. Important and useful implementation techniques are unavailable to subsequent developers without access to the original code.

- *Wheels are reinvented.* Subsequent developers must rediscover important implementation techniques on their own.
- *Knowledge transfer is limited.* Implementation techniques hidden in unpublished code cannot be transferred to other problem domains.
- *Collaboration is inhibited.* Unavailability of reference implementations mean that there is no final arbiter of interpretations of standards. For example, problem instance data files can be interpreted differently by different readers. Also, commercial solver library interfaces all differ, creating vendor lock-in for embedded solvers and inhibiting sharing of code that calls those libraries.

Open-source software is a highly effective vehicle for technology transfer because it reduces to practice every detail of computational research results. It addresses the above problems by providing a path to publishing source code that mirrors the open literature for theory in important ways, such as providing a vehicle for peer review. It also addresses publication issues that are peculiar to software—particularly the need for a living document that can be updated and incorporated into new research that builds on the original code.

Software publishing as a scholarly activity is still not widely recognized in academic circles because publication venues are not well established and the mechanisms for peer review are different from those of archival journals, conference proceedings, and monographs. Hafer and Kirkpatrick (2009) propose ways to integrate software publication into the academic promotion and tenure review process. If reviewers would heed their recommendations, that would encourage scholars to engage in this important endeavor.

How Open Source Works

Companies often find working with open source challenging due to the vast array of licenses that accompany open-source software and the unfamiliarity of users and corporate legal departments with the principles of open source and the details of the various licenses. This section examines those principles and discusses some issues related to some particular popular licenses. *The information presented here does not constitute legal advice. The final arbiters of legal issues are the courts, and readers with legal concerns relating to open source should consult their legal advisers.*

Intellectual Property

Intellectual property (IP) is protected by two bodies of law: copyright law and patent law. These two legal concepts protect different kinds of intellectual property and provide different kinds of recourse to IP holders.

Copyright law protects creative expressions, such as writings, visual arts, musical compositions, and recorded performances. The protections include reserving to the creator or the owner of a copyrighted work the right to make and distribute copies and to create derivative works. A computer program is an expression of an algorithm in a particular computer language, authored by a particular programmer (or more than one) and owned by the author or the author's employer. Such creations are automatically protected with no action necessary on the author's part, although filing a claim can support legal actions for violation. Copyright protection is the primary legal underpinning of open source licenses.

Patent law protects ideas. The protections include reserving to the inventor or patent holder the right to prevent others from using the idea or derivative ideas in products or other inventions. In recent decades, courts have ruled that software can be patented. Software patents are controversial—particularly within the open source community—but they are a side issue with respect to the legal structure of open source licenses. Some open source licenses attach patent licenses for patented ideas that appear in the code or derived works, sometimes with conditions on licensees' enforcement of their own patent rights. The penalties for violating the restrictions are generally limited to revocation of the license to the code.

Open Source and Copyright

Open-source software licenses work legally the same way licenses for any software work. The authors or owners of the intellectual property have rights reserved to them under copyright law to specify the conditions under which the software is distributed to users.

Proprietary licenses generally specify that users must pay license fees, refrain from redistributing the software, limit the number of copies they make, refrain from reverse engineering, restrict usage to certain computers or individuals, and meet other restrictive conditions in order to receive permission to use the software.

Open source licenses use copyright law in the same way: the authors or owners reserve their rights under copyright law to determine the conditions under which users can obtain the software. However, with open source, the conditions explicitly grant users the right to use the software, to obtain the source code in human-readable and -modifiable form, to create derived works, and to redistribute those works. Redistributors and distributors of derived works may also be required by the license to distribute the works under the same license terms and to make source code available.

Open source is not the same as the public domain. Works placed in the public domain (either intentionally by the creator or owner or due to expiration of copyright or patent protection) are free to be used in any fashion by recipients. Open source is protected by copyright law and recipients are required to abide by the terms of the license under which they received the software. There are subtle legal issues associated with placing intellectual property in the public domain and using public-domain works, so if the intention is to make a software package available with no restrictions, it is best to distribute it with an explicit declaration or under a license that specifies that criterion explicitly [see, for example, Lindberg 2008, pp. 299–300].

A key to understanding open source licenses is the notion of a derived work. According to US copyright law [as cited by Rosen 2005], a derived work is "[a] work based upon one or more preexisting works, such as a translation…or any other form in which a work may be recast, transformed, or adapted (17 U.S.C. §101)." In software, derived works are usually created by making changes to the source code to fix bugs, add features, improve interoperability, etc. However, interpretation of the term is critical to the understanding of how different licenses work. As with legal concepts in general, the exact interpretation is a matter of case law. Open source licenses have, to date, faced limited scrutiny in court, so the concepts are not yet well settled.

Open Source Licenses

There are a wide variety of open source licenses. They vary in overall structure and in details. This section explains the basic principles of open source licensing, describes classes of licenses, and examines some of the ones that are common in the operations research community.

The Open Source Initiative

In the mid-1990s, some members of the open source community took on the challenge of advocating the use of open source in the business community. The result was the Open Source Initiative (OSI), which their Web site describes as "a non-profit corporation formed to educate about and advocate for the benefits of open source and to build bridges among different constituencies in the open-source community."

The Initiative published the Open Source Definition (OSD), a set of voluntary standards that licenses must comply with in order to receive OSI approval [reprinted in summary form in Rosen (2005), annotated version available online from the OSI]. The wording of some of the ten points in the OSD is somewhat unclear, but Rosen (2005) summarizes the main ideas in the standards as follows:

- Licensees are free to use open-source software for any purpose whatsoever.
- Licensees are free to make copies of open-source software and to distribute them without payment of royalties to the licensor.
- Licensees are free to create derivative works of open-source software and to distribute them without payment of royalties to the licensor.
- Licensees are free to access and use the source code of open-source software.
- Licensees are free to combine open-source and other software.

The licensor can require that copies and derived works be distributed under the same license that they were received under. Licenses with this provision are called "reciprocal licenses" and are discussed in Section "Reciprocal Licenses." Licenses without this requirement are "academic licenses" and are discussed in Section "Academic Licenses."

Broad Classes of Licenses

The variety of open source licenses can be bewildering. The OSI lists 67 approved licenses (as of this writing), although many are one-off

licenses created for particular individual products. The bulk of open source projects use a relatively small selection of these licenses. Unfortunately, even those licenses can have significantly different conditions, which may conflict if users try to redistribute code combined from multiple sources.

Notwithstanding the proliferation of licenses, they can be mapped to a few categories with broadly similar properties. Rosen (2005) identifies academic licenses and reciprocal licenses as the main categories of open source licenses applying to software. These categories are described in more detail below. He also identifies standards licenses—intended to enforce openness of standard protocols and reference implementations, and content licenses—which apply to non-software creations such as music, literature, and video.

The text of licenses not accompanied by citations in the discussion below can be found at the Web site of the Open Source Initiative.

Academic Licenses

"[S]uch licenses were originally created by academic institutions to distribute their software to the public, allow the software to be used for any purpose whatsoever with no obligation on the part of the licensee to distribute the source code of derivative works... Academic licenses create a public commons of free software, and anyone can take such software for any purpose—including for creating proprietary collective and derivative works—without having to add anything back to that commons (Rosen 2005)."

The best known example of this type of license is the Berkeley Software Distribution (BSD) license [reprinted in Rosen 2005, pp. 316–317], which allows "[r]edistribution and use in source and binary forms, with or without modification," subject to the requirement that the copyright notice be preserved and that the owner's name not be used without permission in an endorsement or promotion of a derived work. The license also includes disclaimers of warranty and liability.

Licenses in this class are easy to use. They are generally compatible with each other and with other licenses, and place few conditions on redistribution. (No open source license restricts use of the code if it is not redistributed.) While the BSD License is probably the most widely used in this class, other academic licenses in use for widely deployed software include the MIT License [reprinted in Rosen 2005, p. 319] and the Apache Licenses [reprinted in Rosen 2005, pp. 320–323].

Reciprocal Licenses

Reciprocal licenses "also allow software to be used for any purpose whatsoever, but they require the distributors of derivative works to distribute those works under the same license, including the requirement that the source code of those derivative works be published... Anyone who creates and distributes a derivative work of a work licensed under a reciprocal license must, in turn, license that derivative work under the same license. Reciprocal licenses, like academic licenses, contribute software into a public commons of free software, but they mandate that derivative works also be placed in that same commons (Rosen 2005)."

Reciprocal licenses are the major legal innovation of the free and open-source software movement. While they are effective at extending the body of work in the public commons, they are also controversial and the interactions of different licenses are complicated.

The GNU General Public Licenses. The GNU General Public License (GPL) is the original "free software" license, developed by Richard Stallman. Versions of the GPL (there are two in wide use, plus some variations) are the most common reciprocal licenses for free and open-source software.

The GPL version 2.0 (GPLv2) [reprinted in Lindberg 2008, pp. 333–340] dates from 1991. The most recent version, version 3.0 (GPLv3) [reprinted in Lindberg 2008, pp. 341–354] was released in 2007. The GNU Library (or "Lesser") General Public License (LGPL) version 2.1 (LGPLv2.1) [reprinted in Lindberg 2008, pp. 319–328] dates from 1999, and version 3.0 (LGPLv3) [reprinted in Lindberg 2008, pp. 329–332] is also from 2007. The GNU Affero Public License version 3 dates from 2007 as well. The distinctions are addressed below.

The most controversial aspect of the GPL is the scope of the reciprocity requirement. The GPL states that its terms apply to a covered Program (a "program or other work") and to "work[s] based on the Program." The definition of a "work based on the Program" broadens the definition of "derived work" in copyright law to include "a work containing the Program or a portion of it, either verbatim or with modifications." The common understanding of this principle is that it is intended to extend the coverage

of the GPL from a library of subroutines and functions covered by the GPL to programs that call subroutines or functions in the library. Thus, except under certain conditions, if a program incorporates a GPL library in such a manner, the program is considered a work based on the library and must in turn be distributed under the GPL. The legality of this interpretation has not been settled in case law and remains a point of controversy.

The LGPL differs from the GPL by explicitly exempting the calling program of a GPL library from the requirement that it also be distributed under the GPL. Version 3.0 of both licenses differ from their predecessors in their treatment of embedded programs that are incorporated into hardware devices and in their treatment of patents. The Affero license applies to programs that are accessed over a network, as contrasted with libraries that run on the same computer as their calling programs.

The Mozilla Public License. The Mozilla Public License [reprinted in Rosen 2005, pp. 351–367] is the license under which the Mozilla and Firefox Web browsers and associated software are distributed. It is a popular reciprocal license and Rosen considers it to be well thought out and constructed. While its history may be familiar to those who remember the "browser wars" of the late 1990s, it does not seem to be a common choice in the operations research community.

The IBM, Common, and Eclipse Public Licenses. Due to the influence of IBM and the COIN-OR initiative on operations research software, this family of licenses is fairly common in the OR community. The IBM Public License (IPL) was the first license in this family. The Common Public License (CPL) [reprinted in Rosen 2005, pp. 358–376] was created by IBM from the IPL so that developers other than IBM could release software under its terms.

The Eclipse Public License (EPL) was adapted from the CPL by the Eclipse Foundation, a consortium of companies involved in development of the Eclipse programmer's development environment. It is essentially the same as the CPL, except for the elimination of a "patent retaliation clause," which revoked license of any patents in the code under license for any user who sues a contributor for infringement of a software patent not related to that code. Recently, the CPL and EPL license stewards agreed to replace the CPL with the EPL, so developers and contributors to CPL projects are encouraged by the stewards of the two licenses (IBM and the Eclipse Foundation) to upgrade them to the EPL.

Open Source in Operations Research

The Computational Infrastructure for Operations Research (COIN-OR)

The COIN-OR initiative supports the development and publication of open-source software for the benefit of the operations research community. The project began as the Common Optimization INterface for Operations Research at IBM Research in 2000 (Lougee-Hiemer 2003; Saltzman 2002), a collection of four related projects (the Open Solver Interface, the Volume Algorithm, the Cut Generator Library, and the Branch-Cut-Price Framework) and two independent projects (Derivative-Free Optimization and Open Tabu Search). In 2004, the initiative was turned over to the COIN-OR Foundation, an organization created for the purpose of supporting the project independent of IBM, and the name was changed to the COmputational INfrastructure for Operations Research to better reflect its expanded mission (while keeping the acronym the same).

Since its inception, the COIN-OR repository has grown to house over 50 separate projects in a variety of areas of computational operations research, including LP solvers, branch-and-cut frameworks and mixed-integer solvers, continuous and discrete nonlinear solvers, algorithmic differentiation tools, modeling tools, and others. The current projects are mostly optimization related, although the COIN-OR Foundation welcomes contributions in other areas (such as stochastic processes, statistics, and simulation) as well.

Development and Dissemination

The COIN-OR initiative provides an infrastructure to support the distributed community development model common to many open source projects and to provide a central forum for publishing software in the operations research field.

The developer infrastructure includes a Web server, a source-code version control system, a mailing list server, a bug tracker and Wiki, and related tools. In addition, Foundation volunteers support a collection of tools to ease the process of compiling and installing

projects that conform to the tool's configuration requirements.

There are several open source infrastructure projects—the largest being SourceForge—which provide similar tools to COIN-OR. Any such centralized service provides advantages over self management: developers need not provide their own repositories or support tools; and Users know where to look for packages and know that the packages and support services work the same way for all projects in the repository.

COIN-OR offers some additional advantages over these generic hosting services for operations researchers:

- *One-stop resource*. Because the initiative is focused on operations research, it serves as a one-stop resource for potential users and developers in the field. SourceForge, by contrast, hosts thousands of open-source projects and does not even list a category for science or engineering applications.
- *OR-focused support*. Because the volunteers on the support staff are operations researchers, they understand the needs of OR users and developers, and they can provide support appropriate to that environment. Developers whose projects meet the requirements of the BuildTools project, for example, don't need to be experts in building and packaging software in order to package and distribute their programs.

A goal of the COIN-OR Foundation is to serve as a peer-reviewed publication venue for operations research software. While the practice of assessing the quality of a journal article is well established, it is an open question how best to evaluate the quality of published source code. Informal, indirect assessment of quality may be based on reputation, penetration, support from the developer community, and other measures of community acceptance (Hafer and Kirkpatrick 2009). The COIN-OR Foundation does review contributed projects for certain features, including:

- *Legal provenance*. The project must satisfy reporting requirements regarding legal documentation. At a minimum, contributors must certify that they understand and have met basic legal requirements to ensure that they have the right to license their contributions. Beyond that minimum, contributors can provide documentation from the owner of the intellectual property certifying that they own the code and license it. The level of certification of each contribution is documented in the project's index entry and is the responsibility of the project manager.
- *Documentation*. The project must include certain documentation, including acknowledgment of contributors, a copy of the license, and instructions for building and installing the software.
- *Functionality*. The projects are also required to "work." That is, an independent reviewer, following the instructions, must be able to successfully build and install the software and run a unit test provided by the contributor.

Providing support for more sophisticated peer review is a long term goal of the foundation.

Using COIN-OR Software

Martin (2010) gives a tutorial on using COIN-OR software. He describes applications in industry, education, and research, and describes how to obtain and use COIN-OR tools.

COIN-OR users fall into two broad categories: users who need a prepackaged tool to solve a particular problem and developers interested in incorporating COIN-OR code into programs that they write themselves. The former group can obtain precompiled binary packages of COIN-OR libraries and programs and use them just as they would other self-contained software products. Developers can check out the source code to the latest versions of COIN-OR programs and either incorporate the code as callable libraries or integrate the source code directly into their own program source. Martin explains both uses.

COIN-OR Projects

The complete collection of COIN-OR projects as of this writing is listed here, by category. The current list is maintained at the COIN-OR Web site. Project URLs can be found by entering the project name and keywords from the description in your favorite WWW search engine. Some projects appear in multiple categories.

Developer Tools

BuildTools COIN-OR Unix developer tools and documentation, tools for managing configuration and compilation of various COIN-OR projects under Linux, Unix, and Cygwin.

CoinBazaar The COIN-OR Bazaar, small examples and extensions of COIN-OR projects.

CoinBinary COIN-OR Binary Distributions, pre-compiled binary distributions of COIN-OR projects.

CoinWeb COIN-OR Web Services, COIN-OR Web pages, Subversion, Trac, etc.

Coopr A COmmon Optimization Python Repository, the Coopr software project integrates a variety of optimization-related Python packages. Coopr supports a diverse set of optimization capabilities that can be used formulate and analyze optimization applications.

TestTools TestTools, Python scripts to automatically download, configure, build, test, and install COIN-OR projects.

Documentation

CoinEasy New user information and support.

Graphs

CGC COIN-OR Graph Classes, a collection of network representations and algorithms.

LEMON Library of Efficient Models and Optimization in Networks, a C++ template library aimed at combinatorial optimization tasks, especially those working with graphs and networks.

Interfaces

AIMMSlinks AIMMS/COIN-OR Links, links between the modeling language AIMMS and solvers that are hosted at COIN-OR.

CMPL Coliop/CoinMathematical Programming Language, a mathematical programming language and a system for modeling.

CoinMP CoinMP, a lightweight API and DLL for CLP, CBC, and CGL.

GAMSlinks GAMS/COIN-OR Links, links between GAMS (General Algebraic Modeling System) and solvers that are hosted at COIN-OR.

NLPAPI Nonlinear Programming API, a subroutine interface for defining and solving nonlinear programming problems.

OS Optimization Services, standards for representing optimization instances, results, solver options, and communication between clients and solvers in a distributed environment using Web Services.

OSI Open Solver Interface, a uniform API for calling embedded linear and mixed-integer programming solvers.

PuLP Python library for modeling linear and integer programs.

SMI Stochastic Modeling Interface, for optimization under uncertainty.

Metaheuristics

Djinni A templatized C++ framework with Python bindings for heuristic search.

METSlib An object oriented metaheuristics optimization framework and toolkit in C++.

OTS Open Tabu Search, a framework for constructing tabu search algorithms.

Modeling Systems

AIMMSlinks AIMMS/COIN-OR Links, links between the modeling language AIMMS and solvers that are hosted at COIN-OR.

CMPL Coliop/CoinMathematical Programming Language, a mathematical programming language and a system for modeling.

Coopr A COmmon Optimization Python Repository, the Coopr software project integrates a variety of Python. optimization-related packages. Coopr supports a diverse set of optimization capabilities that can be used formulate and analyze optimization applications.

FLOPC++ An algebraic modeling language embedded in C++.

GAMSlinks GAMS/COIN-OR Links, links between GAMS (General Algebraic Modeling System) and solvers that are hosted at COIN-OR.

OS Optimization Services, standards for representing optimization instances, results, solver options, and communication between clients and solvers in a distributed environment using Web Services.

PuLP Python library for modeling linear and integer programs, Python library for modeling linear and integer programs.

ROSE Reformulation-Optimization Software Engine, software for performing symbolic reformulations to Mathematical Programs (MP).

Optimization Convex Non-differentiable

OBOE Oracle Based Optimization Engine, optimization of convex problems with

user-supplied methods delivering key first order information (like support to the feasible set, support to the objective function).

Optimization Deterministic Linear Continuous

CLP COIN-OR LP, a simplex solver.

CoinMP CoinMP, a lightweight API and DLL for CLP, CBC, and CGL.

DyLP Dynamic LP, an implementation of the dynamic simplex method.

FLOPC++ An algebraic modeling language embedded in C++.

OSI Open Solver Interface, a uniform API for calling embedded linear and mixed-integer programming solvers.

VOL Volume Algorithm, a subgradient algorithm that also computes approximate primal solutions.

Optimization Deterministic Linear Discrete

ABACUS A Branch-And-CUt System, an LP-based branch-and-cut framework.

BCP Branch-Cut-Price Framework, a framework for constructing parallel branch-cut-price algorithms for mixed-integer linear programs.

CBC COIN-OR Branch and Cut, an LP-based branch-and-cut library.

CGL Cut Generator Library, a library of cutting-plane generators.

CHiPPS COIN-OR High Performance Parallel Search Framework, a framework for constructing parallel tree search algorithms (includes an LP-based branch-cut-price implementation).

DIP Decomposition in Integer Programming, a framework for implementing a variety of decomposition-based branch-and-bound algorithms for solving mixed integer linear programs.

KSP *K* Shortest Paths, algorithms for *K* shortest paths.

SYMPHONY Single- or Multi-Process Optimization over Networks, a callable library for solving mixed-integer linear programs.

VRPH Vehicle Routing Problem Heuristics, a library of heuristics for generating solutions to variants of the vehicle routing problem.

Optimization Deterministic Nonlinear

DFO Derivative-Free Optimization, a package for solving general nonlinear optimization problems when derivatives are unavailable.

filterSD Subroutines for nonlinear optimization, a library for nonlinear optimization written in Fortran.

Ipopt Interior-Point Optimizer, for general large-scale nonlinear optimization.

MOCHA Matroid Optimization. Combinatorial Heuristics and Algorithms, heuristics and algorithms for multicriteria matroid optimization.

NLPAPI Nonlinear Programming API, a subroutine interface for defining and solving nonlinear programming problems.

OptiML Optimization for Machine Learning, interior point, active set method and parametric solvers for support vector machines, solver for the sparse inverse covariance problem.

Optimization Deterministic Nonlinear Discrete

Bonmin Basic Open-source Nonlinear Mixed INteger programming, an experimental open-source C++ code for solving general MINLP (Mixed Integer NonLinear Programming) problems.

Couenne Convex Over and Under ENvelopes for Nonlinear Estimation, a branch-and-bound algorithm for mixed integer nonlinear programming problems.

LaGO Lagrangian Global Optimizer, for the global optimization of nonconvex mixed-integer nonlinear programs.

Optimization Deterministic Semidefinite Continuous

CSDP C Library for Semidefinite Programming, an interior-point method for semidefinite programming.

Optimization Stochastic

Coopr A COmmon Optimization Python Repository, the Coopr software project integrates a variety of Python. optimization-related packages. Coopr supports a diverse set of optimization capabilities that can be used formulate and analyze optimization applications.

SMI Stochastic Modeling Interface, for optimization under uncertainty.

Optimization Utility

ADOL-C Package for the automatic differentiation of C and C++ programs.

CHiPPS COIN-OR High Performance Parallel Search Framework, a framework for constructing parallel

tree search algorithms (includes an LP-based branch-cut-price implementation).

CoinBazaar The COIN-OR Bazaar, small examples and extensions of COIN-OR projects.

CoinUtils COIN-OR utilities, utilities, data structures, and linear algebra methods for COIN-OR projects.

Coopr A COmmon Optimization Python Repository, the Coopr software project integrates a variety of Python optimization-related packages. Coopr supports a diverse set of optimization capabilities that can be used formulate and analyze optimization applications.

CppAD CppAD, a tool for differentiation of C++ functions.

LEMON Library of Efficient Models and Optimization in Networks, a C++ template library aimed at combinatorial optimization tasks, especially those working with graphs and networks.

OS Optimization Services, standards for representing optimization instances, results, solver options, and communication between clients and solvers in a distributed environment using Web Services.

PFunc Parallel Functions, a lightweight and portable library that provides C and C++ APIs to express task parallelism.

Web Services

OS Optimization Services, standards for representing optimization instances, results, solver options, and communication between clients and solvers in a distributed environment using Web Services.

Other Open-Source OR Software

COIN-OR is not the only source of open-source code for OR. Many authors do offer their experimental codes or even production-quality codes individually. Some may be available at SourceForge, GitHub, the GNU project, or other general-purpose repositories; many are offered only on the authors' Web pages. But there is no other centralized location where an operations researcher can go to find those codes.

Below is a list of several OR-related codes that are not part of COIN-OR, of which this author is aware. The list appears on the COIN-OR Web site. URLs can be located through Internet search engines. If you know of other relevant projects, please send this author a link.

cdd The double description method for constructing representations of polyhedra.

Cliquer For finding cliques in graphs.

GLPK The GNU Linear Programming Kit.

Gnumeric Spreadsheet with solvers.

GSL The GNU Scientific Library: C library for mathematical functions, including random variables, statistics, linear algebra, and lots more.

GOBLIN Graph optimization library.

lrs The reverse search algorithm for finding vertices of polyhedra.

Maxima Computer algebra, similar to Mathematica or Maple.

MCFClass Interface for Minimum Cost Flow problems (mix of open-source and other software).

mexclp A MATLAB interface to the COIN-OR LP solver (CLP).

MINLP CMU-IBM Cyber-Infrastructure for MINLP.

MUMPS A MUltifrontal Massively Parallel sparse direct linear system solver.

Octave Matrix based mathematics, similar to and mostly compatible with Matlab.

OpenOffice open-source office suite with spreadsheet optimization using COIN-OR solvers.

OpenSolver Excel plugin for optimization.

OpenForecast The name says it all.

QtsPlus4Calc A collection of OpenOffice spreadsheets that solve a variety of problems related to queuing theory.

R Statistics, graphics, and more. Similar to S-plus (both are based on the language S).

Sage Flexible, extensible system for symbolic and numerical mathematics.

Shogun A large-scale machine learning toolbox.

SolverStudio Cloud-based optimization plugin for Excel.

swIMP SWIG-based interfaces for Mathematical Programming.

Zimpl Translate LP/MIP models into MPS or LP formats.

Concluding Remarks

Open-source software is an important resource for researchers and practitioners of computational operations research. This article reviewed the benefits of open source for academic researchers and practitioners and outlined the legal mechanics of working with open source. The COIN-OR Foundation provides to computational operations researchers an

infrastructure for supporting open source development and a publication forum for open-source software. COIN-OR is the largest repository of open-source software for operations research, comprising more than 50 projects and growing. Other OR-related open-source tools are available, but they are not available from any central source.

Operational Research Society (ORS)

The United Kingdom's Operational Research Society (ORS) had its origins in an informal OR Club, founded in 1948, for "people who are working in or are concerned with problems associated with Operational Research" (Anon 1950b). Membership was limited to one member per industry or organization. In 1950, the Club established a specialist journal, the *Operational Research Quarterly*, that would "assemble in one place as much as possible of the information that operational research workers now find (or fail to find) scattered widely over the very large body of scientific and technical literature" (Anon 1950a). The journal was renamed the *Journal of the Operational Research Society* in 1978.

The Club was reconstituted as a Society in 1953, with no numerical limit on membership. The aims were defined in the Constitution as "the advancement of education through the provision of training in and the promotion and adoption of operational research." Cooperation with the American and French societies, following the first international conference at Oxford in 1957, led to the creation of the International Federation of Operational Research Societies (IFORS) in 1959. Another outcome of the conference in Oxford was the first U.K. national conference in 1958.

Operations Management

Mark A. Vonderembse[1], William G. Marchal[1] and David Dobrzykowski[2]

[1]The University of Toledo, Toledo, OH, USA

[2]Eastern Michigan University, Ypsilanti, MI, USA

Introduction

Organizations exist to meet the needs of society that people working alone cannot. Operations are part of an organization and they are responsible for producing the tremendous array of products in the quantities

consumed each day. Operations are the processes which transform inputs (labor, capital, materials, and energy) into outputs (services and goods) consumed by the public. Operations employ people, build facilities, purchase equipment in order to change materials into finished goods such as computer hardware and/or to provide services such as computer software development.

Services are intangible products and goods are physical products. According to the classification scheme used by the U.S. Department of Commerce and Labor, services include transportation, utilities, lodging, entertainment, health care, legal services, education, communications, wholesale and retail trade, banking and finance, public administration, insurance, real estate, and other miscellaneous services. Goods are described as articles of trade, merchandise, or wares. Manufacturing is a specific term referring to the production of goods. Here, the term product will be used to refer to both goods and services.

Whether an organization is producing services or goods as part of the for-profit private sector or the not-for-profit public sector, the output from operations should be worth more to customers than the total cost of its inputs. As a result, an organization creates wealth for society through decisions and actions made in managing operations.

Operations management is a multi-disciplinary sub-field of management with particular focus on the production or operations function of the firm. Its scope includes decision making involving the design, planning, and management of the many factors that affect operations. Decisions include: what products to produce, how large a facility to build, how many people to hire, and what methods to use to increase product quality. Operations managers apply ideas and technologies to reduce leadtime dramatically, increase productivity and reduce costs, improve flexibility to meet rapidly changing customer needs, enhance quality, and improve customer service.

Organizations can use operations as an important way to gain an advantage on the competition. Synergy results when operations are linked to the overall strategy of the organization (including engineering, financial, marketing, and information system planning). Operations become a positive factor when facilities, equipment, and employee training are viewed as a means to achieve organizational rather than suboptimal departmental goals.

Increasing demand for product variety and shorter product life cycles are forcing operations to respond more frequently and more quickly to customer needs. Competition is no longer based only on price or price and quality. Competition is becoming time-based, with customers expecting high-quality, low-cost and innovative products that are designed and produced quickly to meet specific customer requirements. When flexibility is designed into operations, an organization is able to rapidly and inexpensively respond to changing customer needs. Organizations can use computers and information technology to become more flexible. Improvements in productivity and product quality provide the basis for competing in global markets.

To be successful, an organization should consider issues related to: designing a system that will be capable of producing the appropriate services and goods in the needed quantities; planning how to use the system effectively; and managing key elements of the operations. Each of these topics are described briefly in the following sections.

Designing the System

Designing the system includes all the decisions necessary to determine the characteristics and features of the goods and services to be produced. It also establishes the facilities and information systems required to produce them. When designing a system which is capable of producing services and/or goods several questions arise.

- What products will the organization produce (product development and design)?
- What equipment and/or methods will be used (process design)?
- How much capacity will an organization acquire?
- Where will the facility be located?
- How will the facility be laid out?
- How will individual jobs and tasks be designed?

Product Development is a process for (1) assessing customer needs, (2) describing how products (both services and goods) can be designed to meet those needs, (3) determining how processes can be designed to make quality products efficiently and reliably, and (4) developing marketing, financial, and operating plans to successfully launch those products. Product development is a cross-functional decision

process that requires teamwork. It is a key factor for success because it shapes how the organization competes.

Product Design is the determination of the characteristics and features of the product, i.e., how the product functions. Product design determines a product's cost and quality as well as its features and performance, and these are the primary criteria on which customers make the decision to purchase. Techniques such as Design for Manufacturing and Assembly (DFMA) are being implemented with very successful results. The objective is to improve product quality and lower product costs by focusing on manufacturing issues during product design. DFMA is implemented through computer software that points designers towards designs that would be easy to build by focusing on the economic and quality implications of design decisions. This is often critical because even though design may be a small part of the overall cost of a product, the design decision may fix 70-90% of the manufacturing costs. Quality Functional Deployment is also being used. It is a set of planning and communication routines that focuses and coordinates actions. The foundation is the belief that a product should be designed to reflect customers' desires and tastes.

Process Design describes how the product will be made. The process design decision has two major components; a technical or engineering component and a scale economy or business component. The technical side requires that decisions be made regarding the technology to be used. For example, a fast food restaurant should decide whether its hamburgers will be flame broiled or fried. Decisions must also be made about the sequence of operations. For example, should a car rental agency inspect a car that has been returned by the customer first or send it to be cleaned and washed? Decisions need to be made regarding the type of equipment to be used in making the good or providing the service. In addition, the methods and procedures used in performing the operations must also be determined.

The scale economy or business component involves applying the proper amount of mechanization (tools and equipment) to leverage the organization's work force to make it more productive. This involves determining whether the demand for a product is large enough to justify mass production; if there is sufficient variety in customer demand so that flexible production systems are required; or if demand is so small that it cannot support a dedicated production facility.

Capacity is a measure of an organization's ability to provide the demanded services or goods in the amount requested and in a timely manner. More specifically, capacity is the maximum rate of production that can be sustained over a long period of time. Capacity planning involves estimating demand, determining the capacity of facilities, and deciding how to change the organization's capacity to respond to demand.

Facility Location is the placement of a facility with respect to its customers, suppliers, and other facilities with which it interacts. Normally, facility location is a strategic decision because it is a long-term commitment of resources which cannot easily or inexpensively be changed. When evaluating a location, management should consider: customer convenience, initial investment for land and facilities, operating costs, transportation costs, and government incentives. In addition, qualitative factors, such as availability of financial service, cultural activities for employees, and university research programs that relate to the needs of the firm, should be considered. As world economies become closely linked, the location decision takes on global dimensions.

Facility Layout is the arrangement of the work space within a facility. At it highest level, it considers which departments or work areas should be adjacent so that the flow of product, information, and people can move quickly and efficiently through the production system. Next, within the department or work area, where should people be located with respect to equipment and storage? How large should the department be? Finally, how should each work area within a department be arranged?

Job Design specifies the tasks, responsibilities, and methods used in performing a job. For example, a job design for x-ray technicians would describe what equipment they would use and explain the standard operating procedures including the safety requirement that should be followed.

Planning the System

A plan is a list of actions management expects to take to deal with opportunities and problems present in the environment. Production planning is how management expects to utilize the resource base created when the

production system was designed. One of the outcomes may be to change the design such as increasing or decreasing capacity and rearranging layout to enhance efficiency.

Production planning decisions depend upon the planning time horizon. Long-range decisions include how many facilities to add to match capacity with forecasted demand and how technological change might affect techniques used to manufacture goods and provide services. The time horizon for long-term planning varies with the industry and depends on how long it would take an organization to build new facilities. For example, in electric power generation it often takes ten or more years to build a new plant. So electrical utilities must plan at least that far into the future.

In medium-range production planning, which is normally about one year, organizations find it difficult to make substantial changes in facilities. In this case, production planning involves determining work force size and developing training programs, working with suppliers to improve product quality and improve delivery, and determining how much material to order on an aggregate basis.

Scheduling has the shortest planning horizon. As production planning proceeds from long-range planning to short-range scheduling, the decisions become more detailed. In scheduling, management must decide what product or products will be made; who will do the work; what equipment will be used; which materials will be consumed; when the work will begin; and what will happen to the product when the work is complete. All aspects of production come together to make the product a reality.

Some techniques used in production planning require special mention. Aggregate planning, material requirements planning, just-in-time, and the critical path method are important techniques that can be useful in production planning.

Managing the System

The impact of people, information, materials, and quality on operations is growing. As a result, managing these areas is a key factor for organizational success. Participative management and teamwork are becoming an essential part of successful operations. Motivation, leadership, and training are receiving new impetus.

Information systems are mechanisms for gathering, classifying, organizing, storing, analyzing, and disseminating information. Information requirements in some operations are extensive. From product development through job design and from long-range planning to scheduling, timely information is required to make better decisions.

Material management includes decisions regarding the procurement, control, handling, storage, and distribution of materials. Materials and material management are becoming more and more important because in many operations purchased material costs are over 50% of the total product cost. How much material should be ordered, when should it be ordered, and which supplier should it be ordered from are some of the important questions.

Producing high-quality products is a minimum requirement for a customer to consider buying an organization's product. Quality is increasingly becoming customer-driven with emphasis put on obtaining a product design that builds quality into the product. Then, the process is designed to transform the product design into a quality product and the employees are trained to execute it. The role of inspection is not to enhance quality but to determine if the designs are effective.

Over time, operations management has grown in scope. It has elements that are strategic; it relies on behavioral and engineering concepts; and it utilizes management science/operations research tools and techniques for systematic decision making and problem solving. It also interacts with other functional specialties such as research and development, marketing, engineering, and finance to develop integrated answers to complex interdisciplinary problems.

Operations Research Office and Research Analysis Corporation

Eugene P. Visco[1] and Carl M. Harris[2]
[1]Silver Spring, MD, USA
[2]George Mason University, Fairfax, VA, USA

Introduction

In discussing the early days of operations research in the United Kingdom, Blackett (1962) notes:

> The Armed Services have for many decades made use of civilian scientists for the production of new weapons and vehicles of war, whereas the tactical and strategical use of these weapons and vehicles has been until recently almost exclusively a matter for the uniformed Service personnel. During the first years of the Second World War circumstances arose in which it was found that civilian scientists could sometimes play an important role in the study of tactics and strategy. The essential feature of these new circumstances was the very rapid introduction of new weapons and devices, preeminently radar, into the Services at a time both of great military difficulty and of such rapid expansion that the specialist officers of the Armed Services, who in less strenuous times can and do adequately compete with the problems raised, found themselves often quite unable to do so. I will attempt to describe … how it was that civilian scientists, with initially little or no detailed knowledge of tactics or strategy, came to play a sometimes vital role in these affairs, and how there grew up a virtually new branch of military science – later to be dignified in the United Kingdom by the name 'Operational Research,' or 'Operations Analysis' in the United States. By the end of the war, all three Services had operational research groups of mainly civilian scientists either at headquarters or attached to the major independent Commands. These groups were, in varying degrees, in close touch with all the main activities of the Service operational staffs and were thus in a position to study the facts of operations in progress, to analyze them scientifically, and, when opportunities arose, to advise the staffs on how to improve the operational direction of the war....

While British military operational analysis was in place in all three uniformed services during World War II, U.S. military operations research during the war was carried out primarily in the Army Air Corps (later the Army Air Force) and the Navy. There was no single U.S. Army group comparable to the British Army Operational Research Group. There was a scattering of small groups doing operational analyses in various parts of the Army. The Signal Corps set up an Operational Research Division to prepare instruction manuals for radio communications by using operational experience data. The Office of Field Service, a major subdivision of the Office of Scientific Research and Development, provided civilian scientists, initially to conduct operational analyses, to Army units in the Pacific Theater. However, the scientists were often called upon to carry out work other than operational analysis. Only the Navy and Army Air Force groups were dedicated to operational analyses. By war's end, the U.S. Army Air Force had 26 Operations Analysis sections assigned to the numbered Air Forces, Commands, Areas, Wings, Boards, and Schools. Approximately 250 analysts served in those sections. A wide range of professions were involved: typically 50 engineers, 40 educators and trainers, 35 mathematicians, 25 lawyers, and 21 physicists. Other professions represented included architects, meteorologists, physiologists, a historian, agriculturists,

investment analysts and stock brokers, an astronomer, biologists, and many others – true adherence to the mixed team concept introduced by the British founders. Some analyses conducted at the Army's Aberdeen Proving Ground in its recently formed Ballistic Research Laboratory (BRL) can certainly be considered Army operations analysis, even though those words were not recognized there. A variety of survivability and vulnerability studies, particularly on Army aircraft, were carried out at BRL, as were many weapons effectiveness and bombing pattern analyses. However, there was no central overall Army operations research group, so identified, other than those working with the Air Forces, during World War II.

Post-World War II Activities

After the war, the British and United States wartime groups, in one form or another, continued to conduct operations research and analysis for their respective services. In the U.S., it was clear, due to the demonstrated relevance and importance of military operations research, that operations analysis organizations were needed in all the services.

Thus, within a few years after the end of World War II, the Navy's Operations Evaluation Group (OEG) [later to become the Center for Naval Analyses (CNA)], the Air Force's Operations Analysis Division and Project RAND, and the Army's Operations Research Office (ORO) were formed. Each has played an important role in the history and development of OR/MS. The Operations Research Office of The Johns Hopkins University (JHU) was founded in 1948 (by the U.S. Army) to serve as the Army's civilian run organization for operations research analysis and studies, with offices in the Washington, DC area. ORO was managed by the trustees of JHU and had offices in the Washington, DC area. ORO had the major goal of providing independent, objective, and scientifically sound studies of national security and defense issues.

The ORO Director

The history of ORO is one with the history of Ellis A. Johnson, its founder and only Director. After earning his M.S. and D.Sc. degrees at the Massachusetts Institute of Technology, Johnson went to Washington in 1934 to work on magnetic instruments at the U.S. Coast and Geodetic Survey. In 1935, he joined the Department of Terrestrial Magnetism, Carnegie Institution as a geophysicist. Early in 1940 he moved to the Naval Ordnance Laboratory (NOL), first as a consultant, then as Associate Director of Research, where he worked on degaussing as a countermine tactic, among other things. He quickly became interested in the operational offensive use of mines and countermeasures to mines. Even during the early days of the minecountermine analysis, Johnson believed that analysts and researchers had to maintain a close association with those who had the ultimate responsibility for military operations – the very essence of operations research. Thus, from the outset, ORO reflected Johnson's wartime experiences and the philosophy of analysis. Much of what follows here, particularly in relation to Johnson, draws heavily on the tribute to him published by the Operations Research Society of America following his death (Page et al. 1974). With respect to the start-up of ORO, Page et al. (1974) noted:

> Thus, as ORO began its work, there was a working assumption that something called operations research was in being, and the Army anticipated its value enough to be willing to try to use it. But for the Army, this did not mean that it was clearly defined. Ground warfare was recognized as a more difficult field for operations research than air and sea warfare; on the one hand, ground warfare could not be affected so much by one new technical factor as air warfare was by radar, while, on the other, the analysis of the convenient geometry of the open space in the air or on the sea was quite inapplicable for troop movement on terrain. So, if OR was to play a significant role in support of Army planning, it would have to learn how to structure the problems, identify the elements amenable to analysis, and find methods of analysis by adaptation or invention. There were almost no direct precedents as to what could be expected....

ORO Activities and Projects

The organizational principles that quickly evolved included: a wide breadth of study topics; control and management of analysis in the hands of the researchers conducting the analyses; and close involvement with the operational elements of the Army, including access to real and often raw operational data representing performance of organizations and systems. Research leaders at ORO were also expected to conduct research

themselves, to maintain a connection with the reality of research management.

The first 2 years of ORO included assignments from the Army covering a major study of military aid to other nations, a study of the causation of artillery firing errors, and armored force operations. During this time the staff was brought to the level of about 40 full-time analysts, and a pool of more than 100 consultants was established, with ORO linkages to a number of research and analytic companies to provide additional, on-call support. Arrangements were concluded with the Army to establish a broad program of continuing research on nuclear weapons, tactics, logistics, military costing, psychological warfare, guerrilla warfare, and air defense. A core set of 15 projects was authorized and funded, thus providing a formative and formidable base from which to proceed.

When the Korean War broke out in June 1950, ORO was a functioning institution with a developing reputation for sound and practical analysis on behalf of the operational Army. Johnson quickly recognized a need and an opportunity in the war. He made an early visit to Korea to establish a modus operandus for field analysis teams in the theater of operations. By the fall, ORO had 40 analysts in the field (as many as the full staff only a few months earlier). At the end of the war, over 50% of the professional staff had spent time in the combat theater. Many hundreds of reports were written, with considerable impact on military operations. ORO's influence was felt in the UK and Canada, and operations analysts from those two UN participating countries joined their respective countries' military units operating in Korea.

A small ORO field team was organized at the Continental Army Command Headquarters, Fortress (now Fort) Monroe, Virginia. At that time, CONARC, as the Command was known, was responsible for the development of operational doctrine for the Army and for training related to that doctrine. It was Johnson's view that operations research could make important contributions to the development of doctrine, particularly considering the need for combat formations to adapt to the new considerations of ground combat under conditions of the potential use of atomic (later nuclear) weapons on the battlefield. ORO help design formations, assisting in the structure and doctrine for the Pentomic Division and the Pentagonal (for five combat commands) Division. Other studies looked at the vulnerability of armored formations to tactical nuclear weapons and at the potential for the offensive use of low-yield nuclear weapons. Much attention was paid to tactical operations and logistics in the early days. Later, there were studies related to strategic matters, the most demanding and significant of which was a large study devoted to defense of the U.S. mainland from manned bomber attack involving nuclear weapons.

A field office of the ORO was also established at the headquarters of the U.S. Army Europe in Heidelberg, Federal Republic of Germany, where major contributions to the defense of Europe and NATO operations were made. Heavy use was made of war gaming and exercises for European operations at the Heidelberg office.

ORO was a continuing and positive force in advancing military OR and OR in general. It conducted a series of conferences designed to evaluate the Army's proposed research and development budget to help the Army understand the potential effects of R&D investments and improve the allocation of funds to the many R&D projects competing for support. The PISGAH (named for the mountain from which Moses saw the promised land) conferences brought uniformed officers, operations analysts, industrial scientists, and academics together to examine the Army's future needs. Seminars and colloquia were regular weekly events; the former related to planned or on-going research or outside speakers of note, while the latter focused on more abstruse mathematical analysis topics. ORO conducted experiments to test the capability of bright high-school students to conduct (relatively) independent analyses, under the guidance of senior ORO analysts. Through the years, studies by student teams were done on a wide range of topics, including, for example, the characteristics of effective air raid warning systems for civilians, and deep-thrust armored operations in difficult terrain. During the 5 years of the program, 75 students spent at least one summer at ORO, and a number joined the regular staff after completing college.

During the 13 years of ORO activity, a full range of Army study topics was addressed: air operations and air defense; guerrilla, urban and unconventional warfare; tactical, intra-theater and strategic mobility and logistics; weapons systems; civil defense; intelligence, psychological warfare and civil affairs; and, overall, Army readiness for operations in a complex national security world

(Operations Research Office 1961). Two examples are cited next to demonstrate the wide-ranging impact of ORO studies.

In the arena of tactical operations, ORO examined ways to improve the casualty producing capability of small arms fire. Two unique ideas were introduced and assessed. One was a salvo concept, developed from a patent taken out in the nineteenth century by a serving Army officer. The concept consisted of a system of two projectiles of rifle ammunition, one nested behind the other, with a single cartridge casing and propellant. With one trigger pull, the two rounds came out of the weapon in tandem. ORO analysts predicted, using probability theory, that the natural spread of the two projectiles would greatly increase the hit probability on a man-sized target at operational combat ranges. An ORO analyst, returning to an earlier principle of operations analysis as an experimental science, cast a few bullets in the salvo mode, loaded them with his hand-loading equipment, and fired them on his backyard range. The crude experimental results confirmed the statistical analysis. The Army accepted the results and standardized a two-round salvo projectile for the M14.30 caliber rifle.

The second concept concerning improved effectiveness of small arms fire focused on infantry rifle training. The ORO analysts developed and tested a simulated infantry battlefield target array as an alternative to the known-distance range traditionally used to train infantry. Sets of man-sized targets were scattered over the battlefield and linked with electronic controls that caused the targets to pop-up to vertical positions simulating enemy shooters. The concept was adopted by the Army as the TRAIN-FIRE system.

The second example is a study that ORO did on the use of black soldiers in Korea and the extension of the study to the broader issue of full integration of black troops throughout the Army (Hausrath 1954). From the Revolutionary War to the Korean War, it was traditional for the U.S. military services not to integrate its forces. President Truman's 1948 Presidential Executive Orders, directing equal opportunity in the Executive Branch and the Armed Forces, plus the growing post-World War II economy and major demographic changes, gave impetus for the study requested of ORO by the Army. The study used a wide range of tools: demographic analysis, opinion and attitude surveys, content analysis, critical incident technique, statistical analysis, and community surveys.

The project's summary from Hausrath (1954) notes the following:

> . . . this study provided policy-makers in the U.S. Army with objective evidence in support of integrated units of Negro and white soldiers. This evidence indicated: first, that integrated units allow more effective use of the manpower available through a more even distribution of aptitudes than is possible in segregated units; second, that performance of integrated units is satisfactory; and, third, that the resistance to integration is greatly reduced as experience is gained. The limit, if any, on the level of integration was shown to be above 20% Negroes, and difficulties in extending integration to all parts of the Army were identified and arranged in a sequential order so that a program leading to Army-wide integration could be formulated.

The ORO findings, conclusions and recommendations supported the Army process and success in integration during the 1950s.

End of ORO

In 1961, The Johns Hopkins University, following a disagreement with the Army over management issues, withdrew from the contractual relationship. At midnight on August 31, 1961, the Johns Hopkins University Operations Research Office ceased to exist. Its activities were transferred to the newly formed Research Analysis Corporation (RAC), a Federal Contract Research Center (FCRC).

This brief history of ORO is closed with a statement from the late Ellis A. Johnson, written in the summer of 1961 (Operations Research Office 1961):

> During the last 13 years ORO's accomplishments have indeed been noteworthy. ORO published 648 studies containing thousands of conclusions and recommendations. A majority of these have been adopted and acted on. This survey was written to summarize ORO accomplishments so that these could be considered in perspective and with satisfaction by those responsible for the accomplishments – the entire ORO staff: research staff, support staff, and administrative staff.
>
> We can all be proud of this record.

Transition to RAC

Although the great bulk of RAC's work would be done for defense agencies, RAC sought to diversify its capabilities and its clients. As a result, RAC's activities were expanded to include the White House

and the National Security Council; the Department of Defense; nine other governmental agencies with national security interests; some 40 other governmental agencies of all levels; and private foundations whose primary interests lie outside the field of national security. This range of clients, and their varying interests and requirements for research support, broadened RAC's resources of data and knowledge, analytic capability and interpretative skills. Work done on foreign aid and development further enriched RAC's capabilities to deal with the Army's problems, as did its work for urban clients on problems of crime and delinquency.

Throughout its existence, RAC viewed its major mission to be service to the public interest, chiefly by providing the Army with services, studies, research, and counsel based on operations research and systems analysis. RAC's Army work concentrated on force structure analysis and planning, logistics, military manpower, resource analysis, cost studies, and military gaming. These studies encompassed problems of operations, planning, intelligence, and research and development. In addition, RAC made studies of the nature and purposes of insurgency, counterinsurgency, and operations undertaken to stabilize societies under threat. RAC examined the politico-military aspects of these regions where U.S. land forces were already operating or providing advice and training, or might be called on to do so. These studies considered both current and projected environments. As ORO did, RAC set up field offices to study problems on the scene and to provide analytic support in direct conjunction with local tests and local operations.

RAC's Project Portfolio

Some of the largest projects RAC undertook involved very complex, worldwide logistical and transportation systems. RAC's studies of air mobility for army forces (in both wartime and peacetime) led to specific evaluations later on, after such systems were built, deployed, and put to work, thus creating bodies of hard data suitable for operations analysis.

There was also the continuation of ORO's emphasis on the assessment of weapons requirements and of the comparative effectiveness of competing weapons systems. RAC engineers and scientists also sought ways to improve the management of military research and development, seeking more efficient ways of allocating uncommitted resources to research and development projects. RAC analysts also dealt with communications, proposing new ways to allocate radio frequencies to military users and to improve the dependability of communication nets, early forerunners of today's highly sophisticated command, control and communications systems.

RAC inherited an especially strong program from ORO of basic research into quantitative methods for analyzing a wide variety of OR problems, particularly in the areas of mathematical programming and decision analysis. The term "think tank" was most appropriately applied to RAC at the time.

RAC's work also included economic, political and social science studies of problems arising outside formal military institutions. Most prominent were studies of public safety problems, the administration of justice and control of crime and delinquency, and economic and social development at home and abroad. These grew logically out of RAC's work for defense clients. Also prominent in RAC's work on military subjects were manpower and personnel. Problems in these areas took on new dimensions in the 1960s, under the impact of Vietnam, the draft, and the later shift to an all-volunteer army.

ORO had pioneered the study of military costs and cost analysis, war gaming and simulations, and strategic and limited war. RAC continued these efforts, improving methods and exploring further the possibilities for applying more sophisticated and powerful analytic procedures to the unfolding problems of the 1960s. RAC also conducted studies in arms control and disarmament. It inaugurated a broad range of politico-military analyses relevant to the needs not only of military planners, but also of those concerned with broader questions of national security.

When RAC took over from ORO, a program of advanced research studies was well under way and maintained momentum throughout most of RAC's existence. This continuation was not without conflict, both within the Army and within RAC, since there were serious differences of opinion about how much effort (if any) should be devoted to basic research, as opposed to applications of existing techniques that would be directly useful to the Army in the short run. At the outset, top Army officials decided that such a program was needed and suggested that it form about 10% of the total effort under the RAC-Army

contract. They felt it was necessary to explore ways in which advances in basic methodology might be used to deal with short-run problems. RAC's Advanced Research Group devoted considerable attention to applications, while it continued to make advances primarily in mathematical programming and decision analysis. Fiacco and McCormick's 1968 seminal book on nonlinear programming was a product of the Advanced Research Group.

RAC also conducted a number of studies in the areas of decision, utility, and cognitive theory. In total, these studies were aimed at a comprehensive understanding and theory of decision making at its various levels. In addition to client research applications, this work provided guidance for the establishment of a problem solving rationale within RAC.

In 1972, the General Research Corporation (GRC), a for-profit organization, bought RAC and partly took over its staff, physical assets, and contract relationships with the Army and other RAC clients.

Concluding Remarks

ORO and RAC were important elements of OR/MS history. It would probably be fair to say that their combined contributions played a major role in establishing operations research as a paradigm for rational decision making.

Operations Research Society of America (ORSA)

Founded in 1952, the Operations Research Society of America was the major U.S. society for operations researchers. It was merged with The Institute of Management Sciences (TIMS) into the Institute for Operations Research and the Management Sciences (INFORMS) effective January 1, 1995. The purposes of ORSA were (1) the advancement of operations research through the exchange of information, (2) the establishment and maintenance of professional standards of competence for work known as operations research, (3) the improvement of the methods and techniques of operations research, (4) the encouragement and development of students of operations research, and (5) the useful applications of operations research. During the period of its independent existence, ORSA published the journal *Operations Research* (in 42 volumes), as well as other journals (some jointly with TIMS). In addition, ORSA sponsored national meetings (jointly with TIMS), and other meetings organized by its technical sections and geographic chapters. It was the U.S. representative to International Federation of Operational Research Societies (IFORS).

Opportunity Cost

The cost associated with forgoing an opportunity; the money or other value sacrificed by choosing a nonoptimal course of action. In linear programming, the opportunity cost is the reduced cost of a variable not in the optimal basic solution. If a unit of a nonbasic variable is introduced into the solution, the optimal value of the objective function would decrease by an amount equal to the associated reduced cost.

See

- ▶ Linear Programming
- ▶ Prices
- ▶ Simplex Method (Algorithm)

Optimal Computing Budget Allocation

A statistical ranking and selection framework for choosing the best system design among a finite set of alternatives whose performance must be estimated, usually via simulation, with the objective of maximizing the probability of correct selection.

See

- ▶ Statistical Ranking and Selection

Optimal Control

Branch of engineering and applied mathematics dealing with optimization of a dynamical system in continuous time. Similar to dynamic programming, the (optimal) value function satisfies an optimality condition, the Hamilton-Jacobi-Bellman equation. For the special case of a linear time-invariant dynamical system with quadratic cost, an explicit solution for the optimal feedback control policy can be found by solving the Riccati equation.

Optimal Feasible Solution

For an optimization problem, an optimal feasible solution is a solution that satisfies all the constraints of the problem and optimizes the objective function.

Optimal Solution

- ▶ Optimal Feasible Solution

Optimal Stopping

Sequential decision-making problem under uncertainty in which a decision maker must decide when to stop observing a stochastic process, with the usual objective being to maximize a terminal reward (or minimize cost). Many practical OR/MS applications can be formulated as optimal stopping problems. A well-known example is the so-called secretary problem, in which an employer interviews potential candidates in succession and must decide when to stop the interviewing process and select one

to hire. In finance, the pricing of American options is a well-known class of optimal stopping problems. In discrete time, optimal stopping problems can be formulated as Markov decision problems, in principle solvable by dynamic programming.

Optimal Value

The best value that can be realized or attained; for a mathematical programming problem, the minimum or maximum value of the objective function over the feasible region.

Optimal Value Function

The optimal value of a mathematical programming problem as a function of problem parameters, such as objective function coefficients. Also the name given to the function satisfying the Bellman optimality equation in a Markov decision process or dynamic program, especially in a revenue/profit maximization problem; otherwise sometimes known as the optimal cost-to-go function for a cost minimization problem.

See

- ▶ Approximate Dynamic Programming
- ▶ Bellman Optimality Equation
- ▶ Markov Decision Processes
- ▶ Optimal Value

Optimality Criteria

Mathematical conditions used to test whether or not a given feasible solution is optimal in an optimization problem. Examples include the Karush-Kuhn-Tucker conditions for some nonlinear-programming problems; the simplex algorithm test applied to the reduced costs of the nonbasic variables for linear-programming problems; the Bellman optimality equation for dynamic programming, and the Hamilton-Jacobi-Bellman equation for optimal control.

- ▶ Bellman Optimality Equation
- ▶ Hamilton-Jacobi-Bellman Equation
- ▶ Karush-Kuhn-Tucker (KKT) Conditions
- ▶ Linear Programming
- ▶ Nonlinear Programming
- ▶ Simplex Method (Algorithm)

Optimization

The process of searching for the best value that can be realized or attained. In mathematical programming, this is the minimum or maximum value of the objective over the feasible region. Optimization without constraints is called unconstrained optimization.

See

- ▶ Mathematical Programming
- ▶ Nonlinear Programming
- ▶ Unconstrained Optimization

Optimization of Queues

The process of determining the optimal setting of a particular queueing system parameter. The optimization refers to the minimization or maximization of a cost function where the parameter (or parameters) of interest appear as variables.

See

- ▶ Queueing Theory

Option Pricing

In finance, finding the value of an option, a type of financial derivative.

See

- ▶ Financial Engineering

OR

Operations research or operational research.

OR/MS

Operations research and management science.

Ordinal Optimization

In the simulation optimization setting, an approach that exploits the property that it is easier to select the correct order among noisy measurements than to obtain precise estimates, i.e., ordering converges faster (exponentially) than estimation.

See

- ► Large Deviations
- ► Simulation Optimization

Organization

Richard M. Burton[1] and Børge Obel[2]
[1]Duke University, Durham, NC, USA
[2]Aarhus University, Aarhus, Denmark

Introduction

Organization studies encompass two areas: organization theory as a positive science to explain and understand the structure, behavior, and effectiveness of an organization; and organizational design as a normative science to recommend better designs for increased effectiveness and efficiency. Organization theory attempts to understand and explain; organizational design creates and constructs an organization.

Organizing behavior is evident in history from the earliest of recorded time. Ancient China was a highly organized society, a meritocracy with labor specialization. The Roman Empire, and in particular the Roman army, was efficiently designed. The modern organization is part and parcel to civilization, and its understanding fundamental to modern life. Not only is organization both timely and timeless, its study is basic in management science, political science, economics, sociology, business, and military science, to name a few. Organization study is interdisciplinary and central to all of social science. Scott and Davis's book (2006) is an extraordinarily comprehensive and lucid integrating review of the sociological approach to organization theory. It is a positive science review and considers organizational design only implicitly.

The great insight that management science brought to understanding organization is that the basic work of organization is information processing. The information processing perspective permits one to move easily from the positive view of organization to a normative view of what should be; that is, the way the organization deals with information can be modified. In a rough analogy, the nerve system, which channels information even more than the blood (energy carrier) or the skeleton (structure), provides the fundamental basis for understanding organization in modern life. Despite centuries of organization study, the organization as an information processor is a new insight of the twentieth century — even the latter half of the twentieth century. To study organization without information is analogous to studying the human body but ignoring the nervous system; it can be done, but much is lost, or ignored.

In this brief essay, the focus lies on the contribution of management science and operations research to the study of organization. A more formal description and definition of an organization will be given. Then, a number of management science theories, models, and methods are considered one. Finally, some alternative approaches to organization are briefly mentioned and what the future holds. Throughout, the management science literature is referenced which will provide a beginning point to pursue the issue in greater detail.

Organization as Information Processing

What is an organization? Definitions abound. All have certain elements in common. An organization is a created social entity which is composed of individuals (and machines) who must be coordinated to achieve its purpose. March and Simon (1958), in an early and perhaps the most influential book in modern organization studies, wrote (p. 4):

> A biological analogy is apt here, if we do not take it literally or too seriously. Organizations are assemblages of interacting human beings and they are the largest assemblages in our society that have anything resembling a central coordinative system. Let us grant that these coordinative systems are not developed nearly to the extent of the central nervous system in higher biological organism — that organizations are more earthworm than ape. Nevertheless, the high specificity of structure and coordination within organizations — as contrasted with the diffuse and variable rations among organizations and among unorganized individuals — marks off the individual organization as a sociological unit comparable in significance to the individual organism in biology.

March and Simon's organization examined attitudes, values, and goals and developed propositions about decision makers and problem solvers — a new organizational vocabulary to replace authority, responsibility, and span of control as organizing principles. They provided a new basis for thinking about organizing — the principle of bounded rationality (pp. 140–141):

> Most human decision-making whether individual or organizational, is concerned with the discovery and selection of satisfactory alternatives; only in exceptional cases it is concerned with the discovery and selection of optimal alternatives.

This is in contrast to the rational economic man whomakes optimal decisions in well-defined environments. The information processing model is a powerful metaphor of an organization which processes information to obtain coordination:

- Reads information, or observes the world,
- Stores information, or remembers facts and programs,
- Transmits information, or communicates among the members,
- Transposes information, or makes decisions.

These are the work tasks of the organization. Information processing includes choosing, decision making, and problem solving. At a very basic level, the work of an organization is symbol manipulation. Whether human or machine, the organization is rational only in a bounded sense, reaching less than optimal decisions with the less than perfect information available to it.

Coordination of decisions and their implementation is the fundamental problem. Team theory models (Marschak and Radner 1972) of organization were explicit mathematical models of multi-person organizations who had to make multiple decisions in the face of uncertainty — both uncertainty about the true state of nature and about the information and decisions of other team members. Better prediction, communications, and decision rules reduce the level of uncertainty and obtain more nearly optimal decisions. The team theory models explicitly incorporated information: reading, storing, communicating, and calculating. The best information scheme, or organizational design, balances the returns from nearly optimal coordinated actions and the costs of organizing.

The ship builder's problem is deceptively simple, yet fundamental (p. 132):

> Let a firm have two sales managers, each specializing in a different market for its product. Let it have two production facilities, one producing at low cost and another, more costly, to be used as a standby. This second facility can be visualized as a separate plant or as the use of the same plant at "overtime" periods, which involves higher wages. A conveniently simple case is offered by a shipyard firm with two docks (a new one and an old, less efficient one) and two markets ("East" and "West"). Each sales manager is offered a price for a ship to be delivered in his market. The prices offered in each of the two markets are the two state variables. (That is, the market prices have a priori known probabilities of high or low.) There are two decision variables, each of them taking one of two values: either accept or reject the order.

There are nine possible organizational designs about reading and communicating. For each case, there are decision rules which maximize the expected returns. Here are four of the possible designs:

1. No market information is gathered or communicated;
2. Both market prices are observed and communicated to a central headquarters;

3. Each market price is observed and a decision is made to accept the offer, or not; and
4. The market price is obtained in one market and sent to a central headquarters, but not in the other.

The best design depends upon the returns from better information and cost of observing, communicating, and choosing. The costlier the observations, the fewer the observations. The costlier communications are, the more decentralized the organization. The decision rules depend upon the information available.

Information processing is a core issue. March and Simon begin with the boundedly rational individual and build implications for the organization. Marschak and Radner take a number of perfectly rational individuals who are bounded rationally as a team because of the limited and costly information available, that is, imperfect information at the right time for the right person.

Focusing directly on organizational design, Galbraith (1974) assertively conjectured that the principal managerial task is to reduce uncertainty by processing information: "A basic proposition is that the greater the uncertainty of the task, the greater the amount of information that has to be processed between decision makers during the execution of the task" (p. 28).

Following March and Simon, Galbraith (p. 29) offered three mechanisms to obtain greater coordination among the decision makers:

1. If coordination by rules or programs: operational contingent rules can be stated in "if-then" terms; for example, if the inventory stock is less than four, then reorder ten items. Programs are compositions of large numbers of rules;
2. Hierarchy: with greater uncertainty and no rules, exceptions and new situations are referred up the hierarchy for resolution. (This is a rule itself; *if* there is great uncertainty and no rule about what to do, *then* refer the issue up the hierarchy.); and
3. If coordination by targets or goals: here the rules may be largely unspecified but the desired ends or goals can be stated. Subgoals are developed to obtain coordination among the units.

Adding to these organizational design alternatives, Galbraith (p. 30) then offered four information processing strategies. The first two reduce the need for information processing by creating slack resources (for example, excess personnel to complete a task) and self-contained units; that is, small quasi-independent units. Alternatively, increased information processing capacity can be obtained by investing in vertical information systems, for example, MIS; or by creating lateral relations; that is, the genesis of the matrix organization (Galbraith 1995). Each organizational design alternative is developed and its appropriateness rationalized on the need for information to coordinate activities in the face of uncertainty.

Building upon these ideas, Burton and Obel (1980, 1984) formally modeled a hierarchical, decentralized organization using a Dantzig-Wolfe decomposed linear program – a model of who does what based upon what information. It is an explicit multi-agent information processing model for observing, storing, transferring, and decision making – based upon bounded rationality and localized information among the agents. Divisional units pass up local planning information to the headquarters unit, which evaluates these plans and sends revised guidance on limited resource costs to the units. To replicate actual planning systems, only a very few iterations are permitted prior to implementation. Research questions focus on which organizational design – that is, information and decision making system in the spirit of team theory – would yield the best performance in the face of uncertainty. The empirical results verify Williamson's M-form hypothesis that a divisional organization yields better performance than a functional organization – without invoking opportunism or information misrepresentaion by the divisional agents. The power of this approach is to test alternative organizational designs and the way information is handled in an organization to assess which alternative is more efficient. In a second experiment, these mathematical computer simulations were modified for laboratory experiments (Burton and Obel 1988) to investigate the importance of opportunism; that is, whether individuals give misleading information to better their own situation at the expense of others and the organization as a whole. Indeed, some will behave opportunistically, but the M-form suffered less due to opportunism than the functional U-form. These computational and laboratory studies are

controlled experiments to investigate basic hypotheses in organizational design. The models are explicitly information processing where the individuals in the models face an uncertain environment, are bounded rationally, have limited information, and can behave opportunistically. The first model confirmed the M-form hypothesis without invoking opportunism; the second laboratory study again confirmed the hypothesis invoking opportunism.

More recently, Mihm et al. (2010) modeled hierarchy using an NK approach (where N is the number of variables and K is the degree of dependency among the variables), finding that: assigning a lead function speeds up the problem solving; local search should be delegated to the lowest level; and structure matters less in the middle than the front line, which should be kept small.

These later studies provide a transition to computational modeling of organizations – their decision-making and information processes.

Computational Organization Theory

Computational approaches or simulation offers a complementary approach to the study of organization. In launching a new journal, *Computational and Mathematical Organization Theory*, Carley (1995) outlined how computational methods can be applied to better understand organizations – to develop theory and improve practice. Computational models are frequently complicated but mathematically ill-formulated, and hence do not lend themselves to analytical closed-form solutions. As such, simulation is a very powerful approach to investigate complex phenomenon without the need for inappropriately simplifying assumptions. Computational models are usually explicit in their modeling of organization as an information processing task. On the other hand, computational models can be made too complicated, beyond the purpose or the question at hand. Burton and Obel (1995) argue that a good computational model is a parsimonious balance of the purpose, the model, and the experiment. They outline the role of computational modeling in theory development, suggesting and testing simple mechanisms, testing limits and boundary conditions, developing alternative explanations, and more generally exploring with what-might-be models to develop insight and develop a better understanding of organizations and organizing. In the discussion below, a number of computational models are commented on which are parsimonious and balance complexity and simply of purpose. These applications are varied in nature – ranging from the behavioral theory of the firm to organizational design in NASA.

Computational organization models were pioneered by Cyert and March (1963) and related studies which helped in the development of the behavioral theory of the firm. The store-buyer model and oligopoly model were early applications which confirmed the idea that simulation models could be used both for real-world application and theory development. In short, computational models are laboratories (Burton and Obel 2011) for studying organizations and how they work.

Cohen et al. (1972) developed a "garbage can model" of organizational choice. They, too, began with observing how organizations (here, educational institutions) choose, or make decisions. Their discovery was a process in marked contrast to the normal scientific method which gathers data, defines the problem, lists the alternatives, chooses the best one, and then implements it. Rather, the organization was a garbage can of an unordered set of choices looking for problems; issues and feelings seeking forums for airing; solutions looking for issues; and decision makers looking for work. They translated these observations into an explicit computer simulation model and were able to verify and explain a number of observations. Can such an organization or super-bounded rationality ever accomplish anything? Perhaps surprisingly, yes! One conclusion is that "important problems are more likely to be solved than unimportant ones" (p. 10). This much is reassuring – indeed, such organizations can and do function and can be quite effective. Information is used in very complex ways. Their simulation model was devised to explain and understand these very complex organizational processes; nonetheless, the model itself is parsimonious.

Individuals or organizations learn how to update these routines through experience, including sampling experience, which can be biased. March (1991) introduced two contrasting learning strategies: explore and exploit. He demonstrates that exploitation is more likely to be beneficial in the short run, but self-destructive in the long run. Exploration is not as

beneficial in the short run, but can yield strategies that are viable for the longer run. Each strategy has benefits and risks for the learner. The concept of a slow learner (one that adapts gradually to the code) and the result that a slow learner can yield better outcomes for exploration is perhaps counterintuitive. The fast learner adapts too quickly to realize exploratory behavior and thus puts the organization at risk. These notions have inspired extensive research in organizational learning and strategy – both related computational models and empirical studies. With these computational models, the theory of organizational learning is advanced.

Carley and Prietula (1993) have utilized computational organization theory as a complement to deductive analytical modeling and field-based empirical study, again an information processing perspective. Carley et al. (1992) generalized the SOAR model. SOAR models simulate goal-driven search behavior through problem spaces. SOAR acts through a series of decision cycles which include working memory, permanent memory of if-then production rules, and a preference memory. The task is the retrieval of requested warehouse items involving multiple agents. Carley and Lin (1995) investigated information distortion effects in the SOAR environment. More recently, Carley and Prietula (1998) introduced the concept of a WebBot – a critter which does information work, but can also display more human characteristics, such as trust.

Burton and Obel (2004) and Baligh et al. (1996) have devised the Organizational Consultant. It is a knowledge-based expert system which uses what is known from organization theory and executive experience. The Organizational Consultant then asks questions about the specific organization and, utilizing the knowledge base, diagnoses the organization and offers design recommendations. The Organizational Consultant is a computational model in that data or situational facts are analyzed in order to make specific recommendations or a solution. It is not a numerical calculation; the model is a set of some 300 if-then statements which examine the data in order to develop the design recommendation. A broad range of organizations and case studies have been devised to validate the approach. It is an explicit normative model of organizational design. In the spirit of computational modeling, Baligh (2005) developed a process of design that is systematic; it uses the algebra of decision rules. He defines an organization structure as a set of people connected by decision rules. These are mappings of which an element is of the form (If A, choose (do) one of the elements of B), where A represents a circumstance and B a set of possible decisions. Each rule has a set of makers and a set of users. Different rules and different sets of rules describe many different structures, including all those mentioned above. Decision rules identify their own information needs, and design decisions must consider the returns to decision rules and the costs of the information they require.

Levitt et al. (1994) built a multi-agent network model (SimVision) of a project organization. One purpose is to predict the duration of the project. A second more important purpose is to bring understanding and insight into the management process itself. Managerial bottlenecks become evident in the model before they are realized on the job. The model is an information-processing model of an organization: tasks, agents, communications, tools, and structure. The agents are boundedly rational. Each agent manages in an information-rich environment. The computer processes the set of tasks for a network project – a 3-year petroleum refinery design project. Their experiment compares the decentralized and centralized organizations, and voice mail and no voice mail. Decentralization reduces the total work-days, and voice mail reduces the total effort. The more general purpose and application is to predict managerial problems for the organization and then to devise means to prevent the difficulties rather than create and realize difficult and costly situations for the organization. Jin and Levitt (1996) elaborated on the model's relation to contingency theory and the model's validation.

In a related real-world application, NASA began with a clear purpose to design a high-level multi-location project organization (Carroll et al. 2006). The goal was to determine what should be the project design, with the stipulation that it must be closely related to the current practice and an examination of other what-might-be alternatives. They utilized three different simulation tools to help them develop alternative organizational designs and assess their projected performance. In their triangulation approach, the NASA design team began with DSM (design structure matrix) to map the

information processing or communications and coordination structure of existing and proposed organizations to gain insights about the issues and challenges. Then, applying the OrgCon, an expert system of design rules, and using a top-down approach, the design team examined a large number of what-might-be alternative design tradeoffs and their projected consequences. Finally, using a micro bottoms-up approach for the project and the requirements, they developed a what-should-be SimVision model of the proposed organization. The triangulation of the three approaches served multiple practical purposes for NASA. They had multiple views of the problem, which gave them greater understanding. They also had greater confidence in the recommended design, as it was embedded in current practice and the examination of several alternatives and their implications.

Using an NK agent-based model, Siggelkow and Levinthal (2003) examine performance when the competitive landscape shifts. A temporary decentralization – a form not found in the literature – performs best. As interactions across and within divisions increase, the optimal length of decentralized exploration tends to grow. It is a deeper examination of dynamic relations of a what-might-be situation in order to generate a more nuanced theory. Siggelkow and Rivkin (2005) demonstrate that ample processing power at the bottom of the firm can slow down improvement and narrow overall search by the firm – initially a counterintuitive result. The results are stated as hypotheses that can be tested in other settings. Ethiraj and Levinthal (2009) found that incomplete guides to action prove more effective at directing and coordinating behavior than more complete representations. Fewer goals provide clarity and focus for boundedly rational actors. In these what-might-be studies, insights and some counterintuitive results are found that extend understanding.

The Future

The management science information perspective described above remains a base for the future – after all, information processing is fundamental to what an organization does. Daft and Lewin (1990), in launching a new journal, *Organization Science*, began with a provocative question: "Is the field of organization studies irrelevant?" Where is the audience in business and government? What does it mean to be "relevant?" Perhaps relevancy is developing a better understanding of the future, but not necessarily predicting what will happen. What-might-be studies which explore new ideas and possibilities, investigate mechanisms, alternative plausible explanations, boundaries, limits of explanations are the future. Knowledge from diverse sources and multiple perspectives should be encouraged, given the complexity of organization. No one method or approach can reveal complete understanding – it takes multiple views. Computational modeling can be a very important approach. Organizational design includes the organization processes of culture, decision making, information processing, CEO values, and style, at least. They conclude with a challenge for a new era in organization studies which upholds the rigor of scientific inquiry and embrace multiple perspectives and approaches. In a very short life, *Organization Science* has answered the challenge.

The focus here has been on the information processing view of organization studies, i.e., the nerve system and brain functions of organization. Other perspectives can be found in the journals *Management Science, Organization Science*, and *Computational & Mathematical Organization Theory*, among others.

Out-of-Kilter Algorithm

A special primal-dual algorithm for solving minimum-cost network-flow problem.

See

► Minimum-Cost Network-Flow Problem

Output Process

The stochastic point or marked point process whereby the marks represent some aspect of the queueing customers or the state of the service stage or node and the points represent the times of customers leaving the server. This is contrasted with the departure process, which requires that the customers leave the entire queueing system for good. For example, in queues with feedback, the output process includes both the departure and feedback processes.

See

► Departure Process
► Networks of Queues
► Queueing Theory

Outside Observer Distribution

The probability distribution of the state of a queueing system at an arbitrarily chosen point in time, as opposed to what it would be at arrival or service-completion epochs. For queueing systems with a Poisson arrival process and exponentially distributed service times, all these steady-state distributions are the same.

See

► PASTA
► Queueing Theory

Overachievement Variable

A nonnegative variable in a goal-programming problem constraint that measures how much the left-hand side of the constraint is greater than the right-hand side.

See

► Goal Programming

Overflow Process

The stochastic marked point or point process of customers arriving to a queueing service center or node but not receiving service there. For example, the arrival process is composed of two stochastic processes, those gaining access to the server (i.e., the input process) and the overflow process of those not gaining access to the server. These distinctions are needed to model finite capacity-nodes.

See

► Arrival Process
► Input Process
► Queueing Theory

Overtaking

In queueing networks with alternate paths, the ability of customers leaving a node to use arcs to move ahead of customers not taking those arcs so as to arrive at a subsequent node ahead of customers they were previously behind. This can also occur for customers on the same path if a visited node has multiple servers, since a customer who started service later than other customers there could be served more quickly and thus pass some of those other customers.

P

P_4

Partitioned preassigned pivot procedure. A procedure for arranging the basis matrix of a linear-programming problem into as near a lower triangular form as possible. Such an arrangement helps in maintaining a sparse inverse, given that the original data set for the associated linear-programming problem is sparse.

See

- ▶ Linear Programming
- ▶ Revised Simplex Method

Packing Problem

The integer-programming problem defined as follows:

$$\begin{aligned} &\text{Maximize} \quad \boldsymbol{c}^T\boldsymbol{x} \\ &\text{subject to} \quad \boldsymbol{E}\boldsymbol{x} \leq \boldsymbol{e} \end{aligned}$$

where the components of $\boldsymbol{E}$ are either 1 or 0, the components of the column vector $\boldsymbol{e}$ are all ones, and the variables are restricted to be either 0 or 1. The idea of the problem is to choose among items or combinations of items that can be packed into a container and to do so in the most effective way.

Parallel Computing

Jonathan Eckstein
Rutgers, The State University of New Jersey, Livingston Campus, New Burnswick, NJ, USA

Introduction

Parallel computing is the use of a computer system that contains multiple, replicated arithmetic-logical units (ALUs), programmable to cooperate concurrently on a single task. Between 2000 and 2010, parallel computing underwent a sea change. Prior to this decade, the speed of single-processor computers advanced steadily, and parallel computing was generally employed only for applications requiring more computing power than a standard PC processor chip could deliver. Taking advantage of Moore's Law (Moore 1965), which predicts the steady increase in the number of transistors that can be packed into a given chip area, microprocessor manufacturers built processors that could execute a single stream of calculations at steadily increasing speeds. In the 2000–2010 decade, Moore's law continued to hold, but the way that chip builders used the ever-increasing number of transistors began to change. Applying ever-larger number of transistors to a single sequential stream of instructions began to encounter diminishing returns, and while smaller transistors enabled increasing clock

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

speeds, clock speeds are limited by energy consumption and heat dissipation issues. To use the ever-increasing number of available transistors, processor designers began placing multiple processor cores, essentially multiple processors, on each CPU chip. In the laptop and desktop markets, processors with four cores are now common, and CPU chips with only a single processing core are now rare. Thus, parallel processing is no longer only an effort to advance over the power available from mainstream computing platforms such as desktop and laptop computers; it has now become an integral part of such mainstream platforms.

Kinds of Parallel Computers

The taxonomy of Flynn (1972) classifies parallel computers as either SIMD (Single Instruction, Multiple Data) or MIMD (Multiple Instruction, Multiple Data). In SIMD architectures, a single instruction stream controls all the ALUs in a synchronous manner. In MIMD architectures, each ALU has its own instruction stream and its own instruction decoding hardware. The two approaches are not mutually exclusive: an approach sometimes called MSIMD (Multiple SIMD) combines multiple blocks of SIMD processors, with each block having its own instruction stream. There was active competition between SIMD and MIMD through the 1980s, but MIMD emerged as the clear winner in the 1990s. SIMD, however, has been staging a quiet resurgence in the form of GPUs (Graphics Processing Units), which typically have an MSIMD organization, as discussed below. Some confusion surrounds the term SIMD, as processor manufacturers also apply it to certain graphics-oriented special machine instructions that process blocks of data. These instructions are not necessarily completely parallel in the classic sense, but instead may simply take advantage of pipelining techniques to achieve higher utilization of ALU hardware than for standard scalar-operand instructions.

Another important distinction is between local and shared memory. In pure local-memory architectures, each processor has its own memory bank, and information may be moved between different processors only by messages passed through a communication network. On the other end of the spectrum are pure shared-memory designs, also called SMPs (Symmetric MultiProcessors), in which there is a single global memory bank that is equally accessible to all processors. Such designs provide performance and ease of programming for small numbers of processors, and are currently the most common, since they are used in desktop- and laptop-level multicore processor chips. In a more powerful server or workstation, two or more processor chips, each with four to six processor cores, share a single global memory. As with MIMD and SIMD, it is also possible to blend global and local memory approaches. For example, a system might be composed of dozens or hundreds of processing nodes, each node consisting of two to twelve processor cores sharing a single memory bank.

In large-scale systems without global memory, it is not generally practical to provide a dedicated connection between every pair of processors. Popular interconnection patterns include rings, grids, meshes, toroids, butterflies, and hypercubes. In academic circles, there has been an extensive debate on the merits of various interconnection topologies. However, the details of the interconnection pattern may not be critical for the kinds of parallel computers that currently exist, which generally range in size from a few processing nodes to thousands of nodes. At such scales, the critical considerations are the speed of the interconnection links, the overhead and latency associated with communication, and elementary non-interference properties. Non-interference means that sending a message from processor *A* to processor *B* should generally not interfere with processor *C* sending to processor *D*.

One way to construct a parallel computing system is simply to combine standard desktop or workstation computers, an approach known as a cluster or CoW (Cluster of Workstations). However, the local-area networks that usually connect such systems may significantly limit performance for some applications. Faster, special-purpose communication networks such as Myrinet or Infiniband may be used to improve the performance of dedicated cluster systems. Cooling and energy consumption can become significant limiting factors in constructing large CoW systems, and are also important design considerations in building higher-performance parallel supercomputers.

Another approach is to assemble ad hoc parallel systems from the background or off-hour capacity of collections of desktop computers, an approach known

as grid computing, a term meant to invoke an infrastructure of computing resources resembling the electric power grid. This approach requires no special hardware, but does need specialized software such as the Condor scheduling system (Litzkow et al. 1988). Communication between instruction streams can be particularly slow in such environments, however, and algorithms must be fault tolerant, i.e., resilient to processors unpredictably disappearing from the available pool, possibly in mid-computation.

A nascent trend is GPU computing (Owens et al. 2008). The demands of ever-more sophisticated animation, driven mainly from the personal computer gaming industry, have led graphics adaptors to evolve into special-purpose parallel computing engines, often far more powerful in terms of floating point operations per second (flops) than their host processors. Modern graphic processors typically have an MSIMD structure, consisting of independent blocks of SIMD processing units. Consumer level GPUs typically contain hundreds of ALUs, at a cost of a few dollars each. In GPU computing, one uses GPU hardware for other purposes than graphics processing. Graphics processors typically have a global memory with a high bandwidth connection to their processors, but this memory is often distinct from main CPU memory.

Programming Models

The primary distinction among styles of parallel computer programming is between data-parallel and control-parallel specification of concurrency. In the data-parallel model, also called SPMD (Single Program Multiple Data), the program essentially specifies a single thread of control, but individual statements may manipulate large arrays of data in an implicitly parallel way. For example, if A, B, and C are arrays of the same size of shape, the statement $A = B + C$ might replace each element of A by the sum of the corresponding elements of B and C. Responsibility for portions of each array is typically partitioned between multiple processors, so they divide the work and perform it concurrently. Communication in data-parallel programs is typically invoked through certain standard intrinsic functions. For instance, the expression $SUM(A)$ might represent the sum, across all processors, of all A's elements, computed by whatever algorithm is optimal for the current hardware.

Data-parallel languages were originally developed for SIMD architectures, but data-parallel and SIMD are not synonymous. MIMD systems may be programmed in a data-parallel manner when it suits the application at hand. Currently, the most prevalent data-parallel programming language is High Performance FORTRAN, or HPF (Koelbel et al. 1993). HPF has its roots in FORTRAN 90 (Metcalf and Reid 1990).

In control-parallel programming, the programmer specifies a distinct thread of control for each processing unit capable of one. Often, each processing unit has the same program, but takes a completely different path through it. If shared memory is available, threads may communicate via memory, using mechanisms called locks or critical sections to prevent simultaneous or inconsistent writes to the same location. Otherwise, threads must communicate by sending and receiving messages, a style called message passing. Note that shared-memory systems may also be programmed in a message-passing style, allowing for relatively straightforward migration to larger, non-shared-memory systems. Control parallel programs are typically written in standard sequential programming languages such as C, C++, or FORTRAN, handling messages and memory interlocks via special subroutine libraries. For message passing, the principle standardized, portable subroutine libraries are based on the MPI standard (Snir et al. 1996). At least three open-source implementations of MPI are available, and system manufacturers and integrators often provide their own optimized implementations.

For shared-memory programming, common standards include Posix threads (Butenhof 1997), in which a process spawns new threads by calling special operating system routines, and OpenMP (Dagum and Menon 1998), in which parallelism is specified by special compiler directives intermixed with standard code from the underlying C, C++, or FORTRAN language. Another alternative is Cilk (Blumofe et al. 1995; Leiserson 2009), which extends the standard C and C++ languages with new parallelism-specifying syntax.

It is generally accepted that control-parallel programs are harder to analyze, understand, develop, and debug than data-parallel programs, due to complicated race and deadlock conditions that can easily develop between threads. On the other hand,

the data-parallel programmer must sacrifice significant flexibility. Data parallelism is most readily applied to problems that require large, extremely regular array data structures. Irregular, sparse data structures are more the norm in operations research, and hence most of the field's successful applications of parallel computing have employed control parallelism.

Control-parallel programs can also exhibit nondeterminism: run twice on the same data, they may obtain different solutions or exhibit very different run times. Such effects occur because small differences in the timing of events may cause control-parallel programs to take complete different execution paths (serial programs that base branching decisions on measurements of clocks or timers may exhibit similar behavior). Such nondeterminism can typically be controlled and essentially eliminated, but sometimes at significant cost in performance.

Speedup, Efficiency and Scalability

If T_p is the time to solve a give problem using p processors, and T_1 is the time to solve the same problem with a single processor (using the best sequential algorithm, if it can be defined), then a key concept is speedup, defined to be $S_p = T_1/T_p$. Efficiency is then defined to be S_p/p, or, roughly speaking, the effectively used fraction of the raw computing power available. The main goal of parallel algorithm designers is to obtain *linear* speedups that grow roughly linearly with p, or, equivalently, efficiencies that do not approach 0 as p increases. In principle, speedups cannot be above linear and efficiencies cannot exceed 1; in practice, such effects can sometimes occur for specific problem instance because the "best" sequential algorithm for a particular problem is not always easily defined. In a search problem, for example, a run of a parallel algorithm might explore early in its history a portion of the search space that a standard serial implementation might not encounter until the later portions of its execution. If this portion of the search space contains the problem solution, an apparently superlinear speedup may result.

A key motivation for using parallel computing is to solve ever-larger problems. Thus, rather than concerning oneself with obtaining very large speedups for a fixed-size problem, it may be more important to study the effect on total solution time as the problem data and number of processors grow in some proportional or related way. This concept is called scalability (Kumar and Gupta 1994).

Applications in Operations Research

Parallel computing is taking an increasing role in operations research, but it has not had nearly the effect on the practice of the field as it has, for example, in computational fluid dynamics. This phenomenon is due largely to the lack of efficient parallel methods for factoring and related operations on irregularly structured sparse matrices. Such operations are essential to the sparse active set and Newton methods that form the core of operations research's numerical optimization algorithms. However, successes have been reported for specially structured problems amenable to decomposition methods, including stochastic programming — see for example Gondzio and Grothey (2007) — and on dense problems. Parallelism has also proved very useful in branch-and-bound and related search algorithms, and in a variety of randomized algorithms.

Currently, the leading vendors of linear/integer-programming software all offer some form of parallel branch-and-cut implementation for solving mixed integer programs; such implementations are typically for shared-memory systems; some are deterministic, others nondeterministic, and some offer the option of either a deterministic or nondeterministic mode. Some software vendors also offer parallel interior point linear-programming software, although speedups in pure linear programming are less dependable than for branch and bound.

Parallel open-source software for operations research operations research is becoming increasingly available. Several projects in the COIN-OR collection (Lougee-Heimer 2003) are aimed at parallel computing (typically through MPI), and several others offer the option of parallel execution.

Simulation applications with many independent trials or scenarios are also natural applications for parallel computing. A general principle seems to be that one should take advantage of problem structure to localize troublesome operations, most typically sparse matrix factorization, onto individual processors.

Another approach is to try radically new algorithms that avoid such operations completely, and are highly parallelizable. One should remember, however, that parallelism is not a panacea that can easily make inappropriate or "brute force" methods competitive.

Early references on the relationships between parallel computing and OR/MS include Barr and Hickman (1993) and Eckstein (1993).

Parameter

A quantity appearing in a mathematical model that is subject to controls beyond those affecting the decision variables.

Parameter-Homogeneous Stochastic Process

A stochastic process in which distribution properties between the two index parameter points t_1 and t_2, $t_1 \leq t_2$, depend only on the difference $t_2 - t_1$, and not on the specific values of t_1 and t_2. In the many applications where the parameter set is time, whether discrete or continuous, it is called a time-homogeneous stochastic process.

Parametric Bound

An optimal value function or solution point bound as a function of problem parameters.

Parametric Linear Programming

In the general linear-programming problem of

$$\begin{aligned} \text{Minimize} \quad & \boldsymbol{c}^T\boldsymbol{x} \\ \text{subject to} \quad & \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b} \\ & \boldsymbol{x} \geq 0 \end{aligned}$$

it is often appropriate to study how the optimal solution changes when some of the data are functions of a single parameter λ. Most mathematical programming systems allow parametric analysis of the cost coefficients (PAROBJ), the right-hand-side elements (PARARHS), joint analysis of the objective function and right-hand-side elements (PARARIM), and the parametric analysis of the data in a row (PARAROW).

Parametric Programming

Tomas Gal
Fern Universität in Hagen, Hagen, Germany

Introduction

The meaning of a parameter as used here is best explained by a simple example. Recall that a parabola can be expressed as follows: $y = ax^2$, $a \neq 0$. Setting $a = 1$, a parabola is obtained that has a different shape from the parabola when setting, for example, $a = 5$. In both cases, however, there are parabolas that obey specific relationships; only the shapes are different. Hence, the parabola $y = ax^2$ describes a family of parabolas and the parameter a specifies the shape.

Consider the general mathematical-programming problem:

$$\text{Max } z = f(\boldsymbol{x}) \tag{1}$$

$$\text{subject to } g(\boldsymbol{x}) \leq 0 \tag{2}$$

Introducing one or more parameters into f or g, the model stays the same, but for each value of the parameter(s) one obtains a specific problem.

In setting up a mathematical optimization model, one of the first tasks is to collect data. The collected data might, however, be inaccurate, be of a stochastic character, be uncertain or be deficient in other ways. Therefore, it is appropriate to introduce parameters that enable to analyze the influence of specific data elements on the optimal solution. This can be done by:

1. Introducing the parameter(s) at the beginning when setting up the model, or
2. Introducing the parameter(s) after an optimal solution has been found.

The latter case is called postoptimal analysis (POA) and is applied much more frequently than the first case.

Postoptimal analysis is a very important tool that should be used in the framework of a good report generator (Gal 1993). The corresponding decision maker (DM) would then have information with which the DM can select a firm optimum. POA consists of several analyses, the most important of which is sensitivity analysis (SA). A sort of extended SA is parametric programming (PP). In nonlinear programming, SA corresponds to perturbation analysis, in which, after having found an optimal solution, some of the initial data are perturbed and the influence of the perturbation on the outcome is analyzed (Drud and Lasdon 1997).

Historical Sketch

Advanced methods for SA and PP for linear programming have been developed. In the 1950s, Orchard-Hays (in his master's thesis), Manne (1953), Saaty and Gass (1954), Gass and Saaty (1955) published the first works on parametric programming. By the end of the 1960s, the first monograph on parametric programming appeared (Dinkelbach 1969), followed by the monograph and book by Gal (1973, 1979). In 1979, the first Symposium on Data Perturbation and Parametric Programming was organized by A.V. Fiacco in Washington, D.C., with such a symposium being held every year since. (From 1999, Adi Ben Israel has been the organizer). Several monographs (Bank et al. 1982; Guddat et al. 1991) and special journal issues have been published in the 1970s and 1980s. More details on the history of PP are given in Gal (1980, 1983). A bibliography with over 1,000 items is given in Gal (1994b); see also Gal and Greenberg (1997).

Postoptimal Analysis

Assume that the mathematical optimization model under consideration is a linear program of the form:

$$\text{Max } z = \boldsymbol{c}^T \mathbf{x} \tag{3}$$

$$\text{subject to } \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b}, \ \ \boldsymbol{x} \geq \boldsymbol{0} \tag{4}$$

where $\boldsymbol{c}$ is an n-vector of objective function coefficients (OFC) c_j, x is an n-vector of the decision variables x_j, $\boldsymbol{A}$ is an $m \times n$ matrix of the technological coefficients a_{ij}, $m < n$, $\boldsymbol{b}$ is an m vector of the right-hand-side (RHS) elements b_i. All vectors are column vectors.

Suppose that the problem defined by (3) and (4) has an optimal basic feasible solution $x_{\boldsymbol{B}} = \boldsymbol{B}^{-1}\boldsymbol{b}$, where $\boldsymbol{B}^{-1}$ is the inverse of the $m \times m$ basic matrix $\boldsymbol{B}$ (the basis) consisting of m linearly independent columns of $\boldsymbol{A}$. Here, $x_{\boldsymbol{B}}$ is an m-dimensional solution vector. This means that the following solution elements and simplex method elements are determined:

1. The maximal value of the objective function (OF), $z_{\max}$,
2. The values of the basic variables $x_i, i = 1,\ldots, m$, and
3. The reduced costs $d_j = z_j - c_j, j = 1,\ldots, n$.

In the framework of POA, an evaluation of the above solution elements is to be performed. This means that the DM is provided with information about the meaning of the values of the basic variables, the DM is told which resources are used and are critical (values of slack variables), and interpret the values of the opportunity costs and shadow prices. It is also possible to carry out a suboptimal analysis, that is, show the DM what happens if one or several nonbasic variables were introduced into the solution at a positive level.

Sensitivity Analysis

The POA would continue by performing a SA with respect to the OF and the RHS. This analysis is usually a part of the solution output for just about all linear-programming software. It is called OFC-ranging and RHS-ranging, respectively. Behind such analyses is the introduction of a scalar parameter, t or λ, in the form

$$c_j(t) = c_j + t, \ j \text{ fixed} \tag{5}$$

or

$$b_i(\lambda) = b_i + \lambda, \ \ i \text{ fixed} \tag{6}$$

SA finds a critical interval T_j or Λ_i, such that for all $t \in T_j$ or $\lambda \in \Lambda_i$, respectively, the (found) optimal basis $\boldsymbol{B}$ remains the same (so called optimal basis invariancy. For other kinds of invariancies see, e.g., Hladik 2010; Hadigheh et al. 2007). The critical values, that is, the upper and lower bounds of the critical interval can be easily determined by certain formulas (Gass 1985). A change in a RHS element b_i causes, in general, the values of the basic variables and the value of $z_{\max}$ to change, while a change in an OFC c_j causes, in general, the values of the reduced costs and the value of $z_{\max}$ to change. Such information is of great value to the DM. An assumption of this type of SA is that to investigate how the optimal solution would vary with respect to a change in one data element, while holding all other data fixed. Analysis of multiple changes can be done in a limited manner by the techniques of the hundred percent rule (Bradley et al. 1977) and tolerance analysis (Ashram 2007; Filippi 2005; Hladik 2008a, b; Wendell 1985, 2004).

Parametric Analysis

For an element b_i of the RHS, the question is asked: for what range of values of the parameter λ in (6) does there exist an optimal solution to (3) and (4)? Given such values, one can move from the original optimal basis and generate a sequence of optimal bases, with each basis associated with a critical interval of the parameter. Such an analysis provides the DM with a full range of possible solutions from which a subset of optimal solutions appropriate for the given problem can be selected. The DM then chooses a certain value of the parameter and, thus, a corresponding optimal solution for the parametric range of b_i (λ).

Note that a similar analysis can be performed with respect to the parametric OFC, as given by (5). Moreover, taking into account the possibility that a parameter introduced in the RHS may influence some (or several) OFC or vice versa, it is possible to perform a RIM parametric analysis, that is, find a sequence of optimal bases to each of which a critical interval for the RHS-and for the OFC-parameters are

associated simultaneously. Standard RHS, OFC and RIM parametric analysis procedures are usually included in linear-programming software.

It is also possible to perform a sensitivity or parametric analysis with respect to the elements a_{ij} of the matrix $\boldsymbol{A}$. The corresponding procedures are, unfortunately, not incorporated into linear-programming software as the underlying formulas are a bit too complex. However, some software enables one to compute a series of linear programs in each of which slightly changed values of the $\{a_{ij}\}$ are chosen.

Up to now, the simplest parametric case having one parameter with a coefficient equal to 1 has been discussed. The above cases can, however, also be carried out when:

(i) A scalar parameter is introduced into several elements of the RHS and/or OFC with coefficients which differ from 1, and

(ii) A parameter-vector (vector of parameters) is introduced into several elements of the RHS and/or OFC with their respective coefficients different from 1.

As far as case (i) is concerned, to each optimal basis a critical interval is associated. In case (ii), each optimal basis is associated with a higher dimensional convex polyhedral set of parameters. In the RIM case, each optimal basis is associated with a higher dimensional interval, a box, provided that the parameters in the RHS and OFC are independent from each other. The larger the number of parameters in the parameter-vector, the more difficult it is to interpret the results and for the DM to find an appropriate optimal basis. In such cases, an interactive approach is recommended in which the parametric specialist helps the DM to select an appropriate solution.

Applications

There are two kinds of uses of PP:

1. Introducing parameters into various classes of mathematical-programming problems for solving these problems via parameterization; and
2. Practical applications.

As to (1), the introduction of parameters helps to solve problems from the areas of nonconcave mathematical programming, decomposition, approximation, and integer programming. Also, note that by replacing the OFC in (3) and (4) with a matrix $\boldsymbol{C}$ times a parameter-vector $\boldsymbol{t}$ the following problem is obtained

$$\begin{aligned} &\text{Max } z = (\boldsymbol{C}^T\boldsymbol{t})\boldsymbol{x}, \\ &\text{subject to } \quad \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b},\ \boldsymbol{x} \geq \boldsymbol{0} \end{aligned}$$

which is a scalarized version of a linear multiobjective-programming problem (Steuer 1986). Methods for solving the corresponding homogeneous multi-parameter-programming problem provide a procedure to determine the set of all efficient solutions of the corresponding multiobjective problem (Gal 1994b).

As to (2), SA and/or PP has been used in the pipeline industry, in capital budgeting, for farm decision making, refinery operations, for return maximization in an enterprise, and a number of other applications (Gal 1994b).

SA and PP in Other Fields

Theoretical and methodological works have been published about SA and/or PP in linear and nonlinear complementarity problems, control of dynamic systems, fractional programming, geometric programming, integer and quadratic programming problems, transportation problems. A more detailed survey with corresponding references is given in Gal (1994b) (1988), see also, e.g., Ravi and Wendell (1988), Hladik (2008b), Dawande and Hooker (2000), Faisca et al. (2009), Kheirfam (2010).

Degeneracy

Recall that a basic feasible solution to a linear-programming problem is called primal degenerate when at least one element of this solution equals zero. The corresponding extreme point of the feasible set, that is, of the convex polyhedron, is then also called degenerate. Degeneracy causes various kinds of efficiency and convergence problems and special precautions must be taken when performing SA for a degenerate extreme point. Degeneracy influences even POA, especially the determination of

opportunity costs and shadow prices. When performing SA, the main rule – determining the critical interval such that the original optimal basis does not change – is no longer valid because for a degenerate solution many bases are associated with it. A theoretical discussion of this problem is given in Kruse (1986), a bibliography is found in Gal (1994a). Note that standard software analysis for RHS-or OFC-ranging yield false results when degeneracy is involved.

Concluding Remarks

For linear programming and related mathematical areas, SA and PP have become important tools for analyzing variations in initial data, for obtaining better insight into and gaining more information about the related mathematical model, for improving understanding of model building in general, and as aids in solving a wide range of mathematical problems.

Parametric Solution

A solution expressed as a function of problem parameters.

Pareto-Optimal Solution

If a feasible deviation from a solution to a multiobjective problem causes one of the objectives to improve while some other objective degrades, the solution is termed a Pareto-optimal. Such a solution is also called an efficient or nondominated solution.

Partial Pricing

When determining a new variable to enter the basis by the simplex method, it is somewhat computationally inefficient to price out all nonbasic columns, as is the way of the standard simplex algorithm or its multiple pricing refinement. The scheme of partial pricing starts by searching the nonbasic variables in index order until a set of candidate vectors has been found. These vectors are then used as possible vectors to enter the basis, as is done in multiple pricing. After the candidate set is depleted, another set is found by searching the nonbasic vectors from the point where the first set stopped its search. The process continues in this manner by searching and selecting candidate sets until the optimal solution is found. Although the total number of iterations to solve a problem usually increases, computational time is saved by this type of pricing strategy.

► Simplex Method (Algorithm)

Partially Observed Markov Decision Processes

A Markov decision process (MDP) in which the state of the system cannot be fully or precisely observed, e.g., only part of the state is known and/or the state observation has some error. In principle, such a model can be converted to a fully observed MDP by introducing an "information" or "belief" state that may be infinite dimensional, corresponding to a probability distribution over the original state.

Perturbation

A change in a parameter, function or set.

Perturbation Analysis

Michael C. Fu
University of Maryland, College Park, MD, USA

Introduction

Perturbation analysis (PA) is a sample path technique for analyzing changes in performance measures of stochastic systems due to changes in system parameters. In terms of stochastic simulation, which is the main setting for PA, the objective is to estimate sensitivities of the performance measures of interest with respect to system parameters, preferably without the need for additional simulation runs over what is required to estimate the system performance itself. The primary application is gradient estimation during the simulation of discrete-event systems, e.g., queueing and inventory systems. Besides their importance in sensitivity analysis, these gradient estimators are a critical component in gradient-based simulation optimization methods.

Let $l(\theta)$ be a performance measure of interest with parameter (possibly vector) of interest θ, focusing on those systems where $l(\theta)$ cannot be easily obtained through analytical means and therefore must be estimated from sample paths, e.g., via stochastic simulation. Denote by $L(\theta, \omega)$ the sample performance obtained from a sample path realization ω such that $l(\theta) = E[L(\theta, \omega)]$. Although the assumption here is that the performance measure is an expectation, PA has also been applied more recently to quantiles (Hong 2009; Fu et al. 2009). The goal of PA is to efficiently estimate the effects on l of a perturbation $\theta \to \theta + \Delta\theta$, using information from a sample path ω at θ. PA addresses two different types of problems:

- $\Delta\theta \to 0$: estimating the gradient $\nabla l(\theta)$, when l is differentiable in θ.
- $\Delta\theta \neq 0$: estimating changes due to a finite perturbation, i.e., $l(\theta + \Delta\theta)$.

In the former case, no perturbation is ever actually introduced into the system (or simulation), although the idea of a perturbation may be employed as a heuristic tool in preliminary analysis.

Brief Taxonomy

To sort out the abundance of acronyms in the PA field, a brief definition of each corresponding approach is provided here, accompanied with at least one reference. Among gradient estimation techniques, the most well-known is infinitesimal perturbation analysis (IPA), which simply uses the sample derivative $dL/d\theta$ to estimate $dl/d\theta$. It is straightforward to implement and very computationally efficient; however, as shall be discussed shortly in more detail, its applicability is not universal. The books by Ho and Cao (1991), Glasserman (1991), and Cao (1994) cover IPA in detail. A very general and well-developed extension of IPA is smoothed perturbation analysis (SPA), based on the ideas of conditional expectation (Gong and Ho 1987) Although its applicability is quite broad, its implementation is usually very problem dependent. The book by Fu and Hu (1997) covers this method in full generality. Other gradient estimation techniques include rare perturbation analysis (RPA), originally based on the thinning of point processes (Brémaud and Vázquez-Abad 1992); structural IPA (SIPA), dealing specifically with structural parameters (Dai and Ho 1995); discontinuous perturbation analysis (DPA), based on the use of generalized functions (the Dirac-delta function) to model discontinuities in the sample performance function (Shi 1996); and augmented IPA (APA), another extension of IPA different from SPA (Gaivoronski et al. 1992). Techniques to estimate the effect of a finite perturbation in the parameter include finite perturbation analysis (FPA) – Ho et al. (1983); extended perturbation analysis (EPA) – Ho and Li (1988); and the augmented chain method−Cassandras and Strickland (1989). A related technique is the standard clock (SC) method, based on the uniformization of Markov chains (Vakili 1991). The books by Ho and Cao (1991) and Cassandras and Lafortune (2008) provide further references. This entry focuses on the gradient estimation techniques IPA and SPA, the most well-known and developed of the PA techniques.

Infinitesimal Perturbation Analysis

The applicability of IPA is illustrated through the use of some simple examples, at the same time contrasting the approach with the likelihood ratio/score function (LR/SF) and weak derivative (WD) estimators. Consider first the expectation of a single positive random variable X, written in two forms:

$$\begin{aligned} E[X] &= \int_0^\infty x f(x;\theta)dx \\ &= \int_0^1 X(\theta;u)du, \end{aligned}$$

where f is the PDF of X. In the first interpretation, the parameter appears inside the density, whereas in the second interpretation it appears inside the random variable defined on an underlying $U(0,1)$ random number. For example, the latter could be the inverse transform $X = F^{-1}$, where F is the CDF of X.

Differentiating $E[X]$, assuming the interchange of expectation and differentiation is permissible (via the dominated convergence theorem),

$$\frac{dE[X]}{d\theta} = \int_0^\infty x\frac{df(x;\theta)}{d\theta}dx \quad (1)$$

$$= \int_0^1 \frac{dX(\theta;u)}{d\theta}du. \quad (2)$$

Notice, however, that the conditions for the exchange will be quite different for the two interpretations. In the first interpretation, corresponding to the LR/SF and WD estimators, the conditions will be placed on the underlying density; in the case of discrete-event stochastic simulation, this means the input distributions. Since the input distributions must be known in order to perform the simulation, it is relatively easy to check the conditions. In the second interpretation, corresponding to PA estimators, the conditions will be placed on the sample performance function that is usually defined on an output stochastic process of the system.

As an example, consider an exponential random variable X with mean θ. Then $E[X] = \theta$ and $dE[X]/d\theta = 1$. The respective PDF and one random variable representation are given by

$$\begin{aligned} f(x;\theta) &= \frac{1}{\theta}e^{-x/\theta}1\{x > 0\}, \\ X(\theta;u) &= -\theta \ln u, \end{aligned}$$

where $1\{\cdot\}$ denotes the indicator function. Differentiating,

$$\begin{aligned}\frac{df(x;\theta)}{d\theta} &= \left[\frac{x}{\theta^2}\frac{1}{\theta}e^{-x/\theta} - \frac{1}{\theta^2}e^{-x/\theta}\right]1\{x>0\}\\ &= f(x;\theta)\left[\frac{x}{\theta^2}-\frac{1}{\theta}\right]\\ &= \frac{1}{\theta e}\left[\frac{e}{\theta}\left(1-\frac{x}{\theta}\right)e^{-x/\theta}1\{0<x\le\theta\}\right.\\ &\quad \left.-\frac{e}{\theta}\left(\frac{x}{\theta}-1\right)e^{-x/\theta}1\{x>\theta\}\right],\\ \frac{dX(\theta;u)}{d\theta} &= -\ln u = \frac{X(\theta;u)}{\theta}.\end{aligned}$$

The last expression for the derivative of the density (which is itself *not* a density) expresses the quantity as the difference of two densities multiplied by a constant, known as a weak derivative representation; Fu (2006, 2008) for references. Substituting each of the three expressions into the corresponding equations (1) or (2), yields three unbiased derivative estimators:

$$\begin{aligned}\text{LR/SF}: &\frac{X}{\theta}\left(\frac{X}{\theta}-1\right),\\ \text{WD}: &\frac{1}{\theta e}\left[X^{(2)}-X^{(1)}\right],\\ \text{IPA}: &\frac{X}{\theta},\end{aligned}$$

where $X^{(1)}$ and $X^{(2)}$ are random variables with PDFs $\frac{e}{\theta}\left(\frac{x}{\theta}-1\right)e^{-x/\theta}$, $x>\theta$, and $\frac{e}{\theta}\left(1-\frac{x}{\theta}\right)e^{-x/\theta}$, $0<x\le\theta$, respectively.

Extending to a function of the underlying random variable,

$$\begin{aligned}\frac{dE[L(X)]}{d\theta} &= \int_0^\infty L(x)\frac{df(x;\theta)}{d\theta}dx\\ &= \int_0^1 \frac{dL}{dX}\frac{dX(\theta;u)}{d\theta}du.\end{aligned}$$

The conditions for interchanging expectation and differentiation are unaltered when differentiating the underlying density, since that portion remains unchanged, whereas they are more involved for the sample path derivative. Basically, for the chain rule to be applicable requires some sort of continuity to hold for the sample performance function with respect to the underlying random variable. This translates into requirements on the form of the performance measure and on the dynamics of the underlying stochastic system such that the interchange

$$\frac{dE[L]}{d\theta} = E\left[\frac{dL}{d\theta}\right] \tag{3}$$

holds. Roughly speaking, sample pathwise continuity of L with respect to θ will result in the interchange being valid. An important structural condition for determining the applicability of IPA for general discrete-event systems modeled as generalized semi-Markov processes is the commuting condition (Glasserman 1991).

Smoothed Perturbation Analysis

The main idea of smoothed perturbation analysis (SPA) is to use conditional expectation to smooth out discontinuities in L that cause IPA to fail. This is achieved by selecting a set of sample path quantities $\mathcal{Z}$, called the characterization, such that $E[L|\mathcal{Z}]$ – as opposed to L itself – will satisfy the interchange in (3):

$$\frac{dE[E[L|\mathcal{Z}]]}{d\theta} = E\left[\frac{dE[L|\mathcal{Z}]}{d\theta}\right].$$

Applying SPA is analogous to the variance reduction technique of conditional Monte Carlo, consisting of two main steps: choosing an appropriate $\mathcal{Z}$ and calculating $dE[L|\mathcal{Z}]/d\theta$. For generalized semi-Markov processes, as well as for other stochastic systems, this is fully explored in Fu and Hu (1997).

Queueing Example

IPA and SPA estimators are illustrated for a single-server, first come, first-served (FCFS) queue. Let A_n be the interarrival time between the $(n-1)$th and nth customer (i.i.d. with PDF f_1 and CDF F_1), X_n the service time of the nth customer (i.i.d. with PDF f_2 and CDF F_2), and T_n the system time (in queue plus in service) of the nth customer. Consider the case where θ is a parameter in the service time distribution, and the

sample performance of interest is the average system time over the first N customers $\overline{T}_N = \frac{1}{N}\sum_{n=1}^{N} T_n$. The system time of a customer for a FCFS single-server queue satisfies the well-known recursive Lindley equation:

$$T_{n+1} = X_{n+1} + (T_n - A_{n+1})^+. \tag{4}$$

The IPA estimator is obtained by differentiating (4):

$$\frac{dT_{n+1}}{d\theta} = \frac{dX_{n+1}}{d\theta} + \frac{dT_n}{d\theta} 1\{T_n \geq A_{n+1}\}, \tag{5}$$

where

$$\frac{dX}{d\theta} = -\frac{dF_2(X;\theta)/d\theta}{dF_2(X;\theta)/dX}.$$

For example, for scale parameters, such as if θ is the mean of an exponential distribution, $dX/d\theta = X/\theta$. Using the above recursion, the IPA estimator for the derivative of average system time is given by

$$\begin{aligned}\frac{d\overline{T}_N}{d\theta} &= \frac{1}{N}\sum_{n=1}^{N}\frac{dT_n}{d\theta} \\ &= \frac{1}{N}\sum_{m=1}^{M}\sum_{i=n_{m-1}+1}^{n_m}\sum_{j=n_{m-1}+1}^{i}\frac{dX_j}{d\theta},\end{aligned} \tag{6}$$

where M is the number of busy periods observed and n_m is the index of the last customer served in the mth busy period ($n_0 = 0$). Implementation of the estimator involves keeping track of two running quantities, one for (5) and another for the summation in (6); thus, the additional computational overhead is minimal, and *no alteration of the underlying simulation is required*. IPA is also applicable to multi-server queues and Jackson-like queueing networks (Jackson networks without the exponential distribution assumptions).

The implicit assumption used in deriving an IPA estimator is that small changes in the parameter will result in small changes in the sample performance. For example, small changes in the interarrival and service times lead to small changes in system times, as can be seen by the Lindley equation (4), but can lead to large changes in the derivative given by (5), due to the indicator function. In general, the interchange (3) will hold if the sample performance is continuous with respect to the parameter. For the Lindley equation, although T_{n+1} in (4) has a kink at $T_n = A_{n+1}$, it is still continuous at that point, which explains why IPA works. Unfortunately, the kink means that the derivative given by (5) has a discontinuity at $T_n = A_{n+1}$, so that IPA will fail for the second derivative.

For the FCFS single-server queue, SPA can be used to derive the following estimator for the second derivative of mean system time:

$$\begin{aligned}\left(\frac{d^2\overline{T}_N}{d\theta^2}\right)_{SPA} &= \frac{1}{N}\sum_{m=1}^{M}\sum_{i=n_{m-1}+1}^{n_m}\sum_{j=n_{m-1}+1}^{i}\frac{d^2X_j}{d\theta^2} \\ &\quad + \frac{1}{M}\sum_{m=1}^{M}\frac{f_1(T_{n_m})}{1-F_1(T_{n_m})}\left(\sum_{i=n_{m-1}+1}^{n_m}\frac{dX_i}{d\theta}\right)^2,\end{aligned}$$

where $d^2X/d\theta^2$ is well-defined when $F_2(X;\theta)$ is twice differentiable.

Inventory Example

IPA and SPA estimators are illustrated for a single-item periodic review (s, S) inventory system, in which once every period the inventory level is reviewed and, if necessary, orders are placed to replenish depleted inventory. An (s, S) ordering policy specifies that an order be placed when the level of inventory on hand plus that on order (known as inventory position) falls below the level s, and that the amount of the order be the difference between S and the present inventory position, i.e., order amounts are placed "up to S." For average inventory as the performance measure of interest, derivative estimators with respect to the policy parameters s and $q = S - s$ are provided. Note that the parameters in this example are structural, as opposed to distributional in the previous queueing example.

In the model considered, all excess demand is backlogged and eventually filled, and orders are immediately received (zero lead time), so that. inventory level and inventory position coincide. At the end of a period, demand is satisfied *before* the order placement decision is made. Let D_n be the demand in period n (i.i.d. with PDF f and CDF F), and V_n be the inventory level in period n after demand

satisfaction. This quantity satisfies a recursive equation somewhat analogous to the Lindley equation:

$$V_{n+1} = \begin{cases} V_n - D_{n+1} & \text{if } V_n \geq s, \\ S - D_{n+1} & \text{if } V_n < s. \end{cases} \quad (7)$$

The sample performance is the average inventory level over N periods given by $\overline{V}_N = \frac{1}{N}\sum_{n=1}^{N} V_n$.

From a sample path point of view, the key discrete event in the system is the ordering decision each period. A change in s, with q held fixed, has no effect on these decisions, so infinitesimal perturbations in s result in infinitesimal changes in the inventory level, and hence in the sample performance function $\overline{V}_N$. In particular, for a perturbation of size Δs (of any size, not necessarily infinitesimal), $V_n(s + \Delta s) = V_n(s) + \Delta s$, and hence $\partial \overline{V}_N / \partial s = 1$ is an unbiased estimator for $\partial E[\overline{V}_N]/\partial s$. Intuitively, the shape of sample paths are unaltered by changes in s if q is held constant; the entire sample path is merely shifted by the size of the change. The IPA estimator can also be obtained by simply differentiating the recursive relationship (7), noting that D_n does not depend on s or q:

$$\frac{dV_{n+1}}{d\theta} = \begin{cases} \frac{dV_n}{d\theta} & \text{if } V_n \geq s, \\ 1 & \text{if } V_n < s. \end{cases}$$

for either $\theta = s$ or $\theta = q$. Taking $V_0 = S = s + q$, the expression reduces to 1 for all n, which is in accord with the sample path analysis.

On the other hand, a change in q with s held fixed may cause a change in the set of ordering decisions, resulting in radical changes in the sample path and hence in the sample performance function $\overline{V}_N$. Thus, SPA is required to derive an unbiased derivative estimator with respect to $\theta = q$. An SPA estimator for $\partial E[\overline{V}_N]/\partial s$ that can be easily and efficiently estimated from the original sample path is given by

$$1 + \frac{1}{N} \sum_{n \leq N: V_n < s} \frac{f(V_n + D_n - s)}{1 - F(V_n + D_n - s)} \left[s - E[D] - \overline{V}_N \right].$$

Real-World Application Example

In the October 30, 2000 issue of *Fortune* magazine, an article entitled, "New Victories in the Supply-Chain Revolution" (Siekman 2000) describes "a classic distribution challenge: how to avoid lost sales without incurring the cost of carrying extra inventory" when Caterpillar, the "world's largest builder of construction equipment . . . posed daunting supply chain questions" regarding the distribution of a new line of compact construction machines, specifically related to determining appropriate inventory levels for the U.S. market. "Among the techniques . . . used to attack this complex (supply chain inventory control) problem was . . . infinitesimal perturbation analysis, for which no complete explanation is possible for the faint-hearted or mathematically disadvantaged."

Historical Notes

PA was developed by Ho et al. (1979) when the first author was consulting on a real-world buffer design problem for a Fiat Motor Company serial production line. The single-server queue example was first considered in Suri and Zazanis (1988), and the inventory example in Fu (1994). The other area in which PA has been most widely used after queueing and inventory is financial engineering, where IPA is called the pathwise method in Glasserman (2004); see also Fu and Hu (1995). Other applications include PERT networks, dams, insurance, preventive maintenance, statistical process control, and traffic light signal control; see Ho and Cao (1991), Fu and Hu (1997), and Fu (2006) for examples and references.

Perturbation Methods

Procedures that modify the constraints of a linear-programming problem so that all basic feasible solutions will be nondegenerate, thus removing the possibility of cycling in the simplex method. The modification can be either explicitly done by adding small quantities to the right-hand sides or implicitly by using lexicographic procedures.

Petroleum Refining

David S. Hirshfeld
MathPro Inc., Bethesda, MD, USA

Introduction

By many financial and physical measures, the petroleum industry is the world's largest industry. The industry's operations comprise a global supply chain that produces, transports, refines, and distributes more than 85 million barrels of oil per day – nearly 5 billion tons per year.

Because of its scale, global scope, and huge capital requirements, the petroleum industry is populated with many large, vertically-integrated companies (many of them national oil companies) with global operations. The industry is highly competitive because it has many participants and because it produces basic commodities (e.g., gasoline, diesel fuel, petrochemical feedstocks, etc.) that are difficult to differentiate by brand. The industry's huge volume and low margins mean that even small changes in operating costs have important effects on operating results. The petroleum industry is a leader in the development and application of new technology; it develops and applies advanced technologies in every phase of operations. Consequently, the industry

employs large numbers of scientists, engineers, and applied mathematicians, many with advanced degrees.

For these and other reasons, the petroleum industry has been a pioneer in the application of OR/MS across all of its primary operations and has successfully applied virtually every OR/MS tool in these operations. During the 1960s and 1970s, most large integrated oil companies had strong OR/MS groups or departments with concentrations of expertise in linear programming, simulation, and statistical analysis (Baker, 2000). These groups consistently stretched the limits of OR/MS tools and methods, and they provided the impetus and the financial support for many advances in OR/MS software tools and analytical methods. Most of these groups no longer exist. But even so, OR/MS applications in the petroleum industry are ubiquitous and fully embedded in the various business functions that use them. Nowhere is this more evident than in the petroleum refining sector.

OR/MS and Petroleum Refining

Petroleum refining is a unique and critical link in the petroleum supply chain. The other links add value mainly by performing spatial transformations on petroleum (e.g., lifting crude oil to the surface; moving crude oil from oil fields to storage facilities and then to refineries; moving refined products from refinery to terminals and end-use locations, etc.). Refining adds value by performing chemical transformations and blending operations on petroleum – converting crude oil (which in itself has little end-use value) into a broad spectrum of valuable refined products. The primary economic objective in refining is to maximize that added value.

Petroleum refineries are large, continuous-flow process plants with extremely complex processing schemes for processing multiple crude oils and other input streams into a large number of refined (co-) products, most notably LPG, gasoline, jet fuel, diesel fuel, petrochemical feedstocks, home heating oil, fuel oil, and asphalt. Each refinery has a unique configuration and operating characteristics, determined primarily by its location, vintage, preferred crude oil slate, and market requirements for refined products. More than 660 refineries, in 116 countries, are currently in operation; virtually every one has OR/MS tools, including optimization models, embedded in its operations.

Since the earliest days of OR/MS and continuing to the present, refining has been a particularly rewarding domain for applying OR/MS methods in general, and linear programming (LP) and its extensions in particular (mixed integer programming (MIP), special ordered sets (SOS1 and SOS2), and successive linear programming (SLP), etc.).

OR/MS Applications in Petroleum Refining

Baker (2000) reports, "The refining industry began using linear programming (LP) shortly after its invention (Bodington and Baker 1990). In the early 1950s, many major oil companies began using LP-based product blending models (Charnes et al. 1952) which severely tested the available computational capabilities of that time. As computer capabilities expanded, so did the scope of LP models, encompassing whole refineries (Symonds 1955) and the US refining industry (Manne 1958)."

"The nonlinear nature of petroleum and chemical processes was first incorporated by Shell Oil via successive linear programming (SLP), a straightforward technique based on the iterative solution of linearized models (Griffith and Stewart 1961). SLP... was applied by most major companies in the 1960s (Baker and Lasdon 1985). Distributed recursion (DR), a specific form of SLP dealing with the distribution of nonlinear error terms across [multiple] blended pools, is widely used in contemporary models of petroleum refining."

"Literally... every other form of nonlinear optimization has been applied in the [refining] industry. Lasdon and Waren (1980) provided a comprehensive survey of applications. Production planning and scheduling has seen a wide variety of hybrid approaches combining mathematical programming, expert systems, decision support systems, forecasting techniques and simulation. Klingman et al. (1987) describes the integrated logistics system developed at Citgo. A combination of network flow algorithms, mixed-integer programming, and decision support were applied to ship scheduling at Ethyl Corporation (Miller, 1987). Brown et al. (1987) reports on a vehicle loading and

routing system developed for Mobil Oil. The design and development of integrated systems for planning and scheduling is an area of active interest both in academic and industrial settings (Baker 1994)."

Today, mathematical programming and other OR/MS techniques are embedded in numerous refining sector functions, including (in roughly decreasing order of time horizon):

- Capital investment planning
  - Economic evaluation of alternative designs for new refineries
  - Evaluation of alternative configurations for refinery upgrading projects
- Process design
- Tactical planning
  - Evaluation of inter-company product exchanges and processing agreements
  - Optimization of multi-period operations of multi-refinery, multi-terminal logistics systems
  - Evaluation of new processes and technologies
  - Regulatory compliance
- Operations planning
  - Crude oil valuation and supply planning
  - Crude oil cargo selection (Pawde and Singh 2010)
  - Development of quarterly and monthly refinery operating plans
  - Integration of refinery operations and refined product distribution (Guyonnet et al. 2009)
  - Concurrent multi-product blending
- Operations scheduling
  - Process sequencing
  - Inventory (tankage) management
  - Batch blending of refined products
- Process control

The planning and design applications have time horizons measured in years or months, are forecast-driven, and can return solutions in which multiple operations or operating modes employing the same resources or facilities are executed in the given time period. Scheduling applications, on the other hand, have much shorter time horizons (weeks or days), are order- or sequence-driven, and recognize operating policies or physical constraints on the utilization of specific facilities – e.g., only one activity or operation at a time can be performed in a particular facility. Plans returned by planning models may not be physically implementable without being subjected to a detailed scheduling analysis.

Refining organizations use their refining optimization models across many planning horizons:

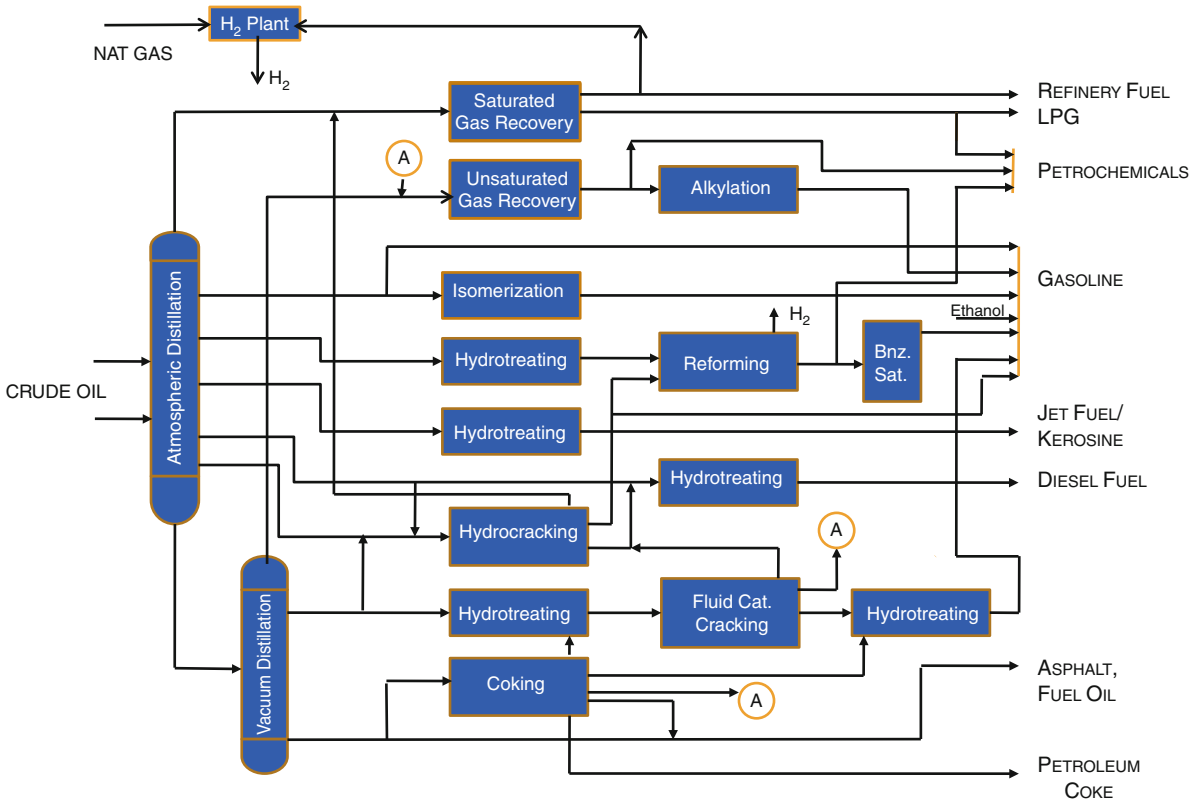
- **Long-term** (3+ years): capital investment planning, regulatory compliance, restructuring
- **Annual**: annual budgeting, evaluation of term contracts for crude supply and product sales, maintenance and turn-around planning
- **Quarterly/monthly**: operations planning to meet product demands and seasonal transitions in product specifications, evaluation of spot transactions for crude purchases and product sales, estimation of dispatches to product pipelines and tankers
- **Weekly**: scheduling operations and batch blending to make optimal use of crudes on hand and available processes

Refinery planning applications are practiced not only by refinery organizations but also by other organizations having interest in the refining sector, such as engineering firms, independent technology providers (e.g., process licensors), catalyst and chemical manufacturers, and consulting firms. Government agencies also apply LP to analyze refining operations, for various purposes – for example, the U.S. Environmental Protection Agency in estimating the costs of new regulatory standards for transportation fuels, and the U.S. Energy Information Administration in producing its annual projections of U.S. energy supply and demand).

Refining Operations and the Driving Forces for Refinery Modeling

Understanding the rationale for and benefits of OR/MS methods in refining industry requires some understanding of refining itself (The National Petroleum Council (2000) Web site includes an excellent tutorial on the fundamentals of refinery operations).

Figure 1 is a highly simplified flow chart of a notional complex refinery, illustrating a typical pattern of oil flow through the refinery – from the crude oil distillation unit that separates crude oil into various boiling range fractions, or cuts, through the various downstream processing units that chemically transform these fractions into blendstocks (the refinery streams that are the constituents of blended products) and ultimately to product blending. For purposes of



Petroleum Refining, Fig. 1 Simplified Flow Chart of a Notional Refinery

this discussion, the importance of Fig. 1 is not in its details, but in the overall picture it conveys of the complexity of refining operations in general.

Several broad aspects of refining operations suggested by Fig. 1 merit comment in the context of refinery modeling applications.

- Refinery operations are extremely complex.

Figure 1 only hints at the actual complexity of refinery operations – with respect to the physical facilities of the refinery, the interaction of these facilities with one another, and the range of operations of which they are capable. The complexity is such that refinery operations can be fully understood only with formal, refinery-wide models and can be optimized, in an economic sense, only through the use of mathematical programming.

Refiners can change the operations of their refineries to respond to the continual changes in crude oil and product markets, but only within physical limits defined by the performance characteristics of their refineries and the properties of the crude oils they process. Mathematical programming models of refinery operations that express these physical constraints are the only reliable means of generating achievable (i.e., feasible) and economic (i.e., optimal) responses to changes in market environment.

- Refineries produce a wide range (or slate) of products – actually co-products.

Refineries produce a range of co-products not only because of market demand for the various products but also because of the constraints imposed by the refining facilities themselves. Refiners need to know the marginal cost of production for each refined product, because these marginal costs are the primary determinants of the products' spot prices – the prices at which products change hands at the refinery gate. Mathematical programming models of refinery operations routinely produce rigorous estimates of marginal production costs that are well grounded in theory, for every co-product produced (The solution values for certain of the dual variables in a refinery

Petroleum Refining, Table 1 Classification of Refining Processes

Primary Classes of Refining Processes in Complex Refineries		
Class	**Function**	**Examples**
Crude distillation	Separate crude oil charge into boiling range fractions for further processing	Atmospheric distillation Vacuum distillation
Conversion	Break down ("crack") heavy crude fractions into lighter, higher-valued streams for further processing	Fluid cat cracking Coking, Hydrocracking
Upgrading	Enhance the blending properties (e.g., octane) and value of gasoline and diesel blendstocks	Reforming Alkylation, Isomerization
Treating	Remove hetero-atom impurities from refinery streams and blendstocks	Hydrotreating Caustic treating
Separation	Separate, by physical or chemical means, constituents of refinery streams for further processing	Fractionation Extraction
Blending	Combine blendstocks to produce finished products that meet product specifications and environmental standards	
Utilities	Supply refinery fuel, power, steam, oil movements, storage, emissions control, etc.	Power generation Sulfur recovery

model are precisely the marginal values in question). Indeed, mathematical programming is essentially the only practical and useful tool for computing the marginal costs of refined products.

All of this was readily apparent to the engineers and applied mathematicians working in the refining sector in the 1950s and provided the impetus for the early adoption of linear and mathematical programming throughout the refining industry.

Refinery Processes and Operations

Complex, world-class refineries (including virtually all U.S. refineries) comprise as many as fifty or more distinct refining processes, which carry out multiple physical and chemical transformations to convert crude oil into a broad slate of refined products. Despite their number and diversity, refining processes can be thought of in terms of a few broad classes based on their functions, as shown in Table 1.

Crude Oil and the Crude Oil Distillation Process

Crude oil distillation, the process at the front end of every refinery, regardless of size or overall configuration, has a unique function that affects all of the processes downstream of it. In a refinery model, the representation of crude oil properties and of the crude distillation process in a refinery model influences all of the other process representations in the model.

Crude oil comprises tens of thousands of chemical compounds (primarily hydrocarbons). These compounds range from the very light – low molecular weight, simple structure, low density, low boiling point ($<60^{o}$ F) – to the very heavy – high molecular weight, complex structure, high density, high boiling point ($>1000^{o}$ F).

Each of the more than 1,500 crude oils in commerce has its own unique signature, with respect to composition, proportions of light and heavy components, and physical properties. The unique composition and properties of a crude oil largely determine its value as a refinery input and the range of refined products that a given refinery can produce from it.

The crude distillation unit in a refinery accepts a combination of different crude oils and separates it into a number of streams (known as crude fractions or cuts). Each fraction leaving the crude distillation unit (1) is defined by a unique boiling point range (e.g., 180^{o}–250^{o} F, 250^{o}–350^{o} F, etc.), (2) contains material from each crude oil fed to the crude distillation unit, and (3) is made up of hundreds of distinct hydrocarbon compounds, all of which have boiling points within the cut range. An essential simplifying assumption in the analysis of refining operations is that the crude distillation unit makes "sharp" cuts – that is, any

given hydrocarbon species in the crude oil mixture is present in one and only one cut (i.e., there is no "overlap" between the crude fractions leaving the crude distillation unit).

Each crude fraction leaving the crude distillation goes to a different refinery process for further processing (Fig. 1). The highest boiling fractions of the crude, collectively known as the heavy ends, have relatively little economic value – indeed lower value than the crude oil from which they come. Refineries must convert, or upgrade, these heavy ends into more valuable light products (gasoline, jet fuel, diesel fuel, etc.).

Stream Properties and Refining Processes

In a refinery model, the specification of the temperature ranges of the cuts and the representation of the various properties of the crude fractions exerts a strong influence on the representations of all of refining processes downstream of the crude distillation and on the results returned by the model.

In general, each refining process handles multiple feed streams and produces multiple outputs (co-products). The yields of the co-products, their physical and chemical properties, and the direct operating costs of each process depend on the properties of the input streams (which in turn depend on the mixture of crude oils processed and the temperature ranges of the crude cuts). Consequently, analyzing refinery operations requires keeping track of not only the various streams flowing through the refinery but also numerous properties associated with each stream.

Tracking stream properties is essential in analyzing the blending operations at the back end of every refinery. Refineries produce a diverse set of co-products (e.g., gasolines, jet fuel, diesel fuels, petrochemical feedstocks, etc.); large, complex refineries may produce as many as forty distinct products. Most of these products are blends of various streams produced in crude distillation or in the downstream processes (usually five to ten refinery streams per product). Each product is blended to meet a vector of specifications on the products' properties (e.g., density, sulfur content) and performance characteristics (e.g., octane, emissions from vehicle tailpipes, etc.). These specifications represent industry standards and government regulations.

The Content of Refinery LP/MP Models

Structure

An LP or MP model of a single refinery in a single time period is essentially an assembly of

- Equations and inequalities representing
  - Volume balances on refinery inputs, refinery-produced streams, and refinery outputs (volume supplied + volume produced = volume consumed + volume blended or sold)
  - Mass balances and energy balances (conservation of mass and energy)
  - Blending property balances linking individual refinery streams and their blending properties to specification-blended product pools
  - Accounting identities to capture refinery-wide operating costs, consumption of energy and utilities, and generation of effluents (including CO_2)
  - Upper limits on the through-put capacity of the various refining processes
  - Special constraints reflecting internal technical restrictions or limitations
  - Special constraints reflecting external requirements
  - Regulatory standards (such as the federal and California standards for reformulated gasoline).
- Variables representing
  - Volumes of refinery inputs, such as crude oil purchases
  - Volumes of refinery streams flowing into or out of each process unit (such as those shown in Fig. 1) at specified operating conditions
  - Volumes of produced refinery streams going to each blended product pools
  - Volumes of finished products leaving the refinery
  - Amounts of new refinery process capacity (if any) added through capital investment

Multi-time-period models contain, in addition to the above elements, equations and variables representing inventory transfers from one time to the next of crude oils, other refinery inputs, certain intermediate refinery streams, and finished products.

Multi-refinery models contain, in addition to the above elements, equations and variables representing the transport of refined products from the refineries to individual destinations (product terminals, end-use sites, etc.) or destination regions, through various capacitated transportation modes.

In all of these variants, the objective function usually represents gross profit or, as it sometimes called, profit contribution:

Refinery netback minus (the sum of direct operating costs + capital recovery charges)

where

- **Refinery netback** is the net revenues (price*quantity) received by the refinery from the sale of all refined products
- **Direct operating costs** include the total purchase costs (price*quantity) of crude oil and other refinery inputs, purchased utilities, and catalyst and chemicals consumption; inventory carrying costs (in multi-period models); transportation costs for product movements to demand sites (in multi-refinery models), and regulatory compliance costs
- **Capital recovery charges** denote return on un-depreciated refinery investment, per unit of throughput.

In multi-period models, the profit contribution terms for future time periods can be discounted by multiplying them by a discount rate factor: $(1+\text{discount rate})^{-t}$, where t is the time-period index.

Models of refinery operations contain distinct representations of each of the refining processes that have a significant effect on the refinery's economics. A complex refinery can comprise forty or more such processes. Each process (or process/refinery combination, in a multi-refinery model) is represented in a discrete sub-matrix of the overall model. Each process sub-matrix consists of one or more operating mode or input/output variables, any number of which can be active in a given solution. Each operating mode variable intersects certain equations representing volume balances on the streams flowing into and out of the process, energy balances, and accounting relationships. The vector of input/output coefficients associated with each operating mode variable denote the quantities of individual inputs (refinery streams, utilities, capacity, costs) and outputs (different refinery streams) per unit of process throughput in a particular operating mode, as well as the relevant properties of the output streams.

Depending on the number of processes and refinery streams represented, a typical single-refinery, single-time-period LP model contains about 1,500–5,000 constraints, and 5,000–15,000 variables. Refinery models have highly structured matrices, composed of the various process and blending sub-matrices, linked by the volume balance and property balance constraints. The matrices are relatively dense, but have low super-sparsity (because the input/output coefficients in the process representations tend to be unique).

Coefficients

The coefficients for the crude oil distillation sub-matrix usually are drawn from *crude oil assays*. A crude oil assay is an assembly of data on the composition and property of a whole crude oil and of 15–20 boiling range fractions of that of that crude, developed through laboratory testing.

Crude assays exist for all crude oils in commerce; many, but not all, of these assays are in the public domain.

Commercial software products called crude oil assay managers with associated assay libraries are widely used to generate the coefficients for representing the crude oil distillation process in a refinery model, with user-specified boiling ranges for the crude fractions.

The coefficients for the sub-matrices representing the refining processes are refinery-specific in most models and are derived, directly or indirectly, from experimental data. Depending on the process, the data may come from laboratory testing, pilot plant operations, refinery-level plant testing, refinery accounting systems, and process simulators (detailed engineering models of individual refining processes). In general, all of these sources of refinery data are proprietary.

Some non-proprietary, generalized correlations and data for characterizing refining processes are available in the open literature, primarily in a few textbooks (e.g., Maples (2000), Gary et al. (2000)) and articles in refining industry trade journals.

Populating a refinery optimization model with realistic input/output coefficients is a highly specialized undertaking, requiring considerable knowledge of refinery operations and refining technology – subjects that are at some remove from operations research.

Nonlinearities in Refinery Models

To this point, this overview of refinery optimization models seems to imply that refining operations are

linear in nature and therefore can be suitably represented as linear programming models. Refining operations are subject to mass balance, energy balance, and volume balance constraints, all of which are linear, as are the constraints that govern multi-ingredient blending to meet product specifications (as long as the blending is simply physical mixing with no chemical interactions between ingredients). Consequently, refinery optimization was a natural pioneering application for linear programming. And even today, LP remains the optimization method of choice for many refinery modeling applications.

However, refinery operations actually embody many nonlinear phenomena, some of which can have a strong influence on refining operations and economics. Almost from the beginning, a steadily increasing number of refining organizations have sought to enhance their capabilities to capture these nonlinearities in their refinery optimization models and thereby more accurately represent the true capabilities and limitations of their refining facilities.

Some of the nonlinearities of interest are economic in nature and bear on the objective function; others involve underlying physical processes and relationships and bear on the constraint set. Many of these nonlinearities, including the five discussed below, are incorporated readily in refinery models, facilitated in many instances by the capabilities of commercial solvers.

Investments in New Refining Capacity

Existing refineries often invest in additional processing capacity – either new process units or expansion of existing ones – in order to increase total production capacity, produce new products, upgrade the value of existing products, or comply with new regulatory standards bearing on product quality or performance characteristics.

Often, the capacity added for a given process is represented by a continuous variable (whose value is expressed in a capacity measure, such as K barrels/day), and the corresponding investment is approximated by multiplying this variable by a constant investment rate coefficient (whose value is in $/(barrel/day)).

$$\mathbf{I} = \mathbf{a}^{*}\mathbf{Q} \tag{1}$$

where **I** is the investment (in K$), **Q** is the capacity added (in $/barrel/day), and **a** is the investment rate factor ($/(barrel/day)). The value of the investment rate factor depends on the refining process and the refinery's location.

However, the capital investment required to add new refining capacity enjoys economies of scale; that is, the investment per unit of added capacity is not a constant, but decreases with increasing total amount of added capacity. The standard relationship between the amount of new capacity added and the required capital investment is

$$\mathbf{I} = \mathbf{b}^{*}\mathbf{Q}^{\beta} \tag{2}$$

where **I** is the investment (in K $), **Q** is the capacity added (in K barrels/day), **b** is a constant whose value depends on the refinery's location, and β is an exponent whose value depends on the refining process in question. Most refining processes have a β value in the range of 0.6–0.7.

Equation (2) is a non-convex function. It can be represented in a refinery MP model in one of several ways.

One approach is to (1) assign a set of binary (0–1) variables to each of three or four standard levels of new capacity addition (e.g., 10 K barrels/day, 20 K barrels/day, etc.) for each refining process that is a candidate for investment and (2) for each such set, add a constraint specifying that at most one of the variables in the set can take on the value 1 in an optimal solution (or, equivalently, define the set of binary variables for each refining process as a Special Ordered Set Type 1 (SOS1)). Each of the binary variables carries a coefficient denoting the capital investment for the capacity addition it represents, obtained from the (2) for each process.

Another approach is to represent (2) for each process that is a candidate for investment as a piecewise linear function by means of a Special Ordered Set Type 2 (SOS2) for each such process.

Semi-Continuous Quantities

In many situations, restrictions exist on the minimum and maximum volume of a particular flow or the minimum and maximum extents to which a particular operation can be performed. For example, pipeline off-takes from a refinery are subject to the pipeline's regulations on the minimum and maximum size shipments that it will accept. Similarly, purchases of tanker-borne crude oil are

subject to volume to volume limits determined by the size of the tanker and its cargo compartments.

These and similar constraints can be represented in refinery models by means of semi-continuous variables: variables that can be either zero or continuous within a range defined by a strictly non-zero lower bound and (optionally) an upper bound. Semi-continuous variable capability is available in most commercial having mixed-integer-programming (MIP) capability.

Quality Blending

In the canonical product blending problem, the ingredients blend linearly with respect to the blend properties that are subject to limits (specifications). That is, the properties of the blended product requirements are the weighted averages of the corresponding properties of the various ingredients. This is linear blending.

Many refinery models represent the blending of refined products to specifications just that way. However, there is more to the specification blending of refined products than simple linear blending. Some of the specifications to which refined products are blended pertain to purely physical properties (e.g., sulfur content, density); other to chemical properties (e.g., octane, volatility, etc.). Blending to specifications on physical properties is indeed linear, as defined above. However, blending of chemical properties often is not linear, because of the interactions among different chemical interactions that occur when individual ingredients (*blendstocks* in refining parlance) are blended together. For example, consider two gasoline blendstocks, one having 90 octane, the other 70 octane. A 50/50 blend of the two might yield a blend octane of, say, 82 or 77 (not 80), depending on the chemical interactions involved. Moreover, the blend octane may vary with the relative amounts of the two blendstocks. This is nonlinear blending.

Several techniques are available for representing nonlinear blending. The most widely used one involves the use of blending indices in place of blendstock properties. A blending index for a given nonlinear property is an empirically determined function of that property such that the function blends linearly, even though the property itself does not. For example, consider the property Reid Vapor Pressure (RVP), a standard measure of gasoline volatility. RVP blends nonlinearly, but the RVP Index, defined here, blends linearly.

$$\text{RVP Index} = \text{RVP}^{\rho} \tag{3}$$

where the value of the exponent ρ is about 1.17 (Different refiners may use slightly different values for ρ).

Some blending indices involve more complicated functions of the underlying property. For example, Pour Point (PP), a measure of diesel fuel's ability to flow at low temperature, has a Pour Point Index given by:

$$\text{PP Index} = \text{EXP}[1.85 + 0.042^{*}(\text{PP})] \tag{4}$$

Many gasoline and diesel fuel blending properties are represented by such blending indices in refinery models.

Gasoline octane blending is a special instance of nonlinear blending for two reasons. First, octane has a relatively high marginal refining cost; refiners do not wish to "give away" octane in the course of meeting the octane standards. Second, the blending octane of a gasoline blendstock (i.e., the apparent octane contribution of the blendstock to the finished blend) is a function not only of the blendstock's native octane but also the composition of the finished blend. The refining industry has developed special methods, based on laboratory data, to estimate blend octanes over a range of compositions. These methods, outlined by Maples (2000), are beyond the scope of this article.

Pooling

Pooling is the mixing or commingling of multiple streams (crude fractions or refinery streams) into a new stream (the pool), whose properties (e.g., density, sulfur content, etc.) are the volume-weighted averages of the properties of the individual streams entering the pool:

$$\mathbf{Q}_j V = \Sigma_i q_{ij} V_i \quad \Rightarrow \quad \mathbf{Q}_j = \Sigma_i q_{ij} V_i \; / \; \Sigma_i V_i \tag{5}$$

where $\mathbf{V}$ is the volume of the pool stream, $\mathbf{Q}_j$ is the j^{th} property (e.g., density) of the pooled stream, V_i is the volume of the i^{th} stream making up the pool, and q_{ij} is the j^{th} property of that stream.

The q_{ij} are constant coefficients, but **V** and the V_i are variables, whose values are known only when the model returns a solution. Thus, the properties ($\mathbf{Q_j}$) of the pooled stream are nonlinear function of model variables and can be determined only after a solution is in hand.

Consequently, it is not possible to define exact representations of those effects on downstream refining operations that depend on the properties of the pooled stream. These effects reside in the refining process and specification blending sub-matrices. Thus, not only do the optimal volumes of the pooled stream, **V**, and the streams making up the pool, V_i, depend on the properties of the pool stream, but also the economic value of the pool stream **V**.

The original, or traditional, approach to formulating refinery models does not address pooling at all – not because the problem was not recognized but because the analytical tools needed to address it were not then at hand. In the traditional approach (still widely used), crude distillation and each of the downstream refining processes are represented in discrete sub-matrices. In the crude distillation sub-matrix, each crude oil is represented by its own input/output vector, in which the output coefficients are the volumetric yields of the various cuts. This representation implies that (1) the various crude oils, each with their own properties and yield patterns, are segregated from one another as they go through the crude distillation unit and (2) the boiling range cuts from the various crude oils are likewise segregated from one another as they move to the downstream processes. In the downstream process sub-matrices, each feed is attributable to a particular crude oil and each is represented by its own input/out vector. This scheme represents each process operating as if it were processing a group of segregated feed streams, each with its own operating mode, rather than one pool stream.

Refinery models formulated in this way tend to contain many more stream flow variables, and many more blendstock variables and blending options, than there are in the "real" refinery. This can lead, in certain situations, to over-optimization – the model's returning solutions indicating better refining economics than the real refinery can achieve.

Explicit representation of the stream pooling that occurs in real refineries calls for special model formulation and solution techniques. The most widely used modeling technique is called Distributive Recursion (DR), a variant of SLP developed expressly to deal with the pooling problem in models of refining and other process flow industries. First developed in the late 1970s, DR has come into increasingly wide use as the required software tools have become more widely available.

In DR, the model user provides initial estimates of the Q_i for all of the pool streams. The procedure uses these estimates to conduct an initial solution pass, which returns (1) the downstream dispositions and marginal value of each pool and (2) the volumes, V_i, of each stream entering each pool. Using the new set of V_i values, the DR procedure re-estimates the various pool qualities. The difference between the n^{th} and $n + 1^{st}$ estimates for a given pool is called its quality error. DR distributes each quality error across the various downstream dispositions of each pool and initiates a new solution pass incorporating the new estimates of pool qualities and quality errors. DR conducts a series of such solution passes that seek to converge to an optimal solution in which the quality errors are driven to zero (to within a user-specified tolerance).

Performance of Refining Processes

In the original, or traditional, approach to formulating refinery models, each downstream process is represented in a discrete sub-matrix. Each process sub-matrix comprises a set of variables (vectors), each denoting a unique combination of (1) a segregated (not pooled) feed stream to the process and (2) a particular operating mode for the process (defined by physical operating conditions, such as temperature). Each such variable has a unique set of input/out coefficients, defining the operation of the process. This representation implies that (1) processes behave linearly, independent of the composition and properties of their feeds and (2) each (notionally) segregated stream can be processed at its own set of operating conditions as it flows through the process. In reality, process performance depends on the properties of the pooled feed to the process.

With the advent of DR, some refining companies sought a more rigorous representation of refining processes that used pooled input streams and captured the effects of input stream properties on the

yields and properties of the output streams. This effort led to the *base-delta* (B-D) approach to representing refining processes in optimization models (Bodington 1995).

In the B-D approach, each downstream process is represented in a discrete sub-matrix, comprising:

- One or more base vectors, each denoting operation of the process with a typical, or base, feed and a standard, or base, operating mode.
  The input coefficients on the base vector(s) denote those properties of the pooled feed that affect the yields and properties of the process outputs. The output coefficients denote the yields and properties of the various outputs, when the process is operating at base conditions.
- A set of delta vectors for each base vector. The solution values taken on by the various delta vectors are determined as part of the overall model solution obtained via DR.
  The coefficients on each delta vector denote the effects of a small change in one pooled feed property (relative to the base property) on the yields and properties of the various outputs. Each delta vector coefficient is, in effect, the partial first derivative of a particular process output property with respect to an input property. The set of all delta vector coefficients for a process is equivalent to a Jacobian matrix for the process.

Both the base yield coefficients and the delta vector coefficients usually are generated by means of detailed engineering models (called process simulators) of the various processes, or (less likely) by generalized correlations or plant testing. Modern refinery modeling systems that offer DR now provide interfaces to process simulators. These interfaces link the process simulators directly to a refinery optimization model and allow them to be invoked at each DR solution pass to dynamically update the some or all of the delta coefficients in response to the current DR solution. Use of this facility increases the likelihood of reaching a local optimum.

Finally, the traditional representation of crude distillation, the refinery's front-end process, treats the cut point temperatures of the various crude fractions (e.g., 160^{o}–250^{o} F for a light naphtha stream) as constants. The advent of DR allows the cut points themselves to be recursed variables, an option that is now widely used.

Comments on Distributed Recursion (DR)

As with any non-linear technique, DR can – and often does – return solutions that are only locally optimal. In particular, the DR procedure requires initial estimates of the properties of each pool and the fractional distributions of each pool to its various downstream dispositions. The specific values of these estimates determine whether the DR procedure converges to a global optimum or to a local optimum. The more pooled streams and the greater the number of pool dispositions in the model, the more likely that the model will return a local optimum.

Capturing the analytical benefits of DR requires considerable software and intellectual resources, including:

- Some means – whether process simulators or sets of correlations – of dynamically representing the effects of process input properties on process output yields and properties;
- An array of special software, including a crude oil assay manager, process simulators (or their functional equivalent), and facilities to execute and control the recursive solution process; and
- Sound model formulation practices, careful estimation of the initial values of stream properties and distributions, and proper settings for the DR procedure's control parameters and tolerances.

Only analysts with access to the necessary system resources and with extensive experience in refinery modeling in general and DR in particular are likely to obtain useful and timely results with DR.

However, many refinery modeling applications do not require the degree of precision that DR is intended to provide in representing the capabilities and limitations of refining facilities. In particular, high accuracy in representing refining facilities may not be warranted in applications, such as tactical and strategic planning, that have planning horizons measured in years, rather than months or weeks. Long planning horizons involve substantial uncertainty regarding crude oil prices, product demands, and other economic factors. These applications place a premium on the ability to rapidly analyze and compare many different model instances, each representing a future economic scenario – as opposed to analyzing a few model instances with greater precision in the representation of refining facilities.

In these situations, the conventional refinery modeling approach, not the DR approach, is usually the method of choice.

Model Management for Refinery Models

Model management is "the care and feeding" of large scale modeling applications. It is a complex of information processing functions that includes model formulation (in an electronic format), data up-dating, case management, matrix generation, optimizer control, solution reporting, model and solution analysis, and model maintenance. All operational use of large scale optimization models involves the performance of these and other functions – whether manually, with an ad hoc collection of software tools, or with a purpose-built software system.

As the size and scope of refinery optimization models increased, the burdens of model management became apparent. The first software tools designed specifically to address elements of model management (as opposed to model solution) were the matrix generation languages fielded in the late 1950s and early 1960s (e.g., Haverly System's MaGen™ and (later) OMNI™; Bonner & Moore's MARVEL™ and (later) GAMMA™). These were procedural programming languages with special functionality and features for generating refinery LP models in optimizer input format and generating output reports on model solutions. The matrix generation languages were a large step forward, but they did not provide a full range of model management functionality.

Somewhat later, a new set of software tools for matrix generation and reporting entered commercial use: the algebraic modeling languages: (e.g., GAMS™, AMPL™, MPL™, MODELER™, and AIMMS™). These are symbolic modeling languages, in which the model formulator expresses the model's constraints and variables symbolically, in an algebra-like syntax. They also provide facilities for model up-dating and report generation.

Starting in the 1950s, many of the major refining companies undertook development of their own comprehensive refinery modeling systems, some using commercial matrix generation languages, others using standard programming languages of the times. Beale (1978) describes British Petroleum's approach to model management. Palmer et al. (1984) describes the conceptual and design foundations for Exxon's PLATOFORM™ model management system. At one time, PLATOFORM routinely handled more than one hundred mathematical programming applications in Exxon. Bodington and Baker (1990) reference other companies' efforts in model management system development.

As a consequence of the waves of consolidation and down-sizing that swept through the petroleum industry starting in the 1980s, most refining companies curtailed or abandoned their efforts to develop and maintain their own model management systems. A few companies still maintain their in-house model management systems. But most refining companies have now supplanted their in-house systems with one of the generalized refinery modeling systems brought into commerce by independent developers (e.g., PIMS™ (AspenTech), GRTMPS™ (Haverly Systems), and RPMS™ (Honeywell Hi-Spec Solutions)).

Commercially available modeling systems must be instantiated with data specific to the refinery of interest: crude oil assays, process capacities and performance characteristics, stream properties, and product specifications. Once instantiated, the generalized refinery modeling systems offer extensive functionality for refinery modeling, including DR (as an option), comprehensive model management functionality, and compatibility with crude oil assay managers, process simulators, spreadsheets, relational databases, and a number of standard commercial solvers.

Concluding Remarks

The petroleum industry pioneered the application of OR/MS across all of its primary operations, and has provided the impetus and the financial support for many advances in OR/MS software tools and analytical methods. This symbiotic relationship is particularly strong in the petroleum refining sector. Since the earliest days of OR/MS, refining has been a particularly rewarding domain for applying OR/MS methods in general, and especially linear programming (LP) and its extensions (in particular, mixed integer programming (MIP), special ordered sets

(SOS1 and SOS2), and successive linear programming (SLP)). As a result, OR/MS applications – especially linear and mathematical programming applications – are ubiquitous and fully embedded in refining operations.

Although petroleum refining is a mature area of application for OR/MS, the tools and methods available to refining industry practitioners continue to improve in terms of speed and functionality. Further advances are likely to come in the realm of model management.

Development and application of optimization models in the refining sector requires deep knowledge of refining technology and economics. Knowledge of optimization algorithms and software tools is necessary but not sufficient for successful application of OR/MS in the refining sector.

Phase-type Probability Distributions

Marcel F. Neuts
The University of Arizona, Tucson, AZ, USA

The probability distributions of phase-type, or *PH*-distributions, form a useful general class for the representation of nonnegative random variables. A comprehensive discussion of their basic properties is given in Neuts (1981). There are parallel definitions and properties of discrete and continuous *PH*-distributions, but the discussion here emphasizes the continuous case.

The simplest example is the Erlang random variable, which can be expressed as the sum of independent exponentially distributed random variables. As a result, one can construct a realization of an Erlang random variable by going through a series of phases, one for each exponential random variable; hence, the Erlang distribution is a phase-type distribution. Generalizing this phase-type idea governs the movement through the phases by a Markov chain that permits movement back and forth between the interior phases, with the final stage being an absorbing barrier.

More specifically, a probability distribution $F(\cdot)$ on $[0, \infty)$ is of phase type if it can arise as the absorption time distribution of an $(m+1)$-state Markov chain with m transient states $1,\ldots, m$ and an absorbing state 0. The generator $\boldsymbol{Q}$ of such a Markov chain is written as

$$\boldsymbol{Q} = \begin{bmatrix} \boldsymbol{T} & \boldsymbol{T}^0 \\ \boldsymbol{0} & \boldsymbol{0} \end{bmatrix},$$

where $\boldsymbol{T}$ is a nonsingular $m \times m$ matrix with negative diagonal elements and nonnegative off-diagonal elements. If $\boldsymbol{e}$ denotes a column vector with all components equal to one, then the vector $\boldsymbol{T}^0$ satisfies $\boldsymbol{T}^0 = -\boldsymbol{T}\boldsymbol{e}$. The initial probability vector of the Markov chain is specified as $(\alpha,\ \alpha_0)$. Without loss of generality, it may be assumed that the generator, $\boldsymbol{Q}^* = \boldsymbol{T} + (1-\alpha_0)^{-1}\boldsymbol{T}^0\alpha$, is irreducible.

The general formula for the *PH*-distribution $F(\cdot)$ is then

$$F(x) = 1 - \alpha\ \exp(\boldsymbol{T}x)\boldsymbol{e}, \qquad \text{for } \boldsymbol{x} \geq \boldsymbol{0}.$$

The pair $(\alpha,\ \boldsymbol{T})$ is called a representation of $F(\cdot)$. The *PH*-distribution $F(\cdot)$ has a point mass α_0 at 0 and a density $F'(x) = -\exp(\boldsymbol{T}x)\boldsymbol{T}\boldsymbol{e} = \alpha\exp(\boldsymbol{T}\boldsymbol{x})\boldsymbol{T}^0$, on $(0, \infty)$. The Laplace-Stieltjes transform $f(s)$ of $F(\cdot)$ is

$$f(s) = \alpha_{m+1} + \boldsymbol{\alpha}(s\boldsymbol{I} - \boldsymbol{T})^{-1}\boldsymbol{T}^0, \quad \text{for Re } s \geq 0.$$

Its moments λ_v, $v \geq 1$, are all finite and given by $\lambda_v = (-1)^v\, v!\, \alpha T^{-v}\ \boldsymbol{e}$. Some special classes of

PH-distributions are the hyperexponential distributions

$$F(x) = \sum_{v=1}^{m} \alpha_v \left(1 - e^{-\lambda_v x}\right),$$

which may be represented by $\alpha = (\alpha_1, \ldots, \alpha_m)$, $\alpha_{m+1} = 0$, and $\boldsymbol{T} = -\text{diag}(\lambda_1, \ldots, \lambda_m)$, and the (mixed) Erlang distributions

$$F(x) = \sum_{v=1}^{m} p_v E_v(\lambda; x),$$

which are represented by $\alpha = (p_m, p_{m-1}, \ldots, p_1), \alpha_{m+1} = 0$, and

$$\boldsymbol{T} = \begin{bmatrix} -\lambda & \lambda & 0 & \cdots & 0 & 0 & 0 \\ 0 & -\lambda & \lambda & \cdots & 0 & 0 & 0 \\ & \cdots & & & & \cdots & \\ 0 & 0 & 0 & \cdots & 0 & -\lambda & \lambda \\ 0 & 0 & 0 & \cdots & 0 & 0 & -\lambda \end{bmatrix}$$

Uses of Phase-type Distributions

The utility of *PH*-distributions is due to their closure properties, which allow standard operations such as convolution and mixing to be represented by matrix operations. Many classical simplifying properties of the exponential distribution have analogs in the matrix formalism for *PH*-distributions. In the analysis of probability models, *PH*-distributions often lead to tractable results without the severe restriction of exponential assumptions. Integrals involving *PH*-distributions also can usually be evaluated by stable recurrence relations or differential equations. Moreover, the phase-type distributions form a dense subset of the probability distributions on $[0, \infty)$, in that any such distribution can in principle be uniformly approximated by a sequence of *PH*-distributions.

Examples of closure properties are:

(a) If $F(\cdot)$ is a *PH*-distribution with representation $(\alpha, \boldsymbol{T})$ and mean λ_1', the corresponding delay distribution $F^*(\cdot)$ with density $(\lambda_1')^{-1}[1 - F(x)]$ is *PH* with representation $(\boldsymbol{\pi}, \boldsymbol{T})$ where $\boldsymbol{\pi} = (\lambda_1')^{-1}\alpha(-\boldsymbol{T})^{-1}$.

(b) If $F(\cdot)$ (with $\alpha_0 = 0$) is the service time distribution of a stable M/G/1 queue with arrival rate θ and service time distribution $H(\cdot)$ of mean μ_1', such that $\rho = \theta\mu_1' < 1$, the (steady-state) distribution $W(\cdot)$ of the waiting time is *PH*. Its representation is given by $(\boldsymbol{\gamma}, \boldsymbol{L})$, where $\boldsymbol{\gamma} = \rho\boldsymbol{\pi}$, $\boldsymbol{L} = \boldsymbol{T} + \rho\boldsymbol{T}^0\boldsymbol{\pi}$. For the *M/PH/1* queue, the distribution $W(\cdot)$ may therefore be computed by integrating a system of linear differential equations, rather than by solving the Pollaczek-Khinchin integral equation.

The fact that any probability distribution on $[0, \infty)$ can be approximated by *PH*-distributions is of somewhat limited practical application, although very good *PH*-approximations to classes such as the Weibull distributions have been obtained. Because of the following general result, that denseness property is, however, of considerable theoretical utility.

Suppose that a stochastic model involves one or more general probability distributions $F_j(\cdot)$, $1 \le j \le N$, on $[0, \infty)$, requiring evaluation of a continuous functional $\Phi[F_1(\cdot), \ldots, F_N(\cdot)]$. If an expression for $\Phi(\cdot)$ can be found for the case where $F_1(\cdot), \ldots, F_N(\cdot)$ are *PH*-distributions and if that expression does not explicitly depend on the formalism of *PH*-distributions, then it is also valid for arbitrary distributions $F_1(\cdot), \ldots, F_N(\cdot)$. This result has been used to establish various moment and other formulas in the theory of queues.

There is an extensive literature on phase-type distributions and their applications, including topics such as the structural geometric properties of families of *PH*-distributions, the approximation of other families of distributions by those of phase-type, and the fitting of *PH*-distributions to data. An important characterization of *PH*-distributions was proved in O'Cinneide (1990). Procedures for the approximation by *PH*-distributions are discussed in Asmussen et al. (1992), Johnson (1993) and Schmickler (1992). The appearance of phase-type distributions in some unexpected places in queueing theory was noted in Asmussen (1992).

Piecewise Linear Function

A function that is formed by linear segments or one that approximates a nonlinear function by linear segments.

Pivot Column

The column vector of coefficients associated with the entering basis variable in a simplex method iteration. Also, more generally, the column that contains the pivot element of a Gaussian elimination step or similar process.

See

- ▶ Gaussian Elimination
- ▶ Matrices and Matrix Algebra
- ▶ Pivot Element
- ▶ Pivot Row
- ▶ Simplex Method (Algorithm)

Pivot Element

In the simplex method, the coefficient of the pivot column whose row index corresponds to the basic variable that is to be dropped from the basis. Also, the element of the pivot column in a Gaussian elimination step that is selected to be on the diagonal of the associated upper triangular matrix.

See

- ▶ Eta Vector

Pivot-Selection Rules

In the simplex method, the pivot selection rules determine which variable is to enter the basic solution and which variable is to be dropped. Depending on the solution at hand, the rules are designed to preserve feasibility (nonnegativity) of the solution (primal-simplex method), or to preserve the optimality conditions (dual-simplex method). In either case, the rules attempt to select an entering variable that would cause and improvement in the objective function. These rules are often augmented with anti-degeneracy or anticycling rules, and procedures for maintaining sparsity and numerical accuracy.

Point Stochastic Processes

Igor Ushakov
Qualcomm Inc., San Diego, CA, USA

Introduction

A point process is a stochastic process $\{N(t), t \geq 0\}$, where $N(t)$ = number of occurrences by time t, which describes the appearance of a sequence of instant random events in time. Usually (though not always) intervals between two neighboring events are considered to be independently distributed. A process of this type is called a point process with restricted memory. If times between occurrences are a sequence of independent and identically distributed (i.i.d.) random variables, the point process is called a renewal or recurrent point process. The Poisson process represents a particular case of a renewal process in which the intervals between occurrences are exponentially distributed (Cox and Isham, 1980; Daley and Vere-Jones, 2002, 2007; Franken et al. 1981).

A special type of point process can be formed by two independent subsequences of random variables that alternate, as in the sequence X_1, Y_1, X_2, Y_2,.... Such a process is called an alternating point process, and more specifically, an alternating renewal process if the X and Y subsequences are themselves ordinary renewal processes.

Thinning of a Point Process

In some cases, events are excluded from the point process with a specified probability. For instance, a unit failure leads to a system failure only if several additional random circumstances happen. This exclusion of events is called a thinning procedure. If the thinning procedure results in the (normalized) probability of the event exclusion going to 1, the resulting point process converges to a Poisson process. This statement is reflected in strong terms in Renyi's Limit Theorem and in its generalization made by Yu. K. Belyaev (see Gnedenko et al. 1969). For practical purposes, the result means that if the mean time between neighboring events in the initial recurrent process equals T, and each event is excluded from this process with the probability p close to 1, the resulting process will be a Poisson process with parameter

$$\lambda = \frac{1-p}{T}.$$

The Superposition of Point Processes

The next important statement concerns the superposition of point processes, which is formulated

in the Khinchine-Osokov Limit Theorem (Khinchine 1960; Osokov 1956) and later generalized in the Grigelionis-Pogozhev Limit Theorem (Grigelionis 1964; Pogozhev 1964). On a qualitative level, the theorem states that a limiting point process, which is formed by the superposition of independent "infinitesimally rare" point processes, converges to a Poisson process. For instance, if a piece of equipment consists of a large number of blocks and modules, the flow of its failures may well be considered to form a Poisson process. The parameter of this resulting process is expressed as a sum of the parameters of the initial processes, that is, if there are n recurrent processes ($n >> 1$), each of them with mean T_i, then the resulting process will be close to a Poisson process with parameter

$$\lambda = \sum_{1 \le i \le n} \frac{1}{T_i}.$$

As a consequence of these results, the Poisson process plays a role in the theory of stochastic processes that is analogous to that of the normal distribution in general probability and statistical theory.

Point-to-Set Map

A function that maps a point of one space into a subset of another.

Poisson Arrivals

Term used when customers coming to a queueing system follow a Poisson process; this also implies that the time between customer arrivals are independent and identical distributed random variables following an exponential distribution with mean equal to the inverse of the Poisson arrival rate.

See

Poisson Process

A stochastic, renewal-counting point process beginning from time $t = 0$ with $N(0) = 0$ that satisfies the following assumptions is called a Poisson process with rate λ: (1) the probability of one event happening in the interval $(t, t + h]$ is $\lambda h + o(h)$, where $o(h)$ is a function which goes to zero faster than h; (2) the probability of more than one event

happening in $(t, t + h]$ is $o(h)$; and (3) events happening in non-overlapping intervals are statistically independent. (Either (1) or (2) can be replaced by: the probability of no event happening in the interval $(t, t + h]$ is $1 - \lambda h + o(h)$). For such a Poisson process, the times between events (renewals) are independent and identically exponentially distributed with mean $1/\lambda$. In Kendall's queueing notation, arrivals following a Poisson process would be represented by "*M*" as in an *M*/*G*/*1* queue. An important property of Poisson arrival processes in queueing theory is PASTA (Poisson arrivals see time averages).

Politics

Frederic H. Murphy[1], Sidney W. Hess[2] and Carlos G. Wong-Martinez[3]
[1]Temple University, Philadelphia, PA, USA
[2]Chadds Ford, Philadelphia, PA, USA
[3]Woosong University, Daejeon, Korea

Introduction

Applications of OR/MS to the representation and electoral processes are considered here. The narrower definition of politics is followed, denoting the theory and practice of managing political affairs in a party sense (Webster's New Collegiate Dictionary 1951). In particular, applications to the following are considered:

- Apportionment
- Districting
- Voting methods and logistics, and
- Election analysis

Apportionment

This is the process of equitably assigning a fixed number of legislators to a lesser number of political subdivisions. In the United States, 435 congressional districts must be apportioned to 50 states with each state receiving at least one district. The method of rounding to an integer solution influences the political result.

Balinski and Young (1982) have provided an exceptional mathematical analysis of the issue along with an historical, nontechnical exposition. In 1791, following the first U.S. census, Jefferson and Hamilton proposed alternative methods for apportionment, the method of greatest divisors (take the ratio of every state's population and the largest divisor such that the integer portions of the ratios add up to the number of representatives to allocate,) and the method of greatest remainders (take the population in a political unit, divide by the total population and multiply by the number of seats, allocate the integer portion, allocate the remaining seats in order of the size of the remainders until there are none left). Washington exercised the first presidential veto when he disagreed with Congress' support of Hamilton's method.

Most methods are biased; for example Jefferson's favors the more populated states while the method used in the United States since 1941, the "method of equal proportions" (also known as the Hill or Huntington method) discriminates against them. In this method a multiplier for adding the nth congressperson to a state is constructed by taking the square root of $1/[n(n-1)]$, $n > 1$. The product of the multipliers and the states' populations are sorted from highest to lowest for all states together. After each state is given one seat, the remaining seats are given to the 385 highest products of the populations and the multipliers. Other methods exhibit the paradox of a state's apportioned number of seats declining as the total number of representatives increases even when all states' populations are unchanged!

Balinski and Young (1982) conclude that there can be no perfect method. However, Senator Daniel Webster promoted a method called "major fractions" (frequently used between 1842 and 1932), which has been felt by many to be preferable. It is simple, and exhibits neither bias nor the population paradox.

Furthermore, Webster's method (find a divisor for the populations of each political unit such that the rounded quotients sum to the total number of legislators to be allocated), is more likely than the other methods to give each state its proportional number of seats, either rounded up or rounded down (Ernst 1994). See Apportionment Politics for detailed descriptions of apportionment methods and examples of the paradoxes that result from the different apportionment methods.

In most countries once the districts are established the candidate with the most votes wins. In Switzerland an alternative approach is taken to ensure that smaller parties are represented, Beroggi (2010). First, seats are allocated to states using major fractions. Second, seats are allocated to parties at the national level using the same method. With these allocations as constraints, the seats in every district are allocated to parties, minimizing the deviations between the real-valued allocation and integer number of seats ultimately given to each party in each district.

Redistricting

This is the process of defining geographic boundaries for the representatives in a political unit such as a city, state, province, or country. Historically, the party controlling the legislature draws districting maps to protect incumbents and increase their party's chances of maintaining control.

In 1962, the Supreme Court required population equality among districts, demanding more careful mapping than the usual prior political process (Baker v. Carr 1962). A variety of techniques to computerize the mapping process appeared. Most approaches incorporated population equality with the additional criteria that each district be:

- Contiguous, a single land parcel,
- Compact, consolidated rather than spread out, and
- Designed without political consideration.

Hess et al. (1965) solved a sequence of transportation linear programs. In each LP, equal population was allocated to trial district centers to minimize total cost. The measure of cost was compactness defined as the second moment of population about its district center. Centroids of the resultant districts became new centers for repeating the linear program. Successive solution of the transportation problems trended to more compactness while maintaining near population equality. Their heuristic handled problems as large as 350 population units by 19 districts. Larger problems were apportioned into smaller ones. This Ford Foundation-supported program was used for districting in at least seven states.

Hojati (1996) used Lagrangian relaxation to determine the center of districts and then the transportation model to assign population units to districts, followed by a capacitated transportation model to rejoin split population units. George et al. (1997) have generalized the transportation LP into a minimum-cost network-flow formulation that permits more flexible objective functions. They demonstrate objective (cost) functions that include penalties for:

- District populations deviating from the average or exceeding some maximum deviation,
- Districts crossing geographic barriers, and
- Changes from prior district boundaries.

The procedure has been applied in preparing New Zealand legislative-district boundaries involving assignment of 35,000 geographic units to 95 Parliamentary districts.

Garfinkel and Nemhauser (1969) developed a tree search algorithm that minimizes compactness while constraining maximum allowable population deviation. Their measure of district compactness is the diameter squared divided by area. Computation speed and capacity limited the problem size to about 50 population units by seven districts.

Nygreen (1988) redistricted Wales by three different solution methods: solving the integer programming formulation directly, using set partitioning (a variant of Garfinkel and Nemhauser's technique), and using implicit enumeration to structure the search of the tree of solutions. Although his example was small, he concluded that the integer programming technique was inferior. He felt problems to about 500 population units by 60 districts could be solved efficiently by set partitioning. Twenty years of computer improvement permit a tenfold larger problem!

All these redistricting techniques require apportioning a problem too large for solution into many smaller and solvable ones. Apportioning first has added benefits: small political subdivisions are more likely to remain intact and district boundaries will more often coincide with political boundaries.

Hess (1971) showed how first apportioning New York legislative seats to groups of counties minimizes the number of counties that must be in more than one district.

Mehrotra et al. (1998) model the problem as a constrained graph-partitioning problem as in Garfinkel and Nemhauser (1969) and develop a specialized branch-and-price based solution methodology rather than use implicit enumeration. Their reason for generating districts and solving the partitioning problem is to guarantee contiguous districts.

They did not work directly with the facility location/p median problem because ensuring contiguity would require an exponential number of constraints as with sub-tour elimination in the traveling salesman problem. Bozkaya et al. (2003) developed a tabu search approach to solving the problem while restricting the search to contiguous districts, again, not representing contiguity directly because of the perceived difficulty of capturing contiguity.

For such a heavily researched problem with so many successful researchers working on it over decades one would not expect an important breakthrough on a problem as difficult as the contiguity problem. However, two approaches represent contiguity directly in a model without any combinatorial explosion. Williams (2002) shows how to enforce contiguity using constraints on trees defined over the primal and dual planar graphs of the districts. Shirabe (2009), building on work by Zoltners and Sinha (1983), imposes contiguity by modeling trees with constraints that require the adjacent nodes connected by a positive flow be in the same district and the root node have an inflow that matches the number of geographic units assigned to the district. Thus, there has been substantial analytic progress in developing usable models for doing districting using integer programming formulations.

Meanwhile, the courts and legislatures have been slow to articulate permissible or required criteria for districting. A multitude of definitions or measures of compactness are available for Court selection, but all suffer from one flaw or another (Young 1988). In the United States "one man, one vote" is still the law of the land. The 1982 Voting Rights Act requires states with histories of racial discrimination to provide a reasonable chance of minority elections (Van Biema 1993). However, the Supreme Court (Shaw v. Hunt 1996) ruled that racial considerations cannot alone justify bizarre shaped districts. While the courts scrutinize the results of districting, they have not yet challenged the process (Browdy 1990), let alone find political gerrymandering to be unconstitutional. Associate Supreme Court Justice Breyer has regretted that the Court failed to take a stand (King 2010).

Political parties have been free to use proprietary software to generate districting plans that would make Governor Gerry blush. Computer services generated over 1,000 plans for Florida alone, making it difficult for the press and public to criticize gerrymandering (Miniter 1992). It is possible to predict when gerrymandering will happen: if only one political party controls the legislature and the politicians control the process without an independent oversight board, the districts will be drawn to the advantage of that party. That is, the process is important in determining the outcome.

The problem with gerrymandered districts after they are drawn is, like pornography, we know it when we see it. However, it is very difficult to define what gerrymandering is in advance. Consequently, any effort to reduce the degree of gerrymandering has to include not only good analytical models but also good governance processes.

Should the courts order an open districting process or bipartisanship necessitate, optimization models and algorithms could provide a viable approach to aid in redrawing representative boundaries (Browdy 1990). Given the unwillingness of politicians to give up the advantages that come from manipulating district boundaries, the likely eventual outcome will be a mix with optimization modeling establishing baselines and politicians making limited adjustments. Designing such a process will be an interesting challenge.

Voting Methods and Logistics

The application of approval voting was pioneered in the election processes of The Institute of Management Sciences (Fishburn and Little 1988). Here, a voter checks off (approves) any number of the candidates on a ballot, from a single one to potentially every one, with the person having the most checks being declared the winner. Regenwetter, and Grofman (1998) confirm the value of approval voting by examining the outcomes of seven elections, one of them being an INFORMS election.

Savas et al. (1972) reduced the number of New York City election districts by locating multiple voting machines at polling places. The City achieved significant cost savings and increased the probability voters would find functioning machines, without a significant increase in voter distance to the polls.

Election Analysis

The literature on OR in elections is sparse. The main roles seem to be in forecasting and game-theoretic analyses of policies. Barkan and Bruno (1972) used allocation techniques and statistical analysis to aid the 1970 California election campaign of Senator Tunney. Their analyses targeted precincts for voter registration and get-out-the-vote efforts. The key to their success was the ability to identify swing precincts by estimating party loyalty. Soberman and Sadoulet (2007) provide a game-theoretic analysis of rules to limit campaign spending.

A great deal of effort has been put into forecasting the outcome of elections. Campbell and Lewis-Beck (2008) survey past work in forecasting U.S. presidential elections and Lewis-Beck (2010) covers European election forecasting. Both of these articles are introductions to special issues on election forecasting, covering the broadly defined approaches of surveys, econometric analyses, and crowd sourcing such as the Iowa Electronic Market where people bet on the outcome and the prices and odds are set as in pari-mutuel betting. See also Kaplan and Barnett (2003).

Pollaczek-Khintchine Formula

For the M/G/1 queueing system, with L defined as the steady-state expected number of customers in the system, λ the customer arrival rate, $1/\mu$ the mean service time and σ^2 the variance of the service distribution, the Pollaczek-Khintchine (P-K) (mean-value) formula gives

$$L = \rho + \left(\rho^2 + \lambda^2\sigma^2\right)/[2(1-\rho)]$$

where $\rho = \lambda/\mu$. Sometimes, the formulas for mean queue size, L_q, mean line delay, W_q, and mean system waiting time, W, which can be easily derived from L using Little's formula, are also called the P-K formulas. More generally, there are associated transform relationships giving the generating function of the steady-state number in system (or queue length) and the Laplace transform of the steady-state delay/waiting times in terms of the Laplace transform of the service time distribution, which are referred to as Pollaczek-Khintchine (P-K) transform formulas.

▶ Queueing Theory

Polling System

Where a single server visits each group of customers (queue) in cyclic order and then polls to see if there is anyone present. If yes, the service facility serves those customers under such rules as gated (serve only those present when polled) or exhaustive (serve until no customers are left at the location).

Introduction

The heart of the portfolio problem is the selection of an optimal set of investment assets by rational economic agents. Although elements of portfolio problems were discussed in the 1930s and 1950s by Allais, De Finetti, Hicks, Marschak and others, the first formal specification of such a selection model was by Markowitz (1952, 1959), who defined a mean-variance model for calculating optimal portfolios. Following Tobin (1958, 1965), Sharpe (1970) and Roll (1972), this portfolio selection model may be stated as

$$\begin{aligned} &\text{Minimize} && \boldsymbol{x}'\boldsymbol{V}\boldsymbol{x} \\ &\text{subject to} && \boldsymbol{x}'\boldsymbol{r} = r_p \\ & && \boldsymbol{x}'\boldsymbol{e} = 1 \end{aligned} \tag{1}$$

where $\boldsymbol{x}$ is a column vector of investment proportions in each of the risky assets, $\boldsymbol{V}$ is a positive semi-definite variance-covariance matrix of asset returns, $\boldsymbol{r}$ is a column vector of expected asset returns, r_p is the investor's target rate of return and $\boldsymbol{e}$ is a column unit vector. An explicit solution for the problem can be found using the procedures described in Merton (1972), Ziemba and Vickson (1975), or Roll (1972).

Restrictions on short selling can be modeled by augmenting (1) by the constraints

$$\boldsymbol{x} \geq \boldsymbol{0} \tag{2}$$

where $\boldsymbol{0}$ is a column vector of zeros. The problem now becomes a classic example of quadratic mathematical programming; indeed, the development of the portfolio problem coincided with early developments in nonlinear programming. Formal investigations of the properties of both formulations,

and variants, appear in Szegö (1980), Huang and Litzenberger (1988), and the references above.

The Use of Mean and Variance

The economic justification for this model is based on the von Neumann-Morgenstern expected utility results, discussed in this context by Markowitz (1959). The model can also be viewed in terms of consumer choice theory together with the characteristics model developed by Lancaster (1971). His argument is that goods purchased by consumers seldom yield a single, well-defined service; instead, each good may be viewed as a collection of attributes, each of which gives the consumer some benefit (or disbenefit). Thus, preference is defined over those characteristics embodied in a good rather than over the good itself. The analysis focuses attention on the attributes of assets rather than on the assets per se. This requires the assumption that utility depends only on the characteristics. With k characteristics, C_k,

$$U = f(W) = g(C_l, \ldots, C_k)$$

where U and W represent utility and wealth. Modeling too few characteristics will yield apparently false empirical results. Clearly, the benefits of this approach increase as the number of assets rises relative to the number of characteristics. The objects of choice are the characteristics $C_1, \ldots, C_k$. In portfolio theory, these are taken to be payoff (return) and risk.

At Markowitz's suggestion, when dealing with choice among risky assets, payoff is measured as the expected return of the distribution of returns, and risk by the standard deviation of returns. Apart from minor exceptions (Ziemba and Vickson 1975), this pair of characteristics form a complete description of assets which is consistent with expected utility theory in only two cases: assets have normal distributions, or investors have quadratic utility of wealth functions. The adequacy of these assumptions has been investigated by a number of authors (e.g., Borch 1969; Feldstein 1969; Tsiang 1972). Although returns have been found to be non-normal and the quadratic utility has a number of objectionable features (not least diminishing marginal utility of wealth for high wealth), several authors demonstrate approximation results that are sufficient for mean-variance analysis (Samuelson 1970; Ohlson 1975; Levy and Markowitz 1979).

A number of authors, including Markowitz (1959), consider alternatives to the variance and suggest the use of the semi-variance. This suggestion has been extended into workable portfolio selection rules. Fama (1971) and Tsiang (1973) have argued the usefulness of the semi-interquartile range as a measure of risk. Kraus and Litzenberger (1976) and others have examined the effect of preferences defined in terms of the third moment, which allows investor choice in terms of skewness. Kallberg and Ziemba (1979, 1983) show that risk aversion preferences are sufficient to determine optimal portfolio choice if assets have normally distributed returns whatever the form of the assumed, concave, utility function.

Solution of Portfolio Selection Model

In the absence of short sales restrictions, (1) can be rewritten as

$$\begin{aligned}\text{Minimize } \boldsymbol{L} = \tfrac{1}{2}\boldsymbol{x}'\boldsymbol{V}\boldsymbol{x} - \lambda_1(\boldsymbol{x}'\boldsymbol{r} - r_p) \\ - \lambda_2(\boldsymbol{x}'\boldsymbol{e} - 1)\end{aligned} \tag{3}$$

The first-order conditions are

$$\boldsymbol{V}\boldsymbol{x} = \lambda_1\boldsymbol{r} + \lambda_2\boldsymbol{e}$$

which shows that, for any efficient $\boldsymbol{x}$, there is a linear relation between expected returns $\boldsymbol{r}$ and their covariances, $\boldsymbol{V}\boldsymbol{x}$.

Solving for $\boldsymbol{x}$:

$$\boldsymbol{x} = \lambda_1\boldsymbol{V}^{-1}\boldsymbol{r} + \lambda_2\boldsymbol{V}^{-1}\boldsymbol{e} = \boldsymbol{V}^{-1}[\boldsymbol{r}\ \boldsymbol{e}]\boldsymbol{A}^{-1}[r_p 1]' \tag{4}$$

where

$$\boldsymbol{A} = \begin{bmatrix} a & b \\ b & c \end{bmatrix} = \begin{bmatrix} \boldsymbol{r}'\boldsymbol{V}^{-1}\boldsymbol{r} & \boldsymbol{r}'\boldsymbol{V}^{-1}\boldsymbol{e} \\ \boldsymbol{r}'\boldsymbol{V}^{-1}\boldsymbol{e} & \boldsymbol{e}'\boldsymbol{V}^{-1}\boldsymbol{e} \end{bmatrix}$$

Substituting (4) into the definition of portfolio variance, $\boldsymbol{x}'\boldsymbol{V}\boldsymbol{x}$, yields

$$\begin{aligned}\boldsymbol{V}_p &= [r_p 1]\boldsymbol{A}^{-1}[r_p 1]', \text{ and} \\ \boldsymbol{S}_p &= \left[\frac{cr_p^2 - 2br_p + a}{ac - b^2}\right]^{1/2}\end{aligned} \tag{5}$$

where V_p and S_p represent portfolio variance and standard deviation, respectively. This defines the efficient set, which is a hyperbola in mean/standard-deviation space (or a parabola in mean/variance space). The minimum risk is at $S_{\min} = c^{1/2}$ and $r_{\min} = b/c$ (both strictly positive). Rational risk averse investors will hold portfolios lying on this boundary with $r \geq r_{\min}$.

Each efficient portfolio, p, has an orthogonal portfolio z (i.e., such that $\mathrm{Cov}(r_p, r_z) = 0$) with return

$$r_z = (a - br_p)/(b - cr_p)$$

Using this, the efficient set degenerates into the straight line tangent to the hyperbola at p which has intercept $\boldsymbol{r}_z$,

$$\boldsymbol{r} = \boldsymbol{r}_z + \lambda \boldsymbol{s} \tag{6}$$

where $\boldsymbol{r}$ and $\boldsymbol{s}$ represent vectors of the expected return and risks of efficient portfolios, and $\lambda = (r_p - r_z)/S_p$ can be interpreted as the additional expected return per unit of risk. This is known as the Sharpe ratio (Sharpe 1966, 1994). Equation (6) shows a two-fund separation theorem, such that linear combinations of only two portfolios are sufficient to describe the entire efficient set.

Under the additional assumptions of homogeneous beliefs (so that all investors perceive the same parameters) and equilibrium, (6) becomes the Capital Market Line. The Security Market Line (i.e., the relationship between expected returns and systematic risk or $\boldsymbol{\beta}$), which is the outcome of the Capital Asset Pricing Model (CAPM), can be derived by pre-multiplying (4) by $\boldsymbol{V}$ and simplifying using the definitions of V_p and r_z:

$$\boldsymbol{r} = r_z \boldsymbol{e} + (r_p - r_z)\boldsymbol{\beta} \tag{7}$$

where $\boldsymbol{\beta} = \boldsymbol{V}\boldsymbol{x}/V_p$. If it exists, the risk-free rate of interest may be substituted for r_z (definitionally, the risk-free return will be uncorrelated with the return on all risky assets). Equation (7) then becomes the original CAPM in which expected return is calculated as the risk-free rate plus a risk premium (measured in terms of an asset's covariance with the market portfolio). The CAPM forms one of the cornerstones of modern finance theory and is not appropriately addressed here. Discussion of the CAPM can be found in Huang and Litzenberger (1988) and Ferson (1995), while systematic fundamental and seasonal violations of the theory are presented in Ziemba (1994) and Keim and Ziemba (1999).

Short Selling

The assumption that assets may be sold short (i.e., $x_i < 0$) is justified when the model is used to derive analytical results for the portfolio problem. Also, when considering equilibrium (e.g., the CAPM), none of the short selling constraints should be binding (because in aggregate, short selling must net out to zero). However, significant short selling restrictions do face investors in most real markets. These restrictions may be in the form of absolute prohibition, the extra cost of deposits to back short selling or self imposed controls designed to limit potential losses.

The set of quadratic programming problems to find the efficient frontier when short sales are ruled out can be formulated as either minimizing the portfolio risk for a specified sequence of portfolio returns (r_p) by repeatedly solving (1) and (2), or maximizing the weighted sum of portfolio risk and return for a chosen range of risk-return tradeoff parameters (μ) by repeatedly solving (8) as below. This latter approach has the advantages of locating only points on the efficient frontier and, for evenly spaced increments in μ, locating more points on the efficient frontier where its curvature is greatest:

$$\begin{aligned} \text{Maximize} \quad & \alpha = \boldsymbol{x}'\boldsymbol{V}\boldsymbol{x} - \mu(\boldsymbol{x}'\boldsymbol{r} - r_p) \\ \text{Subject to} \quad & \boldsymbol{x} \geq \boldsymbol{0} \\ & \boldsymbol{x}'\boldsymbol{e} = 1 \end{aligned} \tag{8}$$

When short sales are permitted, a position (long or short) is taken in every asset, while when short selling is ruled out, the solution involves long positions in only about 10% of the available assets. When short selling is permitted, about half the assets are required to be sold short, often in large amounts, and sometimes in amounts exceeding the initial value of the investment portfolio. Indeed, this is the main activity of 'short seller' funds.

In contrast, most models based on portfolio theory, in particular the CAPM, ignore short selling

constraints (Markowitz 1983, 1987). This change is consistent with the development of equilibrium models for which institutional restrictions are inappropriate (and if imposed would not be binding). However, when short selling is permitted, the number of asset return observations is required to exceed the number of assets, while complementary slackness means that this condition need not be met when short selling is ruled out. Computational procedures to solve mean-variance models with various types of constraints, and the optimal combination of safe and risky assets for various utility functions are discussed by Ziemba et al. (1974).

Estimation Problems

The model (1) requires estimates of $\boldsymbol{r}$ and $\boldsymbol{V}$ for the period during which the portfolio is to be held. This estimation problem has been given relatively little attention, and many authors, both practitioners and academics, have used historical values as if they were precise estimates of future values. However, Hodges and Brealey (1973), among others, demonstrate the benefits obtained from even slight improvements on historical data.

Estimation risk can be allowed for either by using different methods to forecast asset returns, variances and covariances, which are then used in place of the historical values in the portfolio model, or by using the historical values in a modified portfolio selection technique (Bawa et al. 1979). Since the portfolio selection model of Markowitz takes these estimates as parametric, there is no theoretical guidance on the estimation method and a variety of methods have been proposed to provide the estimates. The single index market model of Sharpe (1963) has been widely applied in the literature to forecast the covariance matrix. Originally proposed to reduce the computation required by the full model, it assumes a linear relation between stock returns and some measure of the market, $\boldsymbol{r} = \boldsymbol{\alpha} + \boldsymbol{\beta}'\boldsymbol{m} = \boldsymbol{\varepsilon}$ (for market index $\boldsymbol{m}$ and residuals $\boldsymbol{\varepsilon}$). This uses historical estimates of the means and variances. However, the implied covariance matrix is $\boldsymbol{V}_1 = \upsilon_m \boldsymbol{\beta}\boldsymbol{\beta}' + \boldsymbol{V}$, where υ_m is the variance of the index, $\boldsymbol{\beta}$ is a column vector of slope coefficients from regressing each asset on the market index and $\boldsymbol{V}$ is a diagonal matrix of the variances of the residuals from each of these regressions. A number of studies have found that models based on the single index model outperform those based on the full historical method (e.g., Board and Sutcliffe 1994).

The overall mean method, first proposed by Elton and Gruber (1973), is based on the finding that, although historical estimates of means are satisfactory, data are typically not stable enough to allow accurate estimation of the $N(N-1)/2$ covariance terms. The crudest solution is to assume that the correlations between all pairs of assets expected in the next period are equal to the mean of all the historic correlations. An estimate of $\boldsymbol{V}$ can then be derived from this. Elton et al. (1978) compared the overall mean method of forecasting the covariance matrix with forecasts made using historical values, and four alternative versions of the single index model. They concluded that the overall mean model was clearly superior. A simplified procedure for estimating the overall mean correlation appears in Aneja et al. (1989).

Statisticians have shown increasing interest in Bayesian methods (Hodges 1976) and particularly James-Stein estimators (Efron and Morris 1975, 1977; Judge and Bock 1978; Morris 1983). The intuition behind this approach is that returns that are far from the norm have a higher chance of containing measurement error than those close to it. Thus, estimates of returns, based on individual share data, are cross-sectionally 'shrunk' towards a global estimate of expected returns which is based on all the data. Although these estimators have unusual properties, they are generally expected to perform well in large samples.

Jorion (1985, 1986) examined the performance of Bayes-Stein estimation using both simulated and small real data sets and concluded that the Bayes-Stein approach outperformed the use of historical estimates of returns and the covariance matrix. However, Jorion (1991) found that the index model outperformed Stein and historical models. Board and Sutcliffe (1994) applied these and other methods to large data sets. They found that, in contrast to earlier studies, the relative performance of Bayes-Stein was mixed. While it produced reasonable estimates of the mean returns vector, there were superior methods (e.g., use of the overall mean) for estimating the covariance matrix when short sales

were permitted. They also found that, when short sales were prohibited, actual portfolio performance was clearly improved, although there was little to choose between the various estimation methods.

An alternative approach is to try to control for errors in the parameter estimates by imposing additional constraints on (1). Clearly, ex-ante the solution to such a model cannot dominate (1), however, ex-post, dominance might emerge (i.e., what seems, in advance, to be an inferior portfolio might actually perform better than others). The argument is that adding constraints to (1) to impose lower bounds (i.e., prohibiting short sales) and/or upper bounds (forcing diversification) can be used as an ad hoc method of avoiding the worst effects of estimation risk. Of course, extreme, but possibly desirable, corner solutions will also be excluded by this technique. Cohen and Pogue (1967) imposed upper bounds of 2.5% on any asset. Board and Sutcliffe (1988) studied the effects of placing upper bounds on the investment proportions, which may be interpreted as a response to estimation risk. Using historical forecasts of returns and the covariance matrix, and with short sales excluded, they found that forcing diversification leads to improved actual performance over the unconstrained model. Hensel and Turner (1998) have also studied adjusting the inputs and outputs to improve portfolio performance.

Chopra and Ziemba (1993), following the work of Kallberg and Ziemba (1984), showed that errors in the mean values have a much greater effect than errors in the variances, which are in turn more important than errors in the covariances. Their simulations show errors of the order of 20 to 2 to 1. This quantifies the earlier findings and stresses the importance of having good estimates of the asset means.

Another approach is to use fundamental analysis to provide external information to modify the estimates (Hodges and Brealey 1973). Clearly, among the simplest external data to add are the seasonal (e.g., turn of the year, and month and weekend) effects that have been found in most stock markets around the world. Incorporation of these into the parameter estimates can substantially improve the performance of the model. Ziemba (1994) demonstrated the benefits of factor models to estimate the mean returns.

Concluding Remarks

Only the single period mean-variance portfolio theory model has been considered here. Most of the extensions to multi-period models assume frictionless capital markets, which require the solution of a sequence of instantaneous mean-variance models in which the existence of transactions costs adds enormously to the complexity of the problem. Surveys covering dynamic portfolio theory appear in Constantinides and Malliaris (1995), Ziemba and Vickson (1975), Huang and Litzenberger (1988), and Ingersoll (1987); see also Ziemba and Mulvey (1998).

Practice of Operations Research and Management Science

Hugh J. Miser
Farmington, CT, USA

Introduction

The practice of OR/MS here will mean using the appropriate models, tools, techniques, and craft skills of these sciences to understand the problems of people/machine/nature systems with a view toward ameliorating these problems, possibly by new understandings, new decisions, new procedures, new structures, or new policies. Such practice calls for a suitable form of professionalism in dealing not only with the phenomena of the problem situation but also with the persons with relevant responsibilities, as well as other parties at interest.

OR/MS as a Science

Following Ravetz (1971), science in general may be described as "craft work operating on intellectually constructed objects," each object defining a class. Scientific work is thus aimed at establishing new properties of these objects and verifying that they reflect the reality of the classes of phenomena that

they represent (Miser 1993). This description has four implications:

1. The intellectual objects – that OR/MS workers usually call models – are created by the imagination, informed by earlier knowledge of the phenomena and objects that have described them successfully, as well as innovative ideas or new evidence from reality.
2. There is a continuing reference to the phenomena of reality.
3. Scientific inquiry then becomes the search for new properties of the classes both by manipulating the objects and seeking new evidence from reality as a basis for revising them.
4. The new properties deduced from the objects – or models – must then be compared with the appropriate aspects of the phenomena of reality.

It is essential to observe that the different sciences – such as physics, biology, or OR/MS – are distinguished, not by their methods, techniques, or models (many of which are widely shared among the sciences), but by the portions of reality in which they are undertaking to understand, explain, and solve problems (Kemeny 1959).

Within the framework established by this conception, it is convenient to distinguish three classes of problems, depending on their goals: to paraphrase Ravetz (1971), scientific problems (where the goal of the work is to establish new properties of the objects of inquiry, and the ultimate function is to achieve knowledge in its field); technical problems (those where the function to be performed specifies the problem); and practical problems (where the goal of the task is to serve or achieve some human purpose and the problem is brought into being by recognizing a problem situation in which some aspect of human welfare should be improved).

Against this background, practice can be recognized as the activity centered on practical problems, even while noting that to solve a practical problem often involves solving technical problems, and, when the basic phenomena underlying a problem situation are not understood, solving scientific problems in order to have the models needed for understanding the practical problem. It is also important to note that this view of science includes work on all three classes of problems within the conception of science as a whole. (For a more extended summary of Ravetz's view of science, see Miser and Quade 1988).

The Context of OR/MS

Since sciences are distinguished by their fields of inquiry, it is important to describe this context for OR/MS if it is to be differentiated from other sciences. In this endeavor the OR/MS community has not reached any sort of brief consensus, so what is said here must be regarded as a personal view, based in part on the literature and in part on personal experience.

While OR/MS deals with systems involving people, elements of nature, and machines (where this last term is intended to include not only artifacts but also laws, standard procedures, common behaviors, and social structures and customs), attempts to take the concept of system beyond this primitive statement as the basis for describing the context of OR/MS have, however, not proved fruitful.

The concept of an action program (Boothroyd 1978) is more useful: a function, operation, or response that is related to and given coherence by a human objective, need, or problem, together with the system of people, equipment, portion of nature, organizational elements, and management or social structure involved.

It is easy to see that an element in an action program may also have membership in other action programs; for example, an executive in one may also play a role in many others, as may also be the case for a major facility or organization, such as a large corporation or a government. Too, an action program may produce effects on other action programs, both through the cross memberships of elements and by the direct impacts of what it does. (For a more extended summary of Boothroyd's concept, see Miser and Quade 1988).

The practice of OR/MS can then be described as the activity that brings the knowledge and skills of the science of OR/MS to bear on the problems of action programs (Miser 1997). While this brief description will suffice as a basis for the argument here, the reader should be aware of the facts that, while it is quite general and covers most of what OR/MS does in practice now, it not only may not cover all of today's activities of practice but also may become even more incomplete with the passage of time.

The Situations of Practice

While each situation in practice may properly be seen as unique, it is nevertheless possible to describe one

that contains elements central to most – if not all – of practice, as follows.

An OR/MS analyst is often consulted when someone with a suitable responsibility in an action program discerns a problem situation that needs improvement. While this responsible person may have diagnosed the problem and even may have a notion about a possible solution, it is commonly the case that the forces actually yielding the source of dissatisfaction lie buried deeply enough to make such a diagnosis questionable, and the preconceived fix inappropriate. Thus, typically it is best for the analyst – or the team of analysts if the problem situation is complex – to approach it with an open mind, and aim to explore it thoroughly before deducing its properties and using them to devise a scheme for ameliorating its undesirable properties.

The analysts may be drawn from two sources:

1. There may be an analysis group inside the organization or action program with which the responsible problem-situation identifier – or client – is associated.
2. Analysts may have to be drawn from outside this organization or action program. In either case, there is abundant experience to support the conclusion that a successful outcome of the practice engagement calls for creating a constructive partnership between the analysis team and the parties at interest in the problem situation, as will be discussed in more detail later.

The Processes of Practice

Figure 1 offers a synoptic view of the elements that may be included in a practice engagement that proceeds from the general unease of a problem situation to the implementation of some policy or course of action and evaluates its effects. Since each situation has its own unique properties, few OR/MS practice engagements follow such a procedure exactly, but it is a common experience for many – if not most – of these elements to occur at some stage of the work.

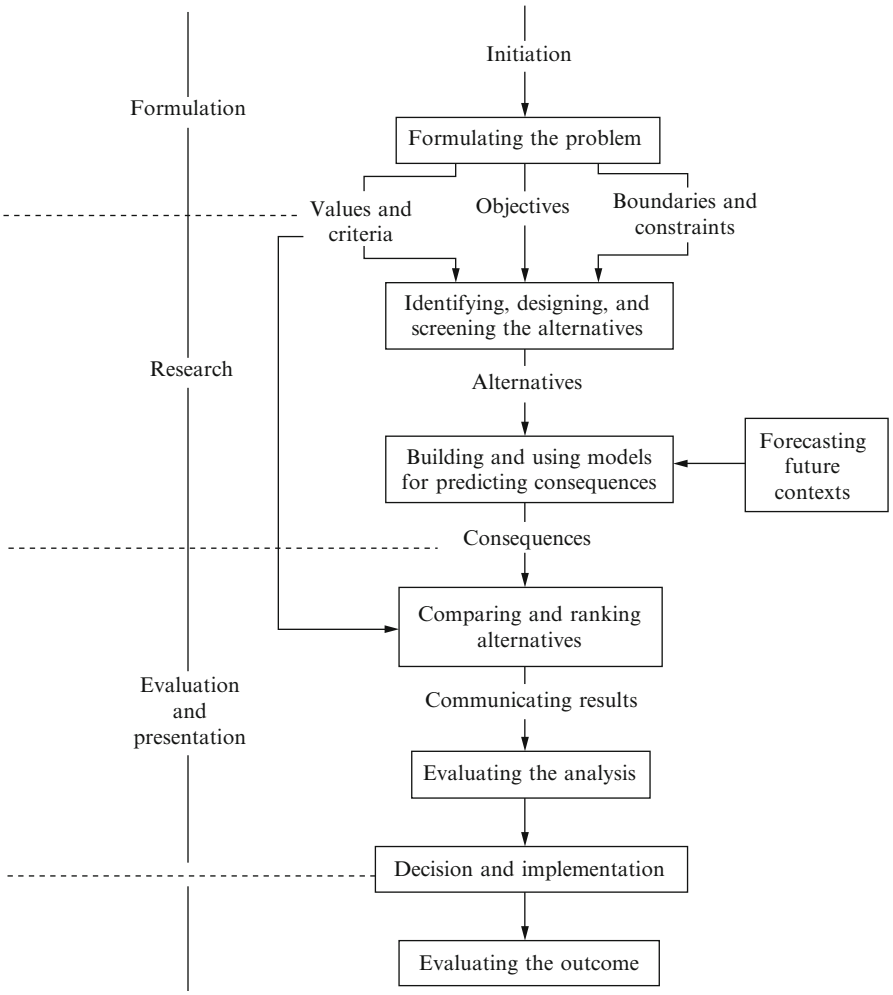
Formulation – The work begins with a thorough exploration of the problem situation in which the client and his/her action program cooperate. The purpose is to formulate the problem to be addressed, which commonly is quite different from the one originally conceived by the client. Once this is done, and the client has agreed with the analysis team on the problem, it is possible to plan the work to be done. This early work also identifies the values and criteria that should inform the choice of what eventually will be done to ameliorate the client's concerns, sets up the objectives to be sought by the solution, and agrees with the client on the boundaries and constraints that must be observed in devising it.

Usually this problem formulation step is one in which the analysts take the lead and work through it in informal cooperation with the client's staff. On occasion, however, it is best for a group consisting of both analysts and members of the client's staff to work together somewhat more formally toward a problem structure. To this end, there are various types of methods (Rosenhead 1996) that can be adapted to these situations. While the results of such a problem-structuring activity are usually a prelude to a more detailed analysis to follow, it sometimes happens that the insights from the group activity shared between the analysts and the client's staff are adequate to show what should be done to ameliorate the problem situation.

Research – This stage extends the information-and data-gathering that began in the formulation stage. The findings that emerge from processing these results allow the analysis team to identify, design, and screen possible alternatives that may help with the problem. Against this background, the analysis team can build models capable of deducing the consequences of adopting each of the alternatives chosen for further investigation within the contexts of possible future conditions.

Evaluation and Presentation – With estimates of the consequences in hand, the analysts may compare – and possibly rank – the alternatives against the criteria chosen earlier in the analysis, plus any new ones that may have emerged during the work. These findings must then be presented to the client and other parties at interest in a way that enables them not only to appreciate the results but also have at least a broad overview of the logic that produced them. These understandings may then enable the client to adopt a suitable policy or course of action.

Although the client, and not the analysts, must decide on what to do and how to carry it out effectively, experience shows that it is very important for the analysis team, or at least analysts who



Practice of Operations Research and Management Science, Fig. 1 Important elements in an OR/MS practice engagement that runs from problem formulation through research and implementation to evaluating the outcome (Source: Miser and Quade (1988), p. 23; reproduced by permission.)

understand and appreciate what was done, to work cooperatively throughout the implementation stage, as discussed later.

Variations

While it is possible to specify a core diagram of the principal elements of OR/MS practice, it must be admitted immediately that few, if any, such engagements follow this outline exactly. Rather, since each problem situation is different, the analysis activity must be adapted to it. Thus, in studying a series of cases, one sees variations like these:

- Instead of proceeding linearly from the top to the bottom of Fig. 1, the work cycles from intermediate stages back to earlier ones as the progress brings new insights and fresh intermediate results that may prompt reconsideration of the beginning foundations of the work.
- Some work may be aimed more at fleshing out the client's understanding of his situation than prompting him/her to change it significantly, so it may stop at one of the intermediate stages.
- The relative effort expended in the various stages may vary tremendously from case to case: one case may have to expend its major effort in just the information-and data-gathering stage, after which what needs to be done may be fairly apparent without much further analysis. Another case may proceed fairly expeditiously through the outline of Fig. 1 and then have a very long and complicated period of work to achieve what may appear to the outsider to be the implementation of a relatively simple set of proposals.

– In some cases an intermediate stage may dominate the work, owing to such factors as technical difficulty in devising proper models, major uncertainties in forecasting future contexts, complexities of the underlying situation, and so on.

In any case, the procedure specified here as the basis for discussion must be regarded as one that has stitched together the key elements that may enter OR/MS practice to varying extents depending on the peculiarities of the situation being studied.

The Importance of Following Through

The interest of the OR/MS professional, particularly if academically oriented, may flag after the research stage is completed and its results obtained. However, experience shows strongly that to stop there is almost always to waste the earlier effort. Two essential steps must follow: effective communication of the results, and cooperative aid in the implementation process.

Communication – This process, which may not be as appealing to the analyst as the research that preceded it, is nevertheless equally important and deserves great care, since communicating the findings inadequately can vitiate their potential effect, and thus waste the earlier effort. In view of the importance of this step in the OR/MS process, it is surprising that there is no systematic literature describing the skills needed and setting forth how they are best used (for a brief exception see Miser 1985). The discussion will be restricted to these points:

– Few clients will devote a large block of time to such communications, so it is very important to work very hard to condense the principal ideas and findings into as economical a space as possible, whether the form used is oral or written. For example, a top executive may want the key findings presented to him or her in a two-page memorandum or a 20-min briefing. It is perhaps surprising to the uninitiated to see how much important information can be condensed into so small a space, but only if great care is taken to make the best use of it. Graphs and charts accompanying the words can do much to aid this condensation.
– To communicate effectively, the client's vocabulary must be used, with as few technical terms introduced as possible.
– The whole must be focused on the interests of the client or the audience; after a major study many different groups may have to be addressed, and when this is the case the communication instruments must in each case be tailored to the group in view.
– The analysts must be prepared to stand behind their work and to discuss its implications, even those that may go beyond what was done as part of the analysis.

Implementation – It is clear that, if the findings of an OR/MS practice engagement do not find their way into some sort of changed reality, the work is ineffective. Therefore, it is obviously important for the analysis to consider the issue of eventual implementation throughout the work, keeping these points in mind:

1. Since the setting in which the work is being done has properties that will affect how change can be achieved, it is important for the peculiarities of this setting to be kept in mind from the beginning of the analysis. For example, can possible prospective changes be accommodated easily within the existing structure, or will it need to be changed significantly?
2. Since the settings in which OR/MS work is done are so various, it is impossible to stipulate a standard pattern for implementation work. This implies that the findings of the analysis may have to include a prospective implementation structure and program for the decision makers to consider as part of their judgment about the worth of the findings.
3. If the analysis considers different programs of action, the comparisons leading to a preferred choice should consider the relative difficulties of implementation as part of the analysis.
4. The history of analysis records that many well developed and clearly desirable program proposals failed to be implemented because the needed resources either did not exist or could not be made available. Therefore, in conceiving an implementation program as part of the findings of an OR/MS study, it is important to consider its resource requirements, as they will almost surely be an important issue to consider in whether or not to adopt the findings and translate them into action.

No matter how thoroughly the client – or members of his or her staff who participated in the analysis – understand what was found and its

prospective implementation, it is a common experience that the implementation process demands the continuing interest and cooperation of the analysis team, or at least some member of it who is able to follow through. The process of change invariably brings up new problems and issues that, wrongly handled, can vitiate the effects of what the original implementation set out to do. Too, these new problems may call for additional complementary analysis that must take account of what was done earlier.

This continuing involvement by analysts in the implementation process may take a variety of forms, ranging from occasional consultation to a continuing direct involvement of a substantial effort over such a long period of time as to make the implementation involvement a more ambitious enterprise than the original analysis (for an example illustrating this last point, see, Mechling 1995).

The roles of the analysts during implementation may include such activities as these:

1. Conducting supplementary analyses when situations arise calling for such work.
2. Helping all concerned keep the goals of the implementation program in sight. (It is all too easy for staff members involved, all of whom have personal in institutional goals in mind, to corrupt what is being done sufficiently that the original goals emerging from the analysis are vitiated.)
3. Proposing changes in the implementation strategy when they are called for by changing circumstance or the appearance of difficulties not foreseen in the beginning.
4. Acting as an on-site agent of persuasion when those directly involved in the implementation program need to have its goals clarified.

In sum, since an effective implementation phase is essential to the success of an OR/MS engagement, analysts should give it as much analytic and administrative importance and support as the analysis phase itself. For further elaboration of these points about implementation, see Tomlinson et al. (1985).

Outcome evaluation – It not infrequently happens that the outcomes of implementations are sufficiently clear to satisfy all concerned. Sometimes, however, in situations complex enough to make the outcomes unclear, it is necessary to conduct additional analysis to estimate the effectiveness of the implemented program or policy. The familiarity of the analysis team with the situation gives it an advantage in conducting such an analysis. However, to eliminate what may appear to be the original analysis team's bias in favor of a good outcome, clients may prefer to call in a new group to conduct such an outcome evaluation.

The Relation Between Analyst and Client

Emerging from a close scrutiny of the relations that should exist between analyst and client for effective cooperation, Schön (1983) advocates a "reflective contract" that works in this way: "... in a reflective contract between practitioner and client, the client does not agree to accept the practitioner's authority but to suspend disbelief in it. He agrees to join the practitioner in inquiring into the situation for which the client seeks help; to try to understand what he is experiencing and to make that understanding accessible to the practitioner; to confront the practitioner when he does not understand or agree; to test the practitioner's competence by observing his effectiveness and to make public his questions over what should be counted as effectiveness; to pay for services rendered and to appreciate competence demonstrated. The practitioner agrees to deliver competent performance to the limits of his capacity; to help the client understand the meaning of the professional's advice and the rationale for his actions, while at the same time he tries to learn the meanings his actions have for the client; and to reflect on his own tacit understanding when he needs to do so in order to play his part in fulfilling the contract."

Under this concept for OR/MS work, the client's obligation to share his experience and understanding of the problem situation is often discharged by assigning a member of his staff to work with the analysis team, an arrangement that has many benefits, among which these may be listed: it helps the analysis team identify and gather the information that it needs as a background and basis for its work; it helps the analysts avoid foolish mistakes related to the client's operations; and it acts to keep the client informed of what is emerging from the analysis, which often helps to pre-sell the findings that eventually merge.

Since OR/MS practice may be viewed as a dialogue between analyst and client related to the problem situation and the problem from it that is eventually

chosen for analysis, this arrangement serves as a useful continuing conduit for this dialogue, beyond what can be achieved with periodic progress meetings with the client (Miser 1994).

Other practical arrangements between the analysis team and the client to implement Schön's concept of a reflective contract must, of necessity, be evolved in the light of the circumstances peculiar to each engagement. An inhouse analysis group that has been able to achieve a reflective contract with the organization of which it is a part has a special opportunity: it can often identify problem situations that may not yet have been observed by executives in the organization, and thus set to work on them before they grow in size and importance.

How to Learn the Skills of Practice

The OR/MS community has, unfortunately, not evolved a comprehensive epistemology of practice and set it down in easily accessible literature that can be used widely in training courses. Some first steps in this direction for systems analysis, the large-scale efforts that can be thought of as part of OR/MS practice, are taken in Miser and Quade (1985,1988) and Miser (1995); much of what they say can apply equally to OR/MS as a whole. Thus, to learn the needed scientific and craft skills, someone aiming for an OR/MS career must pursue a tripartite program assembled from a variety of sources.

The intellectual basis – The foundation of effective OR/MS practice must be a thorough education in mathematics, with special attention to probability and statistics. Since by now certain models have become associated with OR/MS (as any introductory college textbook makes clear), these should be mastered as well. And a broad view of science with knowledge of other branches is also sure to be helpful.

Beyond a good mathematical and scientific education, however, the potential practitioner must not only be willing but also eager to learn from the problem situation, from the people in it, and from the representatives of other specialties, both practical and intellectual, that may have to be called on to help. As Schön's concept makes clear, to undertake an engagement in practice is to enter a multipartite partnership, and the flow of information must reflect this if the work is to be effective.

Since the action programs that OR/MS practice deals with contain people as essential elements, the analysts must know how to deal effectively and sympathetically with them, since they will enter the problem situation at many levels. In sum, interpersonal skills are an important requisite of good practice.

Familiarity with successful cases – There are by now a great many published accounts of successful cases of OR/MS practice. The journal *Interfaces* specializes in presenting them, and since 1975 has been a treasure-house of such accounts, as well as proven advice about the arts of practice. Assad et al. (1992) accompany a selection of these cases with valuable commentary. For a much wider view, one can consult the "Applications Oriented" section of the *International Abstracts in Operations Research*, the comprehensive abstract journal that has been published since 1961; it will not only exhibit the wide variety of practice being undertaken throughout the world but also identify the many journals and books in which cases appear. Rivett (1994) offers a broad introduction to successful practice based on a lifetime of varied experience.

Apprenticeship – Since the OR/MS community has yet to achieve a widely agreed and centrally documented view of its epistemology of practice, the best way for a person to observe and learn the myriad craft skills of practice is to work with an accomplished and skillful analysis team – in sum, to serve an apprenticeship (Miser and Quade 1985, 1988, offer a substantial body of additional information relating to the craft skills needed for effective OR/MS).

Examples of Good Practice

Since 1975, *Interfaces* has published the finalist papers in the Franz Edelman competition for the best papers on practice each year; there are five or more finalists in each competition. These accounts are an excellent central source of examples of good practice; in recent years tapes of the finalist presentations have also been made available.

There are many other sources of such work – too many to list here; however, both *Operations Research* and the *Journal of the Operational Research Society* contain one or more examples of good practice in each issue, as do the sources mentioned earlier.

Preemption

Concept having to do with how priorities are treated. In queueing theory, this means that an arriving higher priority customer pushes a lower one out of service because the newcomer has higher priority; service of the preempted customer later can either continue from the point of its interruption (preemptive resume queue discipline) or start totally anew. In goal programming problem, it is a statement that stipulates the ordering of the goals, so that a solution that satisfies the priority k goal is always to be preferred to solutions that satisfy the lower priority goals $k + 1$,....

Preference Theory

James S. Dyer[1] and Jianmin Jia[2]
[1]The University of Texas at Austin, Austin, TX, USA
[2]The Chinese University of Hong Kong, Shatin, NT, Hong Kong, China

Introduction

Preference theory studies the fundamental aspects of individual choice behavior, such as how to identify and quantify an individual's preferences over a set of alternatives and how to construct appropriate preference representation functions for decision making. An important feature of preference theory is that it is based on rigorous axioms which characterize individual's choice behavior. These preference axioms are essential for establishing preference representation functions, and provide the rationale for the quantitative analysis of preference. Preference theory provides the foundation for economics and the decision sciences. A basic topic of microeconomics is the study of consumer preferences and choices (Kreps 1990). In decision analysis and operations research, knowledge about the decision maker's preference is necessary to establish objective (or preference) functions that are used for evaluating alternatives. Different decision makers usually have different preference structures, which may imply different objective functions for them. Preference studies can also provide insights into complex decision situations and guidance for simplifying decision problems. The basic categories of preference studies can be divided into characterizations of preferences under conditions of certainty or risk and over alternatives described by a single attribute or by multiple attributes. This article begins with the introduction of basic preference relations and then discusses preference representation under certainty and under risk. A preference representation function under certainty will be referred to as a value function, where as a preference representation function under risk will be referred to as a utility function.

Basic Preference Relations

Preference theory is primarily concerned with properties of a binary preference relation $>_p$ on a choice set $\boldsymbol{X}$, where $\boldsymbol{X}$ could be a set of commodity bundles, decision alternatives, or monetary gambles. For example, an individual might be presented with a pair of alternatives, say x and y (e.g., two cars), and asked how they compare (e.g., do you prefer x or y?). If the individual says that x is preferred to y, then write $x >_p y$, where $>_p$ means strict preference. If the individual states that he or she is indifferent between x and y, then this preference is represented as $x \sim_p y$. Alternatively, define $\sim_p$ as the absence of strict preference, i.e., not $x >_p y$ and not $y >_p x$. If it is not the case that $y >_p x$, then write $x \geq_p y$, where $\geq_p$ represents a weak preference (or preference-indifference) relation. Also define $\geq_p$ as the union of strict preference $>_p$ and indifference $\sim_p$ i.e., both $x >_p y$ and $x \sim_p y$.

Preference studies begin with some basic assumptions (or axioms) of individual choice behavior. First, it seems reasonable to assume that an individual can state preference over a pair of alternatives without contradiction, i.e., the individual cannot strictly prefer x to y and y to x simultaneously. This leads to the following definition for preference asymmetry: preference is asymmetric if there is no pair x and y in $\boldsymbol{X}$ such that $x >_p y$ and $y >_p x$.

Asymmetry can be viewed as a criterion of preference consistency. Furthermore, if' an individual makes the judgment that x is preferred to y, then he or she should be able to place any other alternative z somewhere on the ordinal scale determined by the following: either better than y, or worse than x, or both. Formally, define negative transitivity by saying that preferences are negatively transitive if

given $x >_p y$ in $\boldsymbol{X}$ and any third element z in $\boldsymbol{X}$, it follows that either $x >_p z$ or $z >_p y$, or both.

If the preference relation $>_p$ is asymmetric and negatively transitive, then it is called a weak order. The weak order assumption implies some desirable properties of a preference ordering, and is a basic assumption in many preference studies. If the preference relation $>_p$ is a weak order, then the associated indifference and weak preference relationships are well behaved. The following results summarize some of these.

If strict preference $>_p$ is a weak order, then

1. strict preference $>_p$ is transitive (if $x >_p y$ and $y >_p z$, then $x >_p$ z);
2. indifference $\sim_p$ is transitive, reflexive ($x \sim_p x$ for all x), and symmetric ($x \sim_p y$ implies $y \sim_p x$);
3. exactly one of $x >_p y$, $y >_p x$, $x \sim_p y$ holds for each pair x and y; and
4. weak preference $\geq_p$ is transitive and complete (for a pair x and y, either $x \geq_p y$ or $y \geq_p x$).

Thus, an individual whose preferences can be represented by a weak order can rank all alternatives considered in a unique order. Further discussions of the properties of binary preference relations are presented in Fishburn (1970, Chapter 2) and Kreps (1990, Chapter 2).

Preference Representation Under Certainty

If strict preference $>_p$ on $\boldsymbol{X}$ is a weak order, then there exists a numeric representation of preference, a real-valued function v on $\boldsymbol{X}$ such that

$$x >_p y \text{ if and only if } v(x) > v(y),$$

for all x and y in $\boldsymbol{X}$ (Fishburn 1970). A preference representation function v under certainty is often called a value function (Keeney and Raiffa 1976). A value function is said to be order-preserving since the values $v(x)$, $v(y)$, ... ordered by $>$ are consistent with the preference order of x, y, ..., under $>_p$. Thus, any monotonic transformations of v will be order-preserving. As a result, the units of v have no particular meaning.

It may be desirable to consider a "strength of preference" notion that involves comparisons of preference differences between pairs of alternatives. To do so requires more restrictive preference assumptions, including that of a weak order over preferences between exchanges of pairs of alternatives (Krantz et al. 1971, Chapter 4). These axioms imply the existence of a real-valued function v on x such that, for all w, x, y, and z in $\boldsymbol{X}$, the difference in the strength of preference between w and x exceeds the difference between y and z if and only if

$$v(w) - v(x) > v(y) - v(z).$$

Furthermore, v is unique up to a positive linear transformation, i.e., if v' also satisfies the above difference inequality, then it must follow that $v'(x) = a\ v(x) + b$, where a (>0) and b are constants. This means that v provides an interval scale of measurement, such that v is often called a measurable value function to distinguish it from an order-preserving value function.

For multi-attribute decision problems, $\boldsymbol{X} = X_1, X_2 \ldots, X_n$, where n is the number of attributes and an element $x = (x_1, x_2, \ldots, x_n)$ in $\boldsymbol{X}$ represents an alternative. A multi-attribute value function can be written as $v(x_1, x_2, \ldots, x_n)$. Using some preference independence conditions, the multi-attribute value model can be simplified.

The subset $\boldsymbol{Y}$ of attributes in $\boldsymbol{X}$ is said to be preferentially independent of its complementary set $\bar{Y}$ if preferences for levels of these attributes $\boldsymbol{Y}$ do not depend on the fixed levels of the complementary attributes $\bar{Y}$. Attributes $X_1, X_2, \ldots, X_n$, are mutually preferentially independent if every subset of these attributes is preferentially independent of its complementary set.

A multi-attribute value function $v(x_1, x_2, \ldots, x_n)$ $n \geq 3$, has the following additive form

$$v(x_1, x_2, \ldots, x_n) = \sum_{i=1}^{n} v_i(x_i), \tag{1}$$

where v_i is a value function over X_i if and only if the attributes are mutually preferentially independent (Keeney and Raiffa 1976; Krantz et al. 1971). When v is bounded, it may be more convenient to scale V such that each of the single-attribute value functions ranges from zero to one, leading to the following form of the additive value function:

$$v(x_1, x_2, \ldots, x_n) = \sum_{i=1}^{n} w_i v_i(x_i), \tag{2}$$

where v and v_i are scaled from zero to one, and the w_i are positive scaling constants (usually called weights) summing to one. The assessment of models (1) and (2) are discussed in Keeney and Raiffa (1976, Chapter 3).

Dyer and Sarin (1979) proposed multi-attribute measurable value functions based on the concept of preference differences between alternatives that are much easier to assess than the additive form based on preferential independence. In addition to preferential independence, they considered some additional conditions that, loosely speaking, require that the decision maker's comparisons of preference differences between pairs of alternatives that differ in the levels of only a subset of the attributes do not depend on the fixed levels of the other attributes. These conditions allow the decomposition of a multi-attribute value model into additive and multiplicative forms. This development also provides a link between the additive value function and the multi-attribute utility model.

Preference Representation Under Risk

Perhaps the most significant contribution to the area of preference representation for risky options (i.e., lotteries or gambles) was the formalization of expected utility theory by von Neumann and Morgenstern (1947). This development has been refined by a number of researchers and is most commonly presented in terms of three basic axioms (Fishburn 1970).

Let P be a convex set of simple probability distributions or lotteries $\{X, Y, Z, \ldots\}$ on a nonempty set X of outcomes. (X, Y and Z will be used to refer to probability distributions and random variables interchangeably.) For lotteries X, Y, Z in P and all λ, $0 < \lambda < 1$, the expected utility axioms are:

A1. (*Ordering*) $>_p$ is a weak order;

A2. (*Independence*) If $X >_p Y$, then $\lambda X + (1-\lambda) Z >_p \lambda Y + (1-\lambda)Z$ for all Z in P;

A3. (*Continuity*) If $X >_p Y >_p Z$, then there exist some $0 < \alpha < 1$ and $0 < \beta < 1$ such that $\alpha X + (1-\alpha)Z >_p Y >_p \beta X + (1-\beta)Z$.

The von Neumann-Morgenstern expected utility theory asserts that the above axioms hold if and only if there exists a real-valued function u such that for all X, Y in P,

$$X >_p Y, \text{ if and only if } \mathrm{E[u(X)]} > \mathrm{E[u(Y)]},$$

where the expectation is taken over the probability distribution of a lottery. Moreover, such a u is unique up to a positive linear transformation.

The expected utility model can also be used to characterize an individual's risk attitude (Keeney and Raiffa 1976, Chapter 4). If an individual's utility function is concave, linear, or convex, then the individual is risk averse, risk neutral, or risk seeking, respectively. The von Neumann-Morgenstern theory of risky choice presumes that the probabilities of the outcomes of lotteries are provided to the decision maker. Savage (1954) extended the theory of risk choice to allow for the simultaneous development of subjective probabilities for outcomes and for a utility function u defined over those outcomes.

As a normative theory, the expected utility model has played a major role in the prescriptive analysis of decision problems. However, for descriptive purposes, the assumptions of this theory have been challenged by empirical studies (Kahneman and Tversky 1979). Some of these empirical studies demonstrate that subjects may choose alternatives that imply a violation of the independence axiom (A2). Prospect theory (Kahneman and Tversky 1979; Wakker 2010) attempts to explain these discrepancies. One implication of A2 is that the expected utility model is linear in probabilities. A number of contributions have been made by relaxing the independence axiom and developing some nonlinear utility models to accommodate actual decision behavior (Fishburn 1988).

For the case of multi-attribute decisions under risk, when $X = X_1 \times X_2 \times \ldots \times X_n$ in a von Neumann-Morgenstern utility model and the decision maker's preferences are consistent with some additional independence conditions, then $u(x_1, x_2, \ldots, x_n)$, can be decomposed into additive, multiplicative, and other well-structured forms that simplify assessment.

The attributes $X_1, X_2, \ldots, X_n$ are said to be additive independent if preferences over lotteries on $X_1, X_2, \ldots, X_n$ depend only on the marginal probabilities assigned to individual attribute levels, but not on the joint probabilities assigned to two or more attribute levels.

A multi-attribute utility function $u(x_1, x_2, \ldots, x_n)$, can be decomposed as

$$u(x_1, x_2, \ldots, x_n) = \sum_{i=1}^{n} w_i u_i(x_i), \tag{3}$$

if and only if the additive independence condition holds, where u_i is a single-attribute function over X_i scaled from 0 to 1, and the w_i are positive scaling constants (or weights) summing to one. The additive model (3) has been widely used in practice.

If the decision maker's preferences are not consistent with the additive independence condition, a weaker independence condition that leads to a multiplicative preference representation may be satisfied.

An attribute X_i is said to be utility independent of its complementary attributes if preferences over lotteries with different levels of X_i do not depend on the fixed levels of the remaining attributes. Attributes $X_1, X_2, \ldots, X_n$ are mutually utility independent if all proper subsets of these attributes are utility independent of their complementary subsets.

A multi-attribute utility function $u(x_1, x_2, \ldots, x_n)$ can have the multiplicative form

$$1 + ku(x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} [1 + kk_i u_i(x_i)], \qquad (4)$$

if and only if the attributes $X_1, X_2, \ldots, X_n$ are mutually utility independent, where u_i is a single-attribute function over X_i scaled from 0 to 1, the k_i are positive scaling constants, and k is an additional scaling constant. For approaches to the assessment of model (4) and other extensions of multi-attribute utility theory, see Keeney and Raiffa (1976).

The research of multi-attribute utility theory has been advanced from both theoretical and behavioral considerations. In particular, the effort of behavioral research tries to improve the descriptive power of multi-attribute utility models by incorporating psychological factors, such as aspiration level, goal and reference effect, and loss aversion (Tversky and Kahneman 1991). Various decision support systems have also been developed for multi-attribute decision making in the past decades, and applications of the theory and models have been expended to many new areas, including e-commence, public policy and environmental decisions, geographic information systems, and engineering (Dyer et al. 1992; Wallenius et al. 2008).

Prescriptive Model

A model that attempts to describe the best or optimal solution of a man/machine system. For a decision problem, such a model is used as an aid in selecting the best alternative solution.

See

- ▶ Decision Problem
- ▶ Descriptive Model
- ▶ Mathematical Model
- ▶ Normative Model

Prices

In the simplex method, for a nonbasic variable x_j, the price is defined as $d_j = c_j - z_j$ or $d_j = z_j - c_j$, where c_j is the variable's original cost coefficient and $z_j = \boldsymbol{\pi}\mathbf{A}_j$, with $\mathbf{A}_j$ the variable's original column of coefficients and $\boldsymbol{\pi}$ the multiplier (pricing) vector of the current basis. The d_j is termed the reduced or relative cost. It is the difference between the direct cost c_j and indirect cost z_j. The d_j indicates how much the objective function would change per unit change in the value of x_j. The d_j for the variables in the basic feasible solution are equal to zero.

Prim's Algorithm

A procedure for finding a minimum spanning tree in a network. The method starts from any node and connects it to the node nearest to it. Then, for those nodes that are now connected, the unconnected node that is closest to one of the nodes in the connected set is found and connected to these closest nodes. The process continues until all nodes are connected. Ties are broken arbitrarily.

See

Primal Problem

The primal problem is usually taken to be the original linear-programming problem under investigation.

See

- ▶ Dual Linear-Programming Problem

Primal-Dual Algorithm

An adaptation of the simplex method that starts with a solution to the dual problem and systematically solves a restricted portion of the primal problem while improving the solution to the dual. At each step, a new restricted primal is defined and the process continues until solutions to the original primal and dual problems are obtained.

Principle of Optimality

Condition that Richard Bellman derived for dynamic programming: "An optimal policy has the property that whatever the initial state and initial decision are, the remaining decisions must constitute an optimal policy with regard to the state resulting from the first decision." (Bellman 1957, Chap. III.3)

Prisoner's Dilemma

A two-person game where neither player knows the other's play (action or decision) a priori. Imagine a situation where two criminals are isolated from each other and the police interrogator offers each the following deal: if the prisoner confesses and the confession leads to the conviction of the other prisoner, he goes free and the other prisoner gets 10 years in prison. However, if both confess, they each get 5 years. If neither confesses, there is enough evidence to convict both on a lesser offense and they both get one year. If there is no trust, then both will confess, whereas if there is complete trust, neither will. Since complete trust is rare, when the game is played one time, players almost always defect. When the game is played repeatedly and there is a chance for a long-term reward, wary cooperation with a willingness to punish defection is the best strategy. This game illustrates many social and business contracts and is important for understanding group behavior, both cheating and cooperation. It has also been used in studying political and military strategies.

Probability Density Function (PDF)

When the derivative $f(x)$ of a cumulative probability distribution function $F(x)$ exists, it is called the density or probability density function.

Probability Distribution

Term used (loosely) to refer to a function describing the probabilistic behavior of a random variable; could refer to the probability measure, the cumulative distribution function (CDF), the probability mass function (PMF) for discrete random variables, or the probability density function (PDF) for continuous-valued random variables.

Probability Generating Function

For a non-negative integer-valued random variable X with probability mass function $p_j = \Pr\{X = j\}$, the probability generating function (often just called the generating function, and known in other fields as the z-transform) is given by $P(z) = E[z^X] = \sum_{j=0}^{\infty} z^j p_j$. The definition can be extended to the setting where X can take all integer values (i.e., including all negative values).

Probability Integral Transformation Method

One of the primary methods for generating random variates for Monte Carlo or discrete-event simulation, using the cumulative distribution function (CDF) commonly known as the inverse transform method.

See

- ▶ Inverse Transform Method
- ▶ Random Number Generators
- ▶ Random Variates
- ▶ Simulation of Stochastic Discrete-Event Systems

Probability Mass Function (PMF)

Function giving the probability of taking on each of the possible discrete values.

Problem Solving

The process of deciding on actions aimed at achieving a goal. Initially, the goal is defined to represent a solution to a problem. During the reasoning process, subgoals are formed, and problem solving becomes recursive.

Problem Structuring Methods

Jonathan Rosenhead
The London School of Economics and Political Science, London, UK

Introduction

Problem structuring methods (PSMs) are a broad group of model-based problem handling approaches whose purpose is to assist in the structuring of problems rather than directly to derive a solution. They are participative and interactive in character, and normally operate with groups rather than individual clients. In principle they offer OR/MS access to a range of problem situations for which more classical OR techniques have limited applicability. The most widely adopted of these methods are Soft Systems Methodology, the Strategic Choice Approach, and Strategic Options Development and Analysis (SODA).

PSMs developed out of, or at least intertwined with, a critique of the restricted scope of traditional OR techniques. From the 1970s there developed an active debate over claims for the objectivity of OR/MS models, and about the limitations imposed on OR/MS practice by its concentration on well-defined problems. Significant critical contributions were made by

Rittel and Webber (1973), Ackoff (1979), Checkland (1981), Rosenhead and Thunhurst (1982), Eden (1982), Rosenhead (1986), Jackson (1987), Flood and Jackson (1991), Mingers (1992). The general thrust was that standard OR techniques assume that relevant factors, constraints, and objective function are both established in advance and consensual; commonly the function of the technique is to determine an optimal setting of the controllable variables. Consistently with this, standard formulations of OR methodology were seen to assume a single uncontested representation of the problematic situation under consideration.

Critics have recognized that OR's practice has been considerably more diverse than this, and in particular is far from dominated by considerations of optimality; however, the available tools were held to offer little appropriate assistance outside this area. The methodological framework on offer was equally seen as giving scant guidance to analysts confronting less well-behaved circumstances. There are situations in which intangibles, uncertainty, and value diversity as well as complexity are crucial presences. Skilled operational researchers have been able to make progress in such situations, but only by using tacit skills which are not part of the OR/MS canon. Yet the more socially important the decision situation, the more likely it is that such features will come to dominate.

Out of this critique of the shortcomings of traditional OR/MS a family of alternative methods was developed, with both common features and also differences of focus. When their similarities were recognized the label used to describe them as a group was Problem Structuring Methods (though other names such as Soft OR are also in currency). The over-arching emphasis which the methods share is on helping groups of decision-makers to identify what problem they could usefully work on together, and to assist them in making progress with that task. There is no assumption that the decision-makers share a common perspective, so that they are perhaps more accurately described as stakeholders. Nor are these methods to any significant degree quantitative. This is because the approaches are all based on the participation of those who have the problem. If mathematics were to be the language of the discourse, some (perhaps many) of the participants would be disempowered, or at least prevented from enunciating perceptions important to them which could not be expressed in that format, or only by a distortion which changed their content.

Each of the methods within the PSM family consists of a number of technical procedures linked together through social processes. i.e., unlike the algorithmic approaches that have tended to dominate OR/MS, the consultant does not identify and then input some starting conditions from which the 'answer' will be produced without further human intervention. What happens is that at various points the groups discuss the implications of the analysis to date, and on that basis (and aided by a facilitator) decide how to proceed further, or maybe whether enough progress has been made that the stakeholders can proceed without further analytic assistance. For clarity one should perhaps describe PSMs as 'methodologies' rather than 'methods', taking a methodology as an assembly of technical and process elements.

In short these methods bear very little resemblance to those developed within traditional OR/MS. The one key unifying element is the central use of cause-effect models. Each of them uses formal models to represent the problematic situation perceived by the decision-making group, in order to summarise, coordinate and advance their understanding of the situation they confront. The types of model used are specific to each method, but none of them are 'computable'. Indeed quantification has little if any role in any of them. The concepts that are in play are more usually verbal, and the operations on them are mostly performed by the group, who through discussion transform the models based on their changing understanding. The outcomes of a successful application of a PSM will be a group of decision-makers confident enough to take action; a group of decision-makers who have gained a deeper insight into their problem area; and a group of decision-makers whose shared experience has led to improved relations with each other.

Types of Problem

Before going on to outline the PSM field, it should be helpful to address the apparent paradox of two very different types of methodology, sometimes called 'hard' (i.e., traditional) and 'soft' (PSMs), each addressing problems of complexity in an analytic

manner. One simple explanation lies in the quite wide recognition of two substantially different types of problem situation. Rittel and Webber's (1973) characterization of them as tame vs. wicked has achieved wide currency, as has Schon's (1987) extended metaphor of problems of the swamp contrasted with those of the high ground. Tame problems (on the high ground) have precise, unproblematic formulations permitting powerful analyses of great technical sophistication. Wicked problems (in the swamp) have multiple stakeholders, intangible objectives, key uncertainties, contested or doubtful formulations, etc. In the latter there is no unified representation of the issue or issues that can be established *ahead* of analysis. Rather, a representation or representations of the problematic situation which participants find helpful may be a major product of the analysis.

It follows from this diagnosis that methods that are designed to be effective in handling tame problems are likely to be largely irrelevant for wicked ones. (And vice versa of course.) For the latter type of problem situation, methods that assist argumentation, promote negotiation or generate mutual understanding are needed, rather than those that reliably and efficiently identify an optimum. Methods that can only start once there is an agreed problem (but have no methods for reaching that agreement) are liable to ignore or dismiss alternative perspectives and their contrary formulations.

The much remarked difficulty which OR/MS encountered from the late 1960s in securing access to more strategic levels of decision-making may be attributed at least in part to this factor. As Schon observed, problems of major social importance are commonly located in "swamp" conditions. Attempts to address these "messes" using techniques and methodology developed for handling well-structured problems constituted inappropriate technology transfer. Where solutions based on these methods were adopted they were vulnerable to being savaged in practice by the 'wicked' parts of the problem situation that had been excluded. More commonly however such representations were recognised as an overly thin representation of the rich and complex world that managers and decision-makers inhabit – with the result that OR/MS was confined to the tame (less strategic, more repetitive, operational) aspects of organisational life.

Characteristics of Alternative Methods

Problem structuring methods constitute a family of approaches offering appropriate support to decision-making under these less pacified circumstances. They were developed separately by individual innovators or teams of innovators, and each emphasizes or is organized around particular aspects of the wicked problem environment. Indeed each had been independently developed before a recognition arose of their family resemblance. (Subsequent to that recognition, however, many of the principal originators entered into a constructive dialogue with each other, in which a certain amount of mutual borrowing of particular elements took place.: For example, distinctive post-it 'Ovals', originated for use within SODA, became widely used by other methods.) In other words the new methods grew out of practice. However their similarities are by no means coincidental. Many leading developers of PSMs had been active participants in the critique of traditional methods, and their innovations were designed to remedy particular inadequacies of the conventional repertoire in handling wicked problems. So at that fundamental level there was a common theoretical base.

PSM methods have differing rationales, purposes, technical apparatus, etc. Some of these distinctive attributes will be indicated below. However it will be useful, first, to identify the features which they hold in common.

Rosenhead (1989) has provided one formulation, based on inverting the characteristics of the conventional OR/MS paradigm.

PSMs

- Seek solutions which satisfice on separate dimensions (rather than trade-off onto a single dimension to facilitate optimization);
- Integrate hard and soft data with social judgments (reducing data greed with its problems of quality and distortion);
- Produce transparent models which clarify any conflicts (rather than basing a scientific depoliticization on an assumed consensus);
- Treat people as subjects actively engaged in the decision-making process (rather than as passive objects to be modelled or disregarded);
- Facilitate planning from the bottom-up (and not as a process driven by the abstract objectives of a hierarchically located decision-maker); and

- Accept that some uncertainty is irreducible and aim to preserve options (rather than base current and future decisions on a notionally certain future).

The methods clearly assume a decision-making quite different from that of conventional OR/MS applications, and this environment places particular requirements on the interface with the client group. Where consensual values cannot be assumed, there will be a need to achieve agreement among a range of stakeholders representing different interests and/or holding different perspectives. It follows from this that a PSM should be able to accommodate multiple alternative perspectives, often in a group situation in which holders of those viewpoints are present and participating. From this it follows that for a method to be helpful it must operate iteratively and interactively; as participants internalize and adjust to each others' contributions, new formulations of the problematic situation will emerge which in turn feed new modelling and structuring activity. And since participants have different though overlapping organizational agendas, and also because of the prevalence of uncertainty, any resulting consensus on action is likely to constitute a partial rather than a comprehensive solution to the problems present within the situation under discussion.

These social requirements on a PSM have implications for the technical repertoire that it can deploy. Its handling of complexity must not obstruct lay participation — which points to graphical (rather than, for example, algebraic) representations. The existence of multiple perspectives invalidates the search for an optimum; the need is rather for systematic exploration of the solution space. To elicit meaningful judgments from lay participants, abstract continuous variables need to be eschewed in favour of discrete concrete alternatives that can be compared. And, given the need to avoid illusions of precision when confronting uncertainties, possibilities will be more helpful than probabilities, and alternative scenarios will enrich discussion that forecasts might close down.

These outline specifications for a more appropriate decision-aiding technology eliminate much of the scope for advanced mathematics, probability theory, complex algorithms. They identify, rather, an alternative approach employing representation of relationships, symbolic manipulation, and limited quantification within a systematic framework. These are decidedly low-tech methods: some of them have no software support, and even those that do can be operated in manual mode. The lack of mathematics should not however be taken for lack of rigour. These are methods with their own rigour, which is qualitative in nature.

The Methods

There is no definitive list of problem structuring methods. However to give identity to the field it is appropriate to provide some demarcation criteria.

PSMs

- Can be distinguished from traditional OR methods by the six criteria listed in the previous section.
- Can be distinguished from non-OR modes of working with groups, such as Organizational Development, by the core element of an explicit modelling of cause-effect relationships.
- Can be demarcated from other OR approaches which purport to tackle messy, ambitious problems (e.g., the Analytic Hierarchy Process) by PSMs' transparency of method, restricted mathematization, and focus on supporting judgment rather than representing it.

These limits are imprecise and arguable; and there is scope for approaches developed for other or broader purposes (e.g., spreadsheet models) to be used in a similar spirit. Ackoff's Interactive Planning is close in both spirit and intent (see Ackoff 1999) but nevertheless has never been regarded as falling within PSMs. (Rather than changing this de facto if not de jure circumstance, it will not be discussed further.) Methods that have some degree of similarity to PSMs but also significant differences are (for coherence) best regarded as falling outside the category. These include multi-criteria decision methods, outranking methods such as PROMETHEE and ELECTRE, decision conferencing, scenario planning, system dynamics (in some of its versions) and Viable System Diagnosis. Other parts of the PSM perimeter are bordered by the focus group approach, and by Rapid Rural Appraisal and other participative third world development approaches (for which see Rosenhead and Mingers 2001, pp. 345-7).

A brief introduction to the better established PSMs follows (Rosenhead and Mingers 2001):

Strategic Options Development and Analysis (SODA)

This method is described fully in Eden and Ackermann (1998). It is a general purpose problem identification method that uses cognitive mapping as a modelling device. The concepts that individuals use to make sense of their problematic situation, and the causal links thought to exist between those concepts, are elicited in individual interviews and recorded in map form. The maps drawn from separate interviews with stakeholders are subsequently merged into a single 'strategic map' through pinning together concepts common to more than one of them. The strategic map, commonly structured into clusters, provides the framework for discussion in a workshop of the group of map 'owners', at which a facilitator uses the map to guide participants towards commitment to a portfolio of actions. An alternative and more rapid version known as the Oval Mapping Technique operates in workshop mode throughout, and can in principle achieve results in a 1 day session. The participants commit their concepts to 'Ovals' (specially designed PostIt notes), which the facilitator with the participation of workshop members organises into an agreed structure. This then serves as the strategic map for the discussion that follows.

Soft Systems Methodology (SSM)

Soft Systems Methodology is a general method for system design or redesign, which aims to generate debate about alternative system modifications. It adopts a systems theoretic framework for exploring the nature of problem situations, and how purposeful action to change them might be agreed when there are different perceptions of the situation based on contrasting world views. A systematic exploration of the world views of stakeholders leads to the generation of definitions of alternative systems, the investigation of which is expected to be of interest from at least one of those world views. Each of these abstract 'root definitions' is expanded into the component activities which would be necessary for it to operate successfully. This generates a range of contrasting alternatives for the modification of the system, which are used to generate debate about which changes are both culturally feasible and systemically desirable. Full descriptions of the method are available in Checkland (1981, 2006, 1990).

Strategic Choice Approach (SCA)

Strategic Choice is a planning approach centred on the management of uncertainty and commitment in strategic situations. Typically a Strategic Choice engagement takes place entirely in workshop format, with no backroom work by the consultants. There are four modes of analysis:

- Shaping – in which different areas for choice are elicited from workshop members. A subset of these is selected as a problem focus by reference to their urgency, importance and inter-connectedness
- Designing – here the options for action for each of the decision areas within the problem focus are identified, as well as any incompatibilities between option selections in different decision areas. The feasible decision schemes (consisting of one option choice within each decision area) are derived
- Comparing – criteria for choice, often non-quantitative, are agreed by the group. These are used first in satisficing mode to establish a working shortlist of schemes; pairwise comparisons of shortlisted schemes are made, establishing on each criterion a range of relative advantage between the two schemes. This may be repeated for different pairs. Commonly significant uncertainties are revealed by this process. Other uncertainties will usually have been identified in previous modes
- Choosing – bearing in mind the surfaced uncertainties, a 'progress package' is agreed consisting of partial commitments to be made at this stage, explorations to be launched to reduce key uncertainties, contingency plans, and a timetable for later choices.

Facilitators assist with the deployment of the transparent tools available within the method, and in guiding the, possibly recursive, switching between modes. A detailed account of the method is available in Friend and Hickling (2004).

Robustness Analysis

Robustness Analysis is another approach for use where uncertainty is an important issue. It focuses on one specific strategy for managing that uncertainty - that of maintaining useful flexibility. The focus of the approach is on initial commitments rather than on future plans for the system. The flexibility of an initial commitment relates to its compatibility with a range of

acceptable or desirable future states of the system. It is this flexibility left by an initial commitment that is operationalised as a decision-making criterion by the concept of the robustness. This is defined as a ratio where the denominator is the number of states whose performance at the planning horizon is 'good enough'; the numerator is the number of those states which would remain accessible if the commitment under consideration were to be made. Robustness analysis can be conducted with either a single or multiple futures employed to estimate system performance; and it can be used in conventional or interactive mode. In the latter, participants and analysts assess both the compatibility of initial commitments with possible future configurations of the system, and the performance of each configuration in feasible future environments. This enables them to compare the flexibility maintained by alternative initial commitments. It is in this latter mode that Robustness Analysis qualifies as a PSM, though even when used in non-participatory mode it maintains an accessible transparency. For more detail, see Rosenhead and Mingers (2001).

Drama theory

Drama Theory draws on two earlier approaches, metagames and hypergames. It is an interactive method of analysing co-operation and conflict among multiple actors. A model is built from perceptions of the options available to the various actors, and how they are rated. Drama theory looks for the 'dilemmas' presented to the actors within this model of the situation. Each dilemma is a change point, tending to cause an actor to feel specific emotions and to produce rational arguments by which the model itself is redefined. When and only when such successive redefinitions have eliminated all dilemmas is the actors' joint problem fully resolved. Analysts commonly work with one of the parties, helping it to be more effective in the rational-emotional process of dramatic resolution. For more detail, see Howard (1999).

Applications of PSMs

As can be inferred from their remit to structure wicked problems, the problem situations to which PSMs have been applied have a wide variety. A good source for practical applications of the SCA is Chapter 13 of Friend and Hickling 2004, pp. 298-360. An overview of applications across the range of PSMs is provided by Mingers and Rosenhead (2004), which is the review article for a special issue of the *European Journal of Operational Research* on applications of PSMs (Vidal 2004).

A diverse record of successful applications is an indicator of wide relevance, but a disadvantage when it comes to providing a coherent summary. A literature survey covering the period up to 1998 (summarized in Mingers and Rosenhead 2004) categorises 51 reported applications under the headings general organizational/information systems/technology, resources, planning/health services/general research. Two comments seem appropriate: (i) it is plausible to assume that reported cases are the tip of the iceberg; and (ii) 1998 was relatively early in the development of interest in PSMs.

The categories supplied in the previous paragraph are so broad as to give little flavour of the reality of PSM practice. To provide that, some short summaries of projects using PSMs that are described in Mingers and Rosenhead (2004) may be of assistance

- Organisational restructuring at Shell. SSM used to provide the basis of a reconfiguration of a central department of Shell International, in a series of workshops with senior managers
- Models to support a claim for damages. SODA (as well as System Dynamics) used to support a legal case by the Canadian-based multinational Bombardier against Trans Manche Link, for damages resulting from delays in processing designs for the Channel Tunnel shuttle wagons
- Supporting a tenants cooperative. This was an engagement over several years to help a cooperative of residents of an ex-mining village to manage their own housing. Elements of various PSMs, as well as other methods (e.g., spreadsheet financial models) were used to support strategic decisions, and help the cooperative gain confidence
- IT strategy for a supermarket chain. This study reported to the joint chief executives of the leading British supermarket chain Sainsbury's, and worked with a 16-strong senior management task force. SODA, SSM and SCA were all used at different stages, to identify IT systems that would support business objectives

- Planning for a street festival. The largest European street festival (Notting Hill Carnival) was a victim of its own success, with issues of security, congestion, cultural integrity etc. Working with representatives of the carnivalists, local government, transport and emergency services, and arts organisations, SSM and SCA were used to devise escape strategies
- National level planning in Venezuela. A version of SCA has been used at various levels of the state service in Venezuela, up to and including the Cabinet, to agree on strategic decisions in a range of areas
- Local pediatric care strategy. Health care managers and specialists in an Inner London area with some 500,000 population needed to reduce the number of inpatient paediatric care units. SCA was used in a series of workshops to produce agreement between representatives of all stakeholders on (i) how many units should remain (ii) where they should be; and (iii) what consequential changes were needed to other aspects of the health service.

This list indicates the reach of these methods, from grass-roots community groups through senior corporate management issues to the highest levels of national government. The content of many if not all of the projects would have rendered them inaccessible to conventional OR.

Using PSMs

Working with Clients

PSM practitioners have to be able to manage not only the complexity of substantive subject matter but also the dynamics of interaction among workshop participants. The dual roles of analyst and of facilitator of group process place heavy demands on the consultant, who is called upon to deploy a wider range of skills than in conventional operational research practice. When operating as facilitator she has the responsibilities of ensuring that all voices are heard (not suppressed by psychological or hierarchical effects); that apparent agreement is not based on mutual misunderstanding of key terms; and that the precious (and usually expensive) opportunity presented by the gathering of key stakeholders is exploited in a timely and effective manner. (This experience is hard to simulate 'off line', and training should, if possible, include at least a brief experience of practical apprenticeship.) It is useful to have two facilitators with differentiated roles. One of them is likely to be heavily engaged, at times leading the discussion, at others concentrating acutely on the content of the discourse and also on the interpersonal issues that it reveals. The second facilitator can be principally involved with keeping a record, perhaps by direct computer input, of the evolving model. But he will also be able to intervene with insights that his colleague might otherwise miss through following the scent too closely.

PSMs are based on the working assumption that the client is not a sole decision-maker but a client system. Organisational politics is thus an integral aspect of project process, to which the consultants must be sensitive if they are not to be derailed. In order to achieve an effective process and worthwhile outcome it is important that all relevant stakeholders are represented. This requirement may bump up against numerical constraints – most practitioners cite a group size in the range 6–10 as desirable, and 12 should be the absolute maximum for a coherent group conversation to take place. There may be pressures to add people beyond this number for reasons of organisational politics, or to exclude certain clearly relevant stakeholders. These issues of the design of the group are ones that the consultant must address.

To guide the workshop with the consent and indeed respect of the group, the consultant must be, and be seen to be, disinterested – that is, not operating on behalf of any sectional interest. Where political tensions are active, this can require both sensitivity and agility from the facilitator. In inter-organisational working (for which the multi-perspective approach of PSMs makes them particularly appropriate), the question of access to the problem domain potentially acquires an additional twist. Initial contacts with one of the organisational actors will be necessary to gain entry to the problem forum - but that entry route may itself occasion doubts among other stakeholders as to the impartiality of the facilitation that follows.

Selecting Methods

There is no established process for the selection of method or methods to use in a particular engagement. This is often done on an intuitive basis – where uncertainties are seen as particularly salient in the problematic situation, Strategic Choice or Robustness

Analysis are plausible candidate methods; an evident conflict situation may suggest drama theory; and so on. There is of course also a choice to be made between using a traditional method or a PSM of any kind.

The most widely cited and discussed framework for this higher-level choice is due to Jackson and Keys (1984). Their 'system of systems methodologies' proposed two dimensions on which to describe the context of a problem. These were the degree of agreement among participants – which can be unitary (consensus), pluralistic (several viewpoints but agreement possible), or coercive (disagreements resolved through exercise of power); and the nature of the problem - simple or complex. This yielded six cells into which OR/systems methods were placed. For example, traditional hard OR was most suitable for simple–unitary contexts, System Dynamics for complex–unitary contexts, and Problem Structuring Methods for complex–pluralistic contexts.

However the criticism has been advanced that this framework makes the (unwarranted) assumption that the nature of the problem context can unerringly be identified in advance. Commonly, however, this will not be the case in the messy situations that PSMs are appropriate for. It may well be that only *after* the investigation is underway will the view to be taken of the problem context become clear. Furthermore, since the use of PSMs is a form of organised finding out, it is quite possible that this process will change the initial understanding of the problem context. For example, what was initially perceived by the relevant actors to be pluralist in character may, as a result of the intervention be reperceived as falling elsewhere on the spectrum of degree of agreement.

Mixing Methods

Another feature undermining the simplicity of the Jackson and Keys scheme is the fact that many PSMs consist of a loosely articulated set of processes (part technical, part social), with considerable freedom to switch phase or to recycle. They therefore lend themselves to creative re-assembly, in which different methods or parts of different methods are used in conjunction. Before theoretical discussion of this potential took off in the 1990's it was already a de facto reality in practice. The most high profile of many applications was the Sainsbury's case study (Ormerod 1996) already mentioned above, in which SODA, SSM and SCA were employed on a single engagement. In fact several of the cases summarised in the Applications section of this article involved the use of parts or wholes of PSMs in combination, or indeed the joint use of a PSM with a more conventional OR technique.

This ongoing practice was systematised and given a theoretical base by multimethodology (Mingers and Gill 1997). This advocates seeking to combine together a range of methods, perhaps across the hard/soft divide, in order to deal effectively and appropriately with the qualitatively different analytic challenges which a single problem situation may pose. Based on the work of Habermas (1984, 1987), any real-world problem situation can be seen as a complex mix of the material, the social, and the personal. Different methods are appropriate for analysing and making progress in these different strata. Thus material or physical characteristics can be modelled using traditional OR techniques, but social conventions, politics and power, and personal beliefs and values need quite different, qualitative approaches.

Any practical project goes through several stages - understanding and appreciating the situation, analysing information, assessing different options, and acting to bring about change. Moving from one phase to another offers an opportunity to transfer, based on the understanding achieved up to that point, to a different level (say from the material to the social) and to a corresponding type of analysis. The appropriate use of varied methods allows the project to evolve creatively, rather than pursuing the methodology adopted at its start, regardless of the understanding which is progressively developed. These are complementary arguments for combining together different PSMs, and indeed PSMs with other methods. Multimethodology facilitates a more varied palette, to match the developing richness of problem understanding.

Software and Other Technology

Several established PSMs have associated software: examples include STRAD (for Strategic Choice) and Decision Explorer (for SODA). These packages perform a variety of functions. They may display and re-organize concepts and their inter-relationships; identify a feasible range of options for action; elicit preferences using paired comparisons; compute simple quantitative attributes of options derived from the

current problem structure, and so on. They may also perform a variety of roles in the project, from technical assistance to the facilitator between group sessions, through enabling individual participants to pursue solo investigations, to the provision of an online Group Decision Support System. The use of the software during group sessions undoubtedly has an effect on group dynamics, focusing attention and giving a degree of control to whoever is in charge of inputting data or of changing the visual display. For this reason some leading practitioners prefer not to employ computers during the actual workshop sessions. In SODA, however, the computer display of sections of strategic maps is used deliberately in order to influence the group conversation. The computer model (i.e., map) is deployed as a 'facilitative device', so that group members will more easily accept and absorb concepts that are new to them. A concept that is advanced by another group member might provoke resistance – but one which whose presentation is neutrally framed by the computer may be easier to accommodate to.

The distinctive technology of PSMs is low- rather than high-tech. Ongoing models and other notes on deliberations are recoded on A1 flipchart sheets on the meeting room walls. Oval 'postit' notes are used to capture concepts in a way which facilitates re-structuring of model relationships during the session. At the end of a workshop it is normal for these traces to be photographed, and then emailed to participants. This visual record is a vivid reminder not only of the outcome of a workshop, but also of the process by which it was reached.

Implementation

A PSM workshop should leave time at the end for the group to agree an implementation strategy. If it is an intermediate workshop with others to follow, this process will constitute the allocation of responsibilities to group members (including the facilitators) to pursue clarification or uncertainty reduction activities that have been revealed as advantageous, so that the following meeting can take off from an improved position. With some PSMs the intervening work may consist of model development by the consultants – e.g., producing revised SSM 'root definitions'; in SODA reflecting the discussion in redrawn maps; and in SCA carrying out explorations to reduce relevant uncertainties. At what is expected to be a final workshop, where some conclusions have been agreed, the implementation strategy needs to be articulated and bought into by the key players. This will require a thorough discussion to identify the tasks (including for example a dissemination strategy) necessary for sustainable action to take place, and to specify responsibilities for these.

The experience within a PSM workshop, when it is working well, is frequently intense and the sense of release and satisfaction when a breakthrough is made can be palpable. Negotiated accommodations arrived at in this way can be creative escapes from apparently irresolvable tangles. However this almost cathartic experience is not transferable to non-participants. Generally only a part of the client system will be present at the workshop, and those not present may be reluctant to take its outputs on trust. Indeed it is more likely than not that those who can actually set the wheels in motion have not been members of the workshop. A report in conventional form which presents the case for the decisions arrived at in linear fashion the may be needed. For work within a single hierarchically structured organisation, top-down authority may carry the outputs of a PSM-based process towards implementation. In the case of inter-organisational work the situation is more complex, and the generation of acceptance among the various organisational constituencies can be problematic. It is clearly advisable for these problems of multiple acceptance to be discussed by the group, and to inform the implementation strategy.

Concluding Remarks

The progress of Problem Structuring Methods - in development and sophistication of methods, in applications, and in geographic spread - since they were recognised as a category with strong family resemblances has been fairly uninterrupted. There is one exception: the United States. The development of PSMs has been virtually ignored by the US OR/MS community. This was pointed out in an unprecedented letter to *ORMS Today* (Ackerman et al. 2009) signed by 45 academics from 11 countries and four continents. They cited as a strong contributory factor the systematic exclusion of papers on this topic from

US-based academic journals. An article in the same issue (Mingers 2009) explored the phenomenon in greater depth. For a further analysis of the difference in treatment of PSMs between the U.S. and the U.K., see Paucar-Caceres (2011).

In much of the rest of the world, PSMs have effected a breakout from the well developed but relatively confined arena of technocratic solutions to consensually defined problems occupied by OR's traditional methods. This outward movement has brought decision-support modelling in touch with a range of other methods and practices designed to help groups make progress with their problems. It has been suggested elsewhere (Rosenhead and Mingers 2001) that large group methods, development planning methods and community operational research are among the areas from which PSMs can learn, and to which PSMs can contribute.

The presence of Community OR (Midgley and Ochoa-Arias 2004) in this list is due to its natural fit with PSMs. Community OR is an analytic practice aimed at extending the customers of OR to include disadvantaged and non-hierarchical groups. With few resources, many of traditional OR's resource allocation tools are irrelevant. Furthermore the weak are perhaps disproportionately confronted with 'wicked', less well-structured problems; and the bottom-up nature of the PSM approach seems appropriate for the defined clientele. Its transparent modelling approach and group orientation does not present as many obstacles to engagement as would traditional OR's more mathematical approaches. No doubt these are among the reasons for the relatively high penetration of PSMs in this area.

There is now a substantial record of achievement for PSMs. There have been a wide variety of different types of use, both in context and in content. Surveys have shown there to be a good measure of user satisfaction. And there is an exciting range of possible further developments which appear to be reachable from the base that has already been achieved.

Product Form

► Product-Form Solution

Product Form of the Inverse (PFI)

The inverse of a matrix expressed as the product of sequence of matrices. The matrices in the product are elementary elimination matrices.

See

► Eta File
► Simplex Method (Algorithm)

Product-Form Solution

When the steady-state joint probability of the number of customers at each node (station) in a queueing network is the product of the individual probabilities times a multiplicative constant, as in $\Pr\{N_1 = n_1, N_2 = n_2, \ldots, N_J = n_J\} = K\pi(n_1)\pi(n_2)\ldots\pi(n_J)$, the network is said to have a product-form solution. Sometimes the designation of a product-form solution requires that the multiplicative constant K also decompose into separate factors for each node, as holds for open Jackson networks but not for closed Jackson networks. Variants of such product-form solutions also occur in some non-network queues, such as those with vacations.

Introduction

Some of the important objectives of a manufacturing system are to produce in a timely manner products that conform to specifications, while minimizing costs. The strategic measures of performance of a manufacturing system are cost, quality, flexibility, and delivery. Often hundreds of products are produced by a facility, and the entire production process may span several facilities that are geographically dispersed. In many industries the production network consists of plants that are located in different countries.

Production management entails many decisions that are made at all levels of the managerial hierarchy. Manufacturing processes involve a large number of people in many different departments and organizations, and utilize a variety of resources. In addition to the quality of human resources employed, operational efficiency depends upon the location and capacity of the plants, choice of technology, organization of the production system, and planning and control systems used for coordinating the day-to-day activities. The complexity of the problems associated with effectively and efficiently utilizing all the resources — manpower, machines, materials — needed for producing goods often necessitates the development of mathematical models to aid decision making.

Manufacturing decisions can be classified into three categories: strategic, tactical and operational. Strategic decisions pertain to decisions such as degree of vertical integration, items to produced inhouse, size and location of facilities, choice of technology, nature of equipment (general versus special purpose), long-term raw material and energy contacts, skills of employees, organization design, and so forth, that have long-term consequences and can not be easily reversed. Tactical decisions have shorter horizons of 6 month to 2 years. They include decisions such as aggregate production planning (levels of production and inventory, work force, and subcontracting), facility layout, and incremental capacity expansion. Operational decisions pertaining to issues such as order processing, detailed production scheduling, follow up, maintenance routines, and inventory control rules, drive the day to day activities.

The nature of the problems faced by a production manager depends on the characteristics of the market that the facility is competing in. For this reason it is useful to distinguish between different types of manufacturing systems. The variety and volume of products produced are critical for determining the type of the manufacturing system. Manufacturing systems have been classified into job shops, batch shops, flow lines and continuous processes on the basis of the volume and variety of the product mix. Job shops produce many different products in small quantities, each with different processing requirements. Typically the products are customized and are made only after receiving an order. At the other end of the spectrum are flow lines and continuous processes that produce a limited number of products in very high volumes. Demand is met from finished goods inventories. Batch shops lie in between these two extremes. Models for aggregate production planning are described first, followed by the models for job shops, batch shops, flow lines and continuous processes. Hopp and Spearman (2000) provide a detailed coverage of these and related topics.

Aggregate Production Planning is concerned with determination of the levels of production, inventory, work force, and subcontracting to respond to fluctuating demand. With a stable work force, the level of production can be changed by using over-time or undertime. The size of work force can be varied by hiring and layoff. Fluctuating demand can also be met by accumulating seasonal inventory. An organization may also have the option of backordering or losing sales. The relevant costs are for: (1) regular payroll and overtime; (2) carrying inventory; (3) backordering or lost sales (including the possible loss of customer goodwill, lost revenue, and penalties for late delivery): and (4) hiring (including training and learning) and layoff.

Real-world production planning may involve as many as 10,000 products (Hax and Candea 1984). With 10 decision periods, this can mean more than

100,000 variables. If the number of units sold is also a decision variable, the problem may involve more than 200,000 variables. Here quadratic and linear cost models are described. Hwang and Cha (1995), Nam and Logendran (1992), Silver et al. (1997), Thomas and McClain (1993), and Venkataraman and Smith (1996) have discussed other models and methodologies. Penlesky and Srivastava (1994) described the use of spreadsheets for production planning.

Quadratic cost models — Models with quadratic costs have several major advantages. They allow for a realistic cost structure in the planning process. They also allow uncertainties to be handled directly since they minimize the expected cost if unbiased expected demand forecasts are given (Hax and Candea 1984, p. 88; Simon 1956). The resulting solution is fairly insensitive to large errors in estimating cost parameters (Hax and Candea 1984). Hax and Candea also pointed out that this is an attractive property because of the difficulty in providing accurate cost.

The production and work force smoothing model developed by Holt et al. (1960) consists of a quadratic cost function constrained by linear equations to balance production, inventory, and sales. It selects production and work force levels in each of T periods so as to satisfy demand forecast while minimizing the sum of the costs over the T periods. Let P_t, W_t, I_t, and D_t represent production volume, work force level, end of period inventory, and demand forecast for period t, where the initial inventory and work force are given. The cost in period t consists of the following components:

Regular payroll costs :	$C_1 W_t$
Hiring and layoff costs :	$C_2(W_t - W_{t-1} - C_{11})^2$
Overtime costs :	$C_3(P_t - C_4 W_t)^2 + C_5 P_t - C_6 W_t + C_{12} P_t W_t$
Inventory related costs :	$C_7(I_t - C_8 - C_9 D_t)^2$

The model may be formulated as:

$$\text{Minimize Z} = \sum_{t=1}^{T} [(C_1 - C_6)W_t + C_2(W_t - W_{t-1} - C_{11})^2 + C_3(P_t - C_4 W_t)^2 + C_5 P_t + C_{12} P_t W_t + C_7(I_t - C_8 - C_9 D_t)^2] \quad (1)$$

subject to:

$$P_t - D_t = I_t - I_{t-1} \quad (2)$$

Holt et al. focused on an infinite planning horizon with stationary costs and derived the following two linear decision rules for the first period:

$$P_1 = \theta_1 + \theta_2 I_0 + \theta_3 W_0 + \sum_{t=1}^{T} \phi_t D_t$$

$$\text{and } W_1 = \theta_4 + \theta_5 I_0 + \theta_6 W_0 + \sum_{t=1}^{T} \mu_t D_t,$$

where $\theta_1, \theta_2, \theta_3, \theta_4, \theta_5, \theta_6, \theta_t$, and μ_t ($t = 1, 2, \ldots, T$) are functions of the cost coefficients. The infinite series can be truncated after an appropriate number of periods T.

Singhal and Singhal (1996) developed simple computational procedures for finite horizon cases. These can be used for arbitrary time-varying cost coefficients. The complexity of the procedures grows only linearly with T. They generate the values of production, work force, and inventory levels for each period in the planning horizon. Finally, the procedures lend themselves to sensitivity analysis with respect to terminal values and to generate alternate plans.

It is beneficial to generate a collection of alternate plans on the basis of alternative terminal conditions and evaluate them more precisely according to the actual cost structure. This is usually more complex than the quadratic cost function used in the Holt et al. model. Sensitivity analysis can also be used to eliminate plans that may include negative values of P_t, W_t, or I_t. If only I_T is specified, one can compute Z as a simple quadratic function of W_T : $Z = h + kW_T + mW^2_T$ where h, k, and m are functions of the cost coefficients, ending inventory, and demand forecasts. The optimum value of W_T is then easily computed as $W_T = -k/2m$. If W_T, rather than I_T, is specified, then Z can be obtained as a quadratic function of I_T. If the terminal condition is not specified for any variable, one can obtain Z as a quadratic function of both W_T and I_T (or P_T).

One can compute optimal plans for a menu of combinations of terminal values (I_T, W_T) so as to

create a menu of alternative plans which can be evaluated in more detail with respect to alternative cost structures, constraints, and objectives. The alternate plans provide considerable flexibility to the decision maker because they can be evaluated in the context of (a) constraints not included in the model, (b) actual costs, and (c) implications beyond the planning horizon.

Constraints not included in the model — The model does not specify that P_t, W_t, or I_t be non-negative. The solution approaches developed by Holt et al. (1960) or Singhal and Singhal (1996) do not guarantee it either. However, the values of θ_1, θ_2, θ_3, θ_4, θ_5, θ_6, θ_t, and μ_t ($t = 1, 2, \ldots, T$) in the decision rules for an actual problem (Holt et al. 1960) indicate that for most problems, they will be nonnegative. For cases where a solution may include negative values of P_t, W_t, or I_t, sensitivity analysis can be used to determine the ranges of the terminal boundary conditions for which all values of P_t, W_t, and I_t are non-negative. If implementation of the optimal solution is difficult because of extremely low or extremely high levels of inventory, production, or work force in some periods, trade-offs can be made between the additional cost and the ease of implementation of alternate plans that are within the constraints on inventory, production, and work force.

Actual costs — The costs of various plans, including the optimal plan refer to the costs approximated by the linear quadratic model, not to the actual costs. In testing the model for a real-world problem, one may obtain actual costs for one or more alternate plans that are lower than those of the optimal plan.

Implications beyond the planning horizon — The organization may anticipate or plan some changes beyond the planning horizon of the model. For example, it may retire workers or introduce technology that requires fewer or more workers. If the organization plans to introduce technology that requires fewer workers, it would choose a plan that would require a smaller work force towards the end of the planning horizon. Similarly, if some workers are expected to retire in the near future, the organization would choose a plan that would require hiring more workers towards the end of the planning horizon. The exact choice of the plan will depend on the magnitude of the changes beyond the planning horizon and the cost penalty during the planning horizon. In some cases, the optimal levels of inventory and work force in the final period may be incompatible with the demand forecasts for periods beyond the planning horizon (these forecasts may be too imprecise to extend the length of the planning horizon but they may indicate the overall magnitude of demand). In such cases, trade-offs can be made by comparing the possible benefits of an alternate plan and the cost penalty associated with it.

Both the finite and infinite horizon versions can be implemented on the rolling basis. In the infinite horizon version, no consideration is given to information beyond a certain period. In the finite horizon version, the implications beyond the planning horizon are first included in the specification of the terminal conditions and then evaluated through sensitivity analysis.

Bergstrom and Smith (1970) extended the Holt et al. model to a multi-product situation. It is given as

$$\text{Minimize TC} = \sum_{t=1}^{T}\left[C_1 W_t + \sum_{i=1}^{N}\left[C_{i7}(I_{it} - C_{i8} - C_{i9}D_{it})^2\right] + C_3\left(\sum_{i=1}^{N} k_i P_{it} - C_4 W_t\right)^2 + \sum_{n=1}^{N} C_5 k_i P_{it} - C_6 W_t + C_{12} W_t\left(\sum_{i=1}^{N} k_i P_{it}\right) + C_2(W_t - W_{t-1} - C_{11})^2\right]$$

subject to:

$$I_{it} = I_{i,t-1} + P_{it} - D_{it}, \quad i = 1,2,\ldots,N; \quad t = 1,2,\ldots,T,$$

where N and T denote the number of products and periods respectively; P_{it}, D_{it}, and I_{it} represent the production, demand forecast, and inventory of product i during period n; k_i represents the standard labor time to complete one unit of product i; and W_t represents the work force during period t. The C_i are the cost coefficients. Aggregate production L_t,

aggregate inventory I_t, and aggregate demand forecast D_t can be written as

$$L_t = \sum_{i=1}^{k_i} P_{it}, \quad t = 1, 2, \ldots, T$$

$$I_t = \sum_{i=1}^{k_i} I_{it}, \quad t = 1, 2, \ldots, T$$

$$D_t = \sum_{i=1}^{k_i} D_{it}, \quad t = 1, 2, \ldots, T$$

$$I_{it} = I_{t-1} + L_t - D_t, \quad t = 1, 2, \ldots, T$$

All decision variables are unconstrained. Initial conditions I_0, W_0, and I_{0i} ($i = 1, 2, \ldots, N$) and the final conditions (work force and aggregate inventory) are specified. Singhal (1992) developed a simple and efficient non-iterative algorithm for obtaining the optimal values of the levels of production management in, inventory, and work force during the planning horizon. The efficiency is achieved by exploiting the special structure of the recurrence relations obtained by differentiating the cost function. Once the input data are developed, the computation time will remain the same irrespective of the number of products which, as noted earlier, could be as many as 100,000.

Linear cost models — Linear programming models are widely used because they can be easily tailored to a specific situation. Many constraints can be directly included in the model. A major advantage of linear programming models is the availability of computer codes that can solve very large problems. Most cost structures are generally linear within the range of interest. If they are not, one can use linear approximations. Another advantage is parametric and sensitivity analyses. The dual solution can be used to obtain the costs of constraints and one can easily perform sensitivity analysis on cost parameters and demand forecasts. For a more detailed discussion of linear programming models, see Hax and Candea (1984) and Silver et al. (1997). Hax and Candea (1984) described the following general purpose model:

$$\text{Minimize } Z = \sum_{i=1}^{N} \sum_{t=1}^{T} \left(d_{it} P_{it} + c_{it} I_{it}^{+} + b_{it} I_{it}^{-}\right) + \sum_{t=1}^{T} \left(w_t W_t + o_t O_t + h_t H_t + f_t F_t\right)$$

subject to:

$$P_{it} + I_{i,t-1}^{+} - I_{i,t-1}^{-} - D_{it} = I_{it}^{+} - I_{it}^{-} \qquad i = 1, 2, \ldots, N;$$
$$t = 1, 2, \ldots, T,$$
$$W_t - W_{t-1} = H_t - F_t \qquad t = 1, 2, \ldots, T,$$
$$O_t \le pW_t \qquad t = 1, 2, \ldots, T,$$
$$P_{it}, I_{it}^{+}, I_{it}^{-}, W_t, O_t, H_t, F_t \ge 0$$
$$i = 1, 2, \ldots, N; \qquad t = 1, 2, \ldots, T$$

P_{it} = Units of item i to be produced in period t
D_{it} = Forecast demand for item i in period t
d_{it} = Cost of producing one unit of product i in period t
c_{it} = Cost of carrying one unit of inventory of product i from period t to $t + 1$
b_{it} = Cost of backordering one unit of inventory of product i from period t to $t + 1$
w_t = Cost of one regular labor hour in period t
W_t = Regular labor hours employed in period t
o_t = Cost of one overtime labor hour in period t
O_t = Overtime labor hours used in period t
h_t = Cost of hiring one labor hour in period t
H_t = Labor hours of regular work force hired in period t
f_t = Cost of laying off one labor hour in period t
F_t = Labor hours of regular work force laid off in period t
i_{it}^{+} = Inventory of product i at the end of period t
I_{it}^{-} = Units of product i backordered at the end of period t
p = An upper bound on overtime as a fraction of regular hours

The first constraint is similar to the production-inventory balance equation in the linear-quadratic model when $I_{it} = I_{it}^{+} - I_{it}^{-}$, $t = 1, 2, \ldots, T$. The second constraint shows the changes in the level for work force due to hiring and layoff. The third constraint provides a limit on the overtime; the limit is proportional to the level of work force.

Job Shops

Job shops specialize in producing customized products, and the production process has the flexibility to produce many different products. Due to the high variety the flows in job shops are jumbled, thus making it very difficult to predict and manage the completion times of jobs. Since most of the jobs are

produced after receiving an order from a customer, very important managerial tasks are to accurately predict due dates, ensure that the quoted dates are not violated, and use resources effectively and efficiently.

Operational Problems — The challenge of managing day to day operations has given rise to a rich set of combinatorial optimization problems. The most basic operational problem is to determine a schedule that specifies when each job will be allocated different resources. Associated with each job are the arrival time, a due date and a set of operations. Each operation requires a set of resources for some duration, and there may be precedence constraints on the order in which the operations can be performed.

A variety of performance measures have been considered for evaluating alternative schedules. Common performance measures are the average or maximum time a set of jobs remains in the facility, number of jobs that are late, or the average or maximum tardiness for a set of jobs. Most of the problems of job shop schedule optimization problems, except for a small class, are computationally intractable (Lenstra et al. 1977; French 1982). Hence for most practical problems the emphasis has been on heuristics.

Researchers have successfully analyzed job shops with special structures. Many insights have been gained into the single machine and single stage, multiple machine scheduling problems. For multiple stage job shops, analysis has been possible, provided all the jobs follow the same route.

Job shop scheduling models can be classified into static and dynamic models. In static models the set of requirements including job arrival times and processing requirement are known in advance. In contrast, in dynamic job shop models new arrivals are permitted. The arrival times may be stochastic and the processing requirements may also vary dynamically.

Mathematical programming approaches have been employed to study static job shop problems. For performance measure that are non-decreasing in the completion time of the job, dynamic programming techniques have been employed to generate optimal solutions for problems of modest size. Dynamic programming based approaches have also been useful in identifying dominance criteria to reduce the number of schedules to be evaluated. Several heuristics have been developed that exploit dominance criteria. Integer programming formulations of scheduling problems have also been used to generate near optimal solutions. Typically some complicating constraints in the integer program are relaxed to yield tractable sub-problems.

While most of the theory focuses on static job shop models that assume deterministic requirements, most practical problems are dynamic and stochastic. For such complex environments analysis has largely been restricted to simulations of local dispatching rules. Each station employs a dispatching rule — for example, process jobs in increasing order of processing times — and the overall performance of the shop is evaluated via Monte Carlo simulations. Many dispatching rules have been discussed in the literature. Further details regarding scheduling algorithms are given in Conway et al. (1967), Graves (1981), and O'Eigeartaigh et al. (1985).

An important development in the area of scheduling dynamic shops has been to approximate the job shop scheduling problem by a Brownian control problem. Although the size of the networks analyzed is small, since the focus is on bottleneck stations the method is useful in many practical situations. The Brownian control problems have been useful in identifying near optimal scheduling policies for minimizing the average lead times (Wein 1990).

Strategic and tactical problems — Since most of the operational problems of sequencing and scheduling jobs through a shop floor are computationally intractable, there is a need to design the job shops such that simple real time control rules are adequate to obtain good performance. The long term performance of the shop will depend on the types of jobs processed by the facility (product mix), the capacity and technology of different stations, and the rules employed to quote due dates and manage the flow through the shop floor. Tactical and strategic decisions regarding each of these variables require models that predict the medium to long term performance of the job shops.

One approach for assessing the long term performance is to employ Monte Carlo simulations. The strength of simulation models lies in their ability to incorporate many features, such as (i) complex control rules — for example, local dispatching rules, control of input to the shop, etc.; (ii) complex arrival patterns — for example, correlated demands, non-stationary demand, etc.; and (iii) complex

resource requirements and availability — for example, multiple resources, machine failures, etc. A broad range of performance measures can also be assessed through simulation models. These models, however, are time consuming and cannot identify optimal parameters for the policies being investigated.

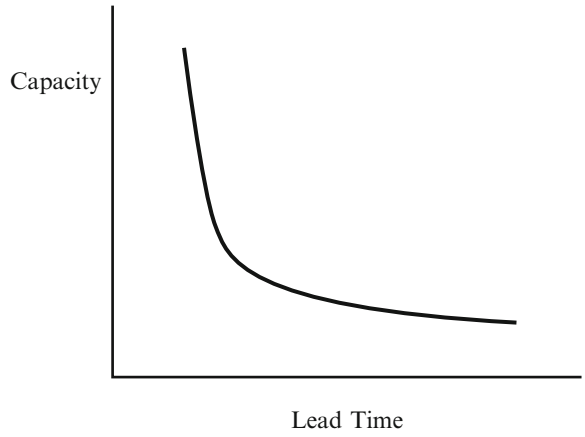
Open queueing network models have been proposed to evaluate the long term performance of job shops. Good approximation procedures have been developed to estimate the average queue lengths in networks with features such as general processing and interarrival time distributions, multiple job classes, and class dependent deterministic routing through the network.

An approximation procedure that has been frequently employed is the parametric decomposition approach (PDA). Under the PDA, each node is treated as being stochastically independent and all the performance measures are estimated based on the first two moments of the inter-arrival and service time distributions at each node. Extensive testing has shown that PDA provides accurate estimates of the average queue length at each node in very general networks. Limitations of the approach are that all the measures are for steady state, only the average queue lengths are accurately predicted, and the analysis is based on the assumption that the jobs are processed on a first come first served basis. Nevertheless, the power of this approach lies in the ease with which complex networks can be analyzed, which in turn facilitates the design of networks.

The PDA has enabled the analysis of several optimal facility design problems. One such problem is:

- Objective: Minimize total cost of equipment.
- Decision Variables: Capacity of each station in the network, and technology.
- Constraints: Upper bounds on the average lead time for different job classes.

This model addresses the relationship between average lead times and the choice of equipment. Since system design is based on multiple criteria, it is useful to develop curves that reflect the trade-off between lead times and cost of equipment. This can be done by parametrically varying the upper bound on the permissible lead times. Figure 1 provides a possible trade-off curve (Bitran and Tirupati 1989). Details regarding the application of queueing models to job shops are given in Bitran and Dasu (1992).



Production Management, Fig. 1 Illustrative trade-off curve

Batch Shops

The variety of jobs processed in a batch shop is less than that in job shops; furthermore, the set of products that are produced by the facility may be fixed. Nevertheless, the production volume of each product is such that several products may share the same equipment. Often the demand for final goods is met from finished goods inventory and production plans are based on demand forecasts. A large number of discrete part manufacturing systems can be classified as batch shops.

Operational problems: The time and cost for switching machines from one product to the next poses one of the biggest problems in managing batch shops. Although job shops can also have significant set-ups, since each job is unique the set-up time can be incorporated in that job's total processing time. On the other hand, in batch shops, the same products are produced repeatedly and there is an opportunity to mitigate the effect of set-ups by combining or splitting orders. Consequently much attention has been paid to problems of determining batch quantity of and the sequence in which each item is produced. The primary trade-offs are between inventory carrying, shortage and set-up costs.

A classic lot sizing problem is the economic lot scheduling problem (ELSP). The ELSP seeks the optimal lot size at a single production stage when the demand rate for each item is fixed and deterministic (Panwalker and Iskander 1977). The objective of the analysis is to determine the frequency with which each item is to be produced so as to minimize the average set-up and holding costs without ever stocking out.

Many of the solution procedures for ELSP consist of three steps. First, ignoring the capacity constraint, the optimal production frequency for each item is determined. Next the frequencies are rounded off to an integer multiple of a base period. In the final step a solution that specifies the sequence in which each item is produced is generated. Roundy (1986) showed that in the second step if the integer multiple is restricted to some power of 2, then a near optimal solution can be found. In recent years researchers have begun to extend the approaches developed for ELSP to multistage multi-machine problems.

ELSP is a continuous time model. In practice production plans are made on a periodic basis, prompting several researchers to develop and analyze discrete time models of the lot-sizing problems. Below a single-stage, multi-item, multi-period, capacitated lot-sizing problem is formulated:

$$\text{Minimize} \sum_{t=1}^{T} \left\{ p_t(X_t) + h_t(I_t) + \sum_{i=1}^{I} s_{it}\delta(X_{it}) \right\}$$

subject to:

$$I_{i,t-1} + X_{it} - I_{it} = D_{it} \quad t = 1,2,\ldots,T; \quad i = 1,2,\ldots,I.$$

$$\sum_{i=1}^{I} X_{it} \le X_t \quad t = 1,2,\ldots,T.$$

$$\delta(X_{it}) = \begin{cases} 1 & \text{if } X_{it} = 0 \\ 0 & \text{otherwise} \end{cases}$$

$$I_{it}, X_{it} \ge 0 \quad t = 1,2,\ldots,T; \quad i = 1,2,\ldots,I.$$

where X_{it}, I_{it}, C_t, D_{it} and s_{it} denote respectively for period t and product i, the production quantity, the ending inventory, the capacity, the demand, and the setup cost; X_{it} and I_{it} are the only decision variables; and X_t and I_t are vector with elements $\{X_{it}\}$ and $\{I_{it}\}$, respectively. The functions $p_t(\cdot)$ and $h_t(\cdot)$ denote respectively the variable production and inventory holding costs.

Once again, except for a small class, the lot-sizing problems are NP-hard (Garey and Johnson 1979); Bitran and Yanasse 1982). The following two lot-sizing problems, however, can be solved in polynomial time and have been the basis of many approximation procedures: (a) the single item lot-sizing problem without capacity constraints, and concave variable production and inventory holding costs; and (b) single item problem, with constant capacity, and concave variable production and inventory holding costs.

Multistage systems producing multiple products with dynamic demands, usually require extensive information and considerable computational effort to find optimal solutions. For these reasons, hierarchical planning systems have been proposed. At the highest level in the hierarchy an aggregate plan with a horizon of several, usually 12, months is developed. If the demand is seasonal, the horizon should cover the full demand cycle. Over such horizons it is impractical to obtain detailed information about demand for each item and the availability of every resource. Hence, it becomes necessary to aggregate the items into families, and the machines into machine centers, etc. The aggregate plan determines the time phased allocation of aggregate resources to different part families. The plan focuses on the primary trade-offs among the cost of varying production resources employed by the firm, the costs of carrying inventory (and possibly backordering demand), and major setup costs. The extended horizon enables the facility to respond to seasonality in demand.

The aggregate plan becomes the basis for determining the detailed production schedule for each item. The detailed resource allocation decisions are constrained by the decisions made at the aggregate planning level.

The number of hierarchical planning stages, the degree of aggregation at each level, and the planning horizon lengths affect the quality of the plan and must be carefully determined for each context. Many researchers have studied hierarchical planning systems. Bitran and Tirupati (1993) and Hax and Candea (1984) contain discussions of this approach.

Once the plans have been disaggregated and the monthly requirements of each item are known, there are a number of approaches for scheduling and controlling the flow of the items through the shop. One approach is to time the release of the orders to the shop so that the required quantities of the items become available by the date specified by the hierarchical planning system. In this approach, also referred to as the push system, an estimate is made of production lead times, and order releases are offset by the lead times. The scheduling decisions at each work station may be made on the basis of the queue in front of each work station. Scheduling models developed for job shops are also useful here.

An alternate approach for operating the shop is the pull system. Under this approach the work-in-process inventory level after a production stage determines the production decisions at that stage. The buffer inventories are maintained at planned levels and a production order is triggered if the inventory level drops below the threshold.

Since the push system operates on the basis of planned lead times, OR/MS models have been developed to understand the relationship between release rules, capacity and lead times. The key decision variable in pull systems is the size of each buffer. Several researchers have examined the impact of buffer sizes on the shop performance (Conway et al. 1988).

Strategic and Tactical Problem — An approach advocated for simplifying the operations of batch shops is to partition the facility into cells. Parts produced by the facility are grouped into families and each family is assigned to a cell. Ideally all operations required for a family of parts are performed in the same cell. The advantages of cellular manufacturing systems are simplified flows, and reduced lead times and setup costs. These benefits may be partially offset by the need for additional equipment. Many different criteria — such as part geometry, production volumes, setups, and route through the shop — have been proposed for forming part families. Researchers have also investigated several algorithms for identifying alternative partitions. Typically these algorithms begin with a product-process matrix. In this matrix rows correspond to parts and columns correspond to machines. An element ij in this matrix is one if a part i requires a machine j and zero otherwise. The columns and rows of the matrix are interchanged so as to produce a block diagonal matrix. Each block identifies a set of resources and jobs that does not interact with the remaining operations, and so corresponds to a cell.

As in the case of job shops, batch shops system design can be improved if the medium to long term performance of the shop can be assessed. Closed and open queueing network models and simulation based models are useful for assessing the long term performance of batch shops. The objective of these models is to determine the relationship among capacity of different cells, lot sizes, and lead times (Bitran and Dasu 1992).

Queueing network models assume that the processing rate at each station is fixed. In practice the processing rate at each station may vary. Variations may be due either to the allocation of additional (human) resources to a stage or simply because the queue length has a motivational effect on the machine operator. Based on these observations, in recent years an alternative class of tactical models of the shop have been proposed (Graves 1986). Here the production rates are assumed to vary as a function of the size of the queue length. The processing rates at each stage are allowed to vary so as to ensure that the time spent at a station is the same for every job. The model therefore enables managers to plan the lead times for each stage.

Flow Lines and Continuous Operations

Included in this class are all systems that are dedicated to the production of (one or few) items in large volumes. Examples of such systems include assembly lines, transfer lines, and continuous operations such as cement and oil derivatives manufacture. The demand is often met from finished goods inventory and thus the main focus tends to be on the management of the corresponding inventory levels and the supply chain. The operational problems are relatively simple and are omitted.

Tactical problems — An important operational problem is to manage the trade-off between the cost of varying the production rate and the cost of finished goods inventory. The aggregate planning models discussed earlier are applicable here. Typically, all the stages of the production system have equal capacity, hence, managing the flow through the facility does not pose a significant problem. In assembly lines, the balance is achieved by carefully assigning tasks to different work stations — a complex combinatorial optimization problem. Several algorithms have been developed for assembly line balancing.

Strategic problems — High volume production systems frequently compete on the basis of low costs and supply large geographically dispersed markets. It is therefore not uncommon to have many plants that cater to different markets. OR/MS models have been developed to aid in the design of the multiplant

networks and the distribution systems (Erlenkotter 1978; Federgruen and Zipkin 1984). Here the discussion is restricted to the plant location problems.

The number of plants their capacity and location have a big effect on production and distribution costs. Models have been developed to analyze the trade-off between the fixed costs of setting up plants and the variable (transportation and production) costs of operating the plants. The models assume that a set of markets with known demands have to be supplied and the decision variables are the number of plants, their location and capacities (Erlenkotter 1978).

Concluding Remarks

Production management involves many complex trade-offs. As a result many mathematical models have been developed to aid decision makers. This is certainly not an exhaustive list and excludes many important problem areas such as inventory management, preventive maintenance, capacity expansion, and quality control. The focus has been on models that are concerned with the flow of goods through a manufacturing system. Even within this domain, in order to provide a broad overview, many important models that deal with specialized systems were not discussed, such as intelligent manufacturing systems.

The problems arising in each type of production system were described as if each plant operated in isolation. In practice, a production system is likely to consist of a network of plants. While some plants may be batch or job shops others are likely to be assembly or continuous processes. The problems of coordinating these networks was not discussed.

Most of the OR/MS models focus on managing the trade-offs among setup costs, inventory carrying costs and cost of varying production rates. On the other hand, many gains in productivity are due to the elimination (or mitigation of) the factors that give rise to these trade-offs. For example reduction in set-up costs and times reduces lead times, increases the ability of the system to produce a wider mix of products, diminishes the role of inventories and simplifies the management of batch shops. Researchers have begun to develop models that quantify the benefits of and guide such process improvement efforts (Porteus 1985; Silver 1993).

Introduction

Program evaluation is not about mathematical programming, but about assessing the performance of social programs and policies. Does capital punishment deter homicide? Which job training programs are worthy of government support? How can emergency medical services be delivered more effectively? What are the social benefits of energy conservation programs? These are the types of questions considered in program evaluation.

Notable evaluations include the Westinghouse evaluation of the Head Start early childhood program (Cicarelli et al. 1969), the Housing Allowance experiment (Struyk and Bendick 1981), the Kansas City preventive patrol experiment (Kelling et al. 1974), and evaluation of the New Haven needle exchange program for preventing HIV transmission among injecting drug users (Kaplan and O'Keefe 1993). As these examples suggest, questions and issues deserving serious evaluation often are in the forefront of social policy debates in areas such as public housing, health services, education, welfare, and criminal justice.

Closely related to program evaluation are the activities of cost-benefit and cost-effectiveness

analysis. These resource allocation methods help decision makers decide which social programs are worth sponsoring, and how much money should be invested in competing interventions. Program evaluation may be construed as an attempt to understand and estimate the benefits associated with the social program under study. While some evaluations attempt to relate these benefits to the costs of program activities, most program evaluations are viewed as attempts to measure benefits alone.

Program evaluation is often conducted by social scientists at the behest of organizations with some interest in the program, either as participants, administrators, legislators, managers, program funders, or program advocates. In such a charged atmosphere, how can OR/MS be useful? Program evaluation contributes to policy making chiefly by informing policy debate. Evaluation can be construed as an activity that produces important information for decision makers in the policy process (Larson and Kaplan 1981). Evaluation is also useful for framing issues, and for identifying and choosing among policy options. Evaluation is crucial to program administrators concerned with improving service delivery. These tasks are about gathering, analyzing, and using information. It is the orientation toward decision making that renders OR/MS particularly useful in the evaluation of public programs.

Program Components and the Scope of Evaluation

In the language of systems analysis, the components of social programs can be classified as inputs, processes, and outputs (Rossi and Freeman 1993). Inputs are resources devoted to the program, while outputs are products of the program. In this framework, program evaluation is usually about assessing a program's effects on outputs. Such evaluation is often called outcome or impact evaluation. Typically, the result of outcome evaluation is the answer to the question: Did the program achieve its goals?

In contrast to outcome evaluation, process evaluation is often referred to, perhaps pejoratively, as program monitoring. As the myriad details of real programs are classified simply as processes in monitoring studies, programs become black boxes. Such a framework is anti-operational. On the other hand, an OR/MS approach to process evaluation focuses on program operations, often with the assistance of appropriate mathematical models. Typical program evaluations too often lead to simplistic conclusions regarding which programs work. Focusing on program operations often results in understanding why some programs are successful and other programs fail. As an example, consider Larson's analysis of the Kansas City Preventive Patrol Experiment (Larson 1975). This experiment attempted to discern the impact of routine preventive patrol on important outcomes such as crime rates and citizen satisfaction, in addition to important intermediate outcomes such as response time and patrol visibility. The empirical results of this experiment resulted in several findings of "no difference" between patrol areas with supposedly low, regular, and high intensities of police preventive patrol. In contrast, Larson's application of back-of-the-envelope probabilistic models to this experiment showed that one should have expected such results due to the nature of the experimental design. He showed, for example, that one should not have expected large differences in police response times given the peculiarities of patrol assignments and call-for-service workloads evident in the experiment. The same models suggested that different experimental conditions, better reflecting police operations in other large American cities, could lead to different results.

An advantage of an OR/MS approach to program evaluation is that goals and objectives are stated as explicitly as possible. What is the purpose of the program under study, and how does one characterize good versus poor program performance? While the importance of such questions may be self-evident to OR/MS practitioners, most actors on the policy stage are not accustomed to such explicitness. The act of asking such questions is often, by itself, a contribution to policy debate. A defining feature of the OR/MS approach to problem solving is the association of one or more performance measures with program objectives. A performance measure quantifies how well a system functions. Performance measures should be measurable (computable if not actually observable), understandable, valid and reliable, and responsive to changes in program

operations. Operational modeling of public programs can even yield performance measures not apparent a priori. For example, the evaluation of the New Haven needle exchange program involved a mathematical model of HIV transmission among drug injectors as modified by the operations of needle exchange (Kaplan and O'Keefe 1993). The model revealed needle circulation time, that is, the amount of time a needle is available for use by drug injectors, as a critical performance measure. Reducing needle circulation time reduces opportunities for needle sharing on a per needle basis. This reduces both the chance that a needle becomes infected, and the chance that an injection with a used needle transmits infection. Needle exchange adjusts the distribution of needle circulation times. The model uncovered a direct link between the exchange of needles and the probability of HIV transmission.

Methodologies

Much of program evaluation is qualitative in nature. Social science methods relying on field observation, case histories, and the like are often used. However, such qualitative data often fail to satisfy critics of particular social programs. In addition, qualitative data generally allow only coarse judgments about program effectiveness. While no panacea, quantitative assessment methods have become standard in evaluating social programs and policies. Assessments of program effects are often made by statistically comparing a group participating in the program to a control group. The randomized experiment is the archetype for this kind of comparison. Since true randomized experiments may be difficult to execute under real program settings, quasi-experimental designs are often used instead. Rather than randomly assigning participants to program and control groups, quasi-experimental methods attempt to find natural or statistical controls. Multiple regression, analysis of variance, or other statistical techniques are often used; Cook and Campbell (1979) is a classic reference on quasi-experimental methods.

The model-based techniques of OR/MS are also applicable to program evaluation. Decision analysis is obviously useful in prospectively selecting among policy options. Queueing theory may be used to analyze the delivery of a wide range of programs, including public housing assignments, 911 hotlines, and dial-a-ride van services for the elderly and disabled. Applied probability models are generally useful, while statistical methods are widely valued. Techniques for multicriteria optimization, data envelopment analysis, and the analytical hierarchy process may be useful in identifying tradeoffs among multiple objectives.

While it seems that a solid understanding of OR/MS modeling is useful in conducting program evaluation, OR/MS has been underutilized. For example, basic optimization techniques such as linear programming have not been widely applied, perhaps because formulating a consensus objective function is usually very difficult. Training in OR/MS is less common than training in statistics and other social sciences. Few of those who have been trained in OR/MS have chosen to concentrate their efforts in the evaluation of public programs. Thus, social program evaluation remains an important and fertile area for further development and application of OR/MS methods.

Professional Opportunities and Organizations

Departments and agencies of federal, state, and municipal government and international organizations typically have offices that perform evaluation activities. Examples include the U.S. Environmental Protection Agency's Office of Policy Planning and Evaluation, the New York City Public School's Office of Research, Evaluation, and Assessment, and the World Bank's Operations Evaluations Unit. A few large private or non-profit organizations under-take many program evaluations. Among such organizations are The Urban Institute, Abt Associates, RAND Corporation, Mathematica Policy Research, and Westat. Much program evaluation is done by academics, largely social scientists. There are opportunities for OR/MS practitioners to get involved. One outlet is the INFORMS College on Public Programs and Processes. The American Evaluation Association is an interdisciplinary group of several thousand practitioners and academics. The journal *Evaluation Review* publishes examples of quality evaluations.

Program Evaluation and Review Technique (PERT)

A method for planning and scheduling a project which models uncertainties in activity by using optimistic, likely and pessimistic time estimates for each activity. PERT evolved when the U.S. Navy was developing a system to plan and coordinate the Polaris missile program (Malcolm et al. 1959).

Project Management

Mark Westcombe and Graham K. Rand
Lancaster University, Lancaster, UK

Project management means different things to different people. Traditionally the domain of engineering, it has concerned itself with managing anything from small construction developments to large complex systems integration projects in defense, aerospace and other industries. A comprehensive survey of the development of project management since the 1940s and the issues involved in accomplishing projects is available in *The Management of Projects* (Morris 1997). In this period, OR/MS almost exclusively focused on the technical aspects of conforming to a contract using the iron triangle paradigm of management: to deliver a project to a pre-defined specification, on time, with an efficient use of resources within budget and with attention to safety. It accepted the project focus as the activities associated with the project lifecycle: defining scope; the work breakdown of the project plan; scheduling these activities; estimating costs; allocating resources and monitoring and controlling progress. OR/MS interested itself predominantly with techniques such as Program Evaluation and Review Technique (PERT) and the Critical Path Method (CPM).

Project management has since become ubiquitous within commercial and public sector organizations having been used to deliver organizational change

(see Balogun et al. 2008). Businesses might now use project management discourse and techniques to manage anything from opening a new store to the acquisition, a merger with an international corporation or to complete an urban regeneration scheme. They may conceive projects, form project teams and appoint project managers to issues that previously would have been dealt with by managers responsible for day-to-day operations. A critique of this projectification of operational management is offered by Hodgson and Cicmil (2006).

This evolution of project management has led to new ways of thinking about projects (Winter and Szczepanek 2009) and the focus of the project manager is now more concerned with defining project success (Atkinson 1999), delivering long-term project outcomes and ensuring benefits that add value to an organization's operations (Cooke-Davies 2007). Similarly OR/MS is engaging more at a strategic level of projects, offering, in particular, ideas from systems thinking for the developing of processes rather than just techniques, such as for the project front-end (Winter 2009), negotiating project objectives amongst differing stakeholder perspectives and managing stakeholder relationships. OR/MS has also contributed significantly to the risk analysis of projects (Williams 1995) as risk management has come to the fore, including: mathematical modeling (Chapman and Ward 2002); qualitative modeling of the systemic nature of risk (Ackerman et al. 2007); the cost impact of disrupted learning curves (Howick and Eden 2001); and the use of system dynamics to model disruption and delay of projects in litigation (Eden et al. 2000). It has also concerned itself with project selection, Monte Carlo simulation of projects and project portfolio management.

Outside of OR/MS, topics of current concern include: project evaluation and improvement; strategic alignment; organizational learning; program management; project leadership; sustainability issues; partnering; project governance; and procurement (see Crawford et al. 2006). A special issue of the *International Journal of Project Management* is of particular interest (Winter et al. 2006), which reviews future trends in the field as well as explores key contemporary themes in depth. A comprehensive breakdown of all the tactical elements of project management can be found in the professional Bodies of Knowledge (Association of Project Management 2006; Project Management Institute 2008), as well as from the growing industry of professional courses and certification in project management, such as PRINCE2, which is widely used in UK public sector projects and offers a particular step by step approach to project management.

Professional association in project management is available through the Association of Project Management, Ibis House, Regent Park, Summerleys Road, Princes Risborough, Buckinghamshire, UK HP27 9LE, which publishes *The International Journal of Project Management*; and the Project Management Institute, which publishes the *Project Management Journal*. Note that the term project management, or project management skills, is often misleadingly appropriated as a term in personal development to cover such transferable skills as time management, prioritization, presentation skills, etc.

Project SCOOP

Project SCOOP (Scientific Computation of Optimal Programs) was a research program of the U.S. Air Force from the late 1940s to early 1950s whose main objective was to study and solve Air Force programming and scheduling problems. It was while working on Project SCOOP problems that George B. Dantzig formulated the linear-programming model and developed the simplex method for solving such problems.

Projection Matrix

For a given matrix $\boldsymbol{A}$, its associated projection matrix is defined as $\boldsymbol{P} = \boldsymbol{A}(\boldsymbol{A}^T\boldsymbol{A})^{-1}\boldsymbol{A}^T$. The matrix $\boldsymbol{P}$ projects any vector $\boldsymbol{b}$ onto the column space of $\boldsymbol{A}$.

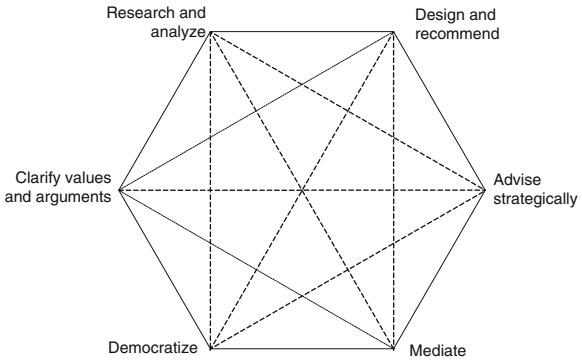
Public Policy Analysis

Warren E. Walker[1] and Gene H. Fisher[2]
[1]Delft University of Technology, Delft, The Netherlands
[2]RAND Corporation, Santa Monica, CA, USA

Introduction

Public policy analysis refers to the activities, methods, and tools that are used to give aid, advice, and support in the context of public policymaking. It covers a wide range of activities conducted with differing primary objectives and perspectives. Mayer et al. (2004) introduced a conceptual framework – the hexagon framework – that classifies the policy analysis activities in a structured manner. According to the hexagon framework, an analyst providing policy support may carry out six major clusters of activities, each having different objectives. The six objectives, represented as the vertices of the hexagon given in Fig. 1, are:

- *Research and analyze*: This type of activity aims for the generation of knowledge that can be used later for policy purposes. The major objective is to understand certain policy-relevant phenomena, and develop insights about them.
- *Design and recommend*: In certain situations the analyst can assist the decision-making process by designing alternative solutions to a problem and analyzing and possibly weighing the consequences



Public Policy Analysis, Fig. 1 Overview of objectives of policy analysis (Mayer et al. 2004)

of these alternative solutions. The main question here is more about evaluating a set of interventions, or changing the system that is related to the already known phenomena. In other words, there is a certain action orientation that ends with a policy choice or recommendation.

- *Provide strategic advice*: In certain situations, an analysis can be a strategic, client-oriented activity. The analyst can advise the client on the most effective strategy for achieving certain goals given a certain political constellation, i.e., the environment in which the client operates, the likely counter-steps of opponents, etc.
- *Mediate*: A given policy problem generally involves multiple parties that have different views and perspectives regarding the issue. Addressing the problem and coming up with an effective (i.e., accepted by all parties) policy may require the understanding of the other parties' perspectives. Hence, the task for the policy analyst may be mediating these multiple parties and promoting communication among them within a policymaking or decision-making process.
- *Democratize*: This type of policy-analytic activity aims mainly at acquiring and maintaining the involvement of all related parties in the policy process in order to make it as democratic as possible. This includes assuring the flow of proper information to all stakeholders, and the provision of opportunities for them to have their say regarding the policy issue.
- *Clarify arguments and values*: The main objective of this type of policy analysis activity is the elicitation of mindset, norms, and values of the stakeholders involved in the problem at hand. In these situations, the analyst can support or help move forward the decision-making process by analyzing the values and argumentation systems that underpin the social and political debate.

In real-life cases and projects, a policy analyst will combine one or more of these activities, albeit not all at the same time. Traditional policy analysis is focused on the 'design and recommend' vertex (see Walker 2000). The approach related to this objective is detailed below, and expanded upon in Thissen and Walker (2013). Its primary purpose is to *assist* policymakers in choosing a preferred course of action to implement in a *complex* system from among multiple alternatives under *uncertain* conditions.

The word "assist" emphasizes that policy analysis is used by policymakers as a decision aid, just as checklists, advisors, and horoscopes can be used as decision aids. Policy analysis is not meant to replace the judgment of the policymakers (any more than an X-ray or a blood test is meant to replace the judgment of medical doctors). Rather, the goal is to provide a better basis for the exercise of that judgment by helping to clarify the problem, presenting the alternatives, and comparing their consequences in terms of the relevant costs and benefits.

The word "complex" means that the system being studied contains so many variables, feedback loops, and interactions that it is difficult to project the consequences of a policy change. Also, the alternatives are often numerous, involving mixtures of different technologies and management policies, and producing multiple consequences that are difficult to anticipate, let alone predict.

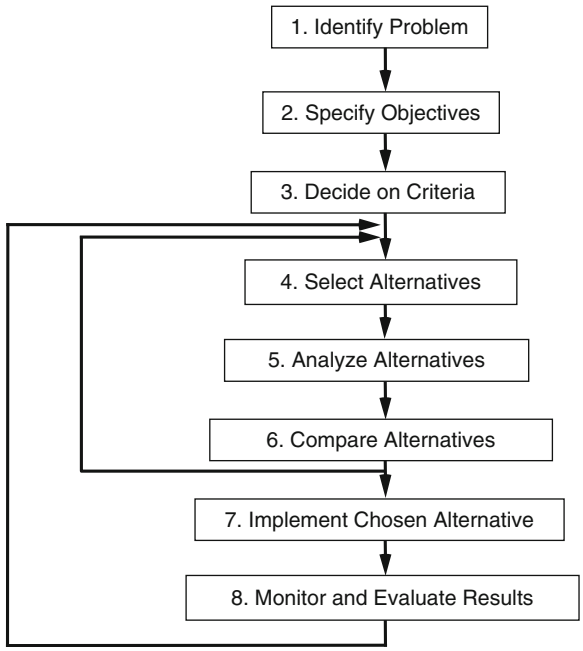
The word "uncertain" emphasizes that the choices must be made on the basis of incomplete knowledge about (a) the future world, (b) the model of the relevant system for that future world, (c) the outcomes from the system, and (d) the weights that the various stakeholders will put on the outcomes. This situation is sometimes referred to as "deep uncertainty".

Policy analysis is performed in government, at all levels; in independent policy research institutions, both for-profit and not-for-profit; and in various consulting firms. It is not a way of solving a specific problem, but is a general approach to problem solving. It is not a specific methodology, but it makes use of variety of methodologies in the context of a generic framework.

The Policy Analysis Steps

The policy analysis process generally involves performing the same set of logical steps, not always in the same order (Walker 2000; Miser and Quade 1985, p. 123). The steps, summarized in Fig. 2, are:

1. *Identify the problem*. This step sets the boundaries for what follows. It involves defining the system of interest, identifying the questions or issues involved, fixing the context within which the issues are to be analyzed and the policies will have to function (this is often done by using "scenarios"), clarifying constraints on possible courses of action, identifying the people who will be affected by the policy decision (the "stakeholders"), and discovering the major operative factors.
2. *Identify the objectives of the new policy*. Loosely speaking, a policy is a set of actions taken to solve a problem. The policymaker(s) and stakeholders have certain objectives that, if met, would "solve" the problem. In this step, the policy objectives are determined. (Most public policy problems involve multiple objectives, some of which conflict with others.)
3. *Decide on criteria (measures of performance and cost) with which to evaluate alternative policies*. Determining the degree to which a policy meets an objective involves measurement. This step involves identifying consequences of a policy that can be measured (either quantitatively or qualitatively) and that are directly related to the objectives. It also involves identifying the costs (negative benefits) that would be produced by a policy, and how they are to be measured.
4. *Select the alternative policies to be evaluated*. This step specifies the policies whose consequences are to be estimated. It is important to include as many as stand any chance of being worthwhile. If a policy is not included in this step, it will never be examined, so there is no way of knowing how good it may be. The current policy should be included as the "base case" in order to determine how much of an improvement can be expected from the other alternatives.
5. *Analyze each alternative*. This means determining the consequences that are likely to follow if the alternative is actually implemented, where the consequences are measured in terms of the criteria chosen in Step 3. This step usually involves using a model or models of the system.
6. *Compare the alternatives in terms of projected costs and benefits*. This step involves ranking the alternatives in order of desirability and choosing the one preferred. If none of the alternatives examined so far is good enough to be implemented (or if new aspects of the problem have been found, or the analysis has led to new alternatives), return to Step 4.
7. *Implement the chosen alternative*. This step involves obtaining acceptance of the new procedures (both within and outside the government), training people to use them, and performing other tasks to put the policy into effect.
8. *Monitor and evaluate the results*. This step is necessary to make sure that the policy is actually accomplishing its intended objectives. If it is not, the policy may have to be modified or a new study performed.



Public Policy Analysis, Fig. 2 Steps in a policy analysis study (Source: Walker 2000)

The individual steps in the process are described in detail by Miser and Quade (1985, Chap. 4), Quade (1989, Chap. 4), Walker (2000), and Enserink et al. (2010).

OR/MS and Public Policy Analysis

Policy analysis is closely related to operations research; in fact, in many respects it grew out of operations research as it was being applied at the RAND Corporation and other applied research organizations in the 1960s and 1970s. Miser (1980) and Majone (1985) describe this evolution. In the beginning, operations research techniques had been applied primarily to problems in which there were few parameters and a clearly defined single objective function to be optimized (e.g., aircraft design and placement of radar installations). Gradually, the problems being analyzed became broader and the contexts more complex. Health, housing, transportation, and criminal justice policies were being analyzed. Single objectives (e.g., cost minimization or single variable performance maximization) were replaced by the need to consider multiple (and conflicting) objectives (e.g., the impacts on health, the economy, and the environment and the distributional impacts on different social or economic groups). Non-quantifiable and subjective considerations had to be considered in the analysis (Schlesinger 1967, provided an early discussion of this issue). Optimization was replaced by satisficing.

Simon (1969, pp. 64–65) defined satisficing to mean finding an acceptable or satisfactory solution to a problem instead of an optimal solution. He said that satisficing was necessary because "in the real world we usually do not have a choice between satisfactory and optimal solutions, for we only rarely have a method of finding the optimum."

Operations research techniques are among the many tools in the policy analyst's took kit. The analyses and comparisons of alternative policies are usually carried out with the help of mathematical and statistical models. Simulation, mathematical programming, and queueing theory are among the many tools that are used in policy analysis study. But modeling is just one part of the process; all of the steps are important.

The policy analysis process has been applied to a wide variety of problems. Miser and Quade (1985, Chap. 3) provide examples of some of these, including improving blood availability and utilization, improving fire protection (for this, see also Walker et al. 1979), protecting an estuary from flooding, and providing energy for the future. More generally, the policy analysis approach has been used in the formulation of policies at the national level, including national security policies, transportation policies, and water management policies (e.g., Goeller and the PAWN Team 1985). Other examples that illustrate the approach can be found in a variety of publications, including Drake et al. (1972), House (1982), Mood (1983), Pollock et al. (1994), Miser (1995), and Walker et al. (2008).

Introduction

The quadratic assignment problem (QAP) is one of the most computationally challenging and well-known problems in the area of combinatorial and integer optimization. In general terms, also known as in the Lawler form (Lawler 1963), the QAP can be be stated as

$$\min_{\pi \in \Pi_n} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij\pi(i)\pi(j)} \tag{1}$$

where Π_n denotes the set of all possible permutations of n elements. In its original introduction due to Koopmans and Beckmann (1957), the statement of the QAP assumes that the cost coefficients c_{ijpq} have the following simple structure:

$$c_{ijpq} = \begin{cases} f_{ij} d_{pq} & \text{if } i \neq j \text{ or p} \neq \text{q}, \\ f_{ii} d_{kk} + a_{ik} & \text{otherwise.} \end{cases} \tag{2}$$

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

This less general version of the problem is known as the QAP in the Koopmans-Beckmann form.

In economic practice, the QAP arises naturally as a class of facility location and layout problems in the following way. Given

- two sets of the same cardinality n, namely, a set of objects (e.g., facilities) and a set of positions (e.g., locations),
- an $n \times n$ matrix $\boldsymbol{D} = \{d_{pq}\}$ of distances between two positions,
- an $n \times n$ matrix $\boldsymbol{F} = \{f_{ij}\}$ of flows from one object to another (e.g., amount of goods transferred from location i to location j), and
- an $n \times n$ matrix $\boldsymbol{A} = \{a_{ip}\}$ of costs of placing a specific object at a given location,

find a bijective assignment of the objects to the respective positions such that the total cost is minimized. In this context, it is commonly assumed that $\boldsymbol{F}$ and $\boldsymbol{D}$ are symmetric matrices with all zeros in the diagonal and nonnegative elements and that matrix $\boldsymbol{A}$ is also nonnegative.

In addition to the aforementioned area, the QAP has applications in various other fields as diverse as ergonomics, electronics and computer manufacturing, telecommunications, sports, archeology, and organic chemistry. In particular, the QAP can be used to place interconnected control and display devices on the backboard panel in such a manner that minimizes the total wire length; to design an ergonomic typewriter keyboard; to create an efficient layout for a hospital; to rank teams in a relay race; to analyze chemical reactions between various organic compounds; and to study archeological data. Other QAP applications include discriminative word alignment used in statistical machine translation systems, and symbol mapping diversity design for optimal retransmission of multiple data packets in wireless communications. For more information regarding applications, see the surveys by Burkard et al. (1999); Loiola et al. (2007); and Pitsoulis and Pardalos (2009).

Computational Complexity

The QAP is famous for its computational complexity, which may be one of the main reasons why the problem has received a considerable amount of attention from the operations research and management science research community. In fact, the QAP was shown by Sahni and Gonzalez (1976) to be strongly NP-hard. This means that the optimal solution for the QAP cannot be computed efficiently, and there are no computationally efficient algorithms that are able to find an approximate solution that is within some constant ratio to the optimal. Formally speaking, the QAP is an NP-hard problem (i.e., the existence of a polynomial time algorithms for solving the QAP implies $\mathcal{P} = \mathcal{NP}$), and furthermore, for an arbitrary $\varepsilon > 0$, a polynomial time ε-approximation algorithm for the QAP does not exist unless $\mathcal{P} = \mathcal{NP}$.

A stronger result obtained by Queyranne (1986) states that, unlike in the case of the traveling salesman problem (TSP), which is also NP-hard and represents a special case of the Koopmans-Beckmann QAP that is polynomially approximable within $3/2$ when the distance matrix is symmetric and satisfies the triangle inequality, there is no polynomial approximation algorithm (unless $\mathcal{P} = \mathcal{NP}$) for finding a feasible solution within some finite approximation ratio to the optimal, even for the QAPs in the Koopmans-Beckmann form with $\boldsymbol{D}$ representing distances of the set of points on a line, a symmetric block diagonal matrix F of flows, and zero linear terms (i.e., $\boldsymbol{A} = 0$). This result can be viewed as a reinforcement for a common belief that the QAP appears to be computationally more challenging as compared to other NP-hard problems in combinatorial and integer optimization. In addition to the TSP, other NP-hard problems such as the maximum clique problem, the subgraph isomorphism problem, the minimum weight feedback arc set problem, the linear arrangement problem, and the graph packing problem can be viewed as a special case of the QAP.

The problems of finding locally optimal solutions for several neighborhood structures (e.g., a Kernighan-Lin-type structure and a pair exchange or 2-opt structure) were investigated for the QAP. Similar to the way the polynomial time decision problems are said to be in $\mathcal{P}$, the problems of this kind, for which polynomial time algorithms exist, are known as the polynomial time local search (PLS) problems. By analogy to NP-complete problems, the PLS-complete problems are the most computationally challenging among the PLS problems. Both Kernighan-Lin-type neighborhoods for the QAP and a commonly used 2-opt neighborhood structure are shown to be the PLS-complete. Burkard et al. (1999) state that there are no known local search criteria for comparing

the quality of the locally optimal solution to the global solution. Furthermore, no computationally efficient algorithms exist for deciding whether a locally optimal solution is also globally optimal for a given QAP instance.

Since in general the QAP is NP-hard and non-approximable, it is of special interest to find some more restricted versions of this problem for which computationally efficient algorithms exist. The motivation behind this is a natural expectation that a better understanding of what makes the QAP so computationally difficult in its general case may be achieved by comparison of the general QAP structure with the problem structure in the polynomially-solvable versions. The approaches commonly used to find new polynomially-solvable cases of the QAP can be divided into two categories:

1. Determine a suitable set of assumptions to be imposed on the structure of coefficient matrices of the QAP in order to get polynomially-solvable instances of the QAP.
2. Analyze other relevant problems that can be viewed a special case of the QAP (e.g., the TSP or the linear arrangement problem) in order to identify their polynomially-solvable versions. Then reformulate these polynomially-solvable versions of the other relevant problems as the QAP instances.

For further details on the computational complexity of the QAP (including discussions of the PLS complexity issues and the polynomially-solvable special cases) see, e.g., Chapters 3 and 10 in Burkard et al. (1999), and Chapter 3 in Pitsoulis and Pardalos (2009).

Formulations

Similarly to many other problems in combinatorial optimization (CO), the QAP can be equivalently reformulated using several alternative representations. Besides the purely combinatorial formulation (1) that represents feasible solutions of the QAP as permutations, the problem can be written as a quadratic integer programming program and as a concave quadratic optimization problem. The QAP can also be given a trace formulation. Alternatively, it can be formulated using the Kronecker product. Moreover, there is a graph-theoretic formulation of the QAP, just like there is one for the linear assignment problem (LAP). Each of these alternative formulations brings with itself a unique set of solution methods and analytical techniques developed for that specific area. For instance, the graph reformulation allows for application of graph-theoretic reasoning to the QAP, whereas a reformulation using semidefinite programming relaxation leads to very different lower bounds than the Gilmore-Lawler-type lower bounds, which are based on the Kronecker product formulation. This section briefly describes some of the most commonly used QAP formulations. For more information on various QAP formulations, see, e.g., Pardalos and Wolkowicz (1994); Burkard et al. (1999); and Loiola et al. (2007).

Since every permutation $\pi \in \Pi_n$ of the n-element set can be equivalently represented by an $n \times n$ 0-1 matrix $\boldsymbol{X} = \{x_{ip}\}$, which is called a permutation matrix and has the following elements:

$$x_{ip} = \begin{cases} 1 \text{ if } \pi(i) = p \\ 0 \quad \text{otherwise,} \end{cases} \tag{3}$$

then the QAP (1) can be stated as the following quadratic 0-1 integer programming problem:

$$\min \quad \sum_{i=1}^{n} \sum_{j=1}^{n} \sum_{p=1}^{n} \sum_{q=1}^{n} c_{ijpq} x_{ip} x_{jq} \tag{4}$$

$$\text{subject to} \quad \sum_{\mathrm{i}=1}^{\mathrm{n}} x_{ip} = 1, \quad p = 1, 2, \ldots, n, \tag{5}$$

$$\sum_{p=1}^{n} x_{ip} = 1, \quad i = 1, 2, \ldots, n, \tag{6}$$

$$x_{ip} \in \{0, 1\}, \; i, p = 1, \ldots, n. \tag{7}$$

The above formulation very naturally facilitates linearization of the quadratic objective function through introduction of new 0-1 integer variables, and so the application of this formulation is a common first step in solving the QAP using several linearization techniques that are discussed in more detail later. Additionally, by defining an inner product of matrices $\boldsymbol{F} = \{f_{ij}\}$ and $\boldsymbol{Y} = \{y_{ij}\}$ as

$$\langle \boldsymbol{F}, \boldsymbol{Y} \rangle = \sum_{i=1}^{n} \sum_{j=1}^{n} f_{ij} y_{ij},$$

and then observing that for any $n \times n$ permutation matrix $\boldsymbol{X}$ corresponding to $\pi \in \Pi_n$ and any $n \times n$ matrix $\boldsymbol{D}$, the following is true:

$$\boldsymbol{XDX^T} = \left\{ \sum_{p=1}^{n} \sum_{q=1}^{n} x_{ip} d_{pq} x_{jq} \right\} = \left\{ d_{\pi(i)\pi(j)} \right\},$$

the QAP in the Koopmans-Beckmann form is compactly written as the following quadratic integer program:

$$\begin{aligned} \min \quad & \left\langle \boldsymbol{F}, \boldsymbol{XDX^T} \right\rangle + \langle \boldsymbol{A}, \boldsymbol{X} \rangle \\ \text{subject to} \quad & \boldsymbol{X} \in \mathbf{X}_n, \end{aligned} \tag{8}$$

where $\mathbf{X}_n$ denotes a set of all possible $n \times n$ permutation matrices, i.e., matrices that satisfy conditions (5), (6), and (7).

Since a number of problems on graphs, including the subgraph isomorphism and the graph partitioning problems, can be viewed as special cases of the QAP, it comes as no surprise that the QAP itself can be given a graph-based formulation. Specifically, given two undirected weighted complete graphs G_F and G_D both having n vertices and $n(n-1)/2$ edges with the weights represented by matrices F and D, respectively, which are symmetric and have all zeros on the diagonal, then a Koopmans-Beckmann QAP with zero linear terms can be formulated as the problem of aligning the vertex sets of the two graphs in such a way as to minimize the sum of products of the aligned edges. As noted in Loiola et al. (2007), this graph formulation of the QAP also leads to the characterization of the feasible solutions as the line-graph automorphisms of the complete graph K_n on n vertices. For a general graph-based formulation of a Lawler QAP, see, e.g., Kaibel (2000).

A very convenient cost structure of a Koopmans-Beckmann QAP also permits its alternative reformulation via trace function. Indeed, since the trace of an $n \times n$ matrix $\boldsymbol{A}$ is defined as:

$$\mathrm{tr}(\boldsymbol{A}) = \sum_{i=1}^{n} a_{ii}$$

then the QAP in Koopmans-Beckmann form can be written as:

$$\begin{aligned} \min \quad & \mathrm{tr}\left(\left(\boldsymbol{FXD^T} + \boldsymbol{A} \right) \boldsymbol{X^T} \right) \\ \text{subject to} \quad & \boldsymbol{X} \in \mathbf{X}_n. \end{aligned} \tag{9}$$

The trace formulation can be utilized to introduce eigenvalue-based lower bounds for the QAP instances, where at least one of the matrices $\boldsymbol{F}$ and $\boldsymbol{D}$ is symmetric. In such case, the nice properties of the trace function actually allow transforming the problem into a QAP where both matrices become symmetric. For example, if F is symmetric and $\boldsymbol{D}$ is not, then introducing a new $\overline{\boldsymbol{D}} = \frac{1}{2}(\boldsymbol{D} + \boldsymbol{D^T})$ does the trick.

The QAP formulation, originally due to Bazaraa and Sherali (1982), as the following quadratic concave minimization problem:

$$\begin{aligned} \min \quad & \boldsymbol{x^T Q x} \\ \text{subject to} \quad & \boldsymbol{x} = \mathrm{vec}(\boldsymbol{X^T}),\ \boldsymbol{X} \in \mathbf{X}_n, \end{aligned} \tag{10}$$

(where $\boldsymbol{Q}$ is an $n^2 \times n^2$ symmetric, negative definite matrix) can be used in cutting plane procedures. Notice that $\boldsymbol{x}$ in (10) represents an $n^2 \times 1$ vector, which is formed by arranging all the rows of some $n \times n$ permutation matrix $\boldsymbol{X}$ successively into a single row of size n^2 and then transposing this long row into a n^2-dimensional column vector. The reformulation (10) is obtained from (4) by first combining the cost coefficients c_{ijpq} into an $n^2 \times n^2$ matrix $\boldsymbol{B} = \{b_{rs}\}$ with $b_{rs} = c_{ijpq}$, for $r = (i-1)n + p$, $s = (j-1)n + q$, then transforming $\boldsymbol{X}$ into $\boldsymbol{x}$ as described above, and lastly defining the $n^2 \times n^2$ matrix $\boldsymbol{Q} = \boldsymbol{B} - \beta \boldsymbol{I}$, where $\boldsymbol{I}$ denotes an $n^2 \times n^2$ identity matrix and β is a positive real number such that $\beta > \max\left\{ \sum_{s=1}^{n} |b_{rs}|,\ 1 \le r \le n^2 \right\} =: \| \boldsymbol{B} \|_\infty$.
Analogously, the QAP can be easily formulated as a quadratic convex minimization problem, by simply adding the $\beta \boldsymbol{I}$ term to $\boldsymbol{B}$ instead of subtracting it.

By introducing an $n^2 \times n^2$ cost matrix $\boldsymbol{B}$ (defined above), using the inner product of matrices, and incorporating the Kronecker product into constraints of the problem, the QAP in the Lawler form can be compactly written as:

$$\begin{aligned} \min \quad & \langle \boldsymbol{B}, \boldsymbol{Z} \rangle \\ \text{subject to} \quad & \boldsymbol{Z} = \boldsymbol{X} \otimes \boldsymbol{X},\ \boldsymbol{X} \in \mathbf{X}_{\boldsymbol{n}}, \end{aligned} \tag{11}$$

where the Kronecker product of $n \times m$ matrix $\boldsymbol{X}$ and $p \times q$ matrix $\boldsymbol{Y}$ is given by an $np \times mq$ matrix

$$\boldsymbol{X} \otimes \boldsymbol{Y} = \begin{bmatrix} x_{11}\boldsymbol{Y} & \dots & x_{1m}\boldsymbol{Y} \\ \vdots & \ddots & \vdots \\ x_{n1}\boldsymbol{Y} & \dots & x_{nm}\boldsymbol{Y} \end{bmatrix}.$$

The formulation (11) represents the QAP as an LAP of size n^2 with the additional quadratic constraint that an $n^2 \times n^2$ permutation matrix $\boldsymbol{Z}$ must be a Kronecker product of a permutation matrix $\boldsymbol{X}$ with itself. Because of the new constraint, the resulting problem cannot be solved efficiently. The trace and the Kronecker product are also used in semidefinite programming relaxations of the QAP, discussed below.

Relaxations

Two approaches commonly used to tackle the QAP are linear programming (LP) and semidefinite programming (SDP) relaxations, which attempt to address the difficulties associated with the quadratic objective function by reformulating the problem based either on linearization techniques or by SDP-based transformations of "stretching" and "lifting" the original matrices into the Euclidean space of high-dimensional square matrices. The resulting significant increase in dimensionality of the problem is the common trade-off with these approaches. In particular, the consequent high dimensionality of the linearized versions of the QAP represents a considerable challenge for efficiently solving the corresponding linear programs. However, the relaxations of the linearized versions or the SDP-based reformulations (especially for QAPs with additional constraints on the costs structure) can be solved to compute lower bounds for the QAP. Therefore, better lower bounds are likely to be produced with a tighter relaxation.

The four fundamental QAP linearization techniques are given by Lawler (1963), Kaufmann and Broeckx (1978), Frieze and Yadegar (1983), and Adams and Johnson (1994). The Lawler linearization represents the QAP as the following 0-1 integer LP with $n^4 + n^2$ variables and $n^4 + 2n^2 + 1$ constraints:

$$\min \sum_{i,j,p,q} c_{ijpq} z_{ijpq} \tag{12}$$

$$\begin{aligned} \text{subject to } & \{x_{ij}\} \in \boldsymbol{X}_n, \\ & \sum_{i,j,p,q} z_{ijpq} = n^2 \\ & x_{ij} + x_{pq} - 2z_{ijpq} \geq 0, \ \forall i,\ j,\ p,\ q, \\ & z_{ijpq} \in \{0,1\}, \ \forall i,j,p,q, \end{aligned}$$

by replacing all the products of the form $x_{ij}x_{pq}$ in (4) with new binary variables $z_{ijpq} = x_{ij}x_{pq}$. Understandably, a large number of variables and constraints in (12) is a disadvantage of this linearization.

Kaufmann and Broeckx (1978) proposed a linearization with the smallest number of variables and constraints. In their linearization, the QAP is equivalently expressed as the following mixed integer linear programming (MILP) problem with n^2 real variables, n^2 binary variables and $n^2 + n$ constraints:

$$\min \sum_{i,j} y_{ij} \tag{13}$$

$$\begin{aligned} \text{subject to } & \{x_{ij}\} \in \mathbf{X}_n, \\ \forall i,j, \quad & \alpha_{ij}x_{ij} + \sum_{p,q} c_{ijpq}x_{pq} - y_{ij} \ \leq \ \alpha_{ij} \\ & y_{ij} \in \{0,1\}, \ \forall i,j, \end{aligned}$$

by introducing new real-valued variables $y_{ij} = x_{ij} \sum_{p,q=1}^{n} c_{ijpq}x_{pq}$ and constants $\alpha_{ij} = \sum_{p,q=1}^{n} c_{ijpq}$.

Similarly to the Lawler's technique, the linearizations by Frieze and Yadegar (1983) and by Adams and Johnson (1994) both introduce new variables $z_{ijpq} = x_{ij}x_{pq}$, but unlike in Lawler's case, the Frieze-Yadegar and the Adams-Johnson linearizations relax the integrality condition by allowing $\{z_{ijpq}\}$ to be real-valued. Therefore, the latter two linearizations result in MILP problems with the same objective function but different constraints. Specifically, the Frieze-Yadegar linearization reformulates the QAP as:

$$\min \sum_{\mathrm{i,j,p,q}} c_{ijpq} y_{ijpq} \tag{14}$$

$$\begin{aligned} \text{subject to } & \{x_{ij}\} \in \mathbf{X}_n, \\ & \sum_{i} y_{ijpq} = \sum_{i} y_{jipq} \\ & = \sum_{i} y_{pqij} = \sum_{i} y_{pqji} = x_{pq}, \ \forall j,p,q, \\ & y_{ijij} = x_{ij}, \ \forall i,j, \\ & 0 \leq y_{ijpq} \leq 1, \ \forall i,j, \end{aligned}$$

whereas the Adams-Johnson linearization rewrites the QAP as:

$$\min \sum_{\mathrm{i,j,p,q}} c_{ijpq} y_{ijpq} \tag{15}$$

$$\begin{aligned} \text{subject to} \quad & \{x_{ij}\} \in \mathbf{X}_n, \\ \forall j,p,q, \quad & \sum_i y_{ijpq} = \sum_i y_{jipq} = x_{pq} \\ & y_{ijpq} = y_{pqij}, \ \forall i,j,p,q, \\ & y_{ijpq} \geq 0, \ \forall i,j,p,q. \end{aligned}$$

As mentioned above, useful QAP relaxations can also be obtained using semidefinite programming (SDP). Interestingly, SDP can be thought as a generalization of LP with the variables that belong to the Euclidean space of matrices, where the inner product between the elements is given by the trace of the product of matrices. Interior point methods or cutting plane procedures are commonly applied for solving the SDP relaxations, and the obtained solutions represent valid lower bounds for the original QAP. In fact, the lower bounds produced by the SDP relaxations are typically rather strong, but they often are computationally very expensive due to high dimensionality of the problems resulting from the SDP relaxations. A thorough explanation of the application of SDP to the QAP can be found in Zhao et al. (1998), where it is shown that based on the trace formulation of the problem below:

$$\min \ \operatorname{tr}\left(\boldsymbol{FXDX}^T - 2\boldsymbol{AX}^T\right) \tag{16}$$

$$\begin{aligned} \text{subject to} \quad & \boldsymbol{XX^T} = \boldsymbol{X^TX} = \boldsymbol{I}, \\ & \boldsymbol{Xe} = \boldsymbol{X^Te} = \boldsymbol{e} = (1,\ldots,1)^T, \\ & x_{ij}^2 - x_{ij} = 0, \end{aligned}$$

the following SDP relaxation of the QAP can be obtained:

$$\min \ \operatorname{tr}(\boldsymbol{KY}) \tag{17}$$

$$\begin{aligned} \text{subject to} \quad & \boldsymbol{b}^0\mathrm{diag}(\boldsymbol{Y}) = \mathbf{o}^0\mathrm{diag}(\boldsymbol{Y}) = \boldsymbol{I}, \\ & \mathrm{arrow}(\boldsymbol{Y}) = \mathbf{e}_0, \\ & \operatorname{tr}(\boldsymbol{RY}) = 0, \\ & \boldsymbol{Y} \succcurlyeq 0, \end{aligned}$$

where

$$K = \left[0 \ \& \ -\mathrm{vec}(\boldsymbol{A})^T - \mathrm{vec}(\boldsymbol{A}) \ \& \ \boldsymbol{D} \otimes \boldsymbol{F}\right],$$

$$\boldsymbol{R} = \left[2n \ \& \ -2\boldsymbol{e}^T \otimes \boldsymbol{e}^T - 2\boldsymbol{e} \otimes \boldsymbol{e} \ \& \ \boldsymbol{I} \otimes \boldsymbol{E} + \boldsymbol{E} \otimes \boldsymbol{I}\right],$$

and $\mathbf{E}$ is an $n \times n$ matrix of all ones, $\preccurlyeq$ denotes the Löwner partial order (i.e., $\boldsymbol{A} \preccurlyeq \boldsymbol{B}$ if and only if $\boldsymbol{B} - \boldsymbol{A} \succcurlyeq 0$, which means that $\boldsymbol{B} - \boldsymbol{A}$ is positive semidefinite). Note that the rows and columns of an $(n^2+1) \times (n^2+1)$ matrix $\boldsymbol{Y}$ are assumed to be numbered starting from 0 to n^2. Then $\mathbf{b}^0\mathrm{diag}$ and $\mathbf{o}^0\mathrm{diag}$, respectively, are the block-0-diagonal and off-0-diagonal operators from the space of $(n^2+1) \times (n^2+1)$ matrices into the space of $n \times n$ matrices given by:

$$\mathrm{b}^0\mathrm{diag}(\boldsymbol{Y}) = \sum_{k=1}^{n} \boldsymbol{Y}_{(k,\cdot)(k,\cdot)},$$

$$\mathrm{o}^0\mathrm{diag}(\boldsymbol{Y}) = \sum_{k=1}^{n} \boldsymbol{Y}_{(\cdot,k)(\cdot,k)}.$$

Here $\boldsymbol{Y}_{(k,\cdot)(k,\cdot)}$ denotes the k-th $n \times n$ matrix on the diagonal of the $n \times n$ array of $n \times n$ matrices, all of which together with the first row $\boldsymbol{Y}_{(0,\cdot)}$ and the first column $\boldsymbol{Y}_{(\cdot,0)}$ compose the $(n^2+1) \times (n^2+1)$ original matrix $\boldsymbol{Y}$. In a similar fashion, $\boldsymbol{Y}_{(\cdot,k)(\cdot,k)}$ denotes an $n \times n$ matrix of the diagonal elements in the position (k,k) of the $n \times n$ matrices, which together form the $n^2 \times n^2$ lower right block of $\boldsymbol{Y}$. Also, arrow$(\cdot)$ in (17) denotes the arrow operator from the space of $(n^2+1) \times (n^2+1)$ matrices into the space of (n^2+1)-dimensional vectors defined as:

$$\mathrm{arrow}(\boldsymbol{Y}) = \mathrm{diag}(\boldsymbol{Y}) - \left(0, \boldsymbol{Y}_{(0,1:n^2)}\right),$$

where $\mathrm{diag}(\boldsymbol{Y}) = \left(\mathbf{y}_{00},\ldots,\mathbf{y}_{\mathrm{n^2\,n^2}}\right)^{\mathrm{T}}$ and $\left(0, \boldsymbol{Y}_{(0,1:n^2)}\right) = (0, y_{01},\ldots,y_{0n^2})^T$ is an (n^2+1)-dimensional vector with zero in the first position and the rest of the elements given by the elements in the first row (i.e., row 0) of $\boldsymbol{Y}$ starting from the position 1 all the way to the last position n^2. Finally, $\boldsymbol{e}_0 = (1,0,\ldots,0)^T$ is a (n^2+1)-dimensional unit vector with a one in the first dimension (i.e., row 0).

For formulations of many additional SDP relaxations, theoretical relationships between them and

a general approach of devising strong SDP relaxations for the QAP and other CO problems using a Lagrangian framework, see, e.g., the survey by Roupin (2009).

Polytopes

Although polyhedral combinatorics has been around since the 1950s and proved quite successful in application to many NP-hard problems in combinatorial optimization (CO), including the TSP, the stable set problem, and the maximum cut problem, polyhedral theory was not applied to the QAP until the 1990s (Kaibel 2000). Generally speaking, polyhedral combinatorics is concerned with understanding the geometric structure imposed by the constraints of CO problems with linear objective functions. Moreover, polyhedral methods can be extended to study the linearized versions of CO problems with nonlinear objectives, such as the QAP.

Since the space of all feasible solutions of a CO problem is represented geometrically as a convex hull called the associated polytope of the problem, and because the polytopes can equivalently be described via the finite systems of inequalities that produce bounded solution spaces and are referred as linear descriptions, polyhedral combinatorics can basically be thought of as the branch of CO that is concerned with finding such linear descriptions for the polytopes arising from CO problems (Kaibel 2000). Investigation of the linear descriptions helps gain structural insights into the corresponding problems and their solution algorithms. Furthermore, by finding a complete linear description for a CO problem and then proving that the so-called separation problem for that linear description is solvable in polynomial time, one can prove that the correspondent problem is in P. Of course, because the QAP is well-known to be NP-hard, instead of searching for a complete linear description, which is unlikely to exist, the focus of the polyhedral methods for the QAP is on finding its partial linear descriptions.

Partial linear descriptions of polytopes based on the linearized versions of the QAP can be used in particular to compute lower bounds on the optimal solution value of an instance via cutting plane algorithms. Obviously, for reasons of efficiency of cutting plane algorithms, it is important that the obtained partial linear descriptions are non-redundant, i.e., no inequality in such systems can be represented as a linear function of the other inequalities with non-negative weights. In particular, this leads to the questions about the polytope's dimension and the dimensional gap. Other important characteristics of the polytopes are its faces of different dimensions, including vertices, edges, ridges, and facets.

As Kaibel (2000) shows, a convenient way to derive a number of important results regarding the polytopes associated with the QAP is by considering a graph formulation of the QAP. In particular, this approach can be used to derive a characterizations for the vertices of the symmetric QAP polytope and the polytope of a general QAP with m objects and n locations. Also the graph-based formulation can be utilized to establish an affine isomorphism between the QAP polytopes for the QAP with $n-1$ objects and n locations and the QAP with n objects and n locations. An analogous result for the symmetric QAP polytopes are also true.

Several interesting results have already been established about the connection between the QAP polytopes and other polytopes (Kaibel 2000). The polytope of a general QAP with m objects and n locations can be thought as a specific face of a cut polytope. This important fact allows utilizing existing extensive knowledge regarding the structure of the cut polytopes. Not very surprisingly (since the TSP is a certain special case of the QAP), the TSP polytope can be viewed as a simple orthogonal projection of the QAP with the equal number of objects and locations. A similar fact is also true for the linear ordering polytope. The change of coordinate representation, called the star-transformation, has been proved exceptionally useful for reducing the dimensional gap and for proving the results about facial descriptions of the QAP polytopes, the polytopes' dimensions, and the so-called box-inequalities for the QAP.

Also it is noteworthy that there exists an interesting connection between the QAP polytopes and the representation theory of the symmetric group, which was exploited to obtain one of the earliest results on the dimension of the QAP polytope. For further references, formulations of theoretical results, and in-depth discussion of the subject of the polyhedral methods for the QAP, see, e.g., the survey by Kaibel (2000).

Lower Bounds

Lower bounds play a fundamental role in combinatorial and integer optimization in general, and are especially useful for solving the QAP. Not only do they serve as a key instrument in evaluating the quality of solutions obtained by heuristic algorithms (i.e., procedures that do not necessarily return optimal solutions), but also they can be very useful in reducing the search space of the implicitly enumerative algorithms (e.g., branch-and-bound-type procedures).

In terms of usability, the two crucial characteristics of lower bounds for the QAP are the tightness of a bound and the computational efficiency. As applied to implicit enumeration methods, lower bounds can provide a guarantee that a given subset of the solution space does not contain the global optimal solution and therefore does not need to be searched. Hence, given that a stronger lower bound lies closer to the optimum, such a lower bound would likely be capable of producing a greater reduction of the search space. Similarly, in application to heuristics, stronger lower bounds are able to provide a better estimate of the quality of the solution found by the heuristic. However, computing a strong lower bound for the QAP typically can be very challenging. For the general QAP, there seems to be a trade-off between the tightness and the computational efficiency of its lower bounds, although results by Mittelmann and Peng (2010) show that for the QAP instances that are based on the Hamming and Manhattan distance matrices, the SDP relaxation can produce lower bounds that are both strong and relatively easy to compute.

Lower bounds for the QAP can loosely be subdivided into the following seven categories:

- Gilmore-Lawler type lower bounds;
- Lower bounds based on LP relaxations;
- Lower bounds based on SDP relaxations;
- Variance reduction lower bounds;
- Eigenvalue-based lower bounds;
- Decomposition-based improved lower bounds for specially structured QAPs;
- Lower bounds based on polyhedral methods.

Gilmore-Lawler type lower bounds (GLTB) are derived using the formulation (11), which represents the QAP as an LAP of size n^2. To compute GLTB, a solution matrix $\boldsymbol{Z}$ is constructed by solving a sequence of LAPs. If the computed matrix $\boldsymbol{Z}$ is a permutation matrix, then it is also a feasible solution of the QAP, and therefore, $\boldsymbol{Z}$ gives the optimal solution of the QAP; otherwise the value of the optimal solution of the QAP is bounded from below by $\langle \boldsymbol{B}, \boldsymbol{Z} \rangle$.

Several lower bounds utilize this basic principle, including the original Gilmore-Lawler bound (GLB). This bound is simple to compute, but the gap between GLB and the QAP optimal value increases very quickly with the size of the problem. One way to improve the quality of GLB is by transforming a given problem so that some of the weight of the cost coefficients in the quadratic terms is moved into the corresponding linear cost coefficient. This can be achieved by means of reduction methods, which work by first suitably decomposing the cost coefficients in the quadratic term and then moving some of their value into the linear term, which, in fact, results in a stronger lower bound. An alternative approach for improving GLB is by using a reformulation. The idea behind this approach is to devise a series of successive reformulations constructed in such a way as to guarantee that the sequence of GLBs computed for the consecutive reformulations is monotonically nondecreasing. Although lower bounds based on reformulation procedures typically have good quality, the tradeoff is that they are time-consuming.

Some GLB-inspired approaches incorporate a dual formulation and LP relaxations. A number of these bounds are based on the reformulation-linearization (RLT) technique and are considered some of the tightest and most computationally efficient lower bounds for the QAP; see, e.g., Loiola et al. (2007). RLT procedures were originally introduced for solving mixed-integer 0-1 programming problems. For a given instance with n 0-1 variables, RLT constructs an n-level hierarchy of relaxations starting from the LP relaxation and ending with the convex hull of feasible solutions. This is essentially an iterative procedure that incorporates two key phases. In the first phase, the problem is reformulated by introducing redundant nonlinear constraints that are obtained by multiplying each of the defining constraints by the product factors. Next, in the linearization phase, each distinct variable in the nonlinear terms of the objective or constraints is replaced by the corresponding single continuous variable. As a result, the problem is formulated as mixed-integer 0-1 LP problem in

a higher-dimensional space. Furthermore, at each level of the hierarchy in RLT, the resulting continuous relaxation is at least as tight as the preceding one, and the highest n-th level gives the convex hull of the entire feasible region of the original QAP. Therefore, the facets of this hull in the variables of the original QAP can be obtained as projections of the final relaxation. Importantly, the RLT procedure is able to exploit the special block-diagonal structure of the Lagrangian dual. This allows to use the dual-ascent procedure to solve the dual of the relaxation and compute lower bounds.

RLT bounds can be viewed as the bounds obtained via the so-called lift-and-project method, which represents the QAP polytope as the projection of some higher-dimensional polytope. Other bounds that also utilize this general method are SDP-based lower bounds. The major difference between the RLT and SDP-based bounds in terms of their application of the lift-and-project method is that the SDP involves semi-definite relaxation in place of the linearization that is used in RLT.

The SDP-based bounds are among those with the smallest gap to the optimal value for many QAP instances from the QAP library (Burkard et al. 1997). Typically, the SDP lower bounds are computed by solving the SDP relaxation by means of cutting plane algorithms or interior point methods. Application of cutting plane algorithms for computing the SDP-based bounds often can speed up the computation, which allows to use the SDP in exact methods by computing bounds for weaker relaxations in a shorter time. Typically, the task of solving the SDP relaxations by interior point methods represents a significant computational challenge, although in some cases it may be possible to exploit group symmetry in the structure of QAP cost coefficients. In fact, using the representation theory of symmetric groups, it was shown that when the QAP coefficient matrices have sufficiently large automorphism groups, it becomes possible to solve the SDP relaxations using interior point methods and obtain extremely strong lower bounds. Roupin (2009) used the connections between partial Lagrangian and SDP relaxations of 0-1 quadratic programs to analytically compare some of the SDP-based lower bounds for the QAP and show theoretical equivalence between the R3 SDP relaxation by Rendl and Sotirov (2007) and the SDP relaxation in the lift-and-project procedure by Burer and Vandenbussche (2006). However, because of their dependence on SDP solvers, these two equivalent SDP relaxations produce lower bounds that differ in their usefulness and numerical behavior, indicating that the results of numerical comparison of the QAP lower bounds' performance may depend heavily on the implementation. Roupin (2009) explains how partial Lagrangian relaxations can be used to easily develop various strong SDP relaxations. Overall, due to their tightness and despite significant computational challenges involved, the approaches utilizing the SDP bounds appear to be very promising for solving large instances of the QAP. For additional information on the SDP relaxations and the performance of their lower bounds for the QAP, see Loiola et al. (2007), Rendl and Sotirov (2007), and Roupin (2009).

Variance reduction lower bounds can be used for the QAP in the Koopmans-Beckmann form (2). These bounds perform well when the flow and distance matrices exhibit high variances. Unfortunately, when the variance of the coefficient matrices is small, they are rather weak, with performance comparable to that of GLB. Eigenvalue-based lower bounds capitalize on the connection between the QAP objective in the trace formulation (9) and the eigenvalues of its coefficient matrices. Although the quality of these bounds is better than GLB, they are disadvantageous in terms of computational time, and their usefulness for reducing the search space diminishes with each subsequent level of the branch and bound. Several QAP lower bounds are based on the idea of decompositions, which involves exploiting special structure of some restricted QAP instances. The approach works well for the rectilinear QAPs called grid QAPs, where the flow and distance matrices are given by the distances of the points on the rectangular grid. Finally, as described by Kaibel (2000), polyhedral methods can used to compute good quality lower bounds for the QAP.

Exact Solution Approaches

Various algorithms for solving the QAP to optimality have been developed. Many of the exact algorithms proposed for the QAP are some type of branch-and-bound (B&B) procedures. Other exact approaches used for solving the QAP are traditional cutting plane methods and polyhedral cutting plane

(or branch-and-cut) methods. B&B algorithms appear to be the most efficient exact procedures for solving the QAP. The performance of B&B algorithms on large-sized QAPs strongly depends on the quality and computational efficiency of the lower bounds employed by such algorithms. As discussed above, as well as in the surveys by Loiola et al. (2007) and Hahn et al. (2010), B&B approaches based on the RLT lower bounds are among the best and are capable of solving difficult large QAP instances.

In terms of the rules used in the construction of a tree or a forest of trees of the branching process, the B&B type procedures can be grouped into three categories:

- Algorithms based on single assignment;
- Algorithms based on pair assignment;
- Relative positioning algorithms.

Single assignment algorithms appear to be the most efficient.

Since the decisions made at the early branching stages clearly play an enormous role in the consequent evolution of the search tree, the idea of strong branching was introduced in an attempt to reduce the computation for the QAP and other hard CO problems. Strong branching utilizes dual information associated with the bounds. Strong branching works by computing bounds either partially or fully for the candidate child nodes in the search tree, and selecting the final branching variables so that the resulting search space is reduced as much as possible. Strong branching appears to be very effective at reducing the size of the B&B tree, which is especially useful for solving large QAPs as illustrated in Anstreicher (2003).

A number of cutting plane algorithms for finding the optimal solution of the QAP exist (Burkard et al. 1999). Traditional cutting plane algorithms for the QAP incorporate MILP formulations, which allow the use of Bender's decomposition. In the application of cutting plane algorithms to the QAP, the performance of these procedures is usually rather slow, due to significant amount of time needed for the upper and lower bounds to converge. Consequently, traditional cutting plane algorithms can solve only QAP instances of a small size. On the other hand, the heuristics derived from these algorithms are able to produce good quality feasible solutions early in the search (Burkard et al. 1999).

Polyhedral cutting plane methods, also known as branch-and-cut algorithms (B&C), can be used for solving the QAP to optimality. Cutting plane algorithms based on the polyhedral results in Kaibel (2000) have several advantages over traditional cutting plane approaches. In particular, the former generate the cuts valid for the entire polytope of feasible solutions, in contrast to traditional techniques. Hence, the polyhedral techniques do not require complete recomputation for different cuts, which means that they need less running time and memory than the traditional cutting plane algorithms. Computational studies indicate B&C methods employing the box inequalities for computing the lower bounds are promising for computing tight lower bounds and even finding optimal solutions. However, the running times of these algorithms on larger QAP instances are considerably slow because of significant computational requirements for computing the bounds. A possible way to improve running times of the polyhedral cutting plane algorithms is to exploit special cost structures, e.g., sparsity of the QAP objective function.

Heuristics

Because solving the QAP has proved to be so hard for even moderately-sized problem instances, a large body of research is devoted to the development of approaches for finding good quality feasible solutions. These heuristic algorithms for the QAP can be categorized into the following groups:

- Constructive heuristics;
- Heuristics derived based on limited enumeration methods;
- Improvement methods;
- Genetic algorithms (GA);
- Simulated annealing (SA);
- Ant colony optimization (ACO) methods;
- Greedy randomized adaptive search procedures (GRASP);
- Tabu search (TS);
- Memetic algorithms (MA);
- Path relinking (PR);
- Artificial neural networks (ANN);
- Hybrid algorithms.

Constructive heuristics are one of the earliest approximate methods for the QAP. They work iteratively often starting with an empty permutation and gradually building partial permutations into

a feasible solution of the QAP, e.g., by assigning a given object to an available location. Heuristics based on limited enumeration methods typically exploit the fact that enumeration methods, e.g., B&B, can often produce a good quality solution in early stages of the search. The disadvantage of these procedures is that the stopping criteria employed by limited enumeration methods tend to eliminate the optimal solution (Loiola et al. 2007).

Improvement methods are local search (LS) algorithms, and as such they depend on the definition of neighborhood structure. Some of the neighborhood structures commonly used for the QAP are the pair-exchange and cyclic triple-exchange neighborhoods, which are based on the permutation representation of a feasible solution. Another important characteristic of LS procedures is the so-called update rule for the selection of the next current solution. The rules commonly used by the improvement methods to search the QAP solution space are the first improvement, the best improvement, and the Heider's rule (Burkard et al. 1999).

Because the QAP has many local optima, the improvement methods are likely to terminate in a local optimum. Therefore, they are usually performed multiple times starting with a new initial solution. Some interesting theoretical results relevant to the LS methods for special cases and general QAP are obtained in Barvinok and Stephen (2003). Several metaheuristic approaches applied to the QAP, such as SA, GRASP, and TS, incorporate LS procedures.

A number of different algorithms based on simulated annealing (SA) exist for the QAP. All of these procedures use the pair-exchange neighborhood, but integrate distinct cooling and thermal equilibrium schemes. Numerical experiments indicate that the performance of SA is significantly impacted by the choice of the cooling scheme and other control parameters. Since SA can be viewed as a non-homogeneous ergodic Markov chain, under suitable conditions SA converges asymptotically to the QAP optimal solution; however, the SA convergence speed for the QAP is hard to analyze theoretically (Burkard et al. 1999).

The GRASP metaheuristic has been applied successfully for solving various hard CO problems, including the QAP. It combines the greedy improvement phase with the random search phase that allows to explore the space of the feasible solutions.

Tabu search (TS) is another LS-based metaheuristic that has been shown to be useful for solving the QAP. It facilitates the efficient exploration of the solution space by placing some solutions in the tabu list and using the aspiration criterion to override the tabu status of the solution. Different implementations of TS for the QAP exist, including the TS with fixed tabu list, the robust TS, and the reactive TS. Based on numerical studies reported in Burkard et al. (1999), the latter TS implementation appears to outperform other traditional TS schemes. Exponentially decreasing tabu effects also appears to improve the performance of TS on the QAP. Useful strategic diversifications can be incorporated into TS for the QAP both with and without hybridization. TS algorithms for the QAP are shown to benefit from hybridization with other heuristics. One example is TS with mutation (where the idea of mutation is borrowed from GA).

Genetic algorithms (GAs) are another metaheuristic that have been applied to solving the QAP. Standard GA procedures perform poorly even on small to moderate size instances of the QAP, so to improve the performance of GAs on the QAP, several hybridization schemes have been proposed, including a method combining GA with TS and another hybrid procedure incorporating a greedy scheme into GA. In particular, the greedy GA performed well on large-scale instances from QAPLIB (Burkard et al. 1997). An alternative improved GA technique is a two-phase approach that works, essentially, by hybridizing GA with itself, since in each phase different GA-based approaches are used. Another improved GA method takes advantage of massive parallelization on GPUs (graphic processing units).

In addition to GAs, another evolutionary-based technique applied to the QAP is a genetic LS, better known as memetic algorithms (MA). These procedures combine recombination of the good solutions with LS algorithms. Numerical experiments show that MA can outperform reactive TS, robust TS and fast ACO. Parallel MA implementations for large QAPs also exist.

Path-relinking (PR) is another approach used for the QAP. Its main advantage is that PR can often quickly find new local optima on its path connecting two high-quality solutions. Such paths may have many non-improving solutions that are typically barriers for standard LS-based procedures. Both serial and parallel PR implementations for the QAP exist.

An interesting alternative to more commonly used methods for solving CO problems is an approach based on artificial neural networks (ANN or simply NN). ANN implementation for the QAP, based on the Hopfield NN, cannot by itself compete with more traditional methods, but can serve to obtain initial solutions for further application of improvement methods. An improved performance of ANN for the QAP can also be achieved by incorporating chaotic behavior and burst noise instead of uniform noise in the Hopfield NN.

Ant colony optimization (ACO) procedures have also been applied to the QAP. These are nature-inspired multi-agent search algorithms that imitate the behavior of ants during the search for food. Ants initially start searching for food randomly, then as they gradually mark the trail leading to promising solutions with the pheromone, the colony's search begin to gravitate more towards following the trails where the good quality solutions were often found at earlier stages. To avoid search stagnation, the pheromone strength is allowed to decrease with time. Although early ACO implementations for the QAP were not competitive with other metaheuristics, numerical results show that ACO appears to be one of the best available procedures for real-life, structured QAP instances.

Hybridizing algorithms for the QAP appears to be a useful and popular technique. In addition to aforementioned hybrid algorithms, a number of hybrid procedures for the QAP appear in the literature, including algorithms combining several methods, e.g., LS and ACO with TS, or LS and ACO with SA, or LS and ACO with GA. Other QAP solution algorithms hybridize GA with LS, GA with TS, GRASP with PR, and even TS and ANN.

Distributed Computing

Parallel implementations for the QAP have appeared since the 1990s. In fact, many large difficult instances of the QAP were solved using distributed algorithms. In distributed computing, a network of connected machines is utilized to perform computationally expensive tasks. The size of such network may vary considerably from small local area networks to the Internet. As described in Anstreicher (2003), parallel implementations of QAP solution algorithms share common difficulties with other computational tasks performed using distributed computations, including load balancing and reliability issues. In fact, worker processes are inherently unreliable, as the availability of CPUs (central processing units) is typically dynamic and the master process utilizes worker processes as they become available. Clearly, fault tolerance is very important for master and worker processes.

In terms of the application of metacomputing and grid computing, which involve geographically distributed computer networks, QAP solution methods based on computationally inexpensive lower bounds (e.g., GLB) appear to be easier to implement in parallel as compared to the more computationally demanding lower bounds (e.g., many SDP-based bounds). Some approaches, such as ACO or TS, are inherently easier to implement in parallel, as they may allow, as in the case of ACO and TS, the search to be easily divided among multiple processes. For further discussion of the application of distributed computing to the QAP, see Anstreicher (2003) and Pardalos and Pitsoulis (2000).

Landscapes and Asymptotics

The investigation of the fitness landscape and the asymptotic properties of the QAP has led to a number of important results. The study by Barvinok and Stephen (2003) investigated the distribution of the objective function values with respect to the Hamming distance on permutations for a general QAP and some special cases, such as TSP, using the representation theory of the symmetric group. These results have interesting interpretations in terms of performance of the LS algorithms.

In CO, the fitness landscape is used to study the performance of LS-based heuristics. The landscape of a given QAP instance can be thought as an ordered quadruple $(S, \mathcal{N}, f, d)$ of the space S of all feasible solutions of the QAP, a neighborhood structure $\mathcal{N}$ on S, a distance d between the pairs of solutions from S, and the solution fitness f. The objective function value is usually referred as the solution fitness. A number of approaches, including fitness-distance correlation coefficient and correlation length, have been applied to analyze the so-called landscape ruggedness. A flat landscape, where the costs between the neighboring solutions are very close on average, appears to be better suited for the LS algorithms as compared to

a more rugged landscape. It turns out that the fitness landscape properties of the QAP depend considerably on the degree of correlation in the structure of cost coefficients as well as the magnitude of the flow dominance characteristic (Krokhmal and Pardalos 2009). The flow dominance is essentially defined as the ratio of the standard deviation of the coefficients in the flow matrix to their average. The numerical analysis of various QAP instances indicates that many QAPs have rather unstructured landscapes, with the exception of the randomly generated QAP instances with cost matrices satisfying the triangle inequality. In fact, it has been observed that the LS-based heuristics appear to perform better on the structured QAPs with low flow dominance.

In general, the asymptotic properties of the QAP with randomly generated cost coefficients differ considerably from the asymptotic behavior exhibited by its linear counterparts, such as the LAP or the multi-dimensional assignment problem (MAP). An interesting property of the randomly generated QAPs is that the ratio of the objective function values between the optimal solution and an arbitrary (including the worst) feasible solution of the QAP converges to one in probability as the size of the problems approaches infinity. However, the convergence rate is rather slow. This convergence implies that despite the complexity of the QAP, for extremely large problems any algorithm can produce a solution of very good quality. In fact, it is possible to prove that a similar result holds not only in probability but also almost surely. As explained in Krokhmal and Pardalos (2009), investigation of the asymptotic behavior of the QAP has led to discovery of a more general class of CO problems with analogous asymptotic properties. Another noteworthy analytic result proves that a relationship similar to the well-known Chebyshev's inequality holds for the optimal solution value of random QAPs.

Additional details on the asymptotic properties and fitness landscape analysis of the QAP, as well as comparison of these two characteristics for other assignment problems, can be found in the survey by Krokhmal and Pardalos (2009).

Generalizations and Related Problems

The relationship of the QAP to many other related problems have been known for some time (Pardalos and Pitsoulis 2000). Not only can numerous hard CO problems (e.g., the TSP, the linear arrangement, the graph partitioning, the maximum clique, the minimum weight feedback arc set, and the graph packing problems) be viewed as special cases of the QAP, but also the QAP itself can be considered as a special case of other CO problems, e.g., the quadratic three-dimensional assignment problem (Q3AP), which can be viewed as a problem of minimizing the quadratic and linear costs associated with finding a tripartite matching. Mathematically, the Q3AP can be compactly formulated as follows:

$$\min_{\pi,\sigma\in\Pi_n} \sum_{i=1}^{n}\sum_{j=1}^{n} c_{i\pi(i)\sigma(i)j\pi(j)\sigma(j)} \tag{18}$$

where as before Π_n denotes the set of all possible permutations of n elements. The Q3AP arises as a problem of minimizing a transmission error bound in the design of the wireless communication systems where a digital message is automatically repeated twice to improve wireless transmission quality. During each message repeat the data are mapped into symbols for a transmission. To minimize the likelihood of a transmission error, the two mappings of the data into transmitted symbols must be as independent as possible. Several solution procedures for the Q3AP have been proposed, including B&B algorithms based on the RLT techniques similar to those used for solving large QAPs. Implementing the exact algorithms for the Q3AP requires solving a three-dimensional extension of the LAP, itself an NP-hard problem (Hahn et al. 2010). A number of heuristic approaches originally developed for the QAP, including stochastic LS, have also been applied for solving the Q3AP. Serial implementations of solution algorithms for the Q3AP have only been able to solve the Q3APs of a moderate size. Overall, solving larger instances of the Q3AP may require development of parallel algorithms.

The survey by Hahn et al. (2010) presents the QAP as a fundamental problem in a growing class of practically important and computationally difficult assignment problems that in addition to the Q3AP, includes the linear three-dimensional assignment problem (3AP), the cubic and generalized cubic assignment problems (CAP and GCAP, respectively), the biquadratic assignment problem (BiQAP), the generalized linear and generalized quadratic assignment problems (G3AP and GQ3AP, respectively), the multi-story

space assignment (MSAP), the cross-dock door assignment problem (CDAP), and the stochastic quadratic assignment problem (SQAP). Other APs related to the QAP include a polynomially-solvable LAP and several NP-hard problems, such as MAP (which is a generalization of the LAP and 3AP), the bottleneck QAP, and the quadratic semi-assignment problem (QSAP). Using the totally ordered commutative semigroups, the so-called algebraic LAP and algebraic QAP are defined as algebraic generalizations of the LAP and the QAP, respectively.

Quadratic Form

A function that can be written as $\boldsymbol{x^T\ Cx}$, where the $n \times n$ matrix $\boldsymbol{C}$ is a matrix of known coefficients and $\boldsymbol{x}$ is a column vector. Matrix $\boldsymbol{C}$ is usually assumed to be symmetric or can be transformed into a symmetric matrix. The form is said to be positive definite if $\boldsymbol{x^T\ Cx} > 0$ for $\boldsymbol{x} \neq 0$. The form is positive semidefinite if $\boldsymbol{x^T\ Cx} \geq 0$ for all $\boldsymbol{x}$. Negative definite and negative semidefinite forms are defined by appropriate reversal of the inequality signs in the preceding definitions.

Introduction

Quadratic programming (QP) deals with a special class of mathematical programs in which a quadratic function of the decision variables is required to be optimized (i.e., either minimized or maximized) subject to linear equality and/or inequality constraints.

Let $\boldsymbol{x} = (\boldsymbol{x_1}, \ldots, \boldsymbol{x_n})^T$ denote the column vector of decision variables. In mathematical programming it is standard practice to handle a problem requiring the maximization of a function $f(\boldsymbol{x})$ subject to some constraints, by minimizing $-f(\boldsymbol{x})$ subject to the same constraints. Both problems have the same set of optimum solutions. Because of this, the discussion is restricted to minimization problems, without any loss of generality.

A quadratic function of decision variables $\mathbf{x}$ is a function of the form

$$Q(\boldsymbol{x}) = \sum_{i=1}^{n} \sum_{j=i}^{n} q_{ij} x_i x_j + \sum_{j=1}^{n} c_j x_j + c_0.$$

Define $\boldsymbol{c} = (c_1, \ldots, c_n)$, and a square symmetric matrix $\boldsymbol{D} = (d_{ij})$ of order n, where

$$d_{ii} = 2q_{ii} \text{ for all } i = 1 \text{ to } n \triangleleft d_{ij} = d_{ji} = q_{ij} \text{ for } j > i$$

Then in matrix notation, $Q(\boldsymbol{x}) = \frac{1}{2}\mathbf{x}^T D\mathbf{x} + \mathrm{c}\mathbf{x} + c_0$. Here $\boldsymbol{D}$ is the Hessian matrix (i.e., the matrix of second order partial derivatives) of $Q(\boldsymbol{x})$.

As an example, consider $n = 3$, $\mathbf{x} = (x_1, x_2, x_3)^T$, and $h(\boldsymbol{x}) = 81x_1^2 - 7x_2^2 + 5x_1x_2 - 6x_1x_3 + 18x_2x_3$. This quadratic function $h(\mathbf{x}) = \frac{1}{2}\mathbf{x}^T\mathbf{D}\mathbf{x}$ where

$$\boldsymbol{D} = \begin{pmatrix} 162 & 5 & -6 \\ 5 & -14 & 18 \\ -6 & 18 & 0 \end{pmatrix}.$$

A quadratic function is the simplest nonlinear function, and hence they have always served as model functions for approximating general nonlinear functions by local models.

A square matrix $\boldsymbol{D}$ of order n is said to be

Positive semidefinite (PSD) if $\boldsymbol{x^TDx} \geq 0$ for all $\boldsymbol{x} \in R^n$;

Positive definite (PD) if $\boldsymbol{x^TDx} > 0$ for all nonzero $\boldsymbol{x} \in R^n$.

These matrix-theoretic concepts are important in the study of QP because the quadratic function $Q(\boldsymbol{x}) = \frac{1}{2}\boldsymbol{x^TDx} + \boldsymbol{cx} + \mathrm{c}_0$ is a convex function over R^n iff the matrix $\boldsymbol{D}$ is PSD.

Superdiagonalization Algorithm to Check Whether a Given Square Matrix is PD, PSD

Let $\boldsymbol{M}_0$ be the square matrix of order n to be checked. Let $\boldsymbol{D}^n = \boldsymbol{M}_0 + \boldsymbol{M}_0^T$. $\boldsymbol{D}^n$ is symmetric. $\boldsymbol{M}_0$ is PSD,

PD iff $\boldsymbol{D}^n$ is. The algorithm consists of at most n steps carried out on $\boldsymbol{D}^n$. In each step, one Gaussian pivot step is carried out; and some rows t and the corresponding columns t are deleted, so the remaining matrix is a symmetric square matrix of smaller order. When the remaining matrix is of order s, denote it by $\boldsymbol{D}^s$. The algorithm begins with $s = n$.

General Step: Let $\boldsymbol{D}^r$ be the current matrix of order r.

If any principal diagonal entry of $\boldsymbol{D}^r$ is negative, $\boldsymbol{M}_0$ is not even PSD; terminate with this conclusion.

If any diagonal entry of $\boldsymbol{D}^r$ is 0, the row and column of $\boldsymbol{D}^r$ of that entry must be 0-vectors; otherwise $\boldsymbol{M}_0$ is not even PSD; terminate with this conclusion. If that row and column are 0-vectors, eliminate them, and continue with the remaining matrix.

Now all diagonal entries of the remaining matrix are positive. Perform a Gaussian pivot step on this remaining matrix in column 1 with its diagonal entry as the pivot element, to convert all nondiagonal entries in this column to 0. After the pivot step, eliminate row 1, column 1 of the resulting matrix, and with the remaining matrix go to the next step.

If the conclusion that $\boldsymbol{M}_0$ is not PSD is never reached, and all the steps are carried out, the algorithm will terminate with a 1×1 matrix, i.e., a positive number. in this case terminate with the conclusion that $\boldsymbol{M}_0$ is PSD. It is also PD if no 0-diagonal entry appeared during the algorithm.

For numerical examples, see Sect. 9.2 in Murty (2010).

Classification of Quadratic Programs

QPs can be classified into the following types.

Unconstrained quadratic minimization problem: minimization of a quadratic function $Q(\boldsymbol{x})$ over the entire space.

Equality constrained quadratic minimization problem: minimization of a quadratic function $Q(\boldsymbol{x})$ subject to linear equality constraints on the variables, $\boldsymbol{Ax} = \boldsymbol{b}$. These equations can be used to eliminate some variables by expressing them in terms of the others, and thereby transform the problem into an unconstrained one in the remaining variables. Thus these problems are mathematically equivalent to (and can be solved by techniques similar to those of) unconstrained quadratic minimization problems.

Inequality constrained quadratic minimization problem: minimization of a quadratic function $Q(\boldsymbol{x})$ subject to linear inequality constraints $\boldsymbol{Bx} \geq \boldsymbol{d}$, and possibly bounds on individual variables $\ell \leq x \leq u$, and may be some equality constraints $\boldsymbol{Ax} = \boldsymbol{b}$.

Quadratic network optimization problem: quadratic program in which the constraints are flow conservation constraints on a pure or generalized network.

Bound constrained quadratic minimization problem: minimization of a quadratic function subject only to bounds (lower and/or upper) on the variables.

Convex quadratic program (**CQP**): any of the above problems in which the objective function to be minimized, $Q(\boldsymbol{x})$, is convex.

Nonconvex quadratic program: any of the above problems in which the objective function to be minimized, $Q(\boldsymbol{x})$, is nonconvex.

Linear complementarity problem (**LCP**): special problem dealing with a system of equations in nonnegative variables in which the variables are formed into various pairs called complementary pairs. A feasible solution in which at least one variable in each pair is zero is desired. There is no objective function to be minimized in this problem. The first order necessary optimality conditions for a QP are in the form of an LCP. And in turn every LCP can be posed as a QP.

Nearest point problems: special type of QPs that require finding the nearest point in the set of feasible solutions of a system of linear constraints, by Euclidean distance, to a given point (Liu and Fathi 2011).

Unconstrained Quadratic Minimization in Classical Mathematics

Historically, quadratic functions became prominent because they provide simple local models for general nonlinear functions. A quadratic function is the simplest nonlinear function, and when used as a local approximation for a general nonlinear function, it can capture the important curvature information that a linear approximation cannot.

The use of quadratic approximations to handle general nonlinear functions goes back a very long time. Some important instances are the following.

1. **Newton's method** Newton developed the celebrated method for finding an unconstrained

minimum of a twice continuously differentiable function, $f(\boldsymbol{x})$, by constructing the local model for $f(\boldsymbol{x}^r + \boldsymbol{y})$ at the current point $\boldsymbol{x}^r$ to be the quadratic function $Q(\boldsymbol{y}) = f(\boldsymbol{x}^r) + \nabla f(\boldsymbol{x}^r)\boldsymbol{y} + \frac{1}{2}\boldsymbol{y}^T H(f(\boldsymbol{x}^r))\boldsymbol{y}$, where $\nabla f(\boldsymbol{x}^r)$ is the row vector of the first order partial derivatives of $f(\boldsymbol{x})$ at $\boldsymbol{x}^r$, and $H(f(\boldsymbol{x}^r))$ is the Hessian matrix of $f(\boldsymbol{x})$ at $\boldsymbol{x}^r$. $Q(\boldsymbol{y})$ is the 2nd order Taylor series approximation for $f(\boldsymbol{x})$ at $\boldsymbol{x}^r$. The method finds the minimizer $\boldsymbol{y}^r$ of the model function $Q(\boldsymbol{y})$ (assuming that $H(f(\boldsymbol{x}^r))$ is PD, then $\boldsymbol{y}^r = -(H(f(\boldsymbol{x}^r)))^{-1}(\nabla f(\boldsymbol{x}^r))^T$), and the next point to be $\boldsymbol{x}^{r+1} = \boldsymbol{x}^r + \boldsymbol{y}^r$.

Thus Newton's method solves an unconstrained quadratic minimization problem in each step. Starting from an initial point $\boldsymbol{x}^0$, it generates the sequence $\{\boldsymbol{x}^r\}$, which under certain conditions can be shown to converge to the minimum of the original function $f(\boldsymbol{x})$.

To treat the case where the Hessian $H(f(\boldsymbol{x}^r))$ may not be PD, several modified Newton methods based on quadratic models different from the 2nd order Taylor series approximation at $\boldsymbol{x}^r$, have been developed.

Also, the mathematically beautiful theory of quasi-Newton methods for unconstrained minimization has also been developed through the study of quadratic models (Bazaraa et al. 1993).

2. **Conjugate gradient method** There is the very efficient Gaussian elimination method for solving a square nonsingular system of linear equations, $\boldsymbol{Ax} = \boldsymbol{b}$ say, of order n. However, when n is very large, this method becomes unwieldy and difficult to implement. The least squares formulation of this system of equations is the unconstrained quadratic minimization problem

$$\text{Minimize } (\boldsymbol{Ax} - \boldsymbol{b})^{\mathrm{T}}(\boldsymbol{Ax} - \boldsymbol{b})$$

and Hestenes and Stiefel developed the conjugate gradient method for solving this problem in the 1950s. Subsequently, through the study of the quadratic model, several researchers have extended this method directly into a variety of conjugate gradient methods for the unconstrained minimization of general nonlinear functions.

3. **Linear least squares** Consider a large system of linear equations (typically overdetermined, i.e., where the number of equations exceeds the number of variables), say $\boldsymbol{Ax} = \boldsymbol{b}$, which has no exact solution. A common approach for handling such a system is to look for a least squares solution, i.e., an optimum solution of the unconstrained quadratic minimization problem

$$\text{Minimize } (\boldsymbol{Ax} - \boldsymbol{b})^{\mathrm{T}}(\boldsymbol{Ax} - \boldsymbol{b})$$

This problem is known as the linear least squares problem. Powerful numerical linear algebra techniques such as singular value decomposition (SVD) have been developed to solve large scale versions of this special class of QPs. Statisticians have been using the linear least squares model for computing the estimates of the coefficients in a linear regression model for a long time.

Types of Solutions

Linear programming (LP) deals with only one type of optimum solution, but not about different types of optima such as local and global optima. That is because every local optimum, and every point satisfying the first order necessary optimality conditions for an LP, is also a global optimum. Unfortunately this is not the case in general QPs.

For a QP, or any mathematical program in which an objective function $\theta(\boldsymbol{x})$ is required to be minimized, there are the following types of optimum solutions:

Local minimum — a feasible solution $\bar{\boldsymbol{x}}$ for which there exists an $\epsilon > 0$ such that $\theta(\boldsymbol{x}) \geq \theta(\bar{\boldsymbol{x}})$ for all feasible solutions within a Euclidean distance of at most ϵ from $\bar{\boldsymbol{x}}$

Global minimum — a feasible solution $\hat{\boldsymbol{x}}$ satisfying $\theta(\boldsymbol{x}) \geq \theta(\hat{\boldsymbol{x}})$ for all feasible solutions $\boldsymbol{x}$

Stationary point or **KKT point** — a feasible solution satisfying the first order necessary optimality conditions (also called the KKT (Karush, Kuhn, Tucker) optimality conditions) for the problem.

In a convex QP, every stationary point (KKT point), or a local minimum, is a global minimum; hence all these concepts converge in a convex QP. The same may not be true in nonconvex QPs, i.e., there may be local minima which are not global minima, and stationary points which are neither global nor local minima. Also, the problem may have some local minima, even when the objective function is unbounded below on the set of feasible solutions.

The first order (KKT) necessary optimality conditions for a QP will be referred to as its KKT system.

What Types of Solutions Can Be Computed Efficiently by Existing Algorithms?

Like LPs, QPs have the property that when the set of feasible solutions is nonempty, either a global minimum exists, or the objective function is unbounded below on the set of feasible solutions. And for both convex and nonconvex QPs, there exist finite algorithms for checking whether the objective function is unbounded below on the set of feasible solutions, and for computing a global optimum solution when one exists.

For convex QPs there are very efficient algorithms for computing a global minimum when it exists, and very high quality software implementing these algorithms is available commercially.

For nonconvex QPs, even though finite algorithms for computing a global minimum are available, they are impractical, because the computational effort needed by them grows exponentially with the size of the problem being solved. Nonconvex QP is NP-hard, and so far there is no algorithm known that is guaranteed to find a global minimum for it within a reasonable time.

Can at least a local minimum for a nonconvex QP be computed efficiently? Unfortunately, even the problem of checking whether a given feasible solution is a local minimum for a nonconvex QP may be a hard problem. In Murty and Kabadi (1987), it has been shown that the problem of checking whether 0 is a local minimum in the following simple QP

$$\begin{aligned} &\text{Minimize} && \boldsymbol{x}^{\mathrm{T}}\boldsymbol{D}\boldsymbol{x} \\ &\text{subject to} && \boldsymbol{x} \geq 0 \end{aligned}$$

is a co-NP-complete problem when $\boldsymbol{D}$ is not PSD. In this paper, it has been explained that when dealing with a nonconvex QP, a reasonable practical goal is to look for an algorithm that produces a descent sequence (i.e., a sequence of feasible points along which the objective value strictly decreases) converging to a KKT point. Some of the algorithms discussed below have this property.

Some Important Applications of QP

Finance Analysis using QP models is an established part of selecting optimum investment strategies. Perhaps Markowitz (1959) is the first published book in this area. The Markovitz model employs the variation in return as measured by the quadratic function $\boldsymbol{x}^T\boldsymbol{D}\boldsymbol{x}$, where $\boldsymbol{D}$ is the variance/covariance matrix, and $\boldsymbol{x}$ is the vector of stock investments; as a measure of the risk. This risk is the objective function to be minimized. Constraints in the model guarantee conservation on the flow of funds, and a lower bound on the expected returns from the portfolio. There may also be bounds placed on the investments in particular sectors of the economy (such as utilities, etc.) to make sure that the model does not put too many eggs in any basket, thus achieving diversification. Many other practical aspects of investing can easily be included by either adding appropriate constraints or modifying the objective function by including quadratic penalty terms.

Portfolio management The portfolio optimization problem discussed above is a widely studied static problem since it only determines the optimum investment amounts in various stocks at one point of time. But the real problem in managing investments, known as portfolio management, is dynamic, as yield and risk data keep changing over time randomly. Many authors (e.g., Mulvey 1987) have designed multiperiod quadratic generalized network flow models in which interest, dividends, and loans are modeled by means of arc multipliers.

Taxation QP models play a very important role in the analysis of tax policies. Political leaders at the national and state levels are relying more and more on such analyses to forecast growth rates in tax revenues, and to set various taxes at levels that are likely to ensure growth at desired rates. White (1983) gives a detailed description of such an analysis carried out for the state of Georgia.

National and state government taxes such as sales tax, motor fuels tax, alcoholic beverages tax, personal income tax, etc. are all set at levels to ensure a healthy economic growth. Government finance is based on the assumption of predictable and steady growth of each tax over time.

If s is the tax rate for a particular tax and S_t the expected tax revenue for this tax in year t, then a typical regression equation used to predict S_t as

a function of s and t is: $\log_e S_t = a + bt + cs$ where a, b, c are parameters to be estimated from past data to give the closest fit by the least squares method. The annual growth rate in this tax revenue is then the regression coefficient b multiplied by 100 to convert it to percent.

The decision variables in the model are: $s_j =$ the tax rate for tax j in the base year (0th year) as a fraction. From the known tax base for tax j in the 0th year, the revenues from tax j in this year can be obtained as: s_j (tax base for tax j) $= x_j$. The instability or variability in this revenue is measured by the quadratic function $Q(\boldsymbol{x}) = \boldsymbol{x}^T \boldsymbol{V} \boldsymbol{x}$, where $\boldsymbol{V}$ is the variance/covariance matrix estimated from past data and $Q(\boldsymbol{x})$ is to be minimized. The constraints in the model consist of bounds on the x_j, and a condition that $\sum x_j = T$, the total expected tax revenue in the 0th year. And there is an equation that the overall growth rate which can be measured by the weighted average of the growth rates of the various taxes j, $\sum(x_j b_j)/T$ should be equal to the desired growth rate λ. Any other linear constraints that the decision variables are required to satisfy can also be included. In fact λ can be treated as a parameter, and the whole model solved as a parametric QP model. Exploring the optimum solution for different values of λ in the reasonable range yields information for the political decision makers to determine good values for the various tax rates that are consistent with expected growth in tax revenues.

Equilibrium models Economists use equilibrium models to analyze expected changes in economic conditions, predict prices, inflation rates, etc. These models often involve QPs. As an example, in Glassey (1978) a simple equilibrium model of interregional trade in a single commodity is described. He considers N regions, and the following data elements and variables.

Data:	$a_i > 0$ the equilibrium price in the ith region in the absence of imports and exports.
	$b_i > 0$ the elasticity of supply and demand in the ith region.
	c_{ij} the cost/unit to ship from i to j.
Variables:	p_i equilibrium price in the ith region.
	y_i net imports into the ith region (may be > 0, or 0, or < 0)
	x_{ij} actual exports from region i to region j.

If $p_i > a_i$, supply locally exceeds demand in the ith region, the difference being available for export. From this follows $p_i = a_i - b_i y_i$. Also, the y_i and x_{ij} are linked through flow conservation equations. The interregional trade equilibrium conditions are

$$p_i + c_{ij} \geq p_j \text{ for all i, j}$$
$$(p_i + c_{ij} - p_j) x_{ij} = 0 \text{ for all i, j}$$

If the first condition above does not hold, exports from i to j will increase until the elasticity effects in markets i and j rise, and prices will adjust so that additional profit from export no longer exists. Also, if $x_{ij} > 0$, then $p_i + c_{ij} - p_j = 0$.

It can be verified that these conditions are the first-order necessary optimality conditions for a quadratic network flow problem in which the quadratic objective function can be interpreted as a net social payoff function. Using this observation, Glassey (1978) describes a procedure for computing the equilibrium prices and flows based on solving the QP.

In the same way, traffic engineers use traffic equilibrium models solved by quadratic network flow algorithms for road and communication network planning. These traffic equilibrium models typically have hundreds of thousands of variables and constraints, and are probably the largest QP models solved on a regular basis.

Electrical networks Even during the physicist J. C. Maxwell's time in the second half of the 19th century, it has been well recognized that the equilibrium conditions of an electrical or a hydraulic network are attained at the point where the total energy loss is minimized. Dennis (1959) has formally shown that the sum of the energy losses in the resistors and at the voltage sources in an electrical network, is a quadratic function of the branch currents, if all devices in the network are of a linear (i.e., ohmic) nature. Using this he formulated the problem of determining the branch currents at equilibrium in an electrical network connecting various devices, voltage sources, diodes, and resistors, as a QP. He then showed that the optimality conditions for this QP are precisely the Kirchoff laws governing the equilibrium conditions of the network, with the Lagrange multipliers representing node potentials. In the distribution of electrical power, this QP model is used to solve the load flow problem concerned with the

flow of power through the transmission network to meet a given demand.

Power system scheduling problem The economic dispatch problem in an electrical power system operation deals with the problem of allocating the demand for power – or system load – among the generating units in operation at any point of time. The optimal allocation of load among the units to achieve a least cost allocation, depends on the relative efficiencies of the units; and can be modeled as a QP; see Wood (1984). In power system operation, this model is usually solved many times during the day with appropriate load adjustments.

Application in solving general nonlinear programs One of the most popular algorithms for solving general nonlinear programming problems is the SQP (sequential or recursive quadratic programming) method. It is an iterative method which in each iteration solves a convex QP to find a search direction, and a line search problem (one dimensional minimization problem for a merit function) in that direction. The original concepts of this method are outlined in the Harvard Ph. D. thesis of R. B. Wilson in 1963, and now it has been developed into a successful approach through the work of many researchers; see Bazaraa, Sherali and Shetty (1993), and Murty (1988). The success of these methods has made QP a very important topic in mathematical programming. A nice software package for nonlinear programs based on this approach is FSQP (Zhou and Tits 1992).

Studies involving Support Vector Machines (SVMs) SVMs are learning methods used for classification and regression. Given training examples of two categories of objects, each object represented as a vector in R^n (this vector may represent the measurements of various characteristics of the object), SVM training algorithm builds a model to construct a hyperplane in R^n (represented by a linear equation in which the coefficients are the parameters to be determined using the model) that separates the sets of points of the two categories; with the largest possible distance to the nearest training data points of any category. This hyperplane is later used to classify new examples into one of the categories based on which side of the hyperplane they fall on. The model to determine the hyperplane is a QP model. Thus algorithms for QP play an important role in applications involving SVMs.

A version of SVM for regression was proposed by Vapnik and others, this method is now called support vector regression. SVMs find many diverse applications in character recognition, image classification, clustering, machine learning, neural networks, statistics, data mining, biosequence analysis, and bioinformatics (Steinwart and Christmann 2008).

Algorithmic Developments

(a) **Frank-Wolfe method** One of the first methods for QP developed in 1950s is that of Frank and Wolfe. It is an iterative method which in each iteration solves an LP to find a search direction, and a line search problem in that direction. It produces a descent sequence such that every limit point of this sequence is a KKT point. However, the method has slow convergence, and is not popular except on problems with special structure that makes it possible to solve the LP in each iteration by an extremely fast special method taking advantage of the structure.

(b) **Reduced gradient methods** The simplex method for LP has been extended to solve problems involving the minimization of a quadratic (or in general a smooth nonlinear) function subject to linear constraints. The method is called the reduced gradient method and is discussed by P. Wolfe in 1959. The name reduced gradient method refers to any method which uses the equality constraints to eliminate some variables (called the dependent or basic variables) from the problem, and treats the remaining problem in the space of the independent (or nonbasic variables) only, either explicitly or implicitly. The reduced gradient is the gradient of the objective function in the space of independent variables. The method is quite popular. The OSL software package uses this method for solving QPs. The MINOS software package uses this method for minimizing a smooth nonlinear function subject to equality constraints.

This method has been generalized directly into the GRG (generalized reduced gradient) method for solving nonlinear programs involving nonlinear constraints. The GRG is a popular

method on which several successful nonlinear programming software packages are based.

(c) **Methods based on the LCP** In the 1950s and 60s several researchers proposed schemes for solving the QP by solving its KKT system. Lemke formulated the KKT system for a QP as an LCP and developed a beautiful algorithm for it called the complementary pivot algorithm. The data for an LCP of order n consists of a square matrix $\boldsymbol{M}$ of order n, and a column vector $\boldsymbol{q} \in R^n$; and it is to find a $\boldsymbol{w} = (w_j) \in R^n$ and a $\boldsymbol{z} = (z_j) \in R^n$ satisfying

$$\begin{aligned} \boldsymbol{w} - \boldsymbol{M}\boldsymbol{z} &= \boldsymbol{q} \\ \boldsymbol{w}, \boldsymbol{z} &\geq 0 \\ w_j z_j &= 0 \text{ for all j} \end{aligned}$$

Checking whether the general LCP has a solution is an NP-complete problem, and there are no efficient algorithms known for it. But the complementary pivot algorithm is a finite path following method for finding a solution, when one exists, to a class of LCPs which includes the KKT systems corresponding to convex QP.

The development of the complementary pivot method is a nice theoretical breakthrough for which Lemke received the von Neuman Theory Award of ORSA/TIMS in 1978. However, the complementary pivot method, and several other methods developed for the LCP, are not preferred for solving even convex QPs, because a QP involving m inequality constraints in n nonnegative variables leads to an LCP of order $m + n$, blowing up the size of the model.

For tackling nonconvex QPs, the complementary pivot approach is clearly unsuitable, as it focusses attention purely on the KKT system, and never even computes the objective value; and if it leads to a KKT point at termination, that point may not even be a local minimum.

However, the formulation of the LCP and the complementary pivot method constituted great contributions to theory. The LCP has a fascinating geometrical interpretation. The study of the geometry of LCP was initiated in the 1968 Ph. D. thesis of Murty and continues to be a very active area of research. And the mathematical principle behind the complementary pivot method has been used to develop simplicial methods (which are also called complementary pivot methods) to solve systems of nonlinear equations and fixed point problems. See Murty (1988) and Cottle, Pang and Stone (1992).

(d) **Active set methods** A popular method for solving QP is based on a combinatorial approach to iteratively determine the set of active constraints at the optimum. This type of strategy for handling inequality constrained optimization problems is called the active set strategy. The method solves a sequence of equality constrained QPs by treating some of the inequality constraints as equations (the active set) and temporarily ignoring the others. Several rules are employed to modify the active set from one iteration to the next, to guarantee finite convergence of the procedure. Several researchers have extended this method to minimize a smooth nonlinear function subject to linear equality and inequality constraints; see Bazaara, Sherali and Shetty (1993).

(e) **Interior point methods** Since the development of a very successful interior point method for LP by Karmarkar (1984), a variety of interior point methods have been developed for convex QPs and the LCPs associated with them. These methods are polynomially bounded, and some versions of them give excellent computational performance on large sparse problems. The monograph (Kojima et al. 1991) establishes the theoretical foundations for primal-dual interior point methods for LP and LCP. The authors won the 1992 Lanchester award for this monograph. Some other references on these methods are Ye (1991), Wright (1997), Vanderbei (2008).

(f) **Sphere methods** These are also interior point methods. They find a largest inscribed sphere with center having an objective value $\leq$ that at the current interior feasible solution, approximately. The problem of minimizing the objective function on that sphere, is known as a trust region problem, for which there are efficient algorithms. Also, good software implementations of these algorithms are available. Sphere methods use the direction from the center of inscribed sphere to the point minimizing the objective function on this sphere as a descent direction. For details, see Chapter 9 in (Murty 2010).

(g) **Methods for nonconvex QP** Efficient polynomially bounded algorithms that are guaranteeed to find a local minimum for some special classes of nonconvex QP have been developed by Vavasis.

The sphere methods discussed above have also been adopted to solve nonconvex QPs, and even 0-1 interger programs through nonconvex QP formulations (Murty 2010).

Software

There are several commercially available software packages for solving QPs, including CPLEX, MINOS (available from The Scientific Press as part of either of the algebraic modeling systems AMPL or GAMS), IBMs OSL, MOSEK, and LINDO (Schrage 1987). Also, the online NEOS server for optimization provides a list of QP software, and solvers offering them.

AMPL (Fourer et al. 1993) is a modeling language for mathematical programming which provides a natural form of input for linear, integer, and nonlinear mathematical models besides QP models. The book is accompanied by a PC student version of AMPL and representative solvers, enough to easily handle problems of a few hundred variables and constraints. Versions that support much larger problems are available from the publisher. AMPL uses either MINOS, OSL, or CPLEX solvers for solving QP models.

GAMS (Brooke et al. 1988) is a high-level language that is designed to make the construction and solution of large and complex mathematical programming models straightforward for programmers, and more comprehensible to users of models. It uses the MINOS or the CPLEX solvers for solving QPs, it has also solvers for linear, integer, and nonlinear programming problems. A student version and a professional version are available.

IBM's OSL is a collection of high performance mathematical subroutines for solving linear, integer and quadratic programming models.

MINOS is a Fortran-based computer system designed to solve large scale linear, quadratic, and nonlinear models developed by Murtagh and Saunders in the Department of OR at Stanford University.

The books by Wright (1997) and Vanderbei (2008) provide details about sources for QP software systems.

Quadratic-Integer Programming

A mathematical program involving the minimization of a quadratic function subject to linear constraints and integer variables.

See

► Quadratic-Programming Problem

Quadratic-Programming Problem

A mathematical-programming problem with a quadratic objective function to be minimized subject to a set of linear constraints.

► Quadratic Programming
► Wolfe's Quadratic-Programming Problem Algorithm

Quality Control

Francis B. Alt[1] and Scott D. Grimshaw[2]
[1]University of Maryland, College Park, MD, USA
[2]Brigham Young University, Provo, UT, USA

Introduction

While interest in quality goes back to the Middle Ages, quality control as a technical and managerial discipline started to become accepted and widely practiced only in the 1940s and 1950s. Statistical methods of quality control, though developed in the United States and Britain, found their most ardent followers among Japanese businessmen and managers in the post-War decades. Statistical quality control (SQC) consultants such as W.E. Deming became household names in Japan although they were scarcely known in their own countries. During the 1980s, however, there was a renewed interest in quality control in the West, spurred no doubt by the globalization of competition and increasing customer awareness of quality. The Baldrige Performance Excellence Program is one continuous improvement program that has had a great impact on putting quality on top managements' agendas throughout the nation. Even those companies that do not apply for the Malcolm Baldrige Award (MBA) are using its criteria to assess the quality management system of their company, identify any existing gaps and determine necessary improvements.

Organizations establish and employ quality management systems to satisfy the requirements of their customers. A Quality Management System (QMS) is the collection of interrelated activities that a firm uses to define and implement its quality policies and attain its quality objectives. The ISO 9000 standard, the Baldrige Criteria for Performance Excellence and programs such as Six Sigma can be used to provide an infrastructure for implementing a QMS.

To ensure that an organization's suppliers will deliver products and services that conform to its requirements in an era of growing international trade, the International Organization for Standardization (ISO) developed and issued a set of international standards called ISO 9000. The International Organization for Standardization is

a non-governmental organization founded in 1947 and is located in Geneva, Switzerland.

The ISO 9000 series first published in 1987 consisted of ISO 9000 (Guidelines for Selection and Use), three 9001 standards and the 9004 standard. The Series has been revised several times since then. One update, designated ISO 9000:2000, was released in late 2000. In this revision, the three ISO 9001 standards were merged into ISO 9001 and renamed "Quality management systems — Requirements." Although an organization is certified using the requirements given in ISO 9001, the organization frequently states that it is ISO 9000 certified.

The latest revision occurred in 2008 and includes ISO 9000:2008 (Quality management systems — Fundamentals and vocabulary) and ISO 9001:2008 (Quality management systems — Requirements). The revisions to the 2008 version are minor compared to the 2000 version and usually clarify terminology. A listing of the specific changes between the 2000 and 2008 versions of ISO 9001 can be found in Annex B of ISO 9001:2008.

ISO 9001:2008 is based on eight quality management principles: customer focus, leadership, involvement of people, process approach, system approach to management, continual improvement, factual approach to decision making and mutually beneficial supplier relationships. The close relationship between these eight principles and those underlying Total Quality is found in Goetsch and Davis (2009).

ISO 9004:2009 is now called "Managing for the sustained success of an organization — A quality management approach." This standard shows how to continually improve the performance of an organization, thereby leading to its long-term success.

An organization wanting to obtain the registration and approval of its quality system needs to go through extensive documentation and assessment and periodic audits by a registrar. An overview of the registration process is found in Foster (2010). The ISO9000 certification has become essential for companies interested in doing business globally.

The 2000 and 2008 revisions of ISO 9000 provide for improved alignment between ISO 9001 and ISO 14001, where ISO 14000 is directed towards the implementation of an effective environmental system. However, as Foster (2010) states: "ISO 14000 is very riskyfor U.S. firms." The reason is that firms are required to report environmental violations to the U.S. Environmental Protection Agency, thereby exposing themselves to fines and penalties.

The use of statistical techniques plays a key role in the ISO 9001:2008 standard and includes those used for process monitoring and the analysis of supplier and customer satisfaction data. To assist in the selection of the appropriate statistical technique, ISO has issued ISO/TR 10017:2003 (Guidance on Statistical Techniques for ISO 9001:2000).

The Baldrige Criteria for Performance Excellence provide another infrastructure for implementing a quality management system. The criteria also allow an organization to determine the current status of its quality journey so that it can improve its performance and competitiveness. The award was named after Malcolm Baldrige, the 26th Secretary of Commerce. The Malcolm Baldrige National Quality Improvement Act was signed into law in 1987. One statement in the Findings and Purposes Section of the law is: "strategic planning for quality and quality improvement programs, through a commitment to excellence in manufacturing and services, are becoming more and more essential to the well-being of our Nation's economy and our ability to compete effectively in the global marketplace."

Applicants for the Malcolm Baldrige Award are graded on the following seven criteria: Leadership (120), Strategic Planning (85), Customer Focus (85), Measurement, Analysis and Knowledge Management (90), Workforce Focus (85), Process Management and Results(450). The point value for each criterion is in parentheses where the total point value is 1,000. The National Institute of Standards and Technology (NIST), which manages the program with assistance from the American Society for Quality (ASQ), states "[The Criteria] have evolved from having a specific focus on manufacturing quality to a comprehensive strategic focus on overall organizational competitiveness and sustainability." The Criteria are built on a set of interrelated Core Values and Concepts including visionary leadership, customer-driven excellence, and a systems perspective.

The number of categories eligible for the award was increased in 2007, and the categories now comprise: manufacturing businesses (2), service companies, small businesses (3), educational organizations (1), health care organizations (1), and nonprofit organizations such as charities, trade and professional

associations and governmental agencies. The numbers in parentheses are the number of recipients in each category for 2010 which marked the first year in the award's history with three small business recipients. Information about the criteria and the award can be found at the NIST/Baldrige Award Web site.

A third infrastructure for quality improvement is Six Sigma, which originated at Motorola in the mid-1980s. However, its adoption by General Electric, led by former CEO Jack Welch, brought Six Sigma to the forefront as a quality framework that merited serious consideration. Six Sigma has at least three perspectives.

One is a level of process performance such that if the process mean shifts by 1.5 standard deviations, the process will not generate more than 3.4 defects per million opportunities (DPMO), where an opportunity is defined as a chance for nonconformance. Allowing a shift of 1.5 standard deviations recognizes that it is very difficult to hold a process on target. The number of defects per million opportunities (DPMO) can be written as

$$\text{DPMO} = 10^6 \cdot \frac{\text{Number of Defects Observed in a Fixed Period of Time}}{(\text{Number of Units Inspected})(\text{Opportunities for Error})}.$$

To determine the sigma level of a process, calculate $z = 1 - [(\text{DPMO})/10^6]$ and then find $\Phi^{-1}(z) + 1.5$, where Φ^{-1} is the inverse cumulative distribution function of the standard normal. This assumes the critical to quality characteristic (measures what is important to customers) has a normal distribution and that the shift is 1.5 standard deviations.

There is nothing sacred about a shift of 1.5 standard deviations and a 6-sigma quality level. Other shifts and quality levels can also yield 3.4 DPMO. Specifically,

Magnitude of shift	Sigma quality level	DPMO
0.00	4.50	3.4
0.50	5.00	3.4
1.00	5.50	3.4
1.50	6.00	3.4

A DPMO other than 3.4 can also be used. The specific combination that is used depends on the objectives of the organization, the resources available to achieve those objectives and the potential benefit. As Evans and Lindsay (2011) state, "... a change from 3- to 4- sigma represents a 10-fold improvement; from 4- to 5- sigma, a 30-fold improvement; and from 5- to 6- sigma, a 70-fold improvement—difficult challenges for any organization."

A second perspective of Six Sigma is that it can be thought of as a data-driven, highly structured approach for improving processes using the DMAIC methodology, where DMAIC is an acronym for the five sequential phases: Define, Measure, Analyze, Improve and Control.

Suppose that a project has been selected and embraced by a champion: usually a senior manager who owns the project and "provides continuing support for the project and validates the results at the end of the project" (Foster 2010). Project selection could involve developing a business case for each project and assessing its risk and return.

In the Define phase, the problem is clearly defined including its goals and customers. The project team is formed in which a team includes master black belts, black belts, green belts, and others. A detailed description of the typical six sigma roles is found in Munro et al. (2008). The team articulates the project's charter, develops a communication plan for the project's stakeholders and a preliminary timeline to monitor the project's progress. Furthermore, a process map or SIPOC diagram is prepared toidentify suppliers (S), inputs (I), the process (P), outputs (O) and customers (C). Preliminary information is obtained on the voices of the customer (VOC), the business (VOB) and the employee (VOE)—what is important to the customer, business and employees.

The Measure phase involves collecting accurate and reliable data to address the problem being studied. This includes identifying key output variables (Y) and input variables (X) where the expression $Y = f(X)$ is used to denote the process by which the X's are transformed into Y's. The Measure phase includes developing data collection plans for all variables and providing their operational definitions to remove ambiguity. Sometimes, a measurement systems analysis is conducted to determine the consistency of measurements, usually via a gage repeatability and reproducibility (Gage R&R) analysis. Repeatability and reproducibility capture the equipment and operator measurement variation,

Q

respectively. Detailed examples for conducting a Gage R&R analysis can be found in Burdick, Borror, and Montgomery (2005). A major goal of the measure phase is to determine the current performance level and capability of the process that can be used as a baseline for future performance after the Improve phase.

In the Analyze phase, the data is methodically examined to identify sources of variation affecting the key input and output variables and the root causes underlying those sources.

The Improve phase entails acting on the data to bring about lasting process improvement by identifying and addressing the root causes and generating potential solutions. The set of solutions is evaluated and prioritized by using such criteria as the time and cost of implementation and the probability of successful implementation. Design of Experiments is frequently used to determine the levels or settings of the X's that yield the optimal values of the Y's. Once improvements/countermeasures are implemented, the results are analyzed and compared to the baselines from the Measure phase.

In the Control phase, procedures are put in place to ensure that the improvements implemented in the Improve phase are sustained. It is also necessary to determine whether cost savings are being realized. Control charts are frequently used to monitor the modified process. The project is completed by returning the improved process back to the process owner who now assumes responsibility for the improved process.

Foster (2010) presents quality tools that could be used at each phase. The American Society for Quality provides formal certification of green, black and master black belts.

A third perspective of Six Sigma is that it can be thought of as an infrastructure for quality improvement throughout an organization: the relentless and vigorous pursuit of the reduction of variation in all critical processes to achieve continuous and breakthrough improvements that positively impact the profit of the organization and increase customer satisfaction.

Lean Six Sigma combines Six Sigma with Lean, where Lean is also known as Lean operations, Lean manufacturing and Lean production. Lean is embodied in the management philosophy and practices of the Toyota Production System. Two key philosophies underlying Lean are the systematic elimination of waste (muda) and the respect for people. Ohno (1988) identified seven sources of waste: Correction or rework, Motion, Overproduction, Inventory, Conveyance, Overprocessing and Waiting. These seven types of waste can be viewed as opportunities for improvement when non-value added activities are identified. A downside of Lean is the possible occurrence of major disruptions in the supply chain. Lean embraces such principles as one-unit-at-a-time flow versus large batches, as well as demand-driven pull systems versus forecast-based push systems. The concept of Statistical Thinking underlies Six Sigma where Statistical Thinking is based on three principles: (i) all work occurs in a system of interconnected processes; (ii)variation exists in all processes; and (iii) understanding and reducing variation are keys to success (Hoerl and Snee 2003). It is not a question of whether to choose between Lean or Six Sigma, because an organization can use both since they focus on different issues. As Meisel et al. (2007) state: "Flow is negatively affected by excessive variation and rework; quality is negatively affected by unnecessary complexity in a process. The ability to go back and forth between the two methodologies, in a Lean Six Sigma culture, is a real plus and results in accelerated improvement."

The development of the Toyota Production System can be found in Ohno (1988) and Womack, Jones, and Roos (1991). Womack and Jones (2003) provide guidelines for implementing Lean in the context of a lean supply chain while Meisel et al. (2007) provide an overview of Lean Six Sigma.

Many organizations have benefited greatly from employing such QMS as ISO 900, Baldrige and Six Sigma. While some organizations have decided to use only one or two of the three, others have employed all three. The QMS chosen and utilized depends on the needs of an organization at a particular point in its quality passage. Although all three QMSs have common elements, they are different. A comparison of the three QMS can be found at the NIST/Baldrige Web site.

While basic statistical process control (SPC) techniques have remained unchanged for over fifty years, developments are taking place, such as the robustness of existing methods, the application of Bayesian decision theory to control charts, the extension to the multivariate case and the relationship between SQC and engineering control. After a brief

introduction, the basic concepts of control charts and classical SPC methods (Shewhart control charts) are discussed. Cumulative sum and moving average quality control procedures, which are more suitable for detecting small persistent changes in a process, are then described.

History of SQC Procedures

Over the years, SQC techniques have found literally thousands of applications in manufacturing, service, and health care organizations, as well as government and education. The basic SQC techniques are relatively simple to use and are often applied by shop floor personnel with little training in statistical methods. SQC techniques can be broadly divided into two categories: statistical process control and acceptance sampling.

Statistical process control (SPC) involves the use of control charts for monitoring a process at regular intervals of time to detect any problems that may develop in the process and to take corrective action if necessary. Control charts provide a clear and visual representation of the status of the process. Often, problems are identified early and corrective action is taken — thus minimizing economic losses.

Montgomery (2009b) listed five main reasons for the popularity of control charts. Control charts are a proven technique for improving productivity, preventing defects and unnecessary process adjustments, and providing diagnostic and process capability information.

The quality of inputs into a process has a significant bearing on the quality of its output. Raw materials from a supplier or semifinished output from a work station may be the input for a particular process. In such a situation, one may receive a batch of products/materials from a source external to the process and one has to then decide whether to accept or reject the batch based on the quality of a representative sample taken from it. This type of quality control where the decision to accept or reject a batch is based on inspection of a sample of incoming/outgoing goods is termed acceptance sampling. Although this is a well-developed branch of SQC, its use has been criticized because quality cannot be inspected into a product. By the time that a sampling plan is used, the possible production of nonconforming items from an out-of-control process has already occurred. A sampling plan will merely detect with a certain probability, the presence of nonconforming product. Quality control is most effective when it is preventive in nature rather than curative. A comprehensive overview of acceptance sampling is found in Schilling and Neubauer (2009).

Deming (1986) was critical of standard sampling plans because they fail to take into account the cost of inspection and the cost associated with the failure to detect a defective item. This has led to the development of Deming's *kp* rule for a stable process, which calls for either 0% inspection or 100% inspection.

The techniques of statistical process control and acceptance sampling have been around since the 1920s. Walter A. Shewhart of the Bell Telephone Laboratories developed control charts in 1924. In the late 1920s, Harold F. Dodge and Harold G. Romig developed the concept of acceptance sampling, again at the Bell Telephone Laboratories. The development and use of SQC techniques grew rather slowly initially. The exigencies created by the defense requirements of World War II provided an impetus to the use of SQC techniques in industry. The late 1940s and 1950s were a period characterized by the consolidation of technical gains in SQC methodology achieved during the war. While the use of SQC spread in the industrialized and industrializing nations, Japan embraced these techniques with a missionary zeal and showed their potential to the world.

The 1950s saw the use of experimental designs for making sequential product and process improvements. Box (1957) suggested an innovative industrial application of (statistical) design of experiments and termed it Evolutionary Operation (EVOP). EVOP involves introducing small, deliberate variations in a process according to a systematic plan (i.e., according to a designed experiment). After a certain number of trials, sufficient information becomes available to guide future trials (in an evolutionary manner) in order to improve productivity, reduce costs, or both. The key idea being that process improvement can be effected right in the plant during regular production runs rather than in a research lab. The concept of designed experiments was championed in Japanese manufacturing through Taguchi's efforts. Taguchi's rationale was that quality has to be built into the product, and any deviation from the target leads to

quality losses that can and should be minimized. Bendell, Disney, and Pridmore (1989) contains many case studies and Ross (1996) gives an overview of the Taguchi approach. Montgomery (2009a) gives a thorough treatment of experimental design. Refer to Myers, Montgomery, and Anderson–Cook (2009) for a general treatment of response surfaces.

Basic SPC Concepts

In this section, some of the key ideas on which SPC procedures (control charts) were developed are presented. A key concept is the realization that two items manufactured on the same machine under nearly identical conditions may nevertheless have different values for the quality characteristic. This is to say, variability is inherent in all processes and that it is impossible to eliminate all variability in manufactured products irrespective of the precision of the process used. Some processes may exhibitless variability than others, but variability is present nonetheless.

There are two broad sources of process variation: Natural variation, and variation produced by assignable causes. Natural variation is the sum total of the effects of numerous factors impacting on a process, each of which has too small an impact to be identified individually. A stable process is one that exhibits only natural variation, which can be monitored by a control chart. This inherent variation in a process is suggested when design engineers provide specification limits instead of a single precisevalue. When a stable process is operating as planned, it will produce products with the desired quality characteristics within specification limits. In such a situation, the process is said to be in control. Deming (1986) referred to natural variation ascommon cause variation.

The other source of variation in processes is that due to one or more assignable causes. When an assignable cause is present in a manufacturing process (such as wear and tear of a tool, a displaced setting, temperature change, introduction of poor qualityraw materials, or even an inspection gauge needing recalibration), the process is said to be out of control. The presence of assignable causes can be identified through the use of control charts and the process returned to stable in-control operation by removing the assignable cause(s). Deming (1986) referred to assignable cause variation as special cause variation.

When a stable process is in control, measurements on the quality characteristic tend to exhibit behavior which may be taken as the model of satisfactory process behavior. A normal distribution is frequently used as a model of satisfactory process behavior. Thus, a stable, in control process has predictable behavior; that is, its measurements follow the normal distribution. If measurements on the quality characteristic and the corresponding value of some statistic indicate that they do not follow the predictable pattern, the implication is that there must be an assignable cause for this out-of-control status. The purpose of SPC is to detect an assignable cause as early as possible so that corrective action may be taken.

A process is monitored by regularly taking random samples of size n from the output, taking measurements on the selected items, computing a relevant statistic (such as the mean, standard deviation, range, proportion nonconforming, etc.), and plotting the summary statistic for each sample on a chart. The Shewhart (1931) control chart has a center line and control limits and is used for monitoring a single quality characteristic.

If the sample statistic falls between the control limits, the process is stable—that is, there is no signal that special causes are present and the variation observed between time periods is due to natural variation. On the other hand, if the statistic falls outside the control limits or if the statistic shows some kind of pattern, the data suggests that an assignable cause has changed the process and the resulting production does not meet the customer's expectations. The process should be stopped and adjusted to remove this assignable cause before restarting.

For the Shewhart charts, the specification of the probability of false alarms (Type I error) associated with an in-control process can be used to determine the control limits. A false alarm occurs when a statistic plots outside the control limits but the process is actually in control. The probability of a false alarm has to be balanced against the probability of the failure to detect an out-of-control process (Type II error). The forms of the control limits are presented later for a variety of control charts.

The relevant sampling issues in the use of control charts include the determination of sample size,

frequency of sampling, and sampling technique. In terms of the sample size, the larger the sample, the higher the probability of detecting a shift in the process mean. In practice, however, small samples ($n = 4$ or 5) are used. In terms of the frequency of sampling, it would be desirable to specify the frequency depending on how fast a process change could occur. If a process could change rapidly, samples would be taken more frequently. Taking smaller samples more frequently is more common than taking large samples infrequently.

Since one is generally interested in monitoring a process over time to detect any process shifts, it makes sense to use the time order of production as a logical basis for drawing samples. Shewhart suggested that samples (subgroups) should be drawn rationally so that, if assignable causes are present, the chance for within group differences is minimized while the chance for between group differences is maximized. The most commonly used approach for rational subgrouping is to include items produced around the same time in a sample. The proper selection of samples is absolutely essential for gaining as much useful information as possible from control chart analysis. Outputs from different machines, work centers, shifts, or operators should not be pooled together to form a rational subgroup because that would make it impossible to pinpoint assignable causes.

The performance of a control chart is judged in terms of its average run length (ARL), which is the mean number of samples taken before an out-of-control signal is observed. An out-of-control signal for an in-control process is nothing but a false alarm. Thus, the ARL of an in-control process should be large while the ARL of an out-of-control process should be small. It can be shown that the in-control ARL for a Shewhart chart equals $1/\alpha$, where α is the probability of Type I error associatedwith the control chart. The out-of-control ARL is $1/(1-\beta)$, where β is the probability of Type II error. The ARL can also be used to determine the sample size and sampling frequency.

Shewhart charts, based only on the latest sample, are effective at detecting large shifts in the process but are insensitive to small and medium shifts as well as to incremental shifts over time. Other quality control charts, specifically the cumulative sum (CUSUM) chart and the exponentially weighted moving average (EWMA) chart are, however, useful for detecting small to moderate shifts in the process though they are less sensitive for detecting large shifts.

Finally, a word about how the control charts are implemented. Consider the case where the quality characteristic is measured (depth, contents). If the use of the control chart is to detect deviation from a target mean (μ_0) and standard deviation (σ_0), the design of control chart procedures is relatively straightforward. If μ_0 and σ_0 are unknown, they are estimated by sampling a process under allegedly stable conditions of production. Data from 20 or more samples (rational subgroups) are frequently used for estimating the process mean and standard deviation.

Using these estimates, trial limits are computed and the process is retrospectively tested to see whether it was in control when the samples were taken. If necessary, the trial limits are revised by excluding samples that resulted in out-of-control signals using the trial limits and for which a root cause was identified and eliminated. Then, the remaining subgroups are iteratively reviewed using the revised limits to determine if they come from a stable process. The process continues to be monitored in the short-term future using the revised limits.

Univariate control charts can be classified into two groups. If the quality characteristic of interest is a continuous variable, control charts based on measurements of that characteristic are referred to as control charts for variables. If the data being collected come from a discrete variable, the relevant control charts are termed control charts for attributes. Each of these groups contains three main types of control charts, namely, Shewhart, CUSUM, and EWMA charts. The next section presents the univariate Shewhart charts, which is followed by a section describing the univariate CUSUM and EWMA charts.

Shewhart Charts

For a continuous variable with a probability distribution (assumed to be normal in this discussion), generally both the central tendency and the variability of the process should be monitored. The central tendency can be monitored using either individual observations (X chart) or sample means ($\overline{X}$ chart) based on grouped observations. Measures typically used for monitoring variability of grouped

observations are the sample range (R chart) and sample standard deviation (S chart). Typically, control charts are used in pairs such as $\overline{X}$ and R charts (or $\overline{X}$ and S charts). It is recommended that process variability be monitored while monitoring the processaverage and that one analyze the R or S chart first.

Monitoring some quality characteristics may involve the classification of each inspected item as conforming or nonconforming to the specifications, such as can be determined by using a go/no-go gauge. Quality characteristics of this type are referred to as attributes, and the control chart is either based on proportion nonconforming (p chart) or number nonconforming (np chart). The basis for these charts is the binomial distribution. It is assumed that the probability (p) of obtaining a nonconforming unit is constant.

Another set of attribute control charts is based on counting nonconformities in a unit. If each sample unit, say, a square yard of fabric, or a roll of wire of given length, can have a number of different nonconformities, a control chart that monitors thenumber (or average number) of nonconformities per unit (c chart or u chart) may be appropriate. These charts are relevant if the probability of occurrence of a nonconformity is constant and very low relative to the opportunities for its occurrence. These charts are based on the Poisson distribution.

Control Chart for Sample Means ($\overline{X}$ Chart)

The control limits for a chart based on sample means are developed using the result that if observations from a process are normally distributed with mean μ_0 and standard deviation σ_0, then the sample mean based on n observations from the same process is normally distributed with mean μ_0 and standard deviation $\sigma_0/\sqrt{n}$. The control limits are:

$$(LCL, UCL) = \mu_0 \pm z_{\alpha/2}\frac{\sigma_0}{\sqrt{n}} = \mu_0 \pm A\sigma_0$$

where the values of A for $z_{\alpha/2} = 3$ and $n = 2, 3, \ldots, 25$ can be found in Montgomery (2009b). The commonly used $z_{\alpha/2} = 3$ results in $\alpha = 0.0027$ and an in-control ARL of 370. For successive random samples of size n, this control chart can be viewed as repeated significance tests of $H_0 : \mu = \mu_0$ vs. $H_1 : \mu \neq \mu_0$ where α is the Type I error associated with the test.

In many cases the in-control values μ_0 and σ_0 are unknown and replaced with unbiased estimates from a sample believed to be representative of the process during stable in-control operation. The estimates are found by using the sample mean $\overline{X}$ and sample standard deviation S for each of m subgroups to compute the overall mean $\overline{\overline{X}}$ and average standard deviation $\overline{S}$. If the range is used instead of the standard deviation, then R is computed for each subgroup, and average range is denoted by $\overline{R}$. Note that $\overline{S}$ and $\overline{R}$ are biased estimators of the process standard deviation, but unbiased estimators are obtained by using $\overline{S}/c_4$ or $\overline{R}/d_2$. The control limits for $\overline{X}$ charts when $\overline{S}$ is used are:

$$(LCL, UCL) = \overline{\overline{X}} \pm 3\frac{\overline{S}}{c_4\sqrt{n}} = \overline{\overline{X}} \pm A_3\overline{S}$$

and if $\overline{R}$ is used the control limits are:

$$(LCL, UCL) = \overline{\overline{X}} \pm 3\frac{\overline{R}}{d_2\sqrt{n}} = \overline{\overline{X}} \pm A_2\overline{R}$$

where the values for A_2 and A_3 for $n = 2, 3, \ldots, 25$ are given in Montgomery (2009b). For a set of m rational subgroups the control limits can be applied retrospectively to check whether the process was stable. If there are any rational subgroups that resulted in out-of-control signals, the estimates $\overline{\overline{X}}$ and $\overline{S}$ or $\overline{R}$ can be recomputed.

Control Charts for Process Variation (R and S Charts)

If samples of size n are taken at regular intervals, the variation or dispersion of the process is monitored using either the range (R chart) or the standard deviation (S chart).

The range is $R = X_{\max} - X_{\min}$, which has $E(R) = d_2\sigma_0$ and $\sqrt{V(R)} = d_3\sigma_0$ where d_2 and d_3 are constants tabled in Montgomery (2009b) for $n = 2, 3, \ldots, 25$. The control limits for the R chart are

$$\begin{aligned}(LCL, UCL) &= E(R) \pm 3\sqrt{V(R)} = d_2\sigma_0 \pm 3d_3\sigma_0 \\ &= (d_2 \pm 3d_3)\sigma_0 = (D_1\sigma_0, D_2\sigma_0)\end{aligned}$$

where the values of D_1, D_2 for $n = 2, 3, \ldots, 25$ are given in Montgomery (2009b).

Since R is not normally distributed, the control limits for the R chart are based on the premise that most of the probability distribution of R is within three standard deviations of its mean. Thus, if a value of R plots outside the control limits, it is highly likely that the process variability has shifted from the target value σ_0.

Because the computation of the sample standard deviation S is not as straightforward as the range, R charts have been used more often than S charts for monitoring the process variation. However, with modern computing replacing hand calculation even on the shop floor, the use of S charts has increased. The efficiency of the S chart relative to the R chart was discussed in Lowry, Champ, and Woodall (1995). While the S charts are superior, the difference isn't dramatic until $n \geq 10$. The target value for the S chart is $c_4\sigma_0$ and the control limits are $(LCL, UCL) = (B_5\sigma_0, B_6\sigma_0)$, with the values of c_4, B_5, B_6 for $n = 2, 3, \ldots, 25$ found in Montgomery (2009b). As was discussed above with R charts, S is not normally distributed and S charts are based on the notion that most of its probability distribution lies within three standard deviations of its mean.

When σ_0 is unknown, the control limits can be constructed using $\overline{S}$ or $\overline{R}$ using the appropriate constant to create an unbiased estimator. In S charts, the control limits become

$$(LCL, UCL) = (B_5\overline{S}/c_4, B_6\overline{S}/c_4) = (B_3\overline{S}, B_4\overline{S})$$

and the control limits for R charts become

$$(LCL, UCL) = (D_1\overline{R}/c_4,\ D_2\overline{R}/c_4) = (D_3\overline{R},\ D_4\overline{R})$$

where values of B_3, B_4, D_3, D_4 are in Montgomery (2009b). Control charts for S, S^2, and R using probability based limits are found in Ryan (2000).

Control Chart for Individual Observations (*X* and *MR* Charts)

In this case each subgroup is of size $n = 1$ and an unbiased estimator of the in-control mean is obtained by averaging m historical observations from the process during in-control operation. A procedure for estimating the in-control variance is based on the average value of the moving ranges where

$$\overline{MR} = \frac{1}{m-1}\sum_{i=1}^{m-1} |X_{i+1} - X_i|.$$

An unbiased estimator of σ is given by $\overline{MR}/d_2 = \overline{MR}/1.128$, using the value for d_2 when $n = 2$. Using this estimate of σ, the control limits for monitoring the process mean are

$$(LCL, UCL) = \overline{X} \pm 2.66\overline{MR}$$

since $3/1.128 = 2.66$.

To monitor process variability, compute the moving range $MR = |X_{i+1} - X_i|$ and compare to the upper control limit $UCL = 3.267\overline{MR}$. An interesting feature of the moving range chart is that if MR exceeds the upper control limit this could actually reflect a change in the level of the process mean between the two adjacent observations. Amin and Ethridge (1998) discussed the value added by using both X and MR charts versus only the X chart. The ARL of the X and MR charts was investigated by Crowder (1987a).

Control Chart for Proportion of Nonconforming Units (*p* Chart)

Suppose that a process is operating in a stable manner and that the probability of producing a nonconforming unit is p_0, the nominal value. If this process is monitored by taking samples of size n at regular time intervals and counting the number (Y) of nonconforming units in each sample, then the random variable Y (the number of nonconforming units) follows a binomial distribution with parameters n and p_0. The mean of Y is np_0 and its variance is $np_0(1 - p_0)$. If the statistic fraction of nonconforming units (Y/n) is used, its mean is p_0 and its variance is $p_0(1 - p_0)/n$. Plugging these values into the structure of the Shewhart chart yields the following control limits:

$$(LCL, UCL) = p_0 \pm 3\sqrt{\frac{p_0(1-p_0)}{n}}$$

where $LCL = 0$ if the computed value is negative.

If this chart is used retrospectively, the process proportion (p) of nonconforming units is estimated by using data from, say, 20 to 30 rational subgroups. The sample fraction of nonconforming units from each of these subgroups is computed and the average of these sample fractions, $\overline{p}$, is used as an estimate of p_0. Replacing p_0 by $\overline{p}$ results in trial control limits for the p chart. If necessary, the trial limits may need to be revised.

The control limits given above apply only if the sample size n is constant. If the sample size changes from subgroup to subgroup, then the upper and lower control limits will change from subgroup to subgroup by using the relevant sample size (n_t) in place of n in the control limits formulae.

As mentioned earlier, sample sizes required for fraction nonconforming units charts are much larger than the sample sizes used in variables control charts. A rule of thumb is that the sample size should be such that the probability of detecting a specified shift, d, on the next sample is 0.5. Using the normal approximation to the binomial distribution and 3σ limits, the minimum sufficient sample size n is given by:

$$n = \frac{9p(1-p)}{d^2}.$$

Montgomery (2009b) gives a method for choosing n such that $LCL>0$.

Control Chart for Number of Nonconforming Units (*np* Chart)

The control limits of this chart are easily obtained from those of the p chart by noting the number of nonconforming units (Y) in a sample of size n has mean np_0 and variance $np_0(1-p_0)$, where p_0 is the in-control probability of a nonconforming unit.

Control Chart for Number of Nonconformities (*c* Chart)

In some processes the inspection unit or area of opportunity is a single item (e.g. a bolt of fabric) or a group of items (e.g. 50 DRAM chips), but the inspection unit is constant. A common assumption is that the random variable counting the number of nonconformities follows a Poisson distribution where c is the mean and variance of the number of nonconformities.

Thus, 3σ control limits for the c chart with in-control nonconformity rate c_0 are:

$$(LCL, UCL) = c_0 \pm 3\sqrt{c_0}.$$

If LCL is negative, it is set equal to zero. Again, every effort should be made to reduce the level of c. If no standard is given, c_0 is estimated by the average number of nonconformities, $\overline{c}$, in a preliminary sample of size m and trial limits are computed using $\overline{c}$ instead of c_0.

Control Chart for Average Number of Nonconformities per Unit (*u* Chart)

The u chart is used in place of the c chart when areas of opportunity vary in size. For example, in monitoring the daily number of medication errors (wrong patient, amount, time, etc.) at a hospital, the area of opportunity (number of patients) would vary day to day. The plotted statistic is $u = c/(\text{area of opportunity})$, and the control limits are

$$(LCL, UCL) = \overline{u} \pm 3\sqrt{\frac{\overline{u}}{n_i}}$$

where $\overline{u} = \sum c_i / \sum n_i$ and n_i is the size of the ith sample.

Interpreting Control Chart Patterns

If a process is operating only under natural or common causes of variation, the points on the control chart should be randomly scattered around the center line. Nonrandom control chart patterns of any kind signal the possibility of assignable causes beingpresent. So, in addition to the 3σ limits, one can use additional rules to identify nonrandom patterns on the control chart.

In addition to the rule of one point falling outside the three-sigma control limits, Western Electric's *Statistical Quality Control Handbook* (1956) recommends three other rules to identify nonrandom patterns based on dividing the region between the LCL and UCL into six zones each with a width of one

standard deviation. The rules given in the handbook are such that the probability of occurrence of those patterns is approximately equal to the probability of a point falling outside the 3σ limits. These rules are: Two out of three successive points outside 2σ limits (same side), or four out of five successive points outside 1σ limits (same side), or eight successive points on the same side of the center line. The occurrence of any of these patterns indicates the possible presence of an assignable cause. Popular software for quality improvement allows one to incorporate these and other additional rules.

If one uses more than one rule for monitoring a process, the probability of detection of special causes increases but the probability of false alarms increases. Refer to Nelson (1984, 1985), Champ and Woodall (1987) and Walker, Philpot, and Clement (1991) for the effects of using these rules. More information on the interpretation of these and other other patterns is available in Western Electric's *Statistical Quality Control Handbook* (1956).

CUSUM and EWMA Charts

The CUSUM chart is based on a statistic that reflects the cumulative sums of the deviations of each sample statistic relative to the target value. The EWMA chart is based on exponentially weighted moving averages of the current and all past observations. The CUSUM procedure gives equal weight to all of the observations. The EWMA procedure, on the other hand, gives the most weight to the latest observation and exponentially decreasing weights to prior observations.

A CUSUM procedure combines information both from previous samples and the current sample to detect process shifts. CUSUM procedures were first proposed by Page (1954, 1961) and are based on repeated applications of the sequential probability ratio test (see Wald 1947; Johnson and Leone 1962). While CUSUM procedures can be derived for many sample statistics, this section will discuss only the use of CUSUM for individual values.

Since the shift in the process mean may be an increase or a decrease, a CUSUM can be constructed using either a mobile V-mask or an equivalent tabular procedure with a decision interval. Suppose the individual values are independent and normally distributed with mean μ_0 and variance σ_0^2. Then, at time t, compute two cumulative sums, L_t and U_t, for detecting shifts in the process mean:

$$L_t = \min\{0, L_{t-1} + (X_t - \mu_0) + K\}$$
$$U_t = \max\{0, U_{t-1} + (X_t - \mu_0) - K\}$$

where $L_0 = U_0 = 0$, and $K \geq 0$ is referred to as the reference value. The value for K is frequently chosen as halfway between the in-control mean μ_0 and the out-of-control mean μ_1, or $K = |\mu_1 - \mu_0|/2$. An out-of-control signal is given atthe first t or which either $L_t < -H$ or $U_t > H$, where Hs called the decision interval. Typically, the use of $H = 4\sigma_0$ or $H = 5\sigma_0$ yields charts with good ARL properties for detecting shifts of one standard deviation in the mean. If the out-of-control signal is the result of $L_t < -H$ there has been a downward shift in the process mean, whereas if $U_t > H$ signals an upward shift in the process mean. The determination of when the process mean has shifted is accomplished by using counters N^+ and N^-, respectively. In the case of an upward shift, N^+ counts the number of consecutive periods from when U_t first became nonzero at period t^* until $U_t > H$. The shift occurred between periods $(t^* - 1)$ and t^*.

Although CUSUM charts are more effective than Shewhart charts in detecting small to moderate shifts in the process mean, these charts are not as effective in detecting large shifts. Hawkins and Olwell (1998) provide details on choosing H and K based on the desired in-control and out-of-control ARLS, as well as modifications like the fast initial response to improve the sensitivity of the CUSUM at process start-up.

The EWMA chart was introduced by Roberts (1959) and a detailed exposition was given by Hunter (1986). Suppose individual observations X_t are made on a process that is normally distributed with in-control mean μ_0, in-control standard deviation σ_0, and that observations are independent over time. At time t, the EWMA statistic is

$$Z_t = \lambda X_t + (1 - \lambda) Z_{t-1}$$

where $Z_0 = \mu_0$ and $0 < \lambda \leq 1$. Montgomery (2009b) recommended values for λ in the interval $[0.05, 0.25]$. It can be shown that Z_t is a weighted average of all

previous observations where the weights add to 1 and decrease geometrically with the age of the sample. The variance of Z_t is given by

$$V(Z_t) = \sigma_0^2 \frac{\lambda[1-(1-\lambda)^{2t}]}{(2-\lambda)}$$

and as t increases $V(Z_t)$ approaches $\sigma_0^2\lambda/(2-\lambda)$. Therefore, the control limits for the EWMA chart are

$$(LCL, UCL) = \mu_0 \pm 3\sigma_0\sqrt{\frac{\lambda}{2-\lambda}}$$

for moderately large t. For small t, control limits should be based on the exact variance of Z_t.

The EWMA chart is very effective in detecting small shifts in the process mean but is not as effective as the Shewhart chart for detecting large shifts in the process mean. Crowder (1987b, 1989) and Lucas and Saccucci (1990) have provided tables for designing optimal EWMA procedures. An optimal EWMA chart is defined as one with a fixed in-control ARL which has the smallest out-of-control ARL for a specified process shift. For example, by using 2.962σ control limits (rather than 3) and $\lambda = 0.20$, the EWMA chart has an in-control ARL of 500 and an out-of-control ARL of 10.5 for a shift of one σ.

Specification Limits and Process Capability

Once the specification limits for a quality characteristic have been established, one needs to make sure that a stable process is capable of meeting these requirements. A commonly used measure of process capability relative to specification limits is called the Process Capability Index. One such index is C_p, which is defined as

$$C_p = \frac{U-L}{6\sigma},$$

where (L, U) denote the lower and upper specification limits for the quality characteristic and σ is the standard deviation of the distribution of the process. Therefore, C_p is a comparison of the specification limits to the natural variation of the process. The 6σ value represents the process has 99.73% of production within three standard deviations of the mean. If the process has been improved so that C_p is increased, the process has become "more capable" of production within the specification limits. The C_p index is frequently written as $C_p = \text{VOC}/\text{VOP}$, where VOC is the voice of the customer and VOP is the voice of the process.

The C_p index assumes the process is centered at the target mean. An index that penalizes for a mean different from the midpoint of the specification limits is

$$C_{pk} = \min\left\{\frac{U-\mu}{3\sigma}, \frac{\mu-L}{3\sigma}\right\}$$

where μ is the mean of the process distribution. C_{pk} is the more commonly applied summary statistic comparing process capability to specification limits. For a Six Sigma process that is centered at the target mean, the distance from the mean to either specification limit is 6σ and $C_{pk} = 2$. If the process mean shifts by 1.5σ, $C_{pk} = 1.5$ and the DPMO = 3.4. In practice, one needs to estimate μ and σ^2, which can be used to obtain a confidence interval for the capability index. A comprehensive treatment of process capability indices and their statistical properties is in Kotz and Johnson (1993).

Queue Inference Engine

Richard C. Larson
Massachusetts Institute of Technology,
Cambridge, MA, USA

Introduction

Imagine receiving your monthly bank statement and with it is your personal probability distribution of the times you spend waiting in bank queues. The queues could include both those involving human tellers and automatic teller machines (ATMs). With the technology of the Queue Inference Engine (QIE) such an innovation is now well within the realm of possibility.

Background, Motivation and Overview

The idea of QIE was born in the late 1980s as a result of M.I.T.-based queueing research for Bay Banks, an eastern Massachusetts bank, under the auspices of a grant from the National Science Foundation. Bay-Banks had provided a large sample of transactional data from three of their ATM sites. Their question was, "Which, if any, of these sites is 'too congested' from a queueing point of view, thereby requiring additional ATM capacity at the site?" The transactional data consisted of the times of each ATM transaction by each customer over a period of up to a month.

The first approach to this problem was traditional: estimate arrival rates and service times from the data and then apply well known (steady state) queueing models, such as Erlang's results or the M/G/1 model. Examining the data set, it was realized that a substantial portion of the sample path of the queue had been preserved in the data set. That is, the data set contained a large subset of the information one would have if one tracked the actual queue with "clipboard and stopwatch." For instance, one could identify which customers had been delayed in queue (rather then enter service immediately) by noting the "signature" of a queued customer: a back-to-back service completion and service initiation at the same ATM, during a time when all N ATM's are busy with customers. The customer entering service in such a back-to-back situation was, with probability near one, delayed in queue. Moreover, by following this signature over time-adjacent customers, one could identify the entire set of customers who were delayed in queue during a single congestion (or busy) period, a continuous period of time during which all N servers are continuously busy (except the small intervals during which a customer whose service is completed departs and the new [queued] customer enters service). Further, the information content of the data set was explored to see if it contained additional queue-related information.

Surprisingly, the partial information in the data set allowed a wide variety of queueing measures for each congestion period to be computed efficiently. Assuming Poisson arrivals, these measures include mean queue delay, mean queue length, probability distribution of the queue length and even the transient mean queue length over the course of the congestion period. Later research extended these first results in a number of important directions.

Here, the focus is four-fold: (1) to illustrate the types of physical situations in which the QIE can be applied; (2) to describe one of three alternative

analytical approaches to obtaining QIE results; (3) to guide the reader through the emerging literature in this new and exciting field; and (4) to discuss briefly several implementation experiences.

Illustrative Queue Inferencing Problems

Retail Sales — With most human server retail service systems, one has to collect the transactional data either from a modern POS (Point Of Sale) computer system that does the time marking or from some type of customer sensing device (e.g., pressure sensitive mats, infrared or ultrasonic sensors). For an ATM, the transactional data are recorded automatically, by time marking the moment that a customer inserts a bank card (corresponding to service initiation) and the moment that the ATM ejects the card (corresponding to service completion). The queue statistics generated by the QIE for ATMs may be used by bank managers to monitor the use of ATM sites, thereby providing an accurate method of identifying those sites requiring additional (or fewer) machines. With human servers in retail sales, at banks, post offices, fast food restaurants, etc., the manager would most likely use the results to (1) monitor service levels throughout the day and week, to assure that queue delays are within prescribed quality limits, and (2) to schedule servers optimally over the course of a day and week.

Invisible Queues in Telecommunication Systems — During periods of congestion, many finite capacity telecommunications systems have invisible queues of customers outside the system continuously trying to gain access to it. One example is a k-channel land mobile radio system. Whenever all k channels are simultaneously in use, potential users having a message to transmit (often in the field, in vehicles) continuously monitor channel use and at-tempt to acquire a channel as soon as any one of the current k communications is completed. If at any given time t there are $n(t)$ such potential users awaiting a channel, they constitute a spatially dispersed invisible queue, a queue in which one of the waiting customers enters service very shortly after another customer completes service. This queue can grow in size due to the Poisson arrivals of new potential users desiring channel access. The user entering service next is the one who successfully "locks in" the channel very shortly after termination of a previous message. Service discipline is most likely not first come first served (FCFS). Within the context of the QIE the customer transaction times are the moments of gaining channel access (service initiation) and message termination (service completion). These times can be routinely monitored and recorded by technology, and thus the QIE can be used to deduce queueing behavior. The same argument, perhaps with minor modifications, can be applied to other telecommunications systems, including phone systems from airplanes, mobile cellular telephone systems, standard telephone systems and various digital communications networks.

Using Order Statistics to Derive QIE Performance Measures

The analysis of the queue inferencing problem is rooted in order statistics. Suppose a homogeneous Poisson process is considered with rate parameter $\lambda > 0$. Over a fixed time interval $[0, T]$, it is known that precisely N Poisson events (e.g., queue system arrivals) occur. The N ordered arrival times are $0 \leq X_{(1)} \leq X_{(2)} \leq \cdots \leq X_{(N)} \leq T$ (by implication $X_{(N+1)} > T$). The N unordered arrival times are $X_1, X_2, \ldots, X_N, 0 \leq X_i \leq T (i = 1, 2, \ldots, N)$. Since the Poisson process is time homogeneous, it is well known that the $\{X_i\}$ are independent and uniformly distributed over $[0, T]$. If the Poisson process is non-homogeneous, that is, having time varying rate parameter $\lambda(t)$, then the N unordered arrival times are independent identically distributed (iid) over $[0, T]$, with a PDF (probability density function) proportional to $\lambda(t)$. For simplicity in this discussion, homogeneous processes are focused on.

A Pedestrian Queueing Example — To illustrate queue inference, consider a signalized pedestrian cross walk having fixed cycle time T. Poisson-arriving pedestrians queue at curbside waiting to cross the street during a time interval of length T, and all such queuers are served in "bulk" fashion when the light changes at time T allowing them safely to cross the street. The number N of queued arrivals in any particular light cycle is Poisson distributed with mean λT. Given N, $X_{(i)}$ is the arrival time during $[0, T]$ of the ith queued pedestrian. Here X_i could be viewed as the arrival time of a random queued pedestrian, selected from, say, a photograph of

all queued pedestrians taken just before the light changed at time T. The Poisson arrival assumption is usually thought of as evolving sequentially over time, with customer interarrival times selected in an iid manner from a negative exponential PDF with mean λ^{-1}.

An equivalent way to conduct the pedestrian cross walk experiment is to first select N from the Poisson distribution, and then, for each of the N queuers, to select the arrival time over $[0, T]$ independently from a uniform PDF. This experiment is probabilistically identical to the sequential Poisson arrival realization of the experiment. Suppose now at some intermediate time T, the total number of queued pedestrians $N(t)$ is focused on, defined as the total number of arrivals (at curbside) during the interval $[0, t)$. The following results, derived from the second model of the process, are well known for $N(t)$:

$$\begin{aligned} &E[N(t)] = (t/T)T \\ &\mathrm{Var}[N(t)] \equiv \sigma^2 N(t) = [N(t)/T]y[(T-t)/T] \\ &\Pr\{N(t) = k\} = \binom{N}{k}\left(\frac{t}{T}\right)^k \left(\frac{T-t}{T}\right)^{N-k} \end{aligned} \tag{1}$$

Here the transactional data are N, the total number of queuers, and T, the time until bulk service. From these data transient values of conditional mean have been found, variance and probability distribution of the queue length. Similar logic can be applied to find other performance measures, such as mean delay in queue, that in this case is trivially equal to $T/2$. This is one of the simplest examples of queue inferencing.

Queue Inference in More General Queues —In most queues, customers usually leave one-at-a-time. Their service completion times within a congestion period, recorded as part of the transactional data set, impose a set of inequality constraints on the arrival times of customers who waited in queue. It is this set of inequality constraints that produces precise conditioning information within the general context of order statistics, conditioning information that can be used to deduce queue behavior.

Suppose for a M/D/1 system, a congestion period having precisely $N = 2$ queued customers is examined. For simplicity the service time is one minute per customer and the server's congestion period starts at time zero. Then since $N = 2$, it is known that precisely 2 customers queued during this congestion period and after their service the server was again idle. The busy period for the server is *3* minutes in length, the time to serve 3 customers, the two who queued and the first arrival who initiated the congestion period. From the transactional data, it is known that zero customers arrived during service of the last customer, the third in the congestion period and the second to queue (assuming FCFS queueing). It is known that at least one of the 2 queued customers must have arrived in [0, 1], else there would be no queued customer to select for service commencement at time $T = 1^+$. Similarly, the second queued customer must have arrived by time $T = 2$.

Without the ordering information, the conditional arrival times for the two queued customers are independent uniformly distributed over [0, 2]. In the joint sample space of random variables X_1 and X_2, this corresponds to X_1 and X_2 uniformly distributed over the square of size *2* in the positive quadrant. The sample space can be split into four equal subsquares, (1) $0 \le X_1 \le 1, 0 \le X_2 \le 1$; (2) $1 \le X_1 \le 2, 0 \le X_2 \le 1$; (3) $0 \le X_1 \le 1, 1 \le X_2 \le 2$; (4) $1 \le X_1 \le 2, 1 \le X_2 \le 2$. Without the additional conditioning information regarding service completion times, the outcome of the experiment is equally likely to be within each of the four subsquares, and conditional on being in a subsquare the r.v.'s X_1 and X_2 are conditionally uniformly distributed over that subsquare. But the additional conditioning information from the transactional data imposes the constraints: $X_{(1)} \le 1$, $X_{(2)} \le 2$, thereby eliminating subsquare (4). The a priori probability of this event, called the master probability, is 3/4. *For any number of queued customers N, the master probability is the a priori probability that the order statistics will obey the ordered inequalities imposed by the transactional data*. Once the master probability can be efficiently calculated, most other quantities of interest are easy to compute.

Continuing with the $N = 2$ example, if it is known that X_1 and X_2 fall in subsquare (1), then these two arrival times are uniform identically distributed over [0, 1]. If one falls in [0, 1] and the other falls in [1, 2], that is, subsquare (2) or (3), then the minimum is uniformly distributed over [0, 1] and the maximum is uniformly independently distributed over [1, 2]. This property generalizes: *once it is known that* n_1 *of*

N arrival times are contained in subinterval $[t_k, t_{k+1})$, *where* t_k and t_{k+1} *are the entry into service times of queued customers* k and k_{+1}, *respectively, during the congestion period, then the* n_1 *arrival times are conditionally uniform and independently distributed over* $[t_k, t_{k+1})$ (Larson 1990). These facts allow one to obtain many useful performance characteristics of the queueing system, conditioned on the transactional data.

A simple application of the above observation yields for the PDF of the arrival time A of a randomly queued customer the step-wise decreasing PDF shown in Fig. 1a. The form of this PDF generalizes to arbitrary N: *the marginal PDF for the arrival time of a random queued customer has a stepwise de creasing PDF over the duration of the congestion period, with each step occurring at an end-of-service time* t_i (Hall 1992; Larson 1990).

As a second illustration, the conditional arrival time $X_{(1)}$ of the first queued customer is either the minimum of two uniform independent r.v.'s over [0, 1] *or* simply uniform over [0, 1], with the former situation applying only if the experimental outcome is within subsquare (1). Likewise the conditional arrival time $X_{(2)}$ of the second queued customer is either the maximum of two uniform independent r.v.'s over [0, 1] or simply uniform over [1, 2], the former applying again only within subsquare (1). Recalling that such minimum and maximum r.v.'s have triangular PDFs and combining results appropriately, the PDFs for the arrival times of the two respective customers are immediately obtained, as shown in Fig. 1b. Finally, assuming a FCFS queueing discipline, the queueing delay for the first queued customer is $1 - X_{(1)}$ and the queueing delay of the second is $2 - X_{(2)}$. The corresponding queue delay PDFs are inverted forms of those in Fig. 1b, as shown in Fig. 1c. If a bank knows that you were the second customer in this congestion period, it then has the required information to begin to build your personal PDF for bank queueing. To obtain the monthly PDF, the bank simply has to add together such conditional PDFs for each banking service session that you had during the month.

A General Result in Order Statistics and Application to Queue Inference — Suppose that the service end/start time transactional data are given by the vector $t = \{t_i; i = 1, \ldots, N\}$. In a queue inferencing setting, t_i has two definitions: (1) it is the observed time of departure of the ith departing customer to leave the system during the congestion period; (2) it is also the observed time for the ith customer from the queue to enter service, not necessarily in a FCFS manner. The two sets of individuals comprising the set of arriving customers and the set of departing customers during a congestion period are never identical and may be disjoint. The number of servers M does not enter into the analysis, nor do any distributional properties of the service times (e.g., there is no requirement for iid service times). It is assumed that service times are independent of arrival times. For any given congestion period, the QIE computations may occur any time after completion of the congestion period.

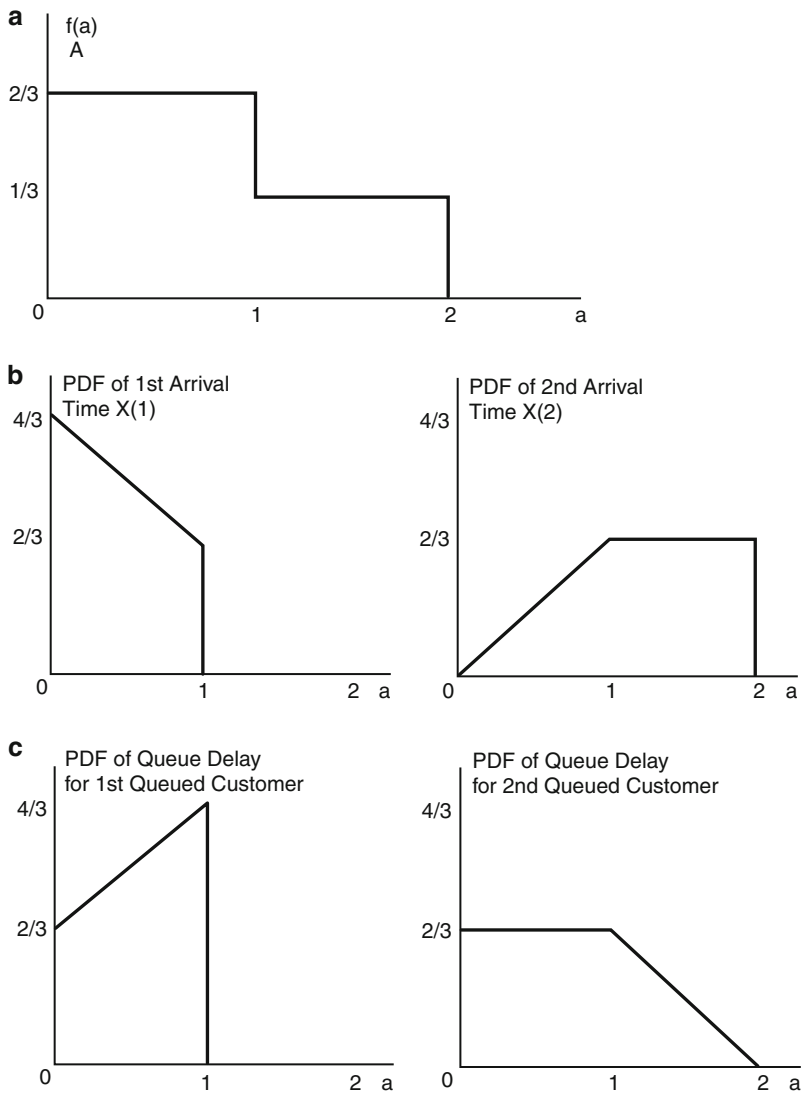
Let $X_1, X_2, = , X_{N(1)}$ be an iid sequence of r.v.'s with values in [0, 1], where the sequence length $N(1)$ is an independent random integer. The goal is to find a computationally efficient algorithm to calculate the probability of an order statistics vector lying in a given N-rectangle,

$$\begin{aligned} \Gamma(\underline{s}, \underline{t}) \equiv \mathrm{P}\{\mathrm{s}_1 < \mathrm{X}_{(1)} \le \mathrm{t}_1, \mathrm{s}_2 \\ < X_{(2)} \le t_2, \ldots, s_N < X_{(N)} \le t_N | N(1) = N\}, \end{aligned} \tag{2}$$

where $\underline{s} \equiv (\mathrm{s}_1, \mathrm{s}_2, \ldots \mathrm{s}_\mathrm{n}), \underline{t}(\mathrm{t}_1, \mathrm{t}_2, \ldots \mathrm{t}_\mathrm{n})$ and without loss of generality the sequences $\{s_i\}$ and $\{t_i\}$ are increasing. Using the fact that the N unordered Poisson arrival times during any fixed time interval $(0, T]$ are iid and now (for convenience) scaling the congestion period to $(0, 1]$, then in our notation, $\Gamma(0, \mathrm{t})$ is the a priori probability that the (unobserved) arrival times $X_{(1)}, X_{(2)}, \ldots, X_{(N)}$ obey the inequalities $X_{(i)} \le t_i$ for all $i = 1, 2, \ldots, N$, that is, it is the "master probability" discussed above. That is, $X_{(i)} \le t_i$ simply says that the ith arriving queued customer must arrive (and enter the queue) before completion of service of the ith departing customer from service.

If the Poisson arrival process is homogeneous, then the unordered arrival times are iid uniform and the rate parameter of the process does not enter the analysis. If the arrival process is nonhomogeneous, then the time-dependent arrival rate parameter $\lambda(t)$ must be known up to a positive multiplicative constant for use in computing the CDF $F(x)$, that is,

$$F(x) = \frac{\int_0^x \lambda(t)dt}{\int_0^1 \lambda(t)dt} \qquad 0(\le x \le 1).$$



Queue Inference Engine, Fig. 1 Probability density functions of arrival times and queueing delays of queued customers

For simplicity, it is assumed that $F(x)$ is strictly monotone nondecreasing continuous. Jones and Larson (1995) have derived an $O(N^3)$ algorithm for finding $\Gamma(\underline{s}, \underline{t})$. Next several of its queue inference applications will be discussed briefly.

The Maximum Experienced Queue Delay — Assume a FCFS queue and consider a congestion period having N customers with observed departure time vector $\underline{t}$, and where the interest is in the maximum time that any of the N customers was delayed in queue, given $\underline{t}$. More precisely, to goal is finding the CDF of the maximum of N nonindependent r.v.'s, the in-queue waiting times of the N queued customers, given $\underline{t}$.

Define $D(\tau/\underline{t})$ as the conditional probability that none of the N customers waited τ or more time units, given the observed departure time data. Set $s_i = \max\{t_i -, 0\}$ for all $i = 1, 2, \ldots, N$. Then $\Gamma(\underline{t} - \tau, \underline{t})$ is the a priori probability that the observed departure time inequalities will be obeyed and that no arrival waits τ or more time units in queue. Clearly,

$$D(\tau|\underline{t}) = \Gamma(\underline{t} - \tau, \underline{t})/\Gamma(0, \underline{t}). \tag{3}$$

Maximum Queue Length — Without any assumption regarding queue discipline, suppose $\underline{s} = \underline{t}^{*k}$ is defined such that $s{*}t_{(i-K)}$ for all

$i = 1, 2, \ldots, N$; $K = 1, 2, \ldots, N$, where a non-positive subscript on t implies a value of zero. These values for $\underline{s}$ imply that each arriving customer i has to arrive after the departure time of departing customer $i = K$ during the congestion period. Now the conditional probability can be computed that the queue length did not exceed K during the congestion period, given $\underline{t}$:

$\Pr\{Q \le k|t\} = P$ {queue length did not exceed K during the congestion period | observed departure time data}, or

$$\Pr\{Q \le K|\underline{t}\} = \Gamma\left(\underline{s}^{*K}, \underline{t}\right)/\Gamma(0, \underline{t}). \tag{4}$$

Probability Distribution of Queue Length — Following the same arguments as in Larson (1990), the $O(N^3)$ computational algorithm can be used to determine for any queue discipline the probability distribution of queue length at departure epochs, and by a balance of flow argument, this distribution is also the queue length distribution experienced by arriving customers.

The Cumulative Distribution of Queue Delay — The algorithm allows computation of points on the conditional in-queue waiting time distribution, given the observed departure data. Again assume a FCFS queue. Define $\beta_i(\tau|\underline{t}) \equiv \mathrm{P}\{j\text{th customer to arrive during the congestion period waited less than } \tau \text{ time units} \mid \text{observed departure time data}\}$. Then setting $\underline{s} = \mathrm{s}^{\mathrm{j}}$, defined so that

$$s_i^j = 0 \; i = 1, 2, \ldots, \; j-1$$
$$s_i^j = \mathrm{Max}\{t_j - \tau, 0\} \quad i = j, \; j+1, \ldots, N$$

it follows that

$$\beta_j(\tau|\underline{t}) = \Gamma\left(\underline{s}^j, \underline{t}\right)/\Gamma(0, \underline{t}). \tag{5}$$

This result allows the determination for any congestion period the probability that a random customer waited less than τ time units, given the observed departure data. Simply compute Eq (5) for each value of j and average the results. Jones and Larson (1995) developed a separate algorithm that allows $O(N^3)$ computation of this average probability of queue delay exceeding some threshold.

Research Literature

Research in queue inferencing is rather extensive. For $O(N^3)$ algorithms for queue performance estimation, see Bertsimas and Servi (1992), Larson (1990), Daley and Servi (1992, 1993); for personnel queue delay PDF, see Hall (1992); for balking, see Larson (1990), Daley and Servi (1993), Jones (1994, 1999); for unknown number of servers, see Kim and Park (2008). Applications of QIE are discussed in Gawlick (1990) and Chandrs and Jones (1994). QIE concepts have been incorporated into a commercial software product Queue Management System (QMS) and has been used by banks, an airline, and the United States Postal Service.

Queueing Discipline

Rules used to select the next customer to be served. The first-come, first-served (FCFS) discipline chooses the head of the line customer, the last-come, first-served (LCFS) chooses the tail of the line, and random order chooses the next customer at random, usually equally likely. Other disciplines include putting customers into priority classes.

Queueing Theory

Daniel P. Heyman
Lincroft, NJ, USA

Introduction

Queueing theory is the study of service systems with substantial statistical fluctuations in either the arrival or service rates. Other names for the subject are stochastic service systems and the theory of mass storage. An example of a stochastic service system from everyday life is a line for bank tellers (human or machine); customers arrive at random, and the transaction lengths will vary depending on the services requested. An example from the world of technology is a computer system; jobs arrive randomly and require different amounts of system resources. An all-too-common source of service-rate variability is a hardware or software crash, which probably occurs randomly even though it might appear that they happen just when you want to use the computer. Looking inside the computer system reveals some more stochastic-service systems. The components (e.g., disk drives, I/O devices, the CPU) have randomly arriving tasks, and the time required to execute a task may be subject to significant statistical fluctuations.

Queueing theory traces its roots back to 1905, starting with the work of A.K. Erlang, who was designing automatic telephone exchanges and needed to know how many calls might be carried simultaneously. Since the calls start at random times and have random durations, the number of calls in progress fluctuates as a stochastic process. Erlang developed several concepts (e.g., birth-and-death processes and statistical equilibrium) about stochastic processes before the formal mathematical theory of stochastic processes was developed. Most of the first 30 years of queueing theory was done in the context of telephony, and telephony continues to be a major consumer of queueing theory. The creation of operations research during World War II led to other applications, such as capacity evaluation of toll booths and port facilities, the order to assign "stacked" airplanes to runways, and scheduling patients in hospital clinics. Areas of extensive current activity include the analysis of production systems, supply chains, call centers, and computer/communication systems.

Basic Notions

The paradigm of a queueing model is that there is a facility consisting of some servers, and customers arrive at the facility to receive some sort of service. Upon arrival, the customers will go to a server if one is available; if all the servers are busy, the customer will either join the queue (also called the waiting room or buffer) or leave. There are two typical reasons that a customer will leave before obtaining service: the queue may be full (in this case the customer is said to be blocked) or the customer may be adverse to waiting in line (in this case the customer is said to have balked).

A departing customer may leave forever or retry after some time. Customers who join the queue may wait until a server is free (the alternative is to bolt from the queue, which is called reneging), and then one of them enters service; the rule that selects the lucky customer is called the queue discipline. Some queue disciplines allow newly arrived customers to displace a customer that is in service, which is called preemption. Once at the server, the customer receives the desired service and then departs. When there is a single facility, the departing customer leaves the system. When there are multiple facilities, the model is called a queueing network, and a routing rule determines where a departing customer goes.

A statistical description of the arrival and service times is almost always given. The objective of the theory is to describe some performance measures, which include the following: the delay of a customer is the time spent in the queue waiting to start service (sometimes it is called the queueing time), the sojourn time of a customer is the total time spent in the facility (it is sometimes called the total waiting time or waiting time), the queue length is the number of customers in the queue, and the number in the system is the queue length plus the number of customers in service. Other performance measures include the number of busy servers, the proportion of blocked customers, and the proportion of non-blocked customers who have a positive delay.

Taxonomy

In the 1950s, D.G. Kendall (1953) introduced a compact notation for describing queueing models. In the current form of the notation, a model is generally described by five parameters, written $A/S/c/K/Q$: A describes the distribution of the times between arrivals, S describes the service time distribution, c is the number of parallel servers, K is the maximum number of customers that can be in queue or in service, and Q is the queue discipline. It is required that $K \geq c$; when $K = \infty$, it is often omitted. Sometimes another parameter is included between K and Q that gives the size of the customer population arrival source, which again is infinite if omitted (see, e.g., Kleinrock 1975).

The following symbols are used for both A and S: M for exponential (Markov), D for deterministic, E_k for Erlang k, H_k for hyperexponential of order k, and PH for phase-type. When the service-times have a general distribution, the letter G is used. The symbol G is used for interarrival times when they are not necessarily independent; independence is emphasized by using the pair of letters GI.

A common queue discipline is FIFO (First-In, First-Out), which is usually taken to be the same as FCFS (First-Come, First-Served). They are identical when there is a single server, but when there are multiple servers, FIFO is stronger than FCFS. Since this is considered the default queue discipline, it is commonly omitted in the notation. Thus, an M/M/1 queue refers to an FCFS single-server queue with a Poisson arrival process and exponentially distributed service times. Other common rules include LIFO (Last-In, First-Out), SIRO (Service In Random Order), and processor sharing. Customers may be partitioned into priority classes, so that more important customers get favored treatment.

There are tacit assumptions that service times are independent and identically distributed (i.i.d.), that service times are independent of interarrival times, that (except for the G case) interarrival times are i.i.d., and that arrivals and services occur one at a time. Other notations are used to represent bulk arrivals or departures, dependencies, and other features.

It is common to denote the mean interarrival time by $1/\lambda$ (λ is the arrival rate) and the mean service time by $1/\mu$. Then $a = \lambda/\mu$ is the rate at which work is brought to the system; it is called the offered load. The offered load is dimensionless, but it is often expressed in Erlangs to honor the contributions of A. K. Erlang. When there are c servers, the load on each server is a/c, which is usually denoted by ρ and is called the traffic intensity.

General Theorems

Most results in queueing theory are formulas for operating characteristics in particular models. There are some theorems that apply to many queueing models, and two of them will be described here. Before doing so, the notion of statistical equilibrium, also called the steady state, is introduced.

Let zero be the time that a queueing system starts operating; for example, for a computer system, it is the time that the installation procedures are completed. Let t be the current time, and let $X(t)$ be the operating characteristic being modeled at time t, for example,

the number in the system t time units after the system started. The initial conditions at time zero usually affect $X(t)$. If there was a backlog of work at time zero, $X(t)$ would be larger than if there was no backlog. The effects of the initial conditions usually decrease as t increases; statistical equilibrium is reached when the effects of the initial conditions have faded away. A queueing system with this property is usually called stable. The mathematical description of this idea starts with defining $p_{ij}(t) = \Pr\{X(t) = j, \text{ given } X(0) = i\}$, and then showing that $p_j = \lim_{t\to\infty} p_{ij}(t)$ exists and is independent of i. Another interpretation of the steady state is that probabilities are not changing with time, that is, the derivatives of $p_{ij}(t)$ with respect to t are zero.

The steady-state solution $\{p_j\}$ is typically much easier to obtain than the transient solution $\{p_{ij}(t)\}$. Interpreting p_j as the long-run proportion of time that X is in state j,

$$p_j = \lim_{t\to\infty}\left[\frac{1}{t}\int_0^t I\{X(s) = j\}\, ds\right] = \lim_{t\to\infty}\left[\frac{T_j(t)}{t}\right] \quad (1)$$

where $I\{\cdot\}$ is the indicator function, which is equal to 1 if the condition is true, 0 otherwise, and $T_j(t)$ is the amount of time $X(s)$ equals j during $(0, t]$. Results of this type are called ergodic theorems, and some conditions on the model are needed for (1) to be valid. The theories of stationary and regenerative processes often are used to prove ergodic theorems.

Among the general theorems, these two are used most frequently.

Little's Theorem (often referred to as Little's Law) – For any stable queueing system, or part of a queueing system, let λ be the arrival rate, L be the steady-state mean number of customers present, and W be the steady-state mean waiting time. If λ and W are well defined, then so is L and $L = \lambda W$.

The use of this theorem is clearly to obviate the need to compute separately both L and W. Three subtler uses of the theorem are the following. It is important to know, and difficult to measure, the average time to get a telephone dial tone (W). It is not so difficult to measure the arrival rate of calls (λ) and the average number of calls waiting to receive dial tone (L). Little's theorem gives an indirect way to estimate the dial tone delay.

In a model with homogeneous servers where all arriving customers are served and the steady-state queue length is finite, suppose the objective is to calculate the mean number of busy servers; this can be very intricate if done in a straightforward way. By considering the servers as "the system," the arrival rate is the arrival rate of customers λ, the "waiting time" of a customer in the system is the service time, with mean $1/\mu$ say, and the "number in the system" is the number of busy servers. Little's theorem shows that our answer is simply λ/μ, which is the offered load. This result shows that at least λ/μ servers are needed. When the queue discipline is such that all servers are equally used, the traffic intensity is the proportion of time a server is busy. The third application concerns comparisons among queue disciplines. Disciplines that produce the same L as FIFO (LIFO and SIRO are examples) must produce the same value of W. Some disciplines use information about service times (e.g., serve the shortest job first, also known as the shortest processing time priority discipline) and reduce L (compared to FIFO); these must also reduce W.

PASTA is an acronym for Poisson Arrivals See Time Averages. Equation (1) shows that p_i can be interpreted as a time average, that is, as the proportion of time i customers are present. A customer is said to see the stochastic process $X(t)$ in state i if $X = i$ just before the customer arrives. Let t_n be the arrival epoch of the nth customer. The state seen upon arrival by the nth customer is $X(t_n)$, and

$$\pi_i = \lim_{N\to\infty}\left[\frac{1}{N}\sum_{n=1}^{N} I\{X(t_n) = i\}\right] \quad (2)$$

is the customer average for state i. A simple example where $\pi_i \neq p_i$ is a $D/D/1$ queue where the times between arrivals are 1 and all the service times are 1/2. Here, $\pi_0 = 1$ yet $p_0 = 1/2$. The PASTA theorem asserts that when the arrivals occur according to a Poisson process, if either π_i or p_i exists, then the other one exists and is equal to it. There is a technical proviso that roughly states that at any time, the future of the arrival process is independent of the past of the X-process. This theorem will be invoked several times in subsequent sections.

Birth-and-Death Queues

The simplest stochastic queueing model has exponentially distributed service and interarrival times. Let $X(t)$ be the number of customers present at time t. When $X(t) = i$, the probability that an arrival will occur in $(t, t + h]$ is $\lambda_i h$, and the probability that a service will be completed in the interval is $\mu_i h$. It is implicit that h is small, and terms of order h^2 can be (and are) ignored. The probability of an arrival and a service occurring, or of more than one arrival or service occurring in $(t, t + h]$, is of order h^2. Implicit in this description is the memoryless property of the exponential distribution. The μ's are called death rates and the λ's are called birth rates because of the interpretation of this model as the size of a population.

The parameter μ_0 will have no role in the analysis; it is convenient to set it equal to zero. Otherwise, it is assumed that $\mu_i > 0$ for $i > 0$ so that the population does not have an a priori lower bound. When $\lambda_n = 0$, a population of size $n + 1$ will not occur after the population drops below $n + 1$, so this is a device to model a finite capacity system. The goal is to obtain $p_i(t) = \Pr\{X(t) = i\}$, where the $\{p_i(0)\}$ are given initial conditions.

Flow of probability argument – Think of probability as a fluid flowing between buckets numbered 0, 1, 2, ..., and $p_i(t)$ as the amount of probability in bucket i at time t. Think of λ_i as the rate at which each molecule of probability in bucket i flows to bucket $i + 1$, and μ_i is the rate at which each molecule of probability flows to bucket $i - 1$. Then the rate at which probability flows from bucket i to bucket $i + 1$ is $\lambda_i p_i(t)$, and the rate of flow in the reverse direction is $\mu_{i+1}\ p_{i+1}(t)$. Since the rate of change of the contents of a bucket is the inward flow rate minus the outward flow rate, for $i = 0, 1, 2, \ldots$,

$$\frac{dp_i(t)}{dt} = \lambda_{i-1}\ p_{i-1}(t) + \mu_{i+1}\ p_{i+l}(t) - (\lambda_i + \mu_i)\, p_i(t) \tag{3}$$

ignoring the $p_{i-1}(t)$ term when $i = 0$. These are called the backward Kolmogorov equations of the birth-and-death process. In the steady-state, the derivatives in (3) equal 0 and the probabilities on the right-hand side equal their steady-state limits, leading to the steady-state balance equations

$$(\lambda_i + \mu_i)p_i = \mu_{i+1}p_{i+1} + \lambda_{i-1}p_{i-1}, \quad i = 0,\ 1,\ 2,\ \ldots \tag{4}$$

These are currently written as second-order difference equations (because they have $i - 1$, i, $i + 1$); the flow-of-probability argument can be used to make them first-order difference equations $\lambda_i p_i = \mu_{i+1} p_{i+1}, i = 0, 1, 2, ...,$ yielding the solution

$$p_i = p_0 \frac{\lambda_0 \lambda_1 \ldots \lambda_{i-1}}{\mu_1 \mu_2 \ldots \mu_i}, \qquad i = 0,\ 1,\ 2,\ \ldots, \tag{5}$$

where p_0 is chosen to make the sum of all the probabilities equal to 1. This can only be done if the sum of the product terms in (5) converges, so some restrictions on the birth and death parameters apply.

M/M/1 queue – In the *M/M/1* queue, the memoryless property of the exponential distribution implies that $\lambda_i = \lambda$ for all i, and $\mu_i = \mu$ for all i, so (5) yields $p_i = p_0\ \rho^i$, where $\rho = \lambda/\mu$ and is called the traffic intensity. The summability condition requires that $\rho < 1$, and then $p_0 = 1 - \rho$ is obtained. (No calculation is required because this was proved via Little's theorem.) The mean of this distribution is $\rho/(1 - \rho)$, and Little's theorem yields $W = 1/[\mu(1 - \rho)]$. The probability that more than k customers are present is ρ^k. The formulas exhibit some of the qualitative features of all stochastic service systems. The operator of the system typically wants to keep the server busy, so the closer ρ is to 1 the better. However, keeping ρ close to 1 will produce very long waiting times, which tend to make customers complain.

To obtain the delay distribution, the memoryless property of the exponential distribution and PASTA are used to argue that at arrival epochs, the remaining service time of the customer in service (if any) is exponential. Thus, a customer who arrives to find i customers in the system has a delay that is distributed as the sum of i independent and identically distributed exponential random variables, which is a gamma (or more specifically, an Erlang) distribution with shape parameter i. PASTA is invoked again to interpret p_i as the probability that an arriving customer sees i other customers. Hence, with probability $1 - \rho$ the delay is zero, and with probability ρ the delay is exponentially distributed with mean $1/(\mu - \lambda)$.

M/M/1/N queue – When at most N customers can be present, set $\lambda_i = 0$ for $i \geq N$. Then (5) yields $p_i = p_0 \rho^i$ and the normalizing condition produces $p_0 = (1-\rho)/(1-\rho^{N+1})$ for $\rho \neq 1$. When $\rho = 1$, $p_i = 1/(N+1)$, for $i = 0,1, \ldots, N$. The condition $\rho < 1$ is not needed here because the normalizing sum has finitely many terms.

M/M/c queue – Here $\lambda_i = \lambda$ for all i, $\mu_i = i\mu$ for $i \leq c$, and $\mu_i = c\mu$ for $i \geq c$.

This is called the Erlang delay or Erlang C model. The quantity $a = \lambda/\mu$ is the offered load; the traffic intensity is $\rho = a/c$. Using (5) leads to

$$p_i = \begin{cases} \frac{p_0 a^i}{i!} & \text{if } 1 \leq i \leq c \\ \frac{p_0 a^i}{c^{i-c} c!} & \text{if } i \geq c \end{cases}$$

where

$$p_0 = \left[\sum_{j=0}^{c-1} \frac{a^j}{j!} + \frac{a^c}{c!(1-\rho)} \right]^{-1}, \qquad a < c.$$

The probability that all servers are busy is given by

$$C(c, a) = \frac{p_0 a^c}{c!(1-\rho)}$$

which is called the Erlang C formula.

The M/M/c/c queue – This is the same as the *M/M/c* queue except that $\lambda_i = 0$ for $i \geq c$. It is called Erlang's loss model or sometimes the Erlang B model. Equation (5) yields

$$p_i = \frac{a^i/i!}{\sum_{k=0}^{c} a^k/k!} \qquad (0 \leq i \leq c)$$

which is a truncation of the Poisson distribution. From PASTA, p_c is the probability that a customer is blocked; it is called Erlang's loss (or sometimes Erlang B) formula and denoted by $B(c, a)$. A remarkable feature of this formula is that it is valid for any service-time distribution with mean $1/\mu$. This is an example of an insensitivity theorem.

M/M/∞ queue – This is the previous model with $c = \infty$. It may be an appropriate model for a self-service system. The steady-state probabilities are given by the Poisson distribution with mean a.

Machine-repair (finite-source) queue – This is a model where there are m machines attended by c mechanics. When the times between machine failures are i.i.d. and exponential, and so are the repair times, then the number of inoperative machines is a birth-and-death process with $\lambda_i = (m-i)\lambda$ and $\mu_i = \min(i, c)\mu$. Equation (5) can be used to calculate the steady-state probabilities, which will be denoted by $p_i(m)$ to emphasize the dependence on m. Since the machine failures do not constitute a Poisson process, it does not necessarily follow that $\sum_{i \geq c} p_i(m)$ is the probability that a failed machine has to wait for repair to begin. A surprising feature of this model is that $p_i(m-1)$ is the probability that i other machines are down at a failure epoch.

When $\lambda_i = 0$ for $i \geq c$, this model is the finite source analog of the *M/M/c/c* queue (sometimes denoted as an *M/M/c/c/m* queue). It is appropriate when the number of sources is not so large that the arrival rate is not diminished when all servers are busy. Let $b = \lambda/\mu$; then Eq. 5 yields

$$p_i(m) = \frac{\binom{m}{i} b^i}{\sum_{k=0}^{c} \binom{m}{k} b^k} \qquad i = 0, 1, \ldots, c$$

An important feature of this model is that this formula is valid for any service-time or interarrival time distributions. This insensitivity result can be extended to sources with different interarrival time distributions. When $m > c$, the probability that all servers are busy at an arrival epoch is

$$\pi_c(m) = p_c(m-1) = \frac{\binom{m-1}{c} b^c}{\sum_{k=0}^{c} \binom{m-1}{k} b^k}$$

which is called the Engset formula.

Balking and reneging – Balking and reneging can be incorporated into the models above by adjusting the birth and death rates. Suppose that customers will balk at a queue of length i with probability b_i. To describe this, replace λ_i with $\lambda_i b_i$. Suppose that when i customers are present, the probability that one of them will renege in a short time interval of length h is $r_i h$. To describe this, replace μ_i with $\mu_i + r_i$.

Output theorem – Let $\Delta(t)$ be the number of departures in an interval of length t in the steady-state. When $\lambda_i \equiv \lambda$, $\Delta(t)$ is a Poisson process. This result is also known as Burke's theorem.

Additional details on these fundamental models are presented in the classic texts of Morse (1958), Cox and Smith (1961), and Prabhu (1965).

Markov Chain Models

The birth-and-death process is the special case of a continuous-time Markov chain in which all transitions are to neighboring states. The added flexibility of the continuous-time Markov chain permits analysis of bulk service and arrival, and some forms of non-exponential service and interarrival times.

A continuous-time Markov chain is described by its rate matrix $\boldsymbol{Q} = (q_{ij})$ where q_{ij} is the rate of making transitions from state i to state j, $i \neq j$, and $q_{ii} = -\sum_{j \neq i} q_{ij}$ by convention, corresponding to the rate of making transitions out of state i. The flow of probability argument is valid for continuous-time Markov chains, and the generalization of (5) is that the row vector of steady-state probabilities, $\boldsymbol{p} = (p_0, p_1, \ldots)$, satisfies the matrix equation $\boldsymbol{pQ} = \boldsymbol{0}$, with the elements of $\boldsymbol{p}$ summing to 1.

Erlang distributions – Erlang devised the following way to use exponential distribution arguments for some non-exponentially distributed random variables. For a random variable with mean $1/\lambda$, imagine that it is constructed by adding k i.i.d. exponential random variables called stages, each having mean $1/(k\lambda)$. The resulting distribution is called an Erlang distribution of order k; it is a gamma distribution with an integer shape parameter, and the density function at t is given by $k\lambda(k\lambda t)^{k-1}e^{-k\lambda t}/(k-1)!$. The standard deviation is $1/(\lambda\sqrt{k})$, which is less than $1/\lambda$ for all $k > 1$, the standard deviation of the exponential distribution with the same mean.

For the $M/E_k/1$ model, the state is taken as the number of customers present and the stage of the customer in service (if any). A customer in stage $j < k$ that completes a service stage moves to the next larger-numbered stage. A customer that completes stage k actually leaves the server. This is called the method of stages. The balance equations for this model are more intricate than for the $M/M/1$ queue, and solving them requires more work. One result is that the steady-state mean delay D is given by

$$D = \frac{k+1}{2k} \frac{\rho}{1-\rho} \frac{1}{\mu}$$

which is the expected delay of the $M/M/1$ model multiplied by $(k + 1)/(2k)$, a number less than 1 for all $k > 1$.

Extended Erlang family of distributions – Extensions of the method of stages are based on the following distributions. A hyperexponential random variable is formed by selecting from among k different exponential distributions according to a probability distribution. Let a_j be the probability of choosing distribution j and $1/\lambda_j$ be the mean of distribution j. Then the density function at t is given by $\sum_{j=1}^{k} a_j \lambda_j e^{-\lambda_j t}$. This produces a larger standard deviation than an exponential distribution with the same mean. This distribution can be used in queueing models in the same way as the Erlang distributions.

Erlang distributions can be pictured as exponential stages in series, and hyperexponential distributions can be pictured as exponential stages in parallel. Replacing these exponential stages by Erlang or hyperexponential distributions yields a broader class of distributions. Repeating this procedure as many times as desired produces the family of general Erlangian distributions. General Erlangian distributions can be pictured as directed graphs. The time required to traverse an edge is an exponential random variable. At each node, an edge is traversed; the choice of which edge to take is determined by a chance event that is independent of how the node was reached. The time to go from the source node to the sink node has a generalized Erlang distribution.

The generalized Erlang distribution is the time to absorption in some continuous-time Markov chain where the initial state is fixed. A phase-type distribution is the time of absorption of a finite continuous-time Markov chain with a single absorbing state, where the initial state can be chosen at random. The representation expands and unifies the extensions of the exponential distribution described above. The family of PH distributions has properties that can be exploited to obtain algorithms for solving

the balance equations when they are used for either the interarrival or service times.

Bulk queues – Heretofore the assumption has been that arrivals and services occur one at a time; this need not be the case. A busload of customers may arrive at a ticket counter, or a bus may serve several customers waiting at a bus stop. The batch sizes may be random variables, for example, partially filled buses. In the bus example, it is natural to assume that the number of customers served will be the smaller than the number of the spaces available and the number of waiting customers. This may not always be valid; when there are large setup costs, a minimum number of customers may be required. Similarly, if there is not enough queueing space for an entire arriving batch, sometimes the entire batch is blocked (some communication systems will not accept part of a message) and sometimes part of the batch is blocked.

In the $M/M/1$ queue with batch arrivals, let c_k be the probability that a batch consists of k customers, and let $\bar{c}$ be the mean batch size. The arrival rate is $\lambda\bar{c}$, so that $\rho = \lambda\bar{c}/\mu < 1$ is required for the steady-state to exist, and Little's theorem yields $p_0 = 1 - \rho$. The number in system goes from i to $i + k$ at rate λc_k and from i to $i - 1$ at rate μ, so the balance equations are

$$\lambda p_0 = \mu p_1,$$

$$(\lambda + \mu)p_i = \mu p_{i+1} + \sum_{k=1}^{i} p_{i-k}c_k, \qquad i = 1,\ 2,\ \ldots$$

These equations can be solved for the probability generating function of the $\{p_n\}$ in terms of the probability generating function of the $\{c_k\}$. For geometrically distributed batch sizes, i.e., $c_k = (1 - \alpha)\ \alpha^{k-1},\ 0 < \alpha < 1$, an explicit solution is

$$p_i = (1 - \rho)[\alpha + (1 - \alpha)\rho]^{i-1}(1 - \alpha)\rho, \qquad i > 0$$

The mean of this probability function is $\rho[(1 - \rho)(1 - \alpha)]^{-1}$, which is the mean of the $M/M/1$ queue with the same traffic intensity multiplied by the mean batch size. A reason why the performance is worse with batches than without is that batches make the arrival process more bursty, i.e., in any interval of time, the batch process will tend to have less epochs where arrivals occur, but those epochs will have several customers appearing at once and the arrivals cluster.

Non-Markovian Queues

The exponential interarrival and service times render the queue length processes Markovian; when these conditions are not valid, there may be other ways to formulate a Markov chain model. The models below have embedded Markov chains instead, which are obtained by restricting attention to selected times.

M/G/1 queue – Here, the service times have a known distribution $G(\cdot)$ with mean $v_g = 1/\mu$, second moment v_{2g}, variance σ_g^2, and Laplace-Stieltjes transform $\tilde{G}(\cdot)$. The mean delay can be obtained without detailed calculations using some general theorems. In the steady-state, let D be the mean delay and Q be the mean queue length. Let R be the mean of the remaining service time of the customer in service (if any) when a customer arrives in the steady-state. Then $D = Qv_g + R$, and Little's theorem asserts that $Q = \lambda D$; solving simultaneously yields $D = R/(1 - \rho)$, where $\rho = \lambda v_g$ is the traffic intensity and the probability that the server is busy. The next two statements are justified by PASTA. When the server is idle, $R = 0$. When the server is busy, renewal theory can be applied to argue that R is the mean of the forward-recurrence time associated with $G(\cdot)$, which is $v_{2g}/2v_g$. Hence, $R = \rho v_{2g}/2v_g$ and $D = \lambda v_{2g}/[2(1 - \rho)]$; this is the Pollaczek-Khintchine formula for the mean delay. It is instructive to write this formula in terms of the squared coefficient of variation $c^2 = \sigma_g^2/v_{2g}$,

$$D = \frac{c^2 + 1}{2}\,\frac{\rho}{1 - \rho}\,\frac{1}{\mu}. \tag{6}$$

From this equation it is easily seen that constant service times produce one-half the mean delay of exponential service times.

The waiting-time distribution is obtained by looking at the number in the system only at service-completion epochs. In any queue where arrivals and services occur one at a time, the number of customers that see state i upon arrival differs from the number of customers that leave state i upon departure by at most 1, so the steady-state distributions at arrival and departure epochs are equal. From PASTA, it follows that looking at only departure epochs will yield time-averaged probabilities.

Let X_n be the number present just after the nth departure, and let A_n be the number of arrivals during the nth service time. To make matters easy, assume that the 0th customer arrives at time 0 and sees an empty system. Then $X_{n+1} = \max(0, X_n - 1) + A_n$, which shows that $\{X_n\}$ forms a Markov chain. When $\rho < 1$, this Markov chain has a limiting distribution independent of the initial state, say $\{\pi_i\}$, with probability generating function $\hat{\pi}(\cdot)$. The transition matrix is

$$\begin{bmatrix} a_0 & a_1 & a_1 & a_3 & a_4 & \cdots \\ a_0 & a_1 & a_2 & a_3 & a_4 & \cdots \\ 0 & a_0 & a_1 & a_2 & a_3 & \cdots \\ 0 & 0 & a_0 & a_1 & a_2 & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \end{bmatrix} \tag{7}$$

where $a_i = \int_0^\infty e^{(-\lambda t)}(\lambda t)^i / i!\, dG(t)$ is the probability that i customers arrive during a service time. It is not hard to show that

$$\hat{\pi}(z) = \frac{(1-\rho)(1-z)\tilde{G}(\lambda - \lambda z)}{\tilde{G}(\lambda - \lambda_z) - z}$$

which is another equation associated with Pollaczek and Khintchine. Let $W(\cdot)$ be the waiting-time distribution when the customers are served FIFO, and $\tilde{W}(\cdot)$ be its Laplace-Stieltjes transform. Then π_i is the probability that i customers arrive in an interval of time whose length is distributed as $W(\cdot)$, so $\pi_i = \int_0^\infty e^{-\lambda t}(\lambda t)^i / i!\, dW(t)$; whence $\hat{\pi}(z) = \tilde{W}(\lambda - \lambda_z)$ or

$$\tilde{W}(s) = \frac{(1-\rho)s\tilde{G}(s)}{s - \lambda[1 - \tilde{G}(s)]}.$$

Moments of the queue length and waiting time can be obtained from the transforms $\hat{\pi}$ and $\tilde{W}$.

Another performance measure is the busy period, which commences when the server goes from idle to busy and ends when the server next becomes idle. Let $\tilde{B}(\cdot)$ be the Laplace-Stieltjes transform of its distribution function, which satisfies the implicit equation $\tilde{B}(s) = \tilde{G}[s + \lambda - \lambda\tilde{B}(s)]$. The mean length is finite when $\rho < 1$ and equals $1/(\mu - \lambda)$.

M/G/1/Priority queue – Let the customers be partitioned into K priority classes, where class i has priority over class j if $i < j$. At a service completion epoch, the next customer to enter service is a member of the class with the lowest priority number among those present. Assume priority is non-preemptive, that is, the customer in service is not replaced when a customer with more priority arrives. The notation is the same as above with the script k denoting class k. The service-time distribution for an arbitrary customer is a mixture of the service-time distributions of the classes, and has mean $1/\mu$ and coefficient of variation c^2. The mean delay of a class j customer is

$$D_j = \frac{c^2 + 1}{2} \frac{\rho}{\left(1 - \sum_{i=1}^{j-1} \rho_i\right)\left(1 - \sum_{i=1}^{j} \rho_i\right)\mu},$$
$$j = 1,\ 2,\ \ldots,\ K.$$

Comparison with the FIFO formula (6) shows that class 1 does better with priorities than without, and class K does worse.

Suppose that the cost of keeping members of class j waiting in queue per unit time is C_j and that priorities can be ordered in any arbitrary manner. The way to minimize the waiting costs is to assign priorities in increasing order of $C_j\mu_j$; this is called the $C\mu$ -rule. Taking $C_j = 1$ shows that the overall mean delay is minimized when priorities are assigned in increasing order of mean service time. Letting the number of priority classes become infinite, so that customer i has priority over customer j if its service time is shorter, shows that "serve the shortest job first" is the optimum non-preemptive priority rule. When preemption is allowed, the optimum rule is "serve the job with the shortest remaining-processing-time first."

GI/M/c queue – The *GI/M/c* queue is analyzed similarly to the *M/G/1* queue. There is an embedded Markov chain at arrival epochs. The c-server model is analyzed similarly to the single-server model and is more intricate, so only the single-server model is presented in detail.

Let Y_n be the number of customers present when the nth customer arrives and B_n be the number of customers served during the nth interarrival time. Then $Y_{n+1} = Y_n + 1 - B_n$. Let $A(\cdot)$ and $1/\lambda$ be the distribution function and mean of a generic interarrival time, respectively, $b_k = P(B_n = k)$, and $\hat{b}(\cdot)$ be its probability generating function. Let $1/\mu$ be the mean service time, then $b_n = \int_0^\infty e^{-\mu t}(\mu t)^n / n!\, dA(t)$. The transition matrix is

$$\begin{bmatrix} 1-b_0 & b_0 & 0 & 0 & 0 & \cdots \\ 1-\sum_{k=0}^{1} b_k & b_1 & b_0 & 0 & 0 & \cdots \\ 1-\sum_{k=0}^{2} b_k & b_2 & b_1 & b_0 & 0 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \end{bmatrix} \tag{8}$$

When $\rho < 1$, this chain has a limiting distribution, say $\{q_i\}$, and $q_i = (1-r)r^i$, where r is the unique root in (0,1) of the equation $\hat{b}(r) = r$. The delay distribution is similar to the M/M/1 model; with probability $1-r$ the delay is zero, and with probability r the delay is exponentially distributed with mean $1/[\mu\ (1-r)]$. The time-averaged probabilities are obtained from $\lambda q_i = \mu p_i$, $i > 0$, which equates upward and downward transition rates.

The analysis with multiple servers is similar. The embedded chain at arrival epochs has the same structure as (8) except care has to be taken to account for the changing number of active servers when the row or column index is less than c.

GI/G/1 queue – For the *GI/G/1/FIFO* queue, for the nth arriving customer, let D_n be the delay, T_n be the arrival time, $U_n = T_{n+1} - T_n$, and S_n be the service time. The departure time is $T_n + D_n + S_n$, so that

$$D_{n+1} = \max(0, D_n + S_n - U_n).$$

When $\rho < 1$, the D_n-process has a proper limit; let $D(\cdot)$ be the limiting distribution. $\{S_i\}$ and $\{U_i\}$ are mutually independent and individually i.i.d., so let $F(t) = P\{S_1 - U_1 \leqslant t\}$. Then

$$D(t) = \int_{-\infty}^{t} D(t-x)dF(x),$$

which is called Lindley's equation. (Note: The recursion for delay D_{n+1} above is also referred to as Lindley's equation; see Lindley 1952). A tractable general solution to this equation is not known; but the equation has proved useful for obtaining qualitative information. For example, it has been shown that the mean delay is no larger than the quotient $\lambda(\sigma_u^2 + \sigma_S^2)/[2(1-\rho)]$, where the σ^2 values are the variances of U_1 and S_1, respectively. When ρ approaches one from below, $D(\cdot)$ approaches an exponential distribution whose mean is the upper bound multiplied by ρ. This is an example of a heavy-traffic approximation.

Numerical Methods

Many results in queueing theory, such as the Pollaczek-Khintchine equations, are given as transforms. These can be numerically inverted using methods that are devised for probability distributions. Abate and Whitt (1992) survey past work and present new algorithms for carrying out numerical inversion.

The models described above have many variants, such as heterogeneous servers, enforced servers idle times, and blocked customers. With suitable probabilistic assumptions, these models are Markovian or possess useful embedded Markov chains. The stationary distribution of the chains is often the desired numerical quantity of interest, or computing it may be an intermediate step. For finite chains, the state-space is often large (hundreds of thousands or more) and sometimes there is a special structure that can be exploited in algorithms for computing the stationary distribution. Stewart (1994) describes many of the methods that can be used.

The *M/M/1*, *M/G/1*, and *GI/M/c* queues are analyzed via Markov chains with infinitely many states. The special structure of these chains is used to obtain analytical results. M. F. Neuts introduced extensions of these models where the special structure is used to obtain algorithmic solutions. The basis for these models is an extension of the Erlang and hyperexponential distributions that can approximate any density with support $[0, \infty]$ and maintain the Markov property. See Neuts (1981) and the entry on matrix-analytic stochastic models.

Control of Queues

The performance models described heretofore can be used to optimize a performance measure subject to resource constraints by trial and error. For example, one might seek the fewest number of servers in an *M/M/c/c* queue setting that make the loss probability no larger than a given target. When a cost structure is introduced to the model, such as server operating and customer waiting costs, optimization models can be formulated directly. When the cost of a lost customer and operating a server are known, instead of choosing the number of servers to achieve a given loss probability, one could choose the number that minimizes the sum of operating and lost customer

costs. Other optimization problems that have been studied include joining rules for heterogeneous customers, server on-off policies, and scheduling rules. Since queueing performance models are frequently analyzed with Markov processes, Markov-decision processes are often used to obtain optimal controls. Stidham (2009) covers these models in depth.

Queueing Networks

In the models above, a customer gets service from one server and then departs. In a queueing network, the departures may join another queue. This may be described as a network, where the nodes represent service centers (a queue and some parallel servers) and a directed arc connects service centers i and j if departures from node i can join the queue at node j. New issues that arise include specifying the routing rule and the disposition of customers that attempt to go to a service center where all the waiting positions are occupied.

Feedback queues – The simplest network is a single node where some departures rejoin the queue. This is called a feedback queue and it can be used to model rework in a manufacturing context. Placing the items to be reworked at the head of the queue is equivalent to using an expanded service time, but placing them at the tail of the queue resembles an increase in the arrival rate.

Tandem networks – A queueing system in which the arrivals first appear at node 1, then go to nodes 2, 3, …, and N in order, and then depart is called a tandem network. This is useful for describing repair or assembly operations. When the arrivals are Poisson, the service times are exponential and independent from node to node, and every arrival to a node will be granted a waiting space, Burke's theorem shows that in the steady state, node i is a birth-and-death queue. Let $p_n(i)$ be the steady-state probability that i customers are present at node n, and let $p(\boldsymbol{i})$, where $\boldsymbol{i} = i_1, i_2, \ldots, i_N$, be the joint probability that i_n customers are at node n, $n = 1, 2, \ldots, N$; then $p(\boldsymbol{i}) = \prod_n p_n(i_n)$. This is a product-form solution, which greatly simplifies computing the joint distribution and shows that the steady-state queue lengths at the various nodes act as independent random variables.

Jackson networks – Let r_{ij} be the probability that a customer will go from node i to node j, and assume that this probability is independent of all other routings of this and all other customers. This is called Markovian routing. The probability that a departure from node i leaves the network is $1 - \sum_j r_{ij}$. A network with birth-and-death assumptions for arrival and service times and Markovian routing is called a Jackson network.

Let α_j be the arrival rate to node j from outside the network and λ_j be the arrival rate including arrivals from other nodes. The arrival rates are related by the traffic equations:

$$\lambda_j = \alpha_j + \sum_i \lambda_i r_{ij}.$$

$j = 1, 2, \ldots, N$, where N is the total number of nodes in the network.

A network is called open if some $\alpha_j > 0$. Open networks have been used to model flexible manufacturing systems and communication networks. When the routing matrix (r_{ij}) is irreducible, the traffic equations have a unique solution for open networks when some row sum of (r_{ij}) is less than 1. Open Jackson networks have a product-form solution based on birth-and-death queues for the steady-state probability $p(\boldsymbol{i})$, with arrival rate λ_j used at node j.

A network is called closed if every $\alpha_j = 0$ and all of the row sums of (r_{ij}) equal 1 and a fixed number of customers, say M, circulate among the nodes of the network. Closed networks have been used to model time-shared computer systems. When the system is almost always heavily loaded, the number of jobs is essentially constant, and they sequentially require work from different components (processors, disks, etc.). Closed networks are also used to model manufacturing systems where the number of pallets in the system is fixed, sometimes called a CONWIP (constant work in process) system. The traffic equations have infinitely many positive solutions for a closed network; if $\boldsymbol{\lambda}$ is a solution, then so is $C\boldsymbol{\lambda}$ for any $C > 0$. There is a product-form solution, $p(\boldsymbol{i}) = C\prod_n p_n(i_n)$, where the $p_n(\cdot)$ are computed from birth-and-death formulas with λ_n taken from some particular solution of the traffic equations. The normalizing constant C must be chosen to make the probabilities sum to 1, which can become computationally intractable. Specifically, there are

${}_{N+M-1}C_M$ ways to place M customers in N service centers, which is roughly 4.25×10^{12} for $M = 100$ and $N = 10$.

There have been many texts written on queueing theory over the years, and some of the classics include Cohen (1969), Cooper (1984), Cox and Smith (1961), Gross et al. (2008), Heyman and Sobel (1982), Kelly (1979), Kleinrock (1975), Morse (1958), Prabhu (1965), Takács (1962), Walrand (1988), and Wolff (1989).

Radon-Nikodym Derivative

If measure P is absolutely continuous w.r.t. measure Q, then dP/dQ is called the Radon-Nikodym derivative. For example, if P is a probability measure (distribution) for a continuous random variable and Q is Lebesgue measure, then the Radon-Nikodym derivative corresponds to the probability density function.

Rail Freight Operations

Carl D. Martland
Massachusetts Institute of Technology, Cambridge, MA, USA

Introduction

In North America, the railroad industry is predominantly privately owned and overwhelmingly oriented toward freight rather than passenger operations. An emphasis on profitability and practical problems has been a characteristic of OR/MS applications in the rail industry. This article focuses on freight car utilization, operations planning and control, and line dispatching, the three rail areas that have had the longest history of successful OR/MS applications.

Freight Car Utilization

There are three main issues in freight car utilization: fleet sizing, allocation of equipment to specific services, and distribution of empty equipment. Each of these issues is complicated by the fact that cars are interchanged among the North American railroads. A complex set of rules has been developed for the use of "foreign" cars owned by another railroad or "private" cars owned by a shipper or a car-supply company. The Freight Car Utilization Research/Demonstration Program (1980), jointly established in 1975 by the Association of American Railroads and the Federal Railroad Administration, conducted a series of studies addressing all facets of freight car utilization. Each study was supervised by an

DOI 10.1007/978-1-4419-1153-7,

industry task force in order to promote consideration of the most important issues, to provide access to data, and to enhance implementation. Task Force I-2 (1977), for example, developed an integrated set of performance measures for car utilization and showed how these measures could be used in both fleet sizing and fleet allocation decisions.

The process of moving cars from an unloading point to a location where they can be reloaded is called empty car distribution. Railroads typically try to hold enough empty cars at each major yard to cover the expected demand in the surrounding region; extra cars can be sent to locations where additional, or more profitable, loads are required. Southern Railway was a leader in the application of linear programming (LP) to car distribution (AAR 1976). They divided the railroad into 37 zones and created monthly supply and demand estimates for each of 13 car types. They then used a linear program to define flow rules that determined where local car distributors should send any extra cars. After Southern merged with Norfolk & Western to form the Norfolk Southern Railroad, this approach to car distribution was expanded to the entire merged system. The program has gone through several revisions and is now run weekly, but the underlying logic is similar to what was originally installed in the late 1960s (Gohring et al. 1993). In 1993, the Norfolk Southern used 70 distribution areas and 15 car types. The revised program addressed shortages and surpluses more realistically and it also provided more flexibility for forecasting supply and demand.

When Philip (1980) surveyed car distribution models, Southern Railway had the most successful intraroad application in the industry. The review by Dejax and Crainic (1987) cited 151 separate studies of the empty vehicle distribution problem, many of which involved railroads, but the Southern Railway's model and two discontinued models were the only ones identified as having been implemented by a railroad.

Two other LP models have been used to overcome problems in the car service rules, which govern car distribution among railroads. The car service rules generally favor the use of system as opposed to foreign cars, which tends to increase fleet sizes and empty mileage. The "Clearinghouse" encouraged member railroads to use each other's cars as if they were system cars, thereby reducing the flow of empty cars (Task Force I-5 1978). A linear program was run on a weekly basis to determine how best to balance the supply of empties among the member railroads. A study conducted in 1977 showed that the percentage of cars reloaded had risen from 55% to 62%, while the percentage of loaded car days increased from 50.7% to 56.2% and the percentage of loaded miles increased from 60% to 64%. The success of the Clearinghouse led to changes in the car service rules that produced similar benefits for the entire industry.

The Multilevel Reload program (I.C.C. Finance Docket 29653, 1981) targeted a particularly expensive and poorly utilized portion of the fleet, namely the two- or three-decked equipment used to transport new automobiles from assembly plants to distribution centers. Historically, separate fleets were assigned to movements between each assembly plant and distribution center, so that the empty mileage equaled the loaded mileage. In 1979, the Multilevel Reload Program combined all the fleets serving General Motors assembly plants (later expanded to the other major manufacturers) and created an industry group that used an LP to minimize empty movements. This led to an immediate, significant reduction in empty mileage of multilevel cars. By 1981, more than 9,000 cars were managed under this program and the ratio of empty to loaded miles had dropped from 0.95 at the outset to 0.55 for the GM fleet and 0.84 for the Ford fleet. The program was still in operation at the end of 1993. It is noteworthy that the analytic application in both of these very successful programs was only a small part of major institutional changes.

Blocking and Scheduling

The consolidation of individual cars into blocks and the movement of blocks on trains is the essence of railroading. A block is a group of cars that move together from one location to another. A block can be carried by one train or by two or more trains. Blocks can be defined based upon the type of traffic, the destination, the priority of the customer, and many other factors. The operating plan specifies how and where cars are classified into blocks, which trains can carry a block, and which blocks are carried by each train. Unfortunately, it has proven impossible so far to define an optimization technique that can solve simultaneously for blocking and scheduling for realistic networks. Successful OR applications have, therefore, focused on specific aspects of operations

planning and paid close attention to the institutional and organizational contexts.

Algorithms have been developed for blocking policy, for assigning blocks to trains, and for scheduling trains. The Automatic Blocking Model and the Train Scheduling System have been widely used in the North American rail industry to determine yard work loads under alternative operating plans (Van Dyke and Davis 1990).

The operating plan implies a trip plan for cars, where a trip plan is the sequence of train movements required to move the car from its origin, through a series of yards, to its destination. For a typical boxcar movement, the shipment will depart on the first available local train after the car is made available by the shipper. The local train is scheduled to bring the car to a nearby yard. The car is next scheduled to move in a particular block that could move on various outbound trains. The car can be scheduled to the first outbound train whose cut-off is later than the car's scheduled arrival time. This process is repeated until the car has a scheduled arrival time at its destination. The first computerized freight car scheduling system was developed by the Missouri Pacific Railroad (1976). In 1991, the rail industry established a plan to implement inter-line car scheduling as a major element of interline service measurement (Ad Hoc Committee 1991).

Predicting the time required for a train connection is the most difficult portion of car scheduling and it is also a critical problem in establishing standards for terminal control systems. Many railroads have terminal control systems that include connection standards, which are usually based upon cutoffs. Problems arise with these systems because it is difficult to maintain a coherent system of cutoffs or connection standards. There is also a conceptual problem. Since operating conditions are variable, better predictions of yard times and connection reliability can be obtained by considering the probability of making a connection, which can be called "PMAKE." It is possible to calibrate PMAKE functions that express the probability of making a connection as a function of the time available, the priority of the car, the priority of the inbound and outbound trains, the time of arrival, and other factors (Martland 1982). PMAKE functions can also be calibrated by convolving yard processing time distributions.

The Service Planning Model uses PMAKE analysis to predict trip times and reliability for a given operating plan and traffic flows (McCarren and Martland 1980). The SPM has been used by the rail industry to set standards for trip time reliability, to evaluate alternative operating plans, and to evaluate merger possibilities.

Network models have also been widely used in railroad rationalization studies. These models are more concerned with traffic flows and line capacity than with the details of operating plans. In many cases, shortest path algorithms are used to route traffic over various proposed networks and the results are displayed graphically (Hornung and Kornhauser 1979).

Line Dispatching

Effective control systems are essential to rail systems. Dispatching is the process of giving trains authority to move along a route, maintaining a safe distance between trains, deciding which sidings to use for meets between trains traveling in opposite directions on a single track railroad, and allowing faster trains to overtake slower trains. In systems where trains routinely run on schedule, train meets and passes are worked out carefully as part of the development of the operating plan. In complex environments, such as is the case in systems with high density passenger operations, it may take a year or more to develop a workable schedule. Various algorithms have been developed to assist in these processes. Here, dispatching involves enforcing the plan and responding to emergencies.

In North American operations, train schedules are seldom planned at this level of detail and departure times vary considerably from one day to the next. As a result, meets and passes are continually different and the dispatching function is very critical to train performance. Several approaches have been take to providing support for dispatching. Sauder and Westerman (1983) formulated the dispatching problem as an integer program, which they solved using a branch and bound solution technique on Southern Railway. Their procedure identifies the optimal set of meets and passes for the upcoming 4 h, that is updated continually and presented as information to the dispatcher. Other systems have used less complex algorithms to plan meets and passes, but implement these plans automatically

unless overridden by the dispatcher. It appears that the savings from making routine decisions in a timely manner (e.g., avoiding delays while the dispatcher is on the phone) are at least as large as the savings from making "optimal" decisions.

Models have been used to study line capacity, line scheduling, and dispatching, many of them building upon the work of Petersen and Taylor (1982). Jovanovich and Harker (1991) developed the SCAN system (1991), which was used by the Burlington Northern Railway to evaluate the potential improvements from advanced line control systems (Smith et al. 1990).

Introduction

As World War II was ending, a number of individuals, both inside and outside the U.S. government, saw the need for retaining the services of scientists for government and military activities after the war's end. They would assist in military planning, with due attention to research and development. Accordingly, Project RAND was established in December 1945 under contract to the Douglas Aircraft Company. The first RAND report was published in May 1946. It dealt with the potential design, performance, and use of man-made

satellites. In February 1948, the Chief of Staff of the Air Force approved the evolution of RAND into a nonprofit corporation, independent of the Douglas Company.

On May 14, 1948, the RAND Corporation was incorporated as an independent non-profit organization and on November 1, 1948, the Project RAND contract was formally transferred from the Douglas Company to the RAND Corporation. The Articles of Incorporation set forth RAND's purpose:

> "To further and promote scientific, educational, and charitable purposes, all for the public welfare and security of the United States of America."

It accomplishes this purpose by performing both classified and unclassified research in programs treating defense, international, and domestic issues. The current staff numbers nearly 1,000 researchers and about 600 support persons, with about 21% of the researchers being operations researchers, mathematicians, physical scientists, engineers, and statisticians. For much of its history, RAND's research departments were discipline based (e.g., mathematics, economics, physics, etc.). However, research is now carried out by five units that address social and economic policy issues both in the United States and overseas; by three federally funded research and development centers (FFRDCs) that focus on national security; by professors and graduate fellows at the Pardee RAND Graduate School; and by RAND Europe, an independently chartered European affiliate.

This article focuses on RAND's contributions to the theory and practice of operations research. However, RAND has also made major theoretical and practical contributions in other areas, including engineering, physics, political science, and the social and behavioral sciences. A broader and more comprehensive history of RAND's early years is contained in Jardini (1996).

The First Ten Years (1948–1957)

The first decade saw RAND accomplishments ranging from the beginning of the development of systems analysis, which evolved from the earlier more specific and more narrowly focused military operations analysis of World War II, to the creation of new methodological concepts and techniques to deal with problems involving many variables and multiple objectives.

Systems analysis may be defined briefly as the systematic examination and comparison of alternative future courses of action in terms of their expected costs, benefits, and risks. The main purpose of systems analysis is to provide information to decision makers that will sharpen their intuition and judgment and provide the basis for more informed choices. From the beginning it was evident that to be successful, systems analysis would require the conception and development of a wide range of methodological tools and techniques. One of the most important sources of these tools and techniques was the emerging discipline of operations research.

In the early 1950s Edwin Paxson led the project that produced a report entitled *Strategic Bombing Systems Analysis*, which is generally regarded as the first major application of the concept of systems analysis, as well as the source of the name for the new methodology. Among other things, the report advocated the use of decoys to help mask bombers from enemy defenders. This study was a catalyst that stimulated the development and rise of a number of analytical methods and techniques. Some of the more important examples are:

- *Game theory* — Mathematics and game theory were prominent subjects in the early research agendas of Project RAND. Lloyd Shapley, J.C.C. McKinsey, Melvin Dresher, Martin Shubik, Rufus Isaacs, and Richard Bellman were among the numerous early RAND contributors to this area, while John Williams and Herman Kahn played an important role in popularizing some of the simpler aspects of game theory. John von Neumann, who is often cited as the father of game theory, and Oskar Morgenstern, who linked game theory to economic behavior, were active RAND consultants, as were many others with connections to major universities.
- *Enhanced computer capabilities* — The Paxson project required computer capabilities beyond those available at that time. This stimulated developments that led to the building of the JOHNNIAC digital computer, which became fully operational in the first half of 1953. Based on a design by John von Neumann, it was one of the six "Princeton class" stored programming machines, and the first operational computer with core memory in the world. After using the JOHNNIAC to implement the first distributed on-line time-shared computer system (1960), RAND built the JOHNNIAC Open Shop System (JOSS),

one of the first interactive programming languages for individual users.

- *Dynamic Programming* — The Paxson project also demanded the examination, through dynamic programming, of key strategic bomber components (e.g. decoys) in the context of an overall enhanced strategic capability. This, along with the demands of other projects in the early 1950s, provided a significant part of the motivation for the development of the mathematical theory of dynamic programming. Richard Bellman, together with a few collaborators, almost exclusively pioneered the development of this theory. The first RAND report on dynamic programming was published in 1953. Bellman's well-known book (*Dynamic Programming*) followed in 1956, and his book with Stuart Dreyfus (*Applied Dynamic Programming*) was published in 1962.

A second large systems analysis study of this period was a study led by Albert Wohlstetter on the selection and use of strategic air bases. It developed basing and operational options for improving the survivability of SAC forces and helped shift the focus of strategic thinking in the United States toward deterrence based on a secure second-strike force.

Another major effort beginning in the 1950s that led to the development of operations research tools was research on logistics policy issues. RAND's involvement with Air Force logistics stressed the demand for spare parts and the need for logistics policies that could cope with demand uncertainty. Major players in this effort were Stephen Enke, Murray Geisler, James Peterson, Chauncey Bell, Charles Zwick, and Robert Paulson. The key analytical issue here was the examination of alternative policy issues under conditions of strategic uncertainty. Early research used "expected value" analysis. Later, RAND researchers developed and used more sophisticated methods, such as:

- The use of sensitivity analysis to determine what areas of uncertainty really matter in final outcomes;
- Iteration of the analysis across several relevant future scenarios to seek problem solutions that are robust for several of the possible (uncertain) scenarios;
- Given the outcomes of the above, design R&D activities that will (1) reduce key areas of uncertainty, (2) provide hedges against key uncertainties, (3) preserve options for several possible courses of action, any one of which might be used when the future environment becomes less uncertain.

Finally, the first decade witnessed the development of a number of methods and techniques that were useful across a range of RAND projects and elsewhere. Some important examples are:

- *Problem Solving with the Monte Carlo Techniques* — Although not invented at RAND, the powerful mathematical technique known as the Monte Carlo method received much of its early development at RAND in the course of research on a variety of Air Force and atomic weapon problems. RAND researchers pioneered the use of the method as a component of a digital system simulation. RAND's main contributions to Monte Carlo lie in the early development of two tools: generating random numbers, and the systematic development of variance-reduction techniques.
- *Cost Analysis* — David Novick, as head of RAND's Cost Analysis Department, developed the fundamental building blocks of cost analysis during the 1950s and 1960s. Gene Fisher documented this work in his seminal book *Cost Considerations in Systems Analysis*.
- *A Million Random Digits with 100,000 Normal Deviates* — The tables of random numbers in this 1955 report have become a standard reference in engineering and econometrics textbooks and have been widely used in gaming and simulations that employ Monte Carlo trials. It is one of RAND's best selling books.
- *Approximations for Digital Computers* — This book, by Cecil Hastings and J.P. Wong, Jr., contained function approximations for use in digital computations of all sorts.
- *Systems Development Laboratory* — This laboratory was set up under the leadership of John Kennedy to help examine how groups of human beings and machines work under stress. The work ultimately led to the formation of the System Development Corporation.

The Second Ten Years (1958–1967)

This period in RAND's history witnessed the beginning of the evolution of systems analysis into

policy analysis. It also witnessed a branching out from national security research into research on domestic policy issues.

One of the most important dimensions of change as systems analysis evolved into policy analysis was the *context* of the problem being analyzed. Contexts became broader and richer over time. What was taken as given (exogenous to the analysis) before became a variable (endogenous to the analysis) later. For example, in the typical systems analysis of the 1950s and early 1960s, many considerations were not taken into account very well, often not at all: for example, political, sociological, psychological, organizational, and distributional effects. Thus, as systems analysis evolved into policy analysis, the boundaries of the problem space expanded. This had important implications for changes in concepts and methods of analysis. For example, with respect to models, the demands of the expanded boundaries of the problem space could not be met by merely trying to make models used in policy analysis bigger and more complex. Of equal importance, was the development of sophisticated strategies for the development and use of models.

While the evolution of systems analysis into policy analysis did not progress very far during this period, there are several areas of RAND research that were conducted in broader contexts than were typical of the 1950s. These included Ed Barlow's Strategic Offense Forces Study (SOFS), Bernard Brodie's work on the development of a strategy for deterrence in the new age of abundant nuclear weapons and ballistic missiles, Herman Kahn's analysis of civil defense in the event of a nuclear war, and Charles Hitch and Roland McKean's book *Economics of Defense in the Nuclear Age*, which espoused the view that the economic use of scarce resources should be a critical aspect of defense planning. This view was adopted by Secretary of Defense Robert McNamara and led to RAND's involvement in the development of the defense Planning, Programming, and Budgeting System (PPBS).

In addition to policy strides like those discussed above, the second ten years witnessed further development of methodological tools for quantitative analysis — primarily operations research tools. Major advances were made at RAND in the areas of mathematical programming, queueing theory, computer simulation, stochastic processes, and operational gaming.

Linear programming (LP) was probably RAND's most important and most extensive contribution to the theory and practice of operations research as well as to economic decision making. Between 1947 and 1952, George Dantzig and others who worked in the Pentagon on the Air Force's Project SCOOP developed the simplex method and other basic features of LP. Dantzig moved to RAND in 1952. During the following decade, RAND was the world's center of LP developments. In addition to methodological developments by Dantzig and other RAND employees and consultants (e.g., the development of the dual simplex algorithm), there was seminal work on classic problems like production planning and the traveling salesman problem. In addition, most of the pioneering computer programming of LP algorithms (e.g., the first code for the revised simplex method) was carried out by William Orchard-Hays and others at RAND. Much of the work of this period is captured in Dantzig's book, *Linear Programming and Extensions*, published in 1963.

Seminal work in other areas of mathematical programming also took place at RAND during the 1950s and 1960s. Ralph Gomory developed the first integer programming algorithms; Philip Wolfe, George Dantzig, and Harry Markowitz initiated work on quadratic programming; and George Dantzig and Albert Madansky initiated work on stochastic programming.

Five other examples of RAND work in the "tools" area during this period are worthy of note:

- *Simulation* — In the early 1960s, after doing complex simulation modeling "the hard way," Harry Markowitz and Herb Karr developed SIMSCRIPT, a programming language for implementing discrete event simulation models. This work led in l968 to SIMSCRIPT II, which introduced ideas that eventually inspired the modern object-oriented programming paradigm.
- *Artificial intelligence* (*AI*) — The man–machine partnerships explored in the Systems Research Laboratory gained new impetus as Allen Newell, Herb Simon, and Cliff Shaw began to construct a general problem solving language that employed symbolic (non-numerical) processes to simulate human thinking on a computer. One of their initial efforts to carry out a "theory of thinking" involved

programming computers to play chess. On a broader scale, this research resulted in several information processing languages (e.g., IPL V), which were similar to LISP and were used in some of the early AI computer work.

- *Flows in networks* — In 1962, Lester Ford, Jr. and Delbert R. Fulkerson, RAND mathematicians, published the first unified treatment of methods for dealing with a variety of problems that have formulation in terms of single commodity flows in capacity-constrained networks. Their book, entitled *Flows in Networks*, introduced concepts (e.g., "max-flow/mincut") and algorithms (e.g., "out-of-kilter") that have been used to treat network problems ever since.
- *Branching processes* — The notion of a branching process concerns individuals from some population that can reproduce and die (become extinct), subject to some probabilistic laws of chance. The theory of branching processes is the mathematical formulation of the development of that population subject to those laws of chance. RAND mathematician Ted Harris was preeminent in this field. His book entitled *The Theory of Branching Processes* was first published in 1964. The theory has been applied to problems associated with such diverse issues as neutron diffusion, cosmic rays, gene attributes, and biological populations.
- *Multi-echelon Inventory theory* — In 1966 the METRIC model was documented by Craig Sherbrooke. This was a pioneering development in dealing with inventory systems having hierarchies of stockage locations.

The year 1964 saw the publication of the first of several RAND books by mathematician Edward Quade, who played a major role in developing and disseminating the methodology of systems analysis and (later) policy analysis. *Analysis for Military Decisions* documents an intensive five-day course that RAND offered to military officers and civilian decision makers in 1955 and 1959.

The Third Ten Years (1968–1977)

This period in RAND's history saw an acceleration of many of the trends begun in the previous ten years. One of these trends involved the development of improved procedures for the use of expert judgment as an aid to military decision making. The Delphi procedures grew out of this effort. These procedures incorporate anonymous response, iteration and controlled feedback, and statistical group response to elicit and refine group judgments where exact knowledge is unavailable.

Other trends involved the continued evolution of systems analysis into policy analysis and an increasing emphasis on analyzing major domestic research issues. Important in the last two trends was the establishment of the New York City-RAND Institute (NYCRI). Important RAND research efforts during 1968–1977 include the work performed at the NYCRI and policy analysis studies for the government of the Netherlands.

The New York City-RAND Institute — In 1968, RAND began a long-term relationship with the City of New York to tackle problems in welfare, health services, housing, fire protection, law enforcement, and water resources. The NYCRI was formally established in 1969. The research staff evaluated job training programs, suggested solutions to shortages of nurses in municipal hospitals, helped change rent control, altered fire department deployment policies, reallocated police manpower, and helped improve Jamaica Bay's water quality.

The most successful of the NYCRI's projects was the one devoted to improving the operations and deployment of the Fire Department of New York. In 1968, the major problem facing the Department was the rising alarm rate. Its increasing workload was not significantly relieved by adding more men and equipment; nor were traditional methods of fire company allocation, dispatching, and relocation working. The Institute's studies altered the way the Department managed and deployed its men and equipment and operated its dispatching system. An integral part of the research involved creation of a wide variety of computer models to analyze and evaluate deployment, which led to the formulation of new policies. Warren Walker and Peter Kolesar were awarded ORSA's 1974 Lanchester Prize for a paper that described how mathematical programming methods were applied to the problem of relocating available fire companies to firehouses vacated temporarily by companies fighting fires. The entire body of work from this project is documented in Walker et al. (Walker et al. 1979).

Policy Analysis Studies for the Dutch Government — Reflecting an increasing interest in

doing policy analysis studies in international contexts, RAND started working for the Dutch government in the 1970s.

One important study was concerned with protecting an estuary from floods. In April 1975, RAND began a joint research venture with the Dutch government to compare the consequences of three alternative approaches for protecting the Oosterschelde, the largest Dutch estuary, from flooding. Seven categories of consequences were considered for each alternative: financial costs, ecology, fishing, shipping, recreation, national economy, and regional effects. Within each category, several types of consequences were considered. In June 1976, the Dutch Parliament adopted one of the alternatives based in large part on the results of the RAND study: to build a 10 km, multi-billion dollar storm surge barrier with large movable gates across the mouth of the estuary. The study required the development of sophisticated computer models of estuaries and coastal seas.

A second study was focused on improving water management in the Netherlands. Begun in April 1977, the Policy Analysis for the Water Management of the Netherlands (PAWN) project was conducted jointly by RAND, the Dutch Government, and the Delft Hydraulics Laboratory. It analyzed the entire Dutch water management system and provided a basis for a new national water management policy for the country. It developed a methodology for assessing the multiple consequences of possible policies, and applied it to generate alternative policies and to assess and compare their consequences. Considering both research and documentation, it directly involved over 125 person-years of effort (including a considerable amount of support from Dutch organizations). The project won a Franz Edelman Award for Management Science Achievement in 1984.

In 1970, RAND established one of the original eight public policy graduate schools in the United States, the Pardee RAND Graduate School (PRGS). PRGS is the world's largest doctoral program in the field. PRGS doctoral fellows take advanced courses in such fields as economics, statistics, political science, and the social sciences. They also work part-time as members of RAND's interdisciplinary research teams, which is how they earn their fellowships. This combination of advanced course work and on-the-job training is unique. Fellows obtain research training in RAND's classrooms, and get to apply it to real problems with RAND mentors and clients.

The Fourth Ten Years (1978–1988)

This period witnessed a number of major institutional milestones. Some examples:

- In 1982 the joint RAND/UCLA Center for Health Policy Study was funded by the Pew Memorial Trust. A year later RAND and UCLA established a joint Center for the Study of Soviet International Behavior.
- In 1984 a new Federally Funded Research and Development Center — the National Defense Research Institute (NDRI) — was established, funded by the Office of the Secretary of Defense.
- The Arroyo Center, the Army's Federally Funded Research and Development Center for studies and analysis, was established at RAND in 1984.
- The Center for Policy Research in Health Care Financing, sponsored by the U.S. Department of Health and Human Services, was created in 1984.

These institutional developments helped RAND to enhance its work in existing areas of the research program — for example, health policy — and to stimulate work in new areas — for example, analysis of Army policy issues.

During this period, RAND's research program increased substantially in size and diversity. Many of the trends of the past continued — for example, the increase in efforts devoted to domestic policy research and the tendency to conduct research in broader contexts. Several new trends began to emerge — for example, an increase in emphasis on research done in international contexts other than the (then) USSR. The development of analytical concepts, methods, and techniques also continued. Some of the more important of these were:

- *RAND Strategy Assessment System* (*RSAS*) — Because of perceived limitations in methods of strategic analysis, in 1982 RAND began to develop methods for strategic analysis that combined classical gaming, systems analysis methods and techniques, artificial intelligence, and advanced computer technology. The RSAS provided a structure and tools for analyzing strategic decisions at the national command level as well as decisions at the operational level. It also

provided great flexibility in choosing which roles are to be played by people and which by machines.

- *Dyna-METRIC* — The Dyna-METRIC logistics support model provided a major new tool for relating the availability of spare parts to wartime aircraft sortie generation capability. The model, which was developed by Richard Hillestad, Manuel Carrillo, and Gordon Crawford, combines elements of queueing theory, inventory theory, and simulation. It is still an integral part of the Air Force logistics and readiness management system.
- *CLOUT* (*Coupling Logistics to Operations to Meet Uncertainties and the Threat*) is a RAND-developed set of initiatives for improving the ability of the Air Force logistics system to cope with the uncertainties and disruptions of a conventional war overseas. The CLOUT initiatives are intended to offset the substantial variability expected in the demand for spare parts, maintenance, and other support activities, as well as the consequences of damage to theater air bases. CLOUT was the basis for the DRIVE model (Distribution and Repair in Variable Environments), developed by Lou Miller and John Abell, that became the kernel of a management system, called EXPRESS, that is still used today in Air Force depots.
- *The Enlisted Force Management System* (*EFMS*)—The EFMS project is notable for the scope and complexity of the decision support system that it developed, and for demonstrating how the tools of operations research could be married with emerging information technologies to provide real-time decision support throughout an organization. Warren Walker led a large RAND team that worked with Air Force counterparts beginning in the early 1980s. Together, they produced an organizational decision support system (ODSS) to help make decisions about the grade structure of the enlisted force, enlisted promotion policies, and the recruitment, assignment, training, compensation, separation, and retirement of Air Force enlisted personnel. Since 1990, the EFMS has been the primary analytical tool used to support major policy decisions affecting the enlisted force. The success of the system motivated the publication of a 1992 book, *Building Organizational Decision Support Systems*.

Concluding Remarks

After the first 40 years, most of the main trends outlined above continue to play themselves out — for example, domestic research represents about half of RAND's $250 million annual research budget, and methodological enhancements driven by the practical needs of the problem-oriented research continue to have high priority. Methodologically, some of the most important advances have involved new approaches for dealing with uncertainty in making decisions. Chief among these approaches are Assumption-Based Planning (Dewar et al. 1993), exploratory modeling (Bankes 1993), and adaptive policies (*RAND* (Europe 1997)). All three of these approaches are combined in a methodology for long-term policy analysis called Robust Decisionmaking (Lempert et al. 2003).

Over the past two decades, RAND has been becoming a more global institution. The RAND research staff now includes citizens of more than 50 nations and RAND now performs research for many countries besides the United States. In 1992, RAND established an affiliate in the Netherlands called RAND Europe. It conducts policy studies to inform public- and private-sector decision making throughout Europe. Major research efforts so far have included studies of the safety of Schiphol Airport, ways of improving river dikes in the Netherlands while preserving the environment, a systematic examination of alternative strategies for reducing the negative effects of road freight transport in the Netherlands, and a cost-effectiveness analysis of strategies for improving shipping safety in the North Sea. Other efforts include pioneering work on widening the application of discrete choice analysis, guiding appraisals of transport infrastructures, and providing cost analysis for the UK Ministry of Defence. RAND Europe now operates from its headquarters in Cambridge, England and a representation office in Brussels. With a diverse range of research areas ranging from defense to healthcare, it has become a key provider of evidence-based policy research across the European Union.

In 2003, RAND established the RAND-Qatar Policy Institute (RQPI). The RQPI is located in Doha, Qatar, and is part of Education City. RQPI serves clients throughout the Middle East, North Africa, and

South Asia, performing studies on such issues as education reform, health services delivery, governmental reorganization, and environmental health. RQPI also helps train analysts and build capacity in Qatar and other countries of the region.

RAND analysts continue to be recognized for their contributions to the profession of operations research and the management sciences. In 1996, Moore et al. were awarded the Richard H. Barchi Prize for the best paper given at the Military Operations Research Society (MORS) Symposium. Brooks et al. won that prize in 1998. Warren Walker received the INFORMS President's Award in 1997 for his "contributions to the welfare of society through quantitative analysis of governmental policy problems."

Random Field

A stochastic process with a multi-dimensional index set; for example, $\{R(x, y), -\infty < x, y < \infty\}$, where $R(x, y)$ equals the amount of rain falling during a given day at location (x, y).

Random Number Generators

Pierre L'Ecuyer
Université de Montréal, Montréal, Québec, Canada

Introduction

Many algorithms and heuristics in operations research and management science require a source of random numbers. This is needed in particular to simulate stochastic models, to estimate multivariate integrals and the solutions of differential equations numerically by Monte Carlo, and in probabilistic algorithms in general. These so-called random numbers are typically produced by a deterministic computer program, and are therefore not random at all. The program that produces them is nevertheless called a random number generator (RNG). Its aim is to imitate the realization of a sequence of i.i.d. (independent and identically distributed) random variables, say from the $\mathcal{U}(0,1)$ distribution (the uniform distribution over the interval between 0 and 1). The generator and the numbers it returns are sometimes called pseudorandom to emphasize their deterministic nature, but the common usage of just random will be adopted here for simplicity.

True random numbers can be produced by physical devices such as noise amplifiers in electric resistances, photon trajectory detectors, and the like. Typically, these devices construct a binary sequence by sampling a signal periodically and returning 1 if the signal is above a given threshold, and 0 otherwise. Simple transformations are applied to this sequence, for example by combining bits, to remove (or reduce) the bias and the dependence between the bits. Although one cannot prove that the returned bits are 1 or 0 with probabilities exactly 1/2 and that they are all independent, the output binary sequences of some of these devices are so close to having these properties that the difference is practically undetectable. Such physical RNGs are appropriate for applications such as cryptography and gaming machines, for example, where unpredictability is essential. But for stochastic simulation, well-crafted algorithmic RNGs, based on a purely deterministic mathematical recurrence, have a good enough statistical behavior and are sufficiently reliable. They are also much more convenient because they require no specialized hardware and their output sequences can be repeated as many times as desired without the need for storage. The ability to repeat the same sequence exactly is a key requirement for the implementation of efficient stochastic simulation techniques (Asmussen and Glynn 2007; L'Ecuyer 2008; Law and Kelton 2000).

There is a well-developed body of theory on the construction and analysis of algorithmic RNGs (Knuth 1998; L'Ecuyer 1994, 2004, 2006; L'Ecuyer and Panneton 2009; Niederreiter 1992; Tezuka 1995). Obvious requirements such as a fast implementation and a very long period are not sufficient. Good and reliable RNGs cannot be constructed at random by just trying arbitrary recurrences and testing them empirically. They must be constructed on the basis of a good understanding of the uniformity of their vectors of output values, by proper analysis of their mathematical structure. Empirical statistical testing is certainly relevant, but it should comes only after a solid theoretical analysis.

Unfortunately, poor and unreliable RNGs still abound in the scientific literature and in popular software (L'Ecuyer and Simard 2007). Typically, their weakness comes from too much structure, due to overly simplified recurrences constructed to

optimize speed. For most applications, it turns out that these weaknesses have little or no noticeable impact on the simulation results, because the random numbers are sufficiently transformed by the application to distort the simple structure and this has the accidental effect of improving the RNG for that particular case. But in some situations, when the RNG structure is not distorted by the application, things can quickly become disastrous in the sense that simulation results are totally wrong, sometimes by huge factors. Examples of specific well-tested and recommended generators, with computer codes, can be found in L'Ecuyer (1999a, b), L'Ecuyer and Touzin (2000), L'Ecuyer et al. (2002), Panneton et al. (2006), for example.

Random variates from non-uniform distributions, such as the normal, exponential, Poisson, and so on, as well as random vectors from multivariate distributions, stochastic processes, and other types of random objects, are generated by transforming uniform random numbers in an appropriate way (Devroye 1986, 2006; Gentle 2003; Hörmann et al. 2004; L'Ecuyer 2004).

Algorithmic Generators

An algorithmic RNG is defined in L'Ecuyer (1994) as a structure $(\mathcal{S}, \mu, f, \mathcal{U}, g)$, where $\mathcal{S}$ is a finite set of states, $s_0 \in \mathcal{S}$ is the seed or initial state selected with the probability distribution μ on $\mathcal{S}$, $f : \mathcal{S} \to \mathcal{S}$ is the transition function, $\mathcal{U}$ is a set of output values taken here as the interval $\mathcal{U} = (0,1)$, and $g : \mathcal{S} \to \mathcal{U}$ is the output function. The generator starts in state s_0, evolves according to $s_i = f(s_{i-1})$, and outputs $u_i = g(s_i)$ at step i. The output sequence u_0, u_1, u_2, ... should behave as the realization of a sequence of i.i.d. $\mathcal{U}(0,1)$ random variables, Since $\mathcal{S}$ is finite, the sequence of states is ultimately periodic. The period is the smallest positive integer ρ such that for some integer $\tau \geq 0$ and for all $n \geq \tau, s_{\rho+i} = s_i$. Usually, $\tau = 0$, in which case the sequence is said to be purely periodic. The role of μ is to allow a random selection of the seed s_0, using an external source of randomness. Generating a truly random seed is much less work and is more reasonable than generating a long sequence of truly random numbers. An RNG with a random seed can be viewed as an extensor of randomness, whose purpose is to save "coin tosses". It stretches a short truly random seed into a long sequence of values that is supposed to behave like a true random sequence.

Basic requirements for a good RNG include a very long period (say, at least 2^{100} and preferably 2^{200} or more), the availability of a fast platform-independent implementation, the possibility of splitting the sequence into long disjoints subsequences (more on this later), and efficient ways of jumping between those sequences and to replay the same sequences over and over again. To show that a long period is not sufficient, consider an RNG defined by $s_0 = 1$, $s_i = (s_{i-1} + 1) \bmod 2^{1000}$, and $u_i = s_i/2^{1000}$. It has a huge period and a fast implementation is trivial to obtain, but it is definitely not an acceptable RNG; the successive output values are very strongly correlated.

Multivariate Uniformity

Uniformity and independence of successive output values can be assessed by studying the uniformity of the sets $\Psi_s = \{(u_0, \ldots, u_{s-1}) = (g(s_0), \ldots, g(f^{s-1}(s_0)) : s_0 \in \mathcal{S}\}$ of all vectors of s successive output values produced the the RNG, from all possible initial seeds s_0, for arbitrary positive integers s. The theoretical ideal that the u_i are i.i.d. $\mathcal{U}(0,1)$ is equivalent to having $(u_i, \ldots, u_{i+s-1})$ uniformly distributed over $(0,1)^s$ for each $s \geq 1$. One can argue that the RNG provides a good approximation of this if Ψ_s covers the unit hypercube $(0,1)^s$ very evenly (or uniformly). The rationale is that the (large) finite set Ψ_s can be viewed as a sample space from which a tiny fraction of the points are taken at random by the generator, without replacement, and this provides a good approximation of the uniform distribution over $(0,1)^s$ only if Ψ_s covers the space very uniformly. This argument also suggests that RNGs should have huge periods, many orders of magnitude larger than whatever will be used in practice, so that only a tiny fraction of the points from Ψ_s are used.

A key issue is how to measure this uniformity. This must be done from a mathematical analysis of the recurrence, without enumerating the points explicitly (which would be infeasible). Measures of uniformity are usually defined in a way that they can be computed efficiently by exploiting the linear structure of the recurrence. This is the main reason why RNGs based on linear recurrences are still the most widely used.

Good RNGs are typically constructed by first selecting a form of recurrence that can be implemented efficiently, choosing a period length (or the cardinality of $\mathcal{S}$), and then searching for parameters of the recurrence for which the target period length is reached and for which Ψ_s has the best possible uniformity, for all s up to a given value. This type of search can take months of computing time (L'Ecuyer 1999a, b; Matsumoto and Nishimura 1998; Panneton et al. 2006).

Multiple Streams and Substreams

Modern stochastic simulation software tools contain uniform RNGs with multiple streams and substreams of random numbers (L'Ecuyer 2008; L'Ecuyer et al. 2002). Each stream provides a very long (practically inexhaustible) sequence of numbers, divided into a large number of long disjoint substreams, and methods (or procedure calls) are readily available to jump ahead to the beginning of the next substream, or jump back to the beginning of the current substream or the beginning of the first stream. These streams and substreams can be taken as independent sequences. Streams can be created at will, in practically unlimited numbers, just like instances of other types of objects in a computer program. For their implementation, one needs efficient jump-ahead algorithms, which permit one to quickly compute the state s_{i+v} for an arbitrarily large v, given the current state s_i (L'Ecuyer 1990; L'Ecuyer et al. 2002).

These streams are certainly convenient when simulating a system on multiple processors; each processor can be given its own stream(s) and run it without having to communicate with other processors or with a central monitor to get its random numbers.

An important situation where multiple streams and substreams are useful even on a single processor is when one wishes to simulate two (or more) similar systems with common random numbers, to reduce the variance when comparing their performance (Asmussen and Glynn 2007; Law and Kelton 2000). For example, suppose one wishes to estimate the sensitivity (or derivative) of some performance measure of a complicated queueing system with respect to a small change in some parameter of the system. The model would be simulated with and without the change, with the same random numbers used for the same purpose (as much as possible) in the two configurations, and this would be repeated several times, independently. To this end, one would reserve a separate random stream for each type of random numbers required in the model (e.g., each type of arrival, each type of service time, each type of routing decision, etc.), to make sure that the same random numbers play the same role even though they are generated in a different order and their required quantity differs across the two simulation runs of any given pair. To ensure that the same random numbers from each stream are reused within any pair of runs, one would advance all streams to a new substream before each pair of runs, simulate the first configuration, rewind the streams back to the beginning of the current substream, simulate the second configuration, then move them ahead to the beginning of the next substream, for the next runs. This example also illustrates an important advantage of algorithmic RNGs compared with those based on physical devices: replaying the same sequence several times, which is frequently needed, is much easier.

Empirical Statistical Tests

Theoretical analysis of RNGs by computing their period and measuring the uniformity of Ψ_s must be complemented by empirical statistical tests. These empirical tests can never prove that an RNG has no defect, no matter how many tests are applied, but at least they can be reassuring. There is no limit on the number of tests that can be defined. The *TestU01* library (L'Ecuyer and Simard 2007) describes and implements a large collection of statistical tests for RNGs, as well as predefined batteries of tests of different strengths. It includes most of the tests previously proposed in Knuth (1998) and Marsaglia (1996), for example, and many more. Ideally, the tests should be selected in relation with the target application. So, when a general-purpose generator provided in a software library is used for a sensitive application, it may be wise to submit it to additional specialized empirical testing. For any RNG whose output sequence is periodic, one can always construct (in principle) statistical tests that this RNG will fail unequivocally (L'Ecuyer 2006). In some sense,

the good RNGs are those for which those tests are more complicated, hard to construct, or take too much time to run.

Linear Recurring Sequences and MRGs

The most popular currently-used RNGs are based on linear recurrences of the form

$$x_i = (a_1 x_{i-1} + \cdots + a_k x_{i-k}) \mod m, \qquad (1)$$

where m is a positive integer called the modulus, $a_1, \ldots, a_k$ are integers between $-m$ and m called the multipliers, with $a_k \neq 0$, and k is the order of the recurrence. Define the state of the recurrence at step n as $s_i = \mathbf{x}_i = (x_i, \ldots, x_{i+k-1}) \in \mathbb{Z}_m^k$. The zero state (0,... ,0) is absorbing and must be avoided. The longest possible period is $m^k - 1$, and it is achieved if and only if m is a prime number and the characteristic polynomial of the recurrence,

$$P(z) = z^k - a_1 z^{k-1} - \cdots - a_k,$$

is a primitive polynomial modulo m. Such primitive polynomials are easy to find once the factorizations of $m - 1$ and $(m^k - 1)/(m - 1)$ and available (Knuth 1998; L'Ecuyer 1990, 1999a). For a full-period recurrence, in any subsequence of ρ consecutive values of the state $_i$, each element of $\{0, \ldots, m-1\}^k$ appears exactly once, except for $\mathbf{x}_i = (0,\ldots,0)$. A multiple recursive generator (MRG), in its classical definition, uses the recurrence (1) with a large m, and returns $u_i = x_i/m$ as its output at step i (L'Ecuyer 1994; Niederreiter 1992). In implementations, the output transformation is modified slightly so that the MRG never returns 0 or 1, for example by taking $u_i = (x_i + 1)/(m + 1)$. When $k = 1$, it is a linear congruential generator (LCG). LCGs with modulus $m \leq 2^{64}$ have been popular in the past, but they should no longer be used except for very short simulations, because their state space (and period) is too small.

The MRG recurrence can be written in matrix form as $\mathbf{x}_i = \mathbf{A}\mathbf{x}_{i-1} \mod m$ for some matrix $\mathbf{A}$, where $\mathbf{x}_i = (x_{i-k+1}, \ldots, x_i)^t$. This form can be exploited to jump ahead by an arbitrary number of steps in a single leap, via the matrix-vector multiplication $\mathbf{x}_{i+v} = (\mathbf{A}^v \mod m)\mathbf{x}_i \mod m$, after having precomputed $\mathbf{A}^v \bmod m$ (L'Ecuyer 1990, 2006).

An important characteristic of MRGs is that the corresponding sets Ψ_s have a lattice structure: Ψ_s is the intersection of a lattice with the unit hypercube $[0, 1)^s$. This implies that all s-dimensional vectors $\mathbf{u}_i = (u_i, \ldots, u_{i+s-1})$, for $i \geq 0$, lie in a relatively small number of equidistant parallel hyperplanes (Knuth 1998). The shorter the distance d_s between those hyperplanes, the better, because this means thinner empty slices of space, and so a more evenly distributed set Ψ_s. This d_s can be computed in reasonable time in up to about 50 dimensions. A standardized figure of merit between 0 and 1 can then be computed by dividing a lower bound on the best possible value of d_s (which depends on s and m^k) by the actual value of d_s, and taking the minimum over a given range of values of s (L'Ecuyer 1996a, 1999a). For good MRGs, the resulting figure should be above 0.6, say.

It is tempting to take m as a power of two in (1), because then the mod m operation can be performed trivially by just chopping-off the high-order bits, without caring for overflow. However, there is a high price to pay in terms of period length and statistical robustness. When $m = 2^e$, the period of (1) cannot exceed $(2^k - 1)2^{e-1}$ if $k > 1$, and 2^{e-2} if $k = 1$ and $e \geq 4$. In the latter case, the period of the j-th least significant bit is at most 2^{j-2} (so the low-order bits have very short periods).

To obtain recurrences with a large period and a fast implementation, it also appears attractive to take a large k, many coefficients a_j equal to 0, and the other ones small. One extreme case is to have only two nonzero coefficients a_j, say a_r and a_k, both equal to ± 1; this is an additive/subtractive lagged-Fibonacci RNG. But in this case, all the vectors (u_i, u_{i-r}, u_{i-k}) produced by the RNG lie in only two parallel planes in $[0, 1)^3$ (L'Ecuyer 1997). This is quite bad. In general, the distance d_{k+1} between the successive hyperplanes in Ψ_{k+1} always satisfies $1/d_{k+1}^2 \leq 1 + a_1^2 + \cdots + a_k^2$ (L'Ecuyer 1997). Thus, there is no chance of having a good lattice structure if the latter sum of squares is small. This means that taking only small coefficients a_j, and many of them equal to 0, is a bad idea. L'Ecuyer and Touzin (2004) point out a similar problem when all nonzero a_j's are equal to the same constant a, as suggested by Deng and Lin (2000), Deng and Xu (2003), for example. A class of generators named

add-with-carry and subtract-with-borrow are slight modifications of MRGs having essentially the same bad properties as the lagged-Fibonacci.

One way to construct reliable and efficient MRGs is combine two or more MRGs for which a fast implementation is available (their coefficients can be small). If they are combined by adding their outputs modulo 1, then the combination turns out to be another MRG, and one should select the components so that the resulting combined MRG has a long period and excellent multivariate uniformity. Good parameters for such constructions have been found by extensive computerized searches and concrete implementations are available in L'Ecuyer (1996a, 1999a) and L'Ecuyer and Touzin (2000), for example.

Linear Recurrences Modulo 2

A second popular and efficient class of RNGs are based on linear recurrences of the form (1) with modulus $m = 2$ and a large k. They are often called $\mathbb{F}_2$ -linear, because this is a linear recurrence in the finite field $\mathbb{F}_2$ with elements $\{0, 1\}$. Following L'Ecuyer (2006) and L'Ecuyer and Panneton (2009), their general form can be given in matrix notation by

$$\begin{aligned} \mathbf{x}_i &= \mathbf{A}\mathbf{x}_{i-1} \bmod 2, \\ \mathbf{y}_i &= \mathbf{B}\mathbf{x}_{i-1} \bmod 2, \\ u_i &= \sum_{\ell=1}^{w} y_{i,\ell-1}\, 2^{-\ell} \end{aligned}$$

where $\mathbf{x}_i = \left(x_{i,0}, \ldots, x_{i,k-1}\right)^{\mathrm{t}}$ is the k-bit state vector at step i, $\mathbf{y}_i = \left(y_{i,0}, \ldots, y_{i,w-1}\right)^{\mathrm{t}}$ is a w-bit output vector, k and w are positive integers, $\mathbf{A}$ is a $k \times k$ binary matrix, $\mathbf{B}$ is a $w \times k$ binary matrix, and $u_i \in [0, 1)$ is the output at step i. This output is usually modified slightly so that u_i is never exactly 0 or 1.

This class includes the Tausworthe or linear feedback shift register (LFSR) generators, the generalized feedback shift register (GFSR), the twisted GFSR, the Mersenne twister, the WELL generator, and combinations of these, among others (L'Ecuyer 1999b, 2004; L'Ecuyer and Panneton 2009; L'Ecuyer and Simard 2007; Matsumoto and Nishimura 1998; Panneton et al. 2006; Tezuka 1995). The maximal period is $2^k - 1$, reached when the characteristic polynomial $P(z)$ of $\mathbf{A}$ is a primitive polynomial modulo 2. Each coordinate of $\mathbf{x}_i$ obeys the recurrence (1) based on this characteristic polynomial. The matrices $\mathbf{A}$ and $\mathbf{B}$ are selected to allow a fast implementation by using just a few simple binary operations such as or, exclusive-or, shift, and rotation, on blocks of bits, while still providing good uniformity of Ψ_s. This uniformity is assessed differently than for MRGs, by measures of equidistribution of the points in rectangular boxes obtained by partitioning the interval [0, 1) for each axis j into subintervals of lengths 2^{-q_j} for some integers $q_j \geq 0$ (L'Ecuyer 1996b; L'Ecuyer and Panneton 2009). Combined generators of this type, obtained by a bitwise exclusive-or of the output vectors Y_i of two or more simple $\mathbb{F}_2$-linear generators, are equivalent to yet another $\mathbb{F}_2$-linear generator (L'Ecuyer 1996b, 1999b; L'Ecuyer and Panneton 2009; Tezuka 1995). They provide fast and good RNGs.

Nonlinear Generators

Many believe that the structure of linear sequences is too regular and that the right way to go is nonlinear (Eichenauer-Herrmann 1995; Niederreiter 1992). One can introduce nonlinearity by either (a) using a linear-type generator but transforming the state nonlinearly to produce the output, or (b) constructing a generator with a nonlinear transition function f. One example of (a) is the inversive generator, which uses (1) but then takes the inverse of x_i modulo m (discarding the zeros) before dividing by m to produce the output (Eichenauer-Herrmann 1995).One example of (b) is the BBS generator, proposed by Blum et al. (1986) for cryptographic applications, which evolves according to a recurrence of the form $x_i = x_{i-1}^2 \bmod m$, and just a few of the least significant bits of x_i are retained. These RNGs have sets Ψ_s with less regularity than the linear ones, but they are slower and less convenient for simulation applications. A nonlinear RNG can also be obtained by combining two linear generators of different types. L'Ecuyer and Granger-Piché (2003) combine an MRG with an $\mathbb{F}_2$-linear generator, and obtain bounds on certain measures of uniformity of Ψ_s for the combination.

Non-uniform Random Variates

The standard approach for generating random variables from non-uniform distributions is to apply further transformations to the output values u_i of a uniform RNG. This is easily done for several distributions, but not all. Devroye (1986), Gentle (2003), and (Hörmann et al. 2004) provide extensive coverages of the most useful methods. In some cases, compromises must be made between simplicity of the algorithm, quality of the approximation, robustness (with respect to parameter changes), and efficiency (speed and memory requirements). As a general rule, simplicity should not be sacrificed for small speed gains.

Inversion. Conceptually, the simplest way to generate a one-dimensional random variable X with cumulative distribution function (cdf) F is by inversion: put $X = F^{-1}(U) \stackrel{\text{def}}{=} \min\{x \mid F(x) \geq U\}$, where U is $\mathcal{U}(0,1)$. With that definition of X, one has $\mathbb{P}[X \leq x] = \mathbb{P}[F^{-1}(U) \leq x] = \mathbb{P}[U \leq F(x)] = F(x)$, and so X has cdf F. This method requires that F^{-1} (or a good approximation of it) be available. In most simulation applications, inversion should be the method of choice, because it is the only monotone non-decreasing transformation of U into X, which makes it most compatible with major variance reductions techniques such as antithetic variates, common random numbers, external control variates, and randomized quasi-Monte Carlo (Asmussen and Glynn 2007; Law and Kelton 2000; L'Ecuyer 2009). However, in situations where speed is the real issue and where monotonicity is not critical, non-inversion methods might be appropriate.

For a specific example of inversion, if X has the Weibull distribution with parameters α and β, then $F(x) = 1 - \exp[-(x/\beta)^{\alpha}]$ for $x>0$, and $F^{-1}(U) = \beta[-\ln(1-U)]^{1/\alpha}$, so X is easy to generate. As another example, if X is geometric with parameter p, then $F(x) = 1 - (1-p)^{x+1}$ for $x = 0, 1, 2, \ldots$ and $F^{-1}(U) = \lfloor \ln(1-U)/\ln(1-p) \rfloor$.

For some distributions, F^{-1} cannot be written in closed form but it can be approximated numerically. For distributions having only scale and location parameters, it suffices to approximate the cdf of a standardized version (say with scale 1 and location 0) and then rescale and shift the result appropriately. For example, several good approximations of the inverse standard normal cdf Φ^{-1} are available, and some provide essentially machine-precision accuracy while being fast to compute (L'Ecuyer 2008).

For distributions with shape parameters, a different approximation of F^{-1} must be constructed for each value of those parameters. If a large number of variates are to be generated from the same F (with the same shape parameters), it can be worthwhile to construct on-demand an approximation of F^{-1} based on interpolation methods, by a setup algorithm that precomputes tables from which $F^{-1}(u)$ can be evaluated quickly for any u (Derflinger et al. 2010; Hörmann et al. 2004).

Tables can be precomputed in a similar way for discrete distributions such as the Poisson and binomial, for example, with fixed parameters. When the support is large or infinite (such as for the Poisson distribution), one would only store a truncated table, over a finite range with probability close to 1, and compute the remaining values only when needed (which would typically be rare). The fastest methods are obtained by using an index, as follows (Devroye 1986; Hörmann et al. 2004). One partitions the interval $(0, 1)$ into c subintervals of equal sizes, $[j/c, (j+1)/c)$ for $j = 0, \ldots, c-1$, and store the smallest and largest possible values of X for each subinterval, namely $L_j = F^{-1}(j/c)$ and $R_j = F^{-1}((j+1)/c)$. Once U is generated, the corresponding interval number $J = \lfloor cU \rfloor$ is readily computed, and the index I of the returned value is searched only in the interval $[L_J, R_J]$, with linear or binary search. By taking a large enough c, this gives a method that works in constant time for practical purposes.

Rejection methods. To generate X from a complicated density f, one can find a simpler dominating function t (called a "hat" function) for which $f(x) \leq t(x)$ for all x and such that generating variates from the density r defined by $r(x) = t(x)/a$, where $a = \int_{-\infty}^{\infty} t(s)ds$, is easy. This r is just the rescaling of t into a density. The random variate X can be generated by repeating: generate Y from the density r and an independent $\mathcal{U}(0,1)$ variate U, until $U \leq f(Y)/t(Y)$; then return $X = Y$. This is the rejection method (Hörmann et al. 2004; Devroye 1986). The number of returns into the repeat loop is a geometric random variable with mean $a > 1$, which can be reduced by having a closer to 1 (or t closer to f). A compromise must be made between reducing a and

keeping t simple. The rejection method is often combined with a change of variable to transform the density f into a new density for which a more effective hat function and a fast implementation can be constructed.

In general, rejection can also be used to generate a point uniformly in a complicated region R, in an arbitrary space (not necessarily the real space). The idea is to define another region B that contains R, and in which it is easy to generate points uniformly. Random points are generated uniformly in B and the first one that falls in R is retained.

A variant of the rejection method, called thinning, is sometimes adopted to generate events from a non-homogeneous Poisson process. If the process has rate $\lambda(t) \leq \bar{\lambda}$ for all t, where $\bar{\lambda}$ is a finite constant, one can generate Poisson pseudo-arrivals at constant rate $\bar{\lambda}$ by generating interarrival times as i.i.d. exponentials of mean $1/\bar{\lambda}$. Then, any pseudo-arrival at time t is accepted (becomes an arrival) with probability $\lambda(t)/\bar{\lambda}$ (i.e., if $U \leq \lambda(t)/\bar{\lambda}$, where U is an independent $\mathcal{U}(0,1)$, and rejected with probability $1 - \lambda(t)/\bar{\lambda}$.

Multivariate distributions. The cdf of a random vector $\mathbf{X} = (X_1, \ldots, X_d)$ does not have a well-defined inverse, so inversion does not apply directly to generate $\mathbf{X}$. In some situations, one can generate X_1 first, then X_2 conditional on X_1, then X_3 conditional on (X_1, X_2), and so on. In other situations, one can generate a vector of d independent random variates by inversion and transform it to obtain $\mathbf{X}$. For example, if the target distribution for $\mathbf{X}$ is multinormal with mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$, then one can first decompose $\boldsymbol{\Sigma} = \mathbf{A}\mathbf{A}^T$ (e.g., via the Cholesky decomposition or via an eigendecomposition), where the superscript "T" denotes matrix transpose, and return $\mathbf{X} = \boldsymbol{\mu} + \mathbf{A}\mathbf{Z}$, where $\mathbf{Z}$ is a vector of d i.i.d. standard normals, which can in turn be generated by inversion. A very general (and rich) way of specifying a multivariate distribution is via a copula, which is basically a multivariate distribution whose one-dimensional marginals are all $\mathcal{U}(0,1)$. If $\mathbf{U} = (U_1, \ldots, U_d)$ is generated from the copula, and $X_j = F_j^{-1}(U_j)$ for each j, then $\mathbf{X}$ is a random vector whose jth marginal cdf is F_j and whose dependence structure is determined by the copula. See Hörmann et al. (2004) and Nelsen (1999) for more details.

Random Search

A search algorithm that uses probabilistic sampling to select search points from a neighborhood of the current solution(s).

See

▶ Metaheuristics

Random Variates

Random values generated according to a specified probability distribution, corresponding to the outcomes of a random variable. Generally, this is realized on a computer through a transformation from IID pseudorandom numbers. The most commonly used procedures are the inverse transform method (inversion) and acceptance-rejection (rejection methods).

Random Walk

If $S_n = X_1 + X_2 + \ldots + X_n$, then S_n is a special discrete-time Markov process called a random walk if $S_0 = 0$ and the random variables $\{X_i\}$ are independent and identically distributed. The most

common form of the random walk is the discrete one in which $X_i = -1$ or + 1.

- ▶ Markov Chains
- ▶ Markov Processes

Randomized Algorithm

An algorithm that employs a probabilistic element in its procedure, as in Monte Carlo sampling implemented using a random number generator. Thus the performance of the algorithm, in terms of results returned and computation time, will be random variables. Examples include random search, evolutionary algorithms, model-based algorithms, and algorithms based on swarm intelligence.

Ranging

A term equivalent to a full sensitivity analysis of an optimal solution to a linear programming problem. Ranging refers to how much the cost coefficients and the right-hand-side elements of the linear program can vary before the optimal feasible basis is no longer optimal or feasible. A ranging analysis could also include variations of a technological coefficient, but it is not standard practice. A full cost and right-hand-side ranging analysis is part of computer-based simplex method solutions.

See

- ▶ Sensitivity Analysis
- ▶ Simplex Method (Algorithm)

Rank

The rank of an $m \times n$ matrix $\boldsymbol{A}$ is the maximum number of linearly independent columns in $\boldsymbol{A}$. The rank of $\boldsymbol{A}$ equals the rank of its transpose $\boldsymbol{A}^T$, with the rank not greater than m or n.

See

- ▶ Matrices and Matrix Algebra

Ranking and Selection

Statistical methods to choose the best (or a rank ordering) among a finite set of alternatives according to some probabilistic criterion, where the performance of each alternative must be estimated through statistical sampling, e.g., through simulation runs (replications).

Introduction

The estimation of rare event probabilities is probably one of the most challenging topics in Monte Carlo

simulation. Interest in rare events arises from many branches of science. Examples include performance analysis in communication theory and computer science where extremely small buffer overflow probabilities are of concern, chemical physics where the transition probabilities from one metastable state to another plays a key role, and risk management where measuring rare but catastrophic losses is a prerequisite. Under these circumstances, one is often interested in both qualitative and quantitative information directly related to the rare event, such as how likely is the rare event and, given that it does occur, how does it happen.

To illustrate the inefficiency of standard Monte Carlo in simulating rare events, consider a simple example. Let X be a random variable defined on some probability space $(\Omega, \mathcal{F}, \mathcal{P})$. Suppose that one is interested in estimating the probability that X is in some given set A:

$$p = P(X \in A).$$

Standard Monte Carlo would generate k independent identically distributed samples $\{X_i : i = 1, \ldots, k\}$ from the distribution of X and form an unbiased estimate

$$\hat{p}_k = \frac{1}{n} \sum_{i=1}^{k} 1_{\{X_i \in A\}},$$

where $1_{\{x \in A\}}$ is the indicator function of the set A:

$$1_{\{x \in A\}} = \begin{cases} 1 & \text{if } x \in A, \\ 0 & \text{if } x \notin A. \end{cases}$$

As the sample size k tends to infinity, the estimate $\hat{p}_k$ converges to p with probability one by the strong law of large numbers. The rate of convergence is determined by the variance of $1_{\{X \in A\}}$. More precisely, by the central limit theorem, the distribution of $\hat{p}_k$ is approximately normal with mean p and variance

$$\mathrm{Var}[\hat{p}_k] = \frac{1}{k} \mathrm{Var}\left[1_{\{X \in A\}}\right] = \frac{1}{k} p(1-p).$$

Even though this variance is very small when p is very small, the relative error associated with the estimate $\hat{p}_k$

$$\text{Relative error} = \frac{\text{standard deviation of } \hat{p}_k}{\text{mean of } \hat{p}_k} = \frac{\sqrt{p - p^2}}{\sqrt{k} p}$$

can be very large. Indeed, the relative error is unbounded as the event A becomes rarer. Therefore, a large number of samples are required in order to achieve a fixed relative error bound.

Two major classes of techniques to improve the efficiency of estimating small probabilities are importance sampling and particle splitting. When properly designed, both algorithms can dramatically reduce the number of samples needed to achieve the desired precision. Here, the focus is on importance sampling, although particle splitting is related to importance sampling in an unexpected way via subsolutions; see Glasserman et al. (1999), Dean and Dupuis (2009), Rubinstein (2010), and the references therein.

The basic idea of importance sampling is to simulate the system based on an alternative probability distribution (i.e., change of measure), and an unbiased estimate is formed by multiplying the original estimate by an appropriate likelihood ratio. Thistechnique was first applied to nuclear-physics calculation around the 1940s. Heidelberger (1995) and Asmussen and Rubinstein (1995) survey much of the research up to the early 1990s, whereas research since then is reviewed here, emphasizing basic concepts and innovative ideas. The precise statements of the theorems and their rigorous proofs can be found in the relevant references.

The next section describes two efficiency criteria for Monte Carlo simulation algorithms. Following that, two examples frequently used throughout are presented. Several different techniques for the design of the change of measure in importance sampling are then discussed, including the cross-entropy method, the game/subsolution approach in dynamic importance sampling, and the Lyapunov function method for heavy-tailed distributions.

Efficiency Criteria

There are two commonly used criteria for the performance of a Monte Carlo algorithm in rare event

simulation. Consider a family of rare event probabilities $\{p_n\}$ such that $p_n \to 0$ as $n \to \infty$. One can think of n as an index for rarity. For example, p_n may denote the probability that a one dimensional simple random walk with negative drift ever crosses a large threshold n, starting at the origin.

Consider a Monte Carlo algorithm for estimating p_n, where the estimate is the sample mean of independent copies of some random variable Y_n that satisfies $E[Y_n] = p_n$. Then the estimate is unbiased. The estimate is said to have bounded relative error if

$$\limsup_{n\to\infty} \frac{\mathrm{Var}[Y_n]}{p_n^2} < \infty.$$

It is not difficult to show that the number of samples required to achieved a fixed relative error remains bounded as n increases.

Since Y_n is unbiased, minimizing its variance is equivalent to minimizing its second moment. By Jensen's inequality, $E\left[Y_n^2\right] \geq (EY_n)^2 = p_n^2$. This motivates a weaker notion of efficiency, namely, the logarithmic asymptotic efficiency or asymptotic efficiency, which holds if

$$\lim_{n\to\infty} \frac{\log E\left[Y_n^2\right]}{\log p_n} = 2. \tag{1}$$

This criterion is particularly convenient when the rare event probabilities $\{p_n\}$ satisfy the large deviation asymptotics

$$\lim_{n\to\infty} \frac{1}{n} \log p_n = -\gamma,$$

where $\gamma > 0$ is some constant. In this situation, logarithmic asymptotic efficiency amounts to

$$\lim_{n\to\infty} \frac{1}{n} \log E\left[Y_n^2\right] = -2\gamma,$$

and implies that the number of samples required to achieve a fixed relative error grow sub-exponentially as n increases. In the literature, logarithmic asymptotic efficiency is sometimes referred to as asymptotic optimality.

Two Illustrative Examples

Even though the methodologies presented here can be applied to general settings, to convey the main ideas, two examples will be used to illustrate various Monte Carlo schemes.

Simple Random Walk [SRW]. Let $\{Z_i\}$ be a sequence of $\mathbb{R}^d$-valued, independent identically distributed random variables with distribution μ, and assume that the log-moment generating function

$$H(\alpha) = \log E\left[e^{\langle \alpha, Z_1\rangle}\right] = \log \int_{\mathbb{R}^d} e^{\langle \alpha, x\rangle} \mu(dx)$$

is finite for every $\alpha \in \mathbb{R}^d$. Define for $n \geq 1$, $S_n = Z_1 + \cdots + Z_n$. For some Borel set $A \subset \mathbb{R}^d$, it is of interest to estimate the probability

$$p_n = P\left(\frac{S_n}{n} \in A\right).$$

Under some mild conditions, the large deviations asymptotics hold, namely,

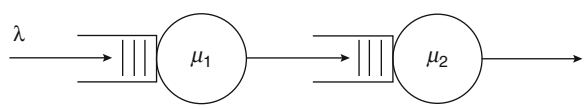
$$\lim_{n\to\infty} \frac{1}{n} \log p_n = -\inf_{\beta\in A} L(\beta), \tag{2}$$

where L is the Legendre transform of H:

$$L(\beta) = \sup_{\alpha\in\mathbb{R}^d} [\langle \alpha, \beta\rangle - H(\alpha)]. \tag{3}$$

Tandem Queueing Network [TQN]. Consider a two-node tandem Jackson queueing network, where the arrival process is Poisson with rate λ and the service times are exponentially distributed with rate μ_1 and μ_2, respectively. The system is assumed to be stable, that is, $\lambda < \min\{\mu_1, \mu_2\}$. See Fig. 1.

Assume that the two queues share a single buffer with total capacity n. The quantity of interest is the buffer overflow probability



Rare Event Simulation, Fig. 1 Two-node tandem queue

$$p_n = P\{\text{network total population reaches } n \text{ before returning to 0, starting from 0}\}.$$

Glasserman and Kou (1995) established the large deviation limit

$$\lim_n \frac{1}{n} \log p_n = -\log \frac{\min\{\mu_1, \mu_2\}}{\lambda}.$$

Importance Sampling

The basic setup of importance sampling is as follows. Suppose that one is interested in estimating

$$p = P(X \in A),$$

where X is a random variable with distribution μ. Importance sampling generates samples from a different probability distribution ν and uses the sample mean of independent copies of

$$Y = 1_{\{X \in A\}} \frac{d\mu}{d\nu}(X)$$

as the estimate. One usually requires that μ be absolutely continuous with respect to ν so that the likelihood ratio $d\mu/d\nu$ is well defined. This requirement can be relaxed as long as the absolute continuity holds for the restrictions of μ and ν to the set A. Note that the estimate Y is unbiased since

$$E_\nu[Y] = \int_A \frac{d\mu}{d\nu}(x) d\nu(x) = \int_A d\mu(x) = P(X \in A).$$

Here $E_\nu[\cdot]$ denotes the expectation taken under the probability distribution ν.

The key question in importance sampling is the choice the sampling distribution ν. Ideally, one would like to find the one that minimizes the variance of Y. To this end, define a measure ν^* such that

$$\frac{d\nu^*}{d\mu}(x) = \frac{1}{p} \cdot 1_{\{x \in A\}}.$$

It is not difficult to verify that ν^* is a probability distribution and the corresponding importance sampling estimator Y has variance zero. However, such a probability measure is of little practical use since it requires the knowledge of p, the unknown quantity one wishes to estimate. Therefore, instead of this unconstrained optimization, it is typical to search within a parameterized family of alternative probability measures. When the problem can be cast into the framework of efficiency criteria, it is desirable for the estimator to achieve logarithmic asymptotic efficiency or bounded relative error.

Remark. For future analysis, observe that the second moment of the importance sampling estimate Y admits a very simple form

$$E_\nu[Y^2] = \int_A \left(\frac{d\nu}{d\mu}\right)^2 (x) d\nu(x) = \int_A \frac{d\nu}{d\mu}(x) d\mu(x) = E_\mu[Y].$$

Classical Results in Importance Sampling

Siegmund (1976) was the first to argue that, using an exponential change of measure, asymptotically efficient importance sampling schemes can be built for estimating gambler's ruin probabilities. The analysis was related to the theory of large deviations, which has since become an indispensable tool for the design of efficient Monte Carlo algorithms.

To illustrate the idea, consider the example of SRW where A is assumed to be a closed convex set. Suppose that instead of generating the increments $\{Z_i\}$ according to μ, samples of $\{Z_i\}$ from an exponential change of measure ν_α are generated where

$$\nu_\alpha(dx) = e^{\langle \alpha, x \rangle - H(\alpha)} \mu(dx)$$

for some $\alpha \in \mathbb{R}^d$. The importance sampling estimate is

$$Y_n = 1_{\{S_n/n \in A\}} \prod_{i=1}^n e^{-\langle \alpha, Z_i \rangle + H(\alpha)} = 1_{\{S_n/n \in A\}} e^{-\langle \alpha, S_n \rangle + nH(\alpha)}.$$

Taking into account Remark 0.1 and application of Varadhan's Lemma, the second moment of Y_n satisfies

$$\lim_{n\to\infty}\frac{1}{n}\log E_{v_\alpha}\left[Y_n^2\right] = \lim_{n\to\infty}\frac{1}{n}\log E_\mu[Y_n] = -\inf_{\beta\in A}\left[\langle\alpha,\beta\rangle - H(\alpha)+L(\beta)\right].$$

The α^* that minimizes the right-hand-side of the above display yields the asymptotically most efficient exponential change of measure (say $v^* = v_{\alpha^*}$), and is the solution to the min/max problem

$$\sup_{\alpha\in\mathbb{R}^d}\inf_{\beta\in A}\left[\langle\alpha,\beta\rangle - H(\alpha)+L(\beta)\right]. \tag{4}$$

Since A is closed and convex, it is valid to exchange of the order of the sup and inf in the above expression. Then it follows from (3) that

$$\lim_{n\to\infty}\frac{1}{n}\log E_{v^*}\left[Y_n^2\right] = -\inf_{\beta\in A}\sup_{\alpha\in\mathbb{R}^d}\left[\langle\alpha,\beta\rangle - H(\alpha)+L(\beta)\right] = -2\inf_{\beta\in A}L(\beta).$$

In other words, $v^* = v_{\alpha^*}$ is logarithmic asymptotically efficient. Furthermore, if β^* minimizes $L(\beta)$ over $\beta\in A$, then α^* can be identified as the conjugate point of β^* or the point that maximizes $\langle\alpha,\beta^*\rangle - L(\beta^*)$ over $\alpha\in\mathbb{R}^d$.

It turns out that v^* coincides with the change of measure used in the classical proof of the large deviations lower bound for the rare event probabilities $P(S_n/n\in A)$. This formal connection between importance sampling and the theory of large deviations has been subsequently explored by many and made rigorous under certain circumstances, e.g., Asmussen (1985), Heidelberger (1995), Asmussen and Glynn (2007) and the references therein. These investigations gave rise to an entirely new community using exponential change of measure as the driving force for importance sampling.

Glasserman and Kou (1995) was the first to challenge the standard heuristic that the change of measure used in the proof of the large deviation lower bound should perform well. The paper considered a change of measure proposed by Parekh and Walrand (1989) for the example of TQN, which amounts to interchanging the arrival rate and the smallest service rate, and showed that it failed to be asymptotically efficient in general. In Glasserman and Wang (1997), counterexamples were constructed, such as SRW with a non-convex target set A, to show that the importance sampling estimator based on the standard heuristic can be less efficient than the standard Monte Carlo. In retrospect, the failure of the standard heuristic even in very simplistic settings is not surprising. In the previous analysis of the SRW model, a key assumption is that A is convex so that the sup and inf in (1) can be interchanged. This is clearly not true when A is a general non-convex set. The work of Glasserman and Kou (1995) and Glasserman and Wang (1997) made it clear that the standard heuristic had to be applied with great caution and motivated the development of general methodologies such as dynamic importance sampling. Some of these development will be reviewed later.

Cross-Entropy Method

The cross-entropy method is a Monte Carlo technique that originated from a sequence of papers Rubinstein (1997, 1999), which can be used not only for estimating rare event probabilities, but also for solving difficult combinatorial optimization problems; seede Boer et al. (2005) for a tutorial and Rubinstein and Kroese (2004) for a comprehensive treatment.

Consider the generic importance sampling problem for estimating $p = P(X\in A)$, where X is a random variable with distribution μ. Assume that the alternative sampling distribution is restricted to a prescribed, parameterized family of distributions, say $\{\mu_\theta : \theta\in\Theta\}$, that contains the original distribution μ. The reference parameter θ is sometimes termed the tilting parameter. As discussed previously, the zero-variance change of measure v^* is defined by

$$\frac{dv^*}{d\mu} = \frac{1}{p}\cdot 1_{\{x\in A\}}. \tag{5}$$

Under the natural assumption that a sampling distribution close to v^* should be a good choice for importance sampling, the cross-entropy method aims to solve for the distribution μ_θ that is closest to v^* under the Kullback-Leibler distance. This leads to the minimization problem

$$\min_{\theta\in\Theta} R(v^* \parallel \mu_\theta), \tag{6}$$

where $R(\cdot\|\cdot)$ is the Kullback-Leibler cross-entropy, or relative entropy, defined by

$$R(\nu \parallel \mu) = \int \log \frac{d\nu}{d\mu}(x) d\nu(x)$$

if ν is absolutely continuous with respect to μ and ∞ otherwise. Note that $R(\nu\|\mu)$ is always non-negative and equals zero if and only if $\nu = \mu$.

The cross-entropy method provides a simple iterative procedure to obtain a solution to the optimization problem (6). Every iteration involves two phases: (1) samples are generated from the distribution μ_{θ_t} where θ_t is the current candidate of the tilting parameter; (2) based on these samples, the tilting parameter θ_t is updated to θ_{t+1} in order to produce better samples in the next iteration. The iteration is terminated when the convergence of $\{\theta_t\}$ is reached. Suppose that θ^* is the final tilting parameter. Then μ_{θ^*} is used as the importance sampling change of measure to estimate p, the probability of interest.

A big advantage of the cross-entropy method is that θ_{t+1} can often be solved analytically. In particular, this happens when the distributions $\{\mu_\theta\}$ belong to the family of exponential changes of measure, as will be shown in more detail later.

The initialization θ_0 of the cross-entropy algorithms is quite flexible in general. For example, in many situations one can simply choose θ_0 that corresponds to the original distribution μ. However, in the context of rare event simulation, the choice of θ_0 becomes less straightforward. These issues will be discussed shortly.

The Adaptive Updating of θ

Consider the minimization problem (6). Denote by W_θ the likelihood ratio function

$$W(x;\theta) = \frac{d\mu}{d\mu_\theta}(x).$$

Plugging in the formula (5), it follows that

$$\begin{aligned} R(\nu^* \parallel \mu_\theta) &= \int \log \frac{d\nu^*}{d\mu_\theta}(x) d\nu^*(x) \\ &= -\log p + \frac{1}{p} \int 1_{\{x\in A\}} \log W(x;\theta) d\mu(x). \end{aligned}$$

Therefore the minimization problem (6) amounts to minimizing over $\theta \in \Theta$ the integral

$$\int 1_{\{x\in A\}} \log W(x;\theta) d\mu(x).$$

Now let $\gamma \in \Theta$ be an arbitrary reference parameter. Then the above integral equals

$$\begin{aligned} &\int 1_{\{x\in A\}} W(x;\gamma) \log W(x;\theta) d\mu_\gamma(x) \\ &= E_\gamma \left[1_{\{X\in A\}} W(X;\gamma) \log W(X;\theta) \right], \end{aligned}$$

where $E_\gamma[\cdot]$ means that the expectation is taken with X distributed according to μ_γ. Therefore the minimization problem (4.5) is equivalent to the minimization problem

$$\min_{\theta\in\Theta} E_\gamma \left[1_{\{X\in A\}} W(X;\gamma) \log W(X;\theta) \right], \tag{7}$$

for any arbitrarily fixed $\gamma \in \Theta$. In the cross-entropy method, the minimizing θ is estimated by solving the corresponding stochastic program

$$\min_{\theta\in\Theta} \frac{1}{N} \sum_{i=1}^{N} 1_{\{X_i\in A\}} W(X_i;\gamma) \log W(X_i;\theta), \tag{8}$$

where $\{X_1,\ldots,X_N\}$ are independent samples from the distribution μ_γ. The function in (8) is convex and differentiable with respect to θ in typical applications. Thus the minimizing θ is the solution to the equation

$$\frac{1}{N} \sum_{i=1}^{N} 1_{\{X_i\in A\}} W(X_i;\gamma) \nabla \log W(X_i;\theta) = 0,$$

where the gradient ∇ is with respect to θ.

Stated below is the basic adaptive updating rule for the tilting parameter θ in the cross-entropy method. The stochastic program (8) will be used in lieu of the deterministic program (7).

The basic updating rule of θ.

Suppose $\hat{\theta}_t$ is the value of the tilting parameter at the end of the last iteration. Generate independent samples $\{X_1,\ldots,X_N\}$ from the distribution $\mu_{\hat{\theta}_t}$. Define

$$\hat{\theta}_{t+1} = \arg\min_\theta \frac{1}{N} \sum_{i=1}^{N} 1_{\{X_i\in A\}} W\left(X_i;\hat{\theta}_t\right) \log W(X_i;\theta). \tag{9}$$

The iteration continues until a prescribed convergence criterion of $\hat{\theta}_t$ is satisfied.

As mentioned previously, the minimization problem (9) can often be solved analytically (the connection between this minimization problem and the maximum likelihood estimate can be found in Asmussen and Glynn 2007). For illustration, consider the case where $\{\mu_\theta\}$ is the family of exponential changes of measures of the original distribution μ. That is,

$$\frac{d\mu_\theta}{d\mu}(x) = e^{\langle\theta,x\rangle - H(\theta)}$$

Then $\log W(X_i;\theta) = H(\theta) - \langle\theta, X_i\rangle$ and $\nabla W(X_i;\theta) = \nabla H(\theta) - X_i$. It follows easily that the minimizing $\hat{\theta}_{t+1}$ satisfies

$$\nabla H\left(\hat{\theta}_{t+1}\right) = \frac{\sum_{i=1}^N 1_{\{X_i\in A\}} W\left(X_i;\hat{\theta}_t\right) X_i}{\sum_{i=1}^N 1_{\{X_i\in A\}} W\left(X_i;\hat{\theta}_t\right)}.$$

Note that $\nabla H(\theta)$ equals the expected value of a random variable with distribution μ_θ. Therefore if the family of distributions $\{\mu_\theta\}$ is reparametrized by the mean v, then the classical cross-entropy updating formula follows:

$$\hat{v}_{t+1} = \frac{\sum_{i=1}^N 1_{\{X_i\in A\}} W(X_i;\hat{v}_t) X_i}{\sum_{i=1}^N 1_{\{X_i\in A\}} W(X_i;\hat{v}_t)}. \tag{10}$$

This formula actually holds when the distributions $\{\mu_\theta\}$ belongs to a more general natural exponential family that is reparametrized by the mean; see Appendix A.3 of Rubinstein and Kroese (2008).

Example 1. Consider the SRW model. Let $X = (Z_1,\ldots,Z_n)$ where Z_j's are independent with common distribution μ. Denote by $\{\mu_\theta : \theta \in \Theta\}$ the family of exponential change of measure of μ, that is,

$$\frac{d\mu\theta}{d\mu}(z) = e^{\langle\theta,z\rangle - H(\theta)}$$

Suppose that the family of candidate sampling distributions of X is $\{v_\theta : \theta \in \Theta\}$ such that under v_θ, Z_j's are independent with common distribution μ_θ. Then the likelihood ratio $W(x;\theta)$ is given by

$$W(x;\theta) = \prod_{j=1}^n e^{\langle\theta,zj\rangle - H(\theta)} = e^{n\langle\theta,\bar{S}(x)\rangle - nH(\theta)},$$

where $x = (z_1,\ldots,z_n)$ and $\bar{S}(x) = (z_1 + \cdots + z_n)/n$. It is not difficult to solve the updating formula (9) to obtain

$$\nabla H\left(\hat{\theta}_{t+1}\right) = \frac{\sum_{i=1}^N 1_{\{X_i\in A\}} W\left(X_i;\hat{\theta}_t\right)\bar{S}(X_i)}{\sum_{i=j}^N 1_{\{X_i\in A\}} W\left(X_i;\hat{\theta}_t\right)},$$

where $X_i = (Z_1^{(i)},\ldots,Z_n^{(i)})$, $i = 1,\ldots,N$, and $Z_j^{(i)}$ are independent samples from the common distribution $\mu_{\hat{\theta}_t}$. As before, reparametrizing the distribution v_θ by the mean v, the formula becomes

$$\hat{v}_{t+1} = \frac{\sum_{i=1}^N 1_{\{X_i\in A\}} W(X_i;\hat{v}_t)\bar{S}(X_i)}{\sum_{i=1}^N 1_{\{X_i\in A\}} W(X_i;\hat{v}_t)}.$$

In other words, the mean of the updated sampling distribution is the weighted average of the sample path means.

Example 2. Consider the TQN model. Suppose that the family of candidate sampling distributions is $\{P_v : v = (v_1, v_2, v_3), v_i > 0\}$ such that under P_v the system is a Jackson network with exponential interarrival times of mean v_1, and exponential service times of mean v_2 and v_3, respectively. The original distribution corresponds to $v_0 = (1/\lambda, 1/\mu_1, 1/\mu_2)$.

Let $X_1,\ldots,X_N$ be independent sample paths generated from the distribution $P_{\hat{v}_t}$, each of which starts from the origin and stops at the first time either the total population hits the level n or the system becomes empty again. For a sample path X, denote by $\tau_1(X)$, $\tau_2(X)$, and $\tau_3(X)$ the total number of interarrivals, service completion at node 1, and service completion at node 2, respectively. Let $\{Y_{1j}(X) : j = 1,\ldots,\tau_1(X)\}$ be the interarrival times. Similarly, let $\{Y_{2j}(X) : j = 1,\ldots,\tau_2(X)\}$ and $\{Y_{3j}(X) : j = 1,\ldots,\tau_3(X)\}$ be the service times at node 1 and node 2, respectively. Then the density of a sample path X under the distribution P_v equals

$$f(X;v) = \prod_{k=1}^3 \prod_{j=1}^{\tau_k(X)} \frac{1}{v_k} e^{-Y_{kj}(X)/v_k}$$

and the likelihood ratio W is given by

$$W(X;v) = \frac{f(X;v_0)}{f(X;v)}.$$

Denote by A the buffer overflow event. It is not difficult to solve the stochastic program (9) to obtain the analytic formula

$$\hat{v}_{t+1,k} = \frac{\sum_{i=1}^{N} 1_{\{X_i \in A\}} W(X_i; \hat{v}_t) \sum_{j=1}^{\tau_k(X_1)} Y_{kj}(X_i)}{\sum_{i=1}^{N} 1_{\{X_i \in A\}} W(X_i; \hat{v}_t) \tau_k(X_i)}$$

for $k = 1,2,3$. This updating formula is actually valid for much more complicated queueing networks; see de Boer et al. (2004) for more details.

The Initialization in Rare Event Simulation

The initialization of the cross-entropy algorithm, or the choice of $\hat{\theta}_0$, can be quite flexible in general. It usually suffices to set $\hat{\theta}_0 = \theta_0$ where θ_0 corresponds to the original distribution. However, this recipe is problematic in the context of rare event simulation, since most likely the indicator $1_{\{X_i \in A\}}$ will be zero for all i if A is a rare event, rendering the minimization problem (9) meaningless.

A possible approach is as follows. Choose a set $B \supseteq A$ so that it is much less rare than A but shares the same qualitative flavor, e.g., in the TQN example one may choose B to be the event of total population overflow with buffer size $m \ll n$. Setting $\hat{\theta}_0 = \theta_0$, a pilot cross-entropy algorithm delivers the nearly optimal tilting parameter (say) θ^* for estimating $P(X \in B)$. Next with $\hat{\theta}_0 = \theta^*$, the main cross-entropy algorithm is performed to yield the optimal tilting parameter for estimating the actual probability of interest $P(X \in A)$. De Boer et al. (2004) used this approach to estimate buffer overflow probabilities in queueing networks, where B is chosen as the buffer overflow event with a small buffer level.

Generalizing this idea, a two-stage iterative scheme where both the set B and the tilting parameter θ are updated seems to be more convenient for most problems. To describe the idea, assume that the probability of interest is

$$p = P(S(X) \geq \gamma) = P\big(X \in A_\gamma\big)$$

where γ is a fixed level, S is some performance measure, and $A_\gamma = \{x : S(x) \geq \gamma\}$. It is assumed that γ is large and A_γ is a rare event. As before, the distribution of X is denoted by μ and $\{\mu_\theta : \theta \in \Theta\}$ is a parametrized family of candidate sampling distribution. In this two-stage approach for estimating p, one generates a sequence of tilting parameters $\{\hat{\theta}_t\}$, as well as a sequence of levels $\{\hat{\gamma}_t\}$ that are determined by the samples and generally increase to the actually fixed large level γ. In essence, these artificial intermediate levels divide the original difficult rare event A into a sequence of easier, less rare events $A_{\hat{\gamma}_t}$.

The algorithm is as follows. Fix a priori a fraction ρ that is not too small, usually between 1 and 10%. Set $\hat{\theta}_0 = \theta_0$ and generate N samples $X_1,\ldots,X_N$ from the distribution $\mu_{\hat{\theta}_0}$. Estimate the $(1-\rho)$-quantile of $S(X)$ by the sample quantile. That is, order the performances $S(X_i)$ from the smallest to the largest: $S_{(1)} \leq \cdots \leq S_{(N)}$ and define

$$\hat{\gamma}_1 = S_{(N_e)},\ N_e = \lceil (1-\rho)N \rceil,$$

where $[x]$ is the ceiling of x or the smallest integer that is greater than or equal to x. Then update the tilting parameter as in (9) with the set A replaced by $A_{\hat{\gamma}_1}$. In other words, $\hat{\theta}_1$ is estimated on the basis of those samples X_i that satisfies $S(X_i) \geq \hat{\gamma}_1$ and there are about ρN of them (elite samples). Iterated these steps until $\hat{\gamma}_t \geq \gamma$. The algorithm is summarized as follows:

Main Cross-Entropy Algorithm for Rare Event Simulation

1. Let $\hat{\theta}_0 = \theta_0$ and $t = 0$ (iteration counter).
2. Generate samples $X_1,\ldots,X_N$ from the distributions $\mu_{\hat{\theta}_t}$. Calculate the performances $S(X_i)$ and order them from the smallest to the largest: $S_{(1)} \leq \cdots \leq S_{(N)}$ and define $\hat{\gamma}_{t+1} = \min\{S_{(N_e)}, \gamma\}$.
3. Use these samples $X_1,\ldots,X_N$ to solve the stochastic program (9) with the set A replaced by $A_{\hat{\gamma}_{t+1}}$.
4. If $\hat{\gamma}_{t+1} < \gamma$, set $t = t + 1$ and reiterate from Step 2. Otherwise, proceed with Step 5.
5. Let T be the final iteration counter. Estimate the rare event probability p by importance sampling, with the final tilting parameter $\hat{\theta}_T$.

Sometimes between Step 4 and Step 5, one can refine the final tilting parameter by running a few extra iterations of the standard cross-entropy updating program (9) with $\hat{\theta}_T$ as the initial tilting parameter and the set A fixed as A_γ. The analysis of the convergence properties of this algorithm can be found in R.Y. Rubinstein and D.P. Kroese (2004) and Costa et al. (2007).

Dynamic Importance Sampling

The notion of dynamic, or state-dependent importance sampling was introduced in Dupuis and Wang (2004). The development of this methodology was partly motivated by the counterexamples in Glasserman and Kou (1995) and Glasserman and Wang (1997) that had challenged the validity of the standard heuristic. It was shown in Dupuis and Wang (2004) that the second moment of an importance sampling estimator can be interpreted as the value of a small noise stochastic game. In this context it was obvious that the heuristic approach, which amounted to allowing only those state independent changes of measure)) or open loop controls in the language of stochastic games), could not possibly be asymptotically efficient in general; see also Bassamboo et al. (2006). This connection also linked importance sampling to the Isaacs equation of a limiting differential game, which turned out to be *equivalent* to the Hamilton-Jacobi-Bellman (HJB) equation associated with the corresponding large deviation rate function. As a consequence, the solution to this HJB equation can be used to construct asymptotically efficient importance sampling schemes.

Dupuis and Wang (2007) explored this connection in further depth and showed that the design and analysis of dynamic importance sampling algorithms could be based on the classical subsolutions to the HJB equation. One can often construct subsolutions that are structurally much simpler than the actual solution, but which correspond to asymptotically efficient importance sampling schemes that reflect this simplicity. Subsolutions provide a unifying and flexible tool and can be used to study to a broad range of process models; see, e.g., Dupuis et al. (2007) and Dupuis and Wang (2007, 2009).

Limit Differential Game and its Isaacs Equation

In order to formally illustrate the connection between importance sampling and small noise stochastic games, consider the SRW model. Recall that $\{Z_1,\ldots,Z_n\}$ is a sequence of independent random variables with common distribution μ. Define the scaled random walk process

$$X_j = \frac{1}{n}\sum_{i=1}^{j} Z_i, \quad j = 1,\ldots,n, \tag{11}$$

with $X_0 = 0$. The probability of interest is $p_n = P(X_n \in A)$. As before, one can define an exponential change of measure ν_α by

$$\nu_\alpha(dx) = e^{\langle \alpha, x\rangle - H(\alpha)}\mu(dx)$$

for every $\alpha \in \mathbb{R}^d$.

Consider a state-dependent change of measure in the following sense. For each $j = 0, 1, \ldots, n-1$, conditional on the simulation history $\{Z_i : i = 1,\ldots,j\}$, Z_{j+1} is sampled from a distribution μ_{α_j}, where α_j is a function of both the scaled time j/n and the scaled state X_j as defined in (11). The corresponding importance sampling estimator is given by

$$Y_n = 1_{\{X_n \in A\}} \prod_{j=0}^{n-1} e^{-\langle \alpha_j, Z_{j+1}\rangle + H(\alpha_j)}.$$

The estimate Y_n is unbiased. The goal is to minimize the variance, or equivalently, the second moment of Y_n.

This minimization problem connects naturally to a partial differential equation when it is recast as a stochastic control problem with $\{\alpha_j\}$ being the control. To this end extend the problem slightly to allow a general initial time and state. For $i \geq 0$ and $x \in \mathbb{R}^d$, define X_j for $j = i,\ldots,n$ as above except that $X_i = x$, and then define

$$V_n(x,i) = \inf_{\{\alpha_j\}} \bar{E}\left[1_{\{X_n \in A\}} \prod_{j=i}^{n-1} e^{-\langle \alpha_j, Z_{j+1}\rangle + H(\alpha_j)}\right]^2,$$

where $\bar{E}$ denotes the expectation taken under the change of measure determined by the control $\{\alpha_j\}$. In other words, $V_n(x,i)$ is the minimal second moment of the importance sampling estimators given that the state process $\{X_j\}$ startsat time i with initial state x. It will be more convenient to express this in terms of the original distributions:

$$V_n(x,i) = \inf_{\{\alpha_j\}} E\left[1_{\{X_n \in A\}} \prod_{j=i}^{n-1} e^{-\langle \alpha_j, Z_{j+1}\rangle + H\{\alpha_j\}}\right],$$

where the expected value is taken such that $\{Z_j,\ldots,Z_n\}$ are independent with common distribution μ.

As the value function of a discrete time stochastic control problem, V_n satisfies the dynamic programming equation

$$V_n(x,i) = \inf_{\alpha\in\mathbb{R}^d} \int e^{H(\alpha)-\langle\alpha,y\rangle} V_n\left(x+\frac{y}{n}, i+1\right)\mu(dy). \tag{12}$$

Owing to the exponential scaling in n, it is natural to consider the logarithmic transform of V_n and assume that

$$-\frac{1}{n}\log V_n(x,i) \approx W(x,i/n) \tag{13}$$

for some smooth function $W : \mathbb{R}^d \times [0,1] \to \mathbb{R}$. This leads to the approximation

$$V_n\left(x+\frac{y}{n}, i+1\right)\cdot V_n^{-1}(x,i) \approx exp\left\{-\langle\nabla W(x,t), y\rangle - \frac{\partial W}{\partial t}(x,t)\right\}$$

where ∇ is the gradient with respect to x, and $t = i/n$. Plugging the above approximation into equation (12), taking log on both sides, and recalling the definition of H, it follows that

$$0 = -\frac{\partial W}{\partial t} + \inf_{\alpha\in\mathbb{R}^d}[H(\alpha) + H(-\nabla W - \alpha)]. \tag{14}$$

Since $V_n(x,n) = 1_{\{x\in A\}}$, W satisfies the boundary condition $W(x,1) = 0$ if $x\in A$ and ∞ otherwise.

Even though a very special model has been used here, equation (14) leads to a few observations that actually hold in much greater generality.

1. Equation (14) is the Isaacs equation associated with a two-person zero-sum game. Indeed, since H and L are convex duals, for every $\alpha\in\mathbb{R}^d$

$$H(\alpha) = \sup_{\beta\in\mathbb{R}^d}[<\alpha,\beta> - L(\beta)].$$

Thus equation (14) can be written as

$$0 = \frac{\partial W}{\partial t} + \sup_{\alpha}\inf_{\beta}[\langle\nabla W,\beta\rangle + L(\beta) + \langle\alpha,\beta\rangle - H(\alpha)].$$

This is the Isaacs equation corresponds to the following zero-sum differential game. The dynamics $\dot{\phi}(t) = \beta(t)$ only involves the β-player. The running cost $L(\beta) + \langle\alpha,\beta\rangle - H(\alpha)$ is affected by both players, and the terminal cost is $\infty\cdot 1_{A^c}$. Because of the intervening minus sign, the maximizing α-player indeed tries to minimize the variance.

2. Thanks to the convexity of H, the maximizing α in equation (14) is

$$\alpha^*(x,t) = -\frac{1}{2}\nabla W(x,t). \tag{15}$$

This is the basic formula for computing the state-dependent change of measure.

3. Plugging the formula of α^* into equation (14), it follows that

$$0 = \frac{\partial W}{\partial t} + 2H(-\nabla W/2). \tag{16}$$

This is equivalent to the HJB equation associated with the corresponding large deviation rate function. To see this, abuse the notation and extend the definition of p_n to

$$p_n(x,t) = P\left(X_n \in A | X_{\lceil nt\rceil} = x\right)$$

for $x \in \mathbb{R}$ and $t\in[0,1]$. Clearly the probability of interest $P(X_n\in A)$ equals $p_n(0,0)$. Then under suitable conditions

$$-\lim_n \frac{1}{n}\log p_n(x,t) = \inf_{\phi}\int_t^1 L\left(\dot{\phi}(s)\right)ds,$$

where the infimum is taken over all absolutely continuous functions ϕ such that $\phi(t) = x$ and $\phi(1)\in A$. Denote by $U(x,t)$ the value function of this minimization problem. Then U satisfies the HJB equation

$$0 = \inf_{\beta}\left[\frac{\partial U}{\partial t} + \langle\nabla U,\beta\rangle + L(\beta)\right] = \frac{\partial U}{\partial t} + H(-\nabla U)$$

with terminal condition $U(x,1) = 0$ if $x\in A$ and ∞ otherwise. Clearly it is equivalent to (16) by a change of variable $W = 2U$. This equivalence also

indicates that the state-dependent change of measure based on the solution to the Isaacs equation (16) is asymptotically efficient since by equation (13),

$$-\lim_n \frac{1}{n}\log V_n(0,0) = W(0,0) = 2U(0,0) = -2\lim_n \frac{1}{n}\log p_n(0,0),$$

and $V_n(0, 0)$ is the second moment of the corresponding importance sampling estimator. A rigorous proof can be found in Dupuis and Wang (2004).

The Idea of Subsolutions

From the previous discussion, it follows that the solution to a related Isaacs equation can be used to build asymptotically efficient importance sampling schemes. A difficulty with this approach is that a solution to a nonlinear partial differential equation such as Isaacs equation is hard to compute. To circumvent this, Dupuis and Wang (2007) proposed importance sampling schemes based on the subsolutions to the Isaacs equation. Subsolutions are functions that satisfy the partial differential equation with inequality instead of equality, and allow much greater flexibility in the design of importance sampling schemes.

In order to understand the sufficiency of subsolution, examine the criterion of logarithmic asymptotic efficiency more closely. Recall the definition of logarithmic asymptotic efficiency (1). Jensen's inequality implies that

$$\log E\left[Y_n^2\right] \geq 2\log E[Y_n] = 2\log p_n.$$

Therefore, if for some $\gamma > 0$ the large deviation asymptotics

$$\lim_{n\to\infty} \frac{1}{n}\log p_n = -\gamma$$

hold, then (1) is equivalent to the inequality

$$\limsup_{n\to\infty} \frac{1}{n}\log E\left[Y_n^2\right] \leq -2\gamma. \tag{17}$$

In other words, in order to show that Y_n is asymptotically efficient, it suffices to establish the upperbound (17) only. The inequalities in the definition of a subsolution [see below] are consistent with this upper-bound, when the subsolution is combined with a verification argument to bound the second moment of Y_n.

To give the definition of a subsolution, consider a family of Isaacs equations of a given form. The definition easily extends to other types of Isaacs equations. For a broad collection of problems, the probability of interest is of form $p_n = P(S_n/n \in A)$, where S_n is the partial sum of independent identically distributed random variables or functionals of Markov chains. Then under suitable conditions, the large deviations asymptotics

$$\lim_{n\to\infty} \frac{1}{n}\log p_n = -\inf_{\beta\in A} L(\beta) := -\gamma$$

hold for some convex rate function L. Denoting by H the Legendre transform of L, then the Isaacs equation takes the familiar form

$$\frac{\partial W}{\partial t} + \sup_\alpha \inf_\beta \left[\langle \nabla W, \beta\rangle + L(\beta) + \langle \alpha, \beta\rangle - H(\alpha)\right] = 0, \tag{18}$$

with boundary condition $W(x,1) = 0$ if $x \in A$ and ∞ otherwise.

Definition. A classical subsolution (18) to the Isaacs equation is a smooth function W that satisfies

$$\frac{\partial W}{\partial t} + \sup_\alpha \inf_\beta \left[\langle \nabla W, \beta\rangle + L(\beta) + \langle \alpha, \beta\rangle - H(\alpha)\right] \geq 0$$

with boundary inequality $W(x,1) \leq 0$ for $x \in A$.

Given a classical subsolution W, the corresponding change of measure is determined by the maximizing α^* for the min/max term, which has exactly the same form as (15). The following theorem is the key result in the performance analysis of those importance sampling schemes based on subsolutions; see Dupuis and Wang (2007) for more details.

Theorem 1. Let W be a classical subsolution to the Isaacs equation and Y_n the corresponding importance sampling estimate of p_n. Then under suitable conditions

$$\limsup_{n\to\infty} \frac{1}{n} \log E\left[Y_n^2\right] \le -W(0,0). \tag{19}$$

In particular, if $W(0, 0) = 2\gamma$, then Y_n is asymptotically efficient.

Construction of Subsolutions

Theorem 1 reduces the problem of building an asymptotically efficient or nearly asymptotically efficient importance sampling scheme to that of a classical subsolution W with $W(0, 0)$ equal or close to 2γ, respectively. For systems with piecewise homogeneous dynamics, a particularly useful technique is to build a piecewise affine subsolution at first and then obtain a classical subsolution by mollification. The construction of a piecewise affine subsolution, which is usually identified as the minimum of a collection of affine functions, is the key step. Once such a piecewise affine subsolution is given, say,

$$\bar{W} = W_1 \wedge \cdots \wedge W_m,$$

a mollification technique called exponential weighting is used to produce a smooth function:

$$W_\varepsilon = -\varepsilon \log \sum_{i=1}^{m} e^{-W_i/\varepsilon},$$

where ε is a small positive number. It is not difficult to show that W_ε approximates $\bar{W}$ as ε approaches zero. Furthermore, analytic formulas for quantities such as ∇W_ε are readily available. There are two important remarks regarding the function W_ε and the corresponding change of measure: (1) In general, W_ε is not exactly a subsolution, but an approximate one in the sense that the inequality (19) is satisfied with the right hand side replaced by a vanishing negative number. This is usually sufficient for asymptotic efficiency; (2) It is sometimes more convenient to use a change of measure slightly different from the one determined by $\alpha^* = -\nabla W_\varepsilon/2$. It is essentially a state dependent mixture of the changes of measure determined by $\{W_i\}$. Theorem 1 still holds in this case; see Dupuis and Wang (2007) for details.

In general, the construction of piecewise affine subsolutions is accomplished by carefully analyzing the properties of the system dynamics and the relevant large deviation properties. For illustration, consider two concrete examples.

Example 3. Consider the SRW model. Without loss of generality assume that $E[X_1] = 0$. First consider the simple case where $A = [\beta,\infty)$ for some $\beta > 0$. Denote by α the conjugate point of β. Then the affine function

$$W(x) = -2\langle \alpha, x - \beta\rangle - 2(1-t)H(\alpha)$$

is a subsolution to the Isaacs equation. Since $-\nabla W/2 = \alpha$, the corresponding change of measure is exactly the classical one.

A more interesting case is when $A = \left(-\infty, \bar{\beta}\right] \cup [\beta, \infty)$ when $\bar{\beta}<0<\beta$. Let $\bar{\alpha}$ be the conjugate point of $\bar{\beta}$. Define

$$\bar{W}(x) = -2\left\langle \bar{\alpha}, x - \bar{\beta}\right\rangle - 2(1-t)H(\bar{\alpha}).$$

Then it is not difficult to check that $W^* = W \wedge \bar{W}$ is a two-piece affine subsolution. Note that

$$-\nabla W^*/2 = \begin{cases} \alpha & \text{if } W < \bar{W} \\ \bar{\alpha} & \text{if } W > \bar{W} \end{cases}$$

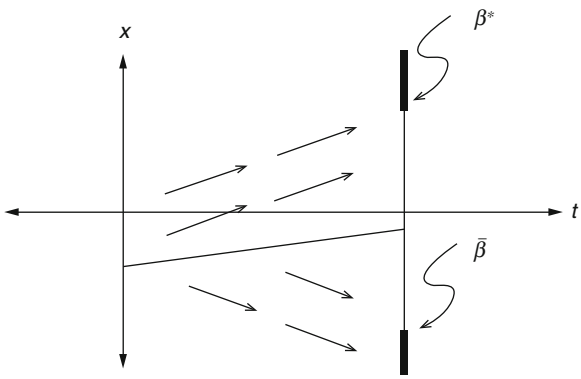
is piecewise constant. Figure 2 illustrates how this would partition the space-time domain.

Example 4. Consider the TQN model. Without loss of generality assume $\lambda + \mu_1 + \mu_2 = 1$. Define by $\left\{Z_k = \left(Z_{k,1}, Z_{k,2}\right) : k = 0, 1, \ldots\right\}$ the embedded discrete time Markov chain, where $Z_{k,i}$ represents the length of the i-th queue at the k-th transition epoch of the network, $i = 1,2$. The space of the possible jumps is

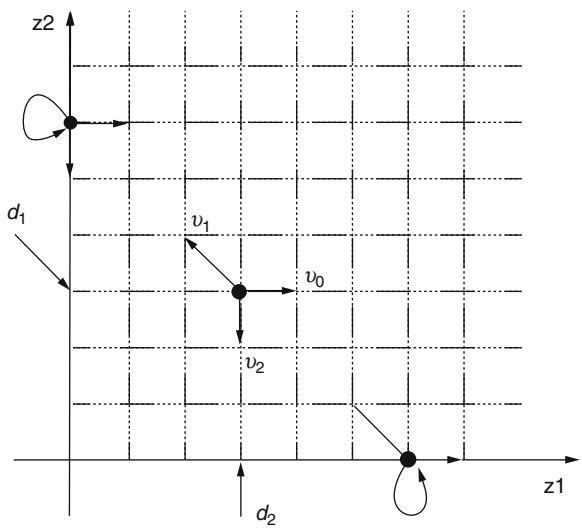
$$\mathbb{V} = \{v_0 = e_1, v_1 = -e_1 + e_2, v_2 = -e_2\}.$$

The system dynamics can be described as $Z_{k+1} = Z_k + \pi[Z_k, Y_{k+1}]$, where $\{Y_k\}$ are random variables taking values in $\mathbb{V}$ and π is the mapping due to the non-negativity constraint on the queue lengths: for $x = (x_1, x_2) \in \mathbb{R}_+^2$ and $y \in \mathbb{V}$

$$x[x; y] = \begin{cases} \text{O if } \mathrm{x_i} = 0 \text{ and } \mathrm{y} = \upsilon_\mathrm{i} \text{ for some i} = 1, 2 \\ y \text{ otherwise} \end{cases}$$



Rare Event Simulation, Fig. 2 Domain decomposition and corresponding drifts



Rare Event Simulation, Fig. 3 The system dynamics

See Fig. 3. Let $\mathcal{P}$ be the space of strictly positive probability measures on $\mathbb{V}$, i.e.,

$$\mathcal{P} = \{\theta = (\theta_0, \theta_1, \theta_2) : \theta_0 + \theta_1 + \theta_2 = 1, \theta_i > 0\}.$$

Under the original distribution, $\{Y_k\}$ are independent identically distributed with distribution $\Theta = (\lambda, \mu_1, \mu_2)$. Recall that $R(\cdot\|\cdot)$ denotes the relative entropy. The relevant Isaacs equation is such that for $x \in \{(x_1, x_2) \in \mathbb{R}_+^2 : x_1 + x_2 < 1\}$

$$\sup_{\bar{\Theta}\in\mathcal{P}} \inf_{\theta\in\mathcal{P}} \left[\left\langle \nabla W(x), \sum_{i=0}^{2} \theta_i \cdot \pi[x, v_i] \right\rangle + \sum_{i=0}^{2} \theta_i \log \frac{\bar{\Theta}_i}{\Theta_i} + R(\theta \,\|\, \Theta) \right] = 0,$$

with the boundary condition $W(x) = 0$ when $x_1 + x_2 = 1$. Here $\bar{\Theta}$ corresponds to the change of measure. Given W, the optimal (maximizing) $\bar{\Theta}$ admits an analytic formula.

The definition of a subsolution is just to replace the "=" by "$\geq$" in the Isaacs equation and replace the boundary condition "$W(x) = 0$" by "$W(x) \leq 0$". Simple piecewise affine subsolutions can be constructed. For example, when $\mu_2 \leq \mu_1$, define vectors

$$r_1 = 2\gamma(-1, -1), r_2 = 2\gamma(-1, 0), r_3 = (0, 0).$$

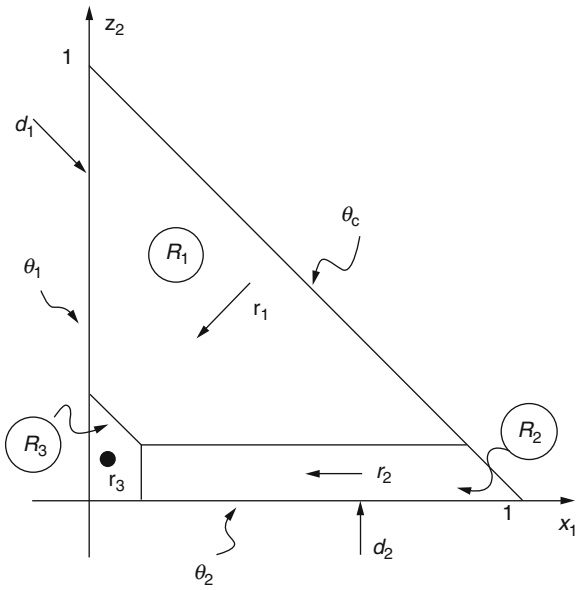
Let δ be a small positive number. Then $\bar{W} = W_1 \wedge W_2 \wedge W_3$ defines a subsolution, where

$$W_k(x) = \langle r_k, x\rangle + 2\gamma - k\delta, \quad k = 1, 2, 3.$$

This subsolution divides the region into three pieces: R_1, R_2, and R_3, such that $\bar{W}(x) = W_k(x)$ for $x \in R_k$. See Fig. 4. The regions R_2 and R_2 are sometimes called "boundary layers". They are closely related to the discontinuity of the dynamics on the boundary $\{x_2 = 0\}$ and the origin, and the large deviations properties of the rare event. Details of the algorithms can be found in Dupuis et al. (2007).

Lyapunov Function Method for Heavy-Tailed Distribution

Much of the previous discussion has assumed that the distributions involved are light-tailed in the sense that their moment generating functions are finite in a small neighborhood of the origin, and thus the exponential changes of measure are meaningful. On the contrary, for a large class of distributions emerging from practice, the tail probabilities decay much more slowly. These heavy-tailed distributions have very different large deviation properties and the exponential scaling is in general not valid. As



Rare Event Simulation, Fig. 4 Piecewise affine subsolution

a consequence, fast rare event simulation algorithms can look very different from those for light-tailed distributions; see Asmussen et al. (2000) and references therein.

Some of the recent works on rare event simulation involving heavy-tailed distributions have been concerned with state-dependent algorithms, e.g., Dupuis et al. (2007). This section reviews a general technique proposed by Blanchet and Glynn (2008) that is based on Lyapunov functions. These Lyapunov functions are closely related to the subsolutions discuss previously (they are in some sense the exponential of subsolutions). Even though the method is applicable to light-tailed distributions as well, the discussion will be made in the context of heavy-tailed distributions, via the example of estimating level crossing probabilities for heavy-tailed random walks.

Let $\{X_i\}$ be a sequence of independent identically distributed heavy-tailed random variables with common distribution μ and strictly negative mean. Define the simple random walk

$$S_n = y + \sum_{i=1}^{n} X_i,$$

with initial condition $S_0 = y$. Here it is assumed that y is a very negative number and the quantity of interest is the level crossing probability

$$p^*(y) = P(S_n \geq 0 \text{ for some } n).$$

Under suitable conditions, as $y \to -\infty$, $p^*(y)$ has the asymptotics

$$p^*(y) \sim \frac{1}{-E[X_1]} \int_{|y|}^{\infty} P(X_1 > s) ds. \tag{20}$$

A useful observation is that if Q^* is a probability measure (Doob's h-transform) that satisfies

$$Q^*(X_{n+1} \in dz | S_n = x) = \frac{p^*(s+x)}{p^*(x)} \mu(dz) \tag{21}$$

for $x < 0$, then Q^* is the zero variance importance sampling change of measure. As before, Q^* is impractical since $p^*(\cdot)$ is unknown.

However, (21) does motivate the use of a change of measure Q such that for $x < 0$

$$Q(X_{n+1} \in dz | S_n = x) = \frac{v(z+x)}{w(x)} \mu(dz), \tag{22}$$

where v is a function that is close to p^* and $w(x)$ is the normalization constant such that

$$w(x) = \int_{\mathbb{R}} v(z+x) \mu(dz). \tag{23}$$

The corresponding importance sampling estimator is just

$$Y = 1_{\{T<\infty\}} \prod_{i=0}^{T-1} \frac{w(S_i)}{v(S_{i+1})},$$

where $T = \inf\{n \geq 1 : S_n \geq 0\}$.

To aid the design of Q, one also need some means to analyze its performance. This is where the Lyapunov function comes into play. Even though the definition here is slightly different from that of Blanchet and Glynn (2008) in the form, they are indeed equivalent.

Definition. A function $H : \mathbb{R} \to [0, \infty)$ is said to be a Lyapunov function associate with the probability measure Q if for every $x < 0$,

$$H(x) \geq \int_{\mathbb{R}} \frac{w(x)}{v(z+x)} H(z+x)\mu(dz).$$

and $H(x) \geq 1$ for $x \geq 0$.

Theorem. Let Y be the importance sampling estimator and H a Lyapunov function associated with Q, then

$$E_Q\left[Y^2 | S_0 = y\right] \leq H(y).$$

Proof. Define the process

$$R_n \doteq H(S_n) \cdot \prod_{i=0}^{n-1} \frac{w^2(S_i)}{v^2(S_{i+1})}.$$

Then it is straightforward to check that the definition of the Lyapunov function H is equivalent to the claim that $R_{T\wedge n}$ is a supermartingale under Q. Therefore by the Optional Sampling Theorem, for $y < 0$

$$E_Q[R_T | S_0 = y] \leq E_Q[R_0 | S_0 = y] = H(y).$$

Observing that $R_T \geq Y^2$ since $H(S_T) \geq 1$, the proof is complete. □

The idea of the Lyapunov function method is to find a pair (v, H) such that (i) v is close to p^* in the sense that they are asymptotically equivalent; (ii) H is a Lyapunov function of the form $H(x) = h(x)v^2(x)$. Then the preceding theorem asserts that the performance of the importance sampling algorithm associated with the change of measure Q is characterized by h. For example, if h is bounded then it is of bounded relative error.

Now consider the objectives (i) and (ii). An immediate problem is that how one can tell if v is close to p^* when p^* is unknown in the first place. The idea is that, comparing (21) and (22), if $v = p^*$ then w defined in (23) should equal p^* as well and thus $w - v = 0$. Therefore, $w - v$ can be used as a criterion to measure how close v and p^* are. With this in mind, it is natural to start with the function on the right-hand-side of (20). Define a non-negative random variable Z that is independent of $\{X_i\}$ and such that for $t > 0$,

$$P(Z > t) = 1 \wedge \int_t^\infty \frac{1}{-E[X_1]} P(X_1 > s)ds.$$

Define $\bar{v}(x) = P(Z > -x)$ for all $x \in \mathbb{R}$. Note that $\bar{v}(x) = 1 = p^*(x)$ if $x > 0$. Furthermore, with $\bar{w}$ defined as in (23) with v replaced by $\bar{v}$, it can be shown that $\bar{w}(x)$ and $\bar{v}(x)$ are asymptotically very close as $x \to -\infty$. Therefore, there exists an $a^* < 0$ such that $v(x) = \bar{v}(x + a^*)$ and $w(x) = w(x + a^*)$ are very close for all $x < 0$. Given the function v, one can find a bounded piecewise constant function h such that $H(x) = h(x)v^2(x)$ defines a Lyapunov function. This leads to an importance sampling scheme with bounded relative error.

It should be mentioned in the end that the sampling distribution is determined by (22), and it is not difficult to check that

$$Q(X_{n+1} \in dz | S_n = x) = P(X_1 \in dz | X_1 + Z > -x - a^*).$$

Samples from this conditional distribution are typically generated by suitable acceptance/rejection schemes, where the acceptance probability remains uniformly bounded away from 0. The design of such schemes is based on the tail behavior of the distribution μ. See Blanchet and Glynn (2008) for the case when μ is regularly varying.

Rate Matrix

The matrix of transition rates (or intensities) in a continuous-time Markov process with discrete state space (sometimes called a continuous-time Markov chain), such as a birth-and-death stochastic process. Each (non-diagonal) entry gives the probability "rate" of making a transition from one state to another, where the time spent in any state is exponentially distributed. By convention, the diagonal entry is selected so that the rows sum to zero; thus it is equal to the negative of the total instantaneous rate out of the state, corresponding to the inverse of the mean (exponentially distributed) holding time in a state. Also called the infinitesimal generator matrix.

Ray

A ray is a collection of points $(\boldsymbol{x}_0 + \lambda\, \boldsymbol{d})$, where $\boldsymbol{d}$ is a nonzero vector and $\lambda \geq 0$. The vector $\boldsymbol{d}$ is called the direction of the ray and $\boldsymbol{x}_0$ the origin of the ray.

Reasoning

A problem-solving process. Two paradigms are logical and analogical reasoning. Logical reasoning includes deductive and inductive. Deductive reasoning is arriving at a conclusion from premises and rules of inference. Inductive reasoning is forming a general conclusion that explains multiple observations. Analogical reasoning uses analogy of a current situation to familiar ones from previous experiences. One paradigm for analogical reasoning is a neural network.

Redundancy

Igor Ushakov
Qualcomm Inc., San Diego, CA, USA

Redundancy is an engineering method of improving system and equipment reliability. Mainly, redundancy consists in using extra units (subsystems, modules and/or additional elements) within the system to increase reliability. This kind of redundancy is usually called structural. Redundancy might be called functional when a system may perform the same operation by several different ways. For instance, a communication network may be able to bypass its failed links or switches. Another possibility is time redundancy, where the system has extra time for possible repetition of the same operation after a failure. As an example, one can consider a computer system with restarting in the case of error. This article only considers structural redundancy.

Redundancy may be implemented on the system or unit levels. System-level redundancy means that an entire system would be replaced upon its failure by an identical structure; unit-level redundancy means that an individual unit would be replaced upon failure by a devoted or shared backup element. Let p_k equal the reliability of unit k, n be the number of system units connected in series, and m the degree of redundancy

(i.e., there are $m-1$ replacements standing by). Further assume that the system is operating under hot standby redundancy, wherein items age as they wait to be used. Then it follows for the system-level case that the system reliability is given by $P_1 = 1 - \left(1 - \prod_{k=1^n} p_k\right)^m$ since total failure occurs when the original and all backup series systems fail. For hot standby at the unit level in the case that each unit is backed up by $m-1$ identical others, the reliability of such a series system would be given by $P_2 = \prod_{k=1^n} [1 - (1-p_k)^m]$ since all m of at least one type must fail for the system to fail. For any fixed set of parameters, one always has $P_2 > P_1$. (An analogous result can be formulated for cold standby wherein each backup unit only begins to age upon connection).

Redundancy on the unit level can also be done using a shared backup pool. A good example might be a group of n redundant units assigned to the simultaneous support of a main group of k units, as would be typical in spares provisioning. Illustrations of system-level redundancy, as in the calculation of P_1 above, could include enclosed power packs and printed circuit boards.

When considering redundant systems, one must take into account the monitoring of main and redundant units, the time needed to switch from failed unit to redundant one, and the reliability of switching devices. One special type of redundancy is represented by voting systems. A common use of a voting system is in mission critical software decisions. In these systems, n independent outputs (signals) are compared against each other, such that if k signals coincide, the system is assumed to be operating successfully. If several outputs are possible, then the output that appears most often is taken as correct one (unless there is a tie).

The effect of redundancy can be dramatically increased by the use of renewal (repair or replacement) of failed units. Thus far, the implicit assumption has been that failed units are never repaired but replaced with new ones when needed. However, most failed units are not thrown out but are repaired where appropriate and retained for future use. In this case, system failure can occur only if all units of the redundant group fail during the renewal procedure. So, reliability of a repairable system depends on the duration of repair. For comparison of redundancy with and without repair, consider a duplicated system (one main with a single redundant unit). Let the distributions of time-to-failure and repair time be exponential with parameters λ and μ, respectively. For hot standby, a system without repair has a mean time-to-failure equal to $T_1 = 1.5/\lambda$, whereas for a system with repair, the mean time-to-failure is $T_2 = (1/\lambda)(\mu + 3\lambda)/2\lambda$ (see Kozlov and Ushakov 1970; Ushakov 1994). For instance, if $\lambda = 0.001$ (i.e., the unit's mean time-to-failure = 1,000 hr) and $\mu = 1$ (i.e., mean repair time = 1 hr), then $T_1 = 1,\ 500$ hr and $T_2 \approx 500,000$ hr. For cold standby, $T_1{}^* = 2/\lambda$ and $T_2{}^* = (1\ /\lambda)(\mu + 2\lambda)/\lambda$, respectively, which for the above numerical data gives $T_1 = 2,000$ hr and $T_2 \approx 1,000,000$ hr. These numerical examples show the effectiveness of repair for redundant systems.

Though redundancy improves system reliability, it requires extra resources and money. Cost effectiveness analysis of redundancy is considered as the problem of optimal redundancy.

Consider a system consisting of n independent units. For simplicity, assume that the considered system is series, i.e., failure of any main unit of the system leads to total system failure. To increase the reliability of the system, one uses redundant units in the following way. Let unit i of the system have x_i redundant units and write the probability of successful operation (PSO) of this group as $R_i(x_i)$.

For independent groups of units, the system PSO can be written as

$$R(X) = \prod_{i=1}^{n} R_i(x_i)$$

where $X = (x_1, \ldots, x_n)$. At the same time, introducing x_i redundant units leads to the expenditure of $C(x_i)$ cost units. Usually, one assumes that $C(x_i) = c_i x_i$. In this case, the system total cost equals

$$C(X) = \sum_{i=1}^{n} c_i x_i$$

Then the optimal redundancy problem consists of solving one of the following problems: find the vector solution that delivers either

$$\max_X \left\{ \prod_{i=1}^{n} R_i(x_i) \middle| \sum_{i=1}^{n} c_i x_i \le C^0 \right\} \qquad (1)$$

or

$$\min_{X} \left\{ \sum_{i=1}^{n} c_i x_i \middle| \prod_{i=1}^{n} R_i(x_i) \geq R^0 \right\}. \qquad (2)$$

These problems are conditional discrete optimization problems that can be solved by means of standard tools such as steepest descent, branch and bound, dynamic programming, and integer programming. Notice that both goal functions, $R(X)$ and $C(X)$, are concave. One of the best ways to solve is by use of Kettelle's Algorithm, which represents a convenient computational modification of dynamic programming (Gnedenko and Ushakov 1995).

Cases of multi-constraint versions of problem (1) and its solution are considered in Barlow and Proschan (1981) and Ushakov (1994). The optimal redundancy problem for multi-functional systems, an important extension of problem (2), is solved in Ushakov (1994) as well.

Redundant Constraint

An inequality or equation of a mathematical programming problem that does not define part of the solution space. An equivalent problem can be formed by removing redundant constraints.

Regeneration Points

If there exists a time epoch T_1 in a stochastic process such that the continuation of the process beyond T_1 is a probabilistic replica of the process starting at time 0, then the process is said to be regenerative. For such a regenerative process, the existence of subsequent times T_2, T_3, ..., having the same properties follows by repeating the argument, and the set $\{T_1, T_2, T_3, \ldots\}$ are said to be regeneration points of the process.

Regenerative Simulation

Peter J. Haas
IBM Almaden Research Center, San Jose, CA, USA

Introduction

Regenerative simulation refers to a collection of statistical techniques for analyzing the output of a discrete-event stochastic simulation whose underlying stochastic process $\{X(t) : t \geq 0\}$ is a regenerative process – here $X(t)$ denotes the (random) state of the simulated system at time t. A regenerative stochastic process has the characteristic property that there exists an infinite sequence of random times, called regeneration points, at which the process probabilistically restarts. The essence of regeneration is that the evolution of the process between any two successive regeneration points is an independent probabilistic replica of the process in any other such cycle. The basic ideas were

initially hinted at by Cox and Smith (1961) and the method itself was pioneered by Crane and Iglehart (1974, 1975) and Fishman (1974). Books and surveys on the regenerative method and regenerative process theory include Asmussen (2003), Asmussen and Glynn (2007), Haas (2002), Henderson and Glynn (2001), Shedler (1993), and Thorisson (2000).

When applicable, regenerative simulation techniques provide a theoretically rigorous and elegant means of studying the limiting or steady-state behavior of $\{X(t) : t \geq 0\}$. Initial applications of regenerative simulation centered on the problem of obtaining point estimates and confidence intervals for system performance measures comprising time-average limits of the form $r(f) = \lim_{t\to\infty}(1/t)\int_0^t f(X(u))\,du$, where f is a real-valued performance function. Under mild conditions, the value of a time-average limit is determined by the expected behavior of the process in a single regenerative cycle – a fact that has important implications for simulation analysis. Under some additional regularity conditions, the time-average limit can also be interpreted as a steady-state or limiting expected value. In general, when estimating steady-state performance measures, one has to worry about the fact that the initial distribution – i.e., the distribution of $X(0)$ – differs from the steady-state distribution, and that the $X(t)$ process is autocorrelated. Thus the effects of initialization bias persist over time and, moreover, estimation methods based on independent and identically distributed (i.i.d.) observations cannot be directly applied. These problems vanish in the regenerative setting. Later work on regenerative simulation has focused on improving the basic estimators, applying the methodology to other system performance measures, extending the theory and methodology to more general classes of stochastic processes, and identifying conditions on the building blocks of a stochastic model under which the regenerative method is applicable.

Regenerative Processes

Regenerative stochastic processes were originally defined by Smith (1955, 1958). The following discussion focuses on processes that evolve in continuous time, but the results carry over to discrete-time process in a straightforward manner – indeed, one can obtain results for a discrete-time process $\{X_n : n \geq 0\}$ by simply applying continuous-time theory to the process $\{X_{\lfloor t \rfloor} : t \geq 0\}$, where $\lfloor x \rfloor$ denotes the largest integer less than or equal to x.

A stochastic process $\{X(t) : t \geq 0\}$ with state space S is a regenerative process in continuous time if there exists an increasing sequence $0 \leq T_0 < T_1 < T_2 < \cdots$ of almost surely (a.s.) finite random times such that the post-T_k process $\{X(T_k + t) : t \geq 0; \tau_{k+l} : l \geq 1\}$

1. Is distributed as the post-T_0 process $\{X(T_0 + t) : t \geq 0; \tau_l : l \geq 1\}$, and
2. Is independent of the pre-T_k process $\{X(t) : 0 \leq t < T_k; \tau_1, \ldots, \tau_k\}$

for $k \geq 1$, where $\tau_k = T_k - T_{k-1}$ for $k \geq 1$. The sequence $\{T_k : k \geq 0\}$ of regeneration points is a (possibly delayed) renewal process that decomposes sample paths of $\{X(t) : t \geq 0\}$ into i.i.d. cycles; the kth cycle is $\{X(t) : T_{k-1} \leq t < T_k\}$. The random variable τ_k defined above is the length of the kth cycle. When $T_0 = 0$ the process $\{X(t) : t \geq 0\}$ is called a nondelayed regenerative process; otherwise, it is called a delayed regenerative process. For a delayed regenerative process $\{X(t) : t \geq 0\}$, the 0th cycle $\{X(t) : 0 \leq t < T_0\}$ need not have the same distribution as the other cycles. Similarly, the length of this cycle – denoted by τ_0 – need not have the same distribution as τ_1, τ_2, and so forth.

Typically, each random point T_k is a stopping time with respect to the $X(t)$ process, in that, for $t \geq 0$, the occurrence or nonoccurrence of the event $\{T_k \leq t\}$ is completely determined by $\{X(u) : 0 \leq u \leq t\}$. In this case, the cycle lengths are determined by the $X(t)$ process, and verifying the regenerative property amounts to showing that for each $k \geq 1$, the distribution of $\{X(t) : t \geq T_k\}$, is distributed as $\{X(t) : t \geq T_0\}$ and is independent of $\{X(t) : 0 \leq t < T_k\}$.

As a simple example of a regenerative process, let $X(t)$ be the number of jobs waiting or in service at time t in a $GI/G/1$ queue, and let T_k denote the kth time at which a job arrives to an empty system, so that $X(T_k) = 1$ for all k. Assume that $T_0 = 0$, so that the simulation starts with such an arrival. Then the random times $\{T_k : k \geq 0\}$ form a sequence of regeneration points for $\{X(t) : t \geq 0\}$. Similarly, if W_n is the waiting time in the queue (exclusive of service time) experienced by the nth job to arrive at the queue, and if

$N(k)$ is the random index of the kth job that arrives and finds the system empty, so that $W_{N(k)} = 0$, then the random indices $\{ N(k) : k \geq 0 \}$ form a sequence of regeneration points for the discrete-time process $\{ W_n : n \geq 0 \}$. An irreducible positive recurrent continuous time Markov chain (CTMC) having a discrete (i.e., finite or countably infinite) state space S is also a regenerative process, with one set of regeneration points comprising the successive times that the chain enters a fixed state $s \in S$, and another set comprising the successive times just after the chain jumps out of a fixed state s. Indeed, such a chain has many sequences of regeneration points that correspond to different choices of s. Discrete-time Markov chains and semi-Markov processes also have regenerative structure, and hence are amenable to regenerative-process theory and methods.

Because a regenerative process has an embedded i.i.d. cycle structure, classical results for i.i.d. random variables can be readily adapted to study the limiting behavior of a regenerative process $\{ X(t) : t \geq 0 \}$ with state space S and regeneration points $\{ T_k : k \geq 0 \}$. E.g., suppose that the process is non-delayed, and for a real-valued function f defined on S, set $Y_k(f) = \int_{T_{k-1}}^{T_k} f(X(u))\, du$ for $k \geq 1$. Also define the function $|f|$ by setting $|f|(s) = |f(s)|$ for $s \in S$. It follows from the definition of a regenerative process that the sequence $\{ (Y_k(f), \tau_k) : k \geq 1 \}$ consists of i.i.d. random pairs. Defining $r(f)$ as before to be a time-average limit, a relatively straightforward application of the strong law of large numbers (SLLN) for i.i.d. random variables establishes the regenerative ratio formula

$$r(f) = \frac{E[Y_1(f)]}{E[\tau_1]}, \tag{1}$$

provided that $E[\tau_1] < \infty$ and $E[Y_1(|f|)] < \infty$. This SLLN for regenerative process illustrates one sense in which the steady-state behavior is determined by the behavior of the process within a cycle.

This result can be extended to steady-state and limiting expected values. Specifically, call a real-valued random variable X aperiodic if there exists no real number d such that $\sum_{n=0}^{\infty} P\{ X = nd \} = 1$. In the literature such random variables are also called non-arithmetic or non-lattice. If, in addition to the foregoing assumptions for the SLLN, it also holds that $\{ X(t) : t \geq 0 \}$ has right-continuous sample paths and that τ_1 is aperiodic, then there exists a random variable X having state space S such that $\lim_{t\to\infty} P\{ X(t) \leq x \} = P\{ X \leq x \}$ for all x at which the function $F(x) = P\{ X \leq x \}$ is continuous; i.e., $X(t)$ converges in distribution to X as $t \to \infty$, denoted by $X(t) \Rightarrow X$. For any function f having a set $D(f)$ of discontinuity points, the continuous mapping theorem ensures that $f(X(t)) \Rightarrow f(X)$ as $t \to \infty$, provided that $P\{ X \in D(f) \} = 0$; moreover, it follows from some basic results in renewal theory – see, e.g., Asmussen (2003) – that $r(f) = E[f(X)]$. That is, $r(f)$ can be interpreted not only as a time-average limit, but also as a steady-state expected value. Finally, if the process $\{ f(X(t)) : t \geq 0 \}$ is uniformly integrable, then a classical result from probability theory shows that $\lim_{t\to\infty} E[f(X(t))] = E[f(X)] = r(f)$, so that $r(f)$ can also be viewed as a limiting expected value. (A stochastic process $\{ Y(t) : t \geq 0 \}$ is uniformly integrable if $\lim_{c\to\infty} \sup_t E[|Y(t)| I(|Y(t)| > c)] = 0$, where $I(A)$ denotes the indicator of event A.)

The Standard Method

The power of the ratio formula (1) lies in the fact that it reduces the problem of estimating steady-state quantities – such as time-average limits or steady-state expected values – to a classical ratio-estimation problem in statistics. The goal of ratio-estimation methods is to obtain point estimates and confidence intervals for quantities of the form $r = E[U]/E[V]$, based on i.i.d. samples $(U_1, V_1), (U_2, V_2), \ldots, (U_n, V_n)$ from the joint distribution of (U, V). In the current setting, $U_i = Y_i(f)$ and $V_i = \tau_i$.

The standard version of the regenerative method simply applies the delta method from statistics to estimate the ratio of interest. Specifically, suppose that a fixed number n of cycles of $\{ X(t) : t \geq 0 \}$ have been observed, so that observations $Y_1(f), Y_2(f), \ldots, Y_n(f)$ and $\tau_1, \tau_2, \ldots, \tau_n$ are available. Set

$$\hat{r}(n) = \frac{\bar{Y}(n)}{\bar{\tau}(n)}, \tag{2}$$

where $\bar{Y}(n) = (1/n) \sum_{k=1}^{n} Y_k(f)$ and

$$\bar{\tau}(n) = \frac{1}{n}\sum_{k=1}^{n} \tau_k. \quad (3)$$

A simple application of the SLLN for i.i.d. random variables shows that $\lim_{n\to\infty}\hat{r}(n) = r(f)$ a.s.; i.e., $\hat{r}(n)$ is strongly consistent for $r(f)$. Similarly, application of the classical central limit theorem (CLT) to the i.i.d. random variables $Z_1, Z_2, \ldots, Z_n$ – where $Z_i = Y_i(f) - r(f)\tau_i$ for $1 \le i \le n$ – leads to the following CLT. Set

$$s^2(n) = (n-1)^{-1}\sum_{i=1}^{n} (Y_i(f) - \hat{r}(n)\tau_i)^2. \quad (4)$$

Here $s^2(n)$ is a consistent estimator of the common variance of the Z_i's. Then, if $E[\tau_1^2] < \infty$, $E\left[Y_1^2(|f|)\right] < \infty$, and $\mathrm{Var}[Z_i] > 0$,

$$\frac{\sqrt{n}(\hat{r}(n) - r(f))}{s(n)/\bar{\tau}(n)} \Rightarrow N(0,1)$$

as $n \to \infty$, where $N(0,1)$ is a standard (mean 0, variance 1) normal random variable. That is, for large n, the distribution of the estimator $\hat{r}(n)$ is approximately normally distributed with mean $r(f)$ and variance $s^2(n)/(n\bar{\tau}^2(n))$. These results immediately lead to the standard regenerative method, which proceeds as follows. Fix $p \in (0,1)$ and let z_p be the unique nonnegative real number such that $P\{-z_p \le N(0,1) \le z_p\} = p$. Then

1. Select a sequence $\{T_k : k \ge 0\}$ of regeneration points for the process $\{X(t) : t \ge 0\}$.
2. Simulate the process $\{X(t) : t \ge 0\}$ and observe a fixed number n of cycles defined by the random times $\{T_k : k \ge 0\}$.
3. Compute the length τ_k of the kth cycle and the quantity $Y_k(f) = \int_{T_{k-1}}^{T_k} f(X(u))\,du$ for $1 \le k \le n$.
4. Form the strongly consistent point estimate $\hat{r}(n) = \bar{Y}(n)/\bar{\tau}(n)$ for $r(f)$.
5. Form the asymptotic $100p\%$ confidence interval

$$\left[\hat{r}(n) - \frac{z_p\, s(n)}{\bar{\tau}(n)\sqrt{n}}, \hat{r}(n) + \frac{z_p\, s(n)}{\bar{\tau}(n)\sqrt{n}}\right]$$

for $r(f)$.

For simplicity, the key limit theorems that underlie the regenerative method have not been presented here in their strongest possible forms; the necessary conditions for these theorems, and hence for applicability of the method, can be weakened in a variety of ways; see, e.g., Asmussen (2003) and Glynn and Iglehart (1993).

The regenerative method also applies directly to a wide range of performance measures other than simple time-average limits and steady state means of the $X(t)$ process. A key observation is that the foregoing ratio estimation methods work for any random pair (U, V) such that U and V are each completely determined by the behavior of the $X(t)$ process within a cycle; the pair $(Y(f), \tau)$ is only one possibility. For example, suppose that $\{X(t) : t \ge 0\}$ is a regenerative process having a discrete state space and piecewise-constant sample paths (as in the case of a continuous-time Markov chain). Let $U_i =$ the number of transitions from a fixed state s_1 to another fixed state s_2 during the ith cycle and $V_i =$ the total number of state transitions during a cycle. Then by applying the regenerative method with U_i and V_i replacing $Y_i(f)$ and τ_i as the input data, one obtains a point estimate and confidence interval for the long-run fraction of state transitions that go from s_1 to s_2. Similarly, performance measures such as discounted rewards and mean time to failure fall within the ratio-estimation framework (Haas 2002, p. 249), as do many performance measures involving delays in discrete-event systems. More generally, the delta method can be applied to permit estimation of smooth nonlinear functions of one or more time-average limits, i.e., performance measures of the form $\alpha = g(r(f_1), r(f_2), \ldots, r(f_l))$, where g is a differentiable nonlinear function and each $r(f_i)$ is a time-average limit of the form discussed previously.

When multiple sequences of regeneration points are available, as in the CTMC setting, a natural question is whether the choice of regeneration-point sequence makes a difference and, if so, which sequence to choose. In general, some quantities in regenerative simulation are sensitive to the particular choice of regeneration points and other quantities are not. For example, the expected length of the confidence interval for $r(f)$ based on a simulation of length t (see below) is asymptotically insensitive to the choice of regeneration points as $t \to \infty$, whereas the variance of the confidence-interval length is extremely sensitive to the choice of regeneration points. See Calvin (1994) for a detailed discussion of this issue.

Variants

Many variants of the basic method have been proposed. Some of these concern the run length of the simulation. One variant, for example, runs the simulation until a fixed (simulated) time t. Point estimates and confidence intervals are computed as above, except that statistics are computed for the random number $n(t)$ of cycles completed by time t. Other variants attempt to automatically determine the number of cycles to simulate so as to achieve a desired precision, either based on an initial pilot sample or by means of a fully sequential estimation procedure.

Various researchers have adapted the regenerative method to estimate steady-state quantities other than means, such as quantiles, central moments, discounted costs, extreme values, and mean time to failure in highly reliable systems. Regenerative simulation can also be used for estimating the gradient of a performance measure that depends on a parameter, such as $dh(\theta)/d\theta$, where $h(\theta) = E_\theta[f(X, \theta)]$; see, e.g., (Asmussen and Glynn 2007, Sec. VII.4) and (Haas 2002, Sec. 6.3.6). Here $X(t) \Rightarrow X$, the function f depends explicitly on θ, and the subscript θ on the expectation operator indicates that the distribution of the regenerative process $\{ X(t) : t \geq 0 \}$ depends on θ.

One serious concern with the standard method is that, even if a sequence of regeneration points exists, the regenerations will not occur frequently enough for the method to be practical. Several algorithm variants therefore try to increase the frequency of regenerations. Andradottir et al. (1994) provide such a scheme for Markov processes. Another example is the almost regenerative method; see Calvin et al. (2006) for a discussion and references.

A number of approaches modify the standard estimator in an attempt to reduce the bias, using, e.g., jackknifing techniques. In the case of simulation until a fixed time t, Meketon and Heidelberger (1982) show that bias can be reduced simply by continuing the simulation until the first regeneration point $T_{n(t)+1}$ after time t. Results of Awad and Glynn (2007), however, indicate that the results of such efforts can be mixed.

Similarly, a number of authors discuss various schemes for reducing the variance of the standard point estimator for the regenerative method. Some of these schemes adapt classical variance reduction methods for i.i.d. random variables – such as control variates, importance sampling, or conditional Monte Carlo – to the regenerative setting. Other approaches exploit particular properties of the system being simulated, e.g., a queueing system or a Markov model of a highly reliable system, to obtain a hybrid simulation-analytic method. Several approaches that are specific to the regenerative setting apply to simulations with multiple sequences of regeneration points, and use resampling or stratified-sampling methods to reduce the variance; see, e.g., Calvin et al. (2006).

Extensions

Some key extensions to the regenerative method, important both theoretically and practically, center around generalizations of regenerative processes that allow some limited dependence between cycles. One setting in which such processes arise is related to estimation of time-average limits for a sequence of delays that is defined in terms of an underlying regenerative process. It is common in such settings that a delay can begin in one cycle and end in another cycle, so that the delay sequence does not inherit the regenerative property. Another setting concerns Markov chains having a general (possibly uncountable) state space. Such chains can be viewed as fundamental processes underlying discrete-event systems. E.g., generalized semi-Markov processes (GSMPs) and stochastic Petri nets (SPNs) – both well-studied frameworks for specification of discrete-event systems – are defined in terms of a general state space Markov chain (GSSMC) that records the physical state of the system along with nonnegative, real-valued "clock readings," i.e., the remaining times until various events are scheduled to occur (Haas 2002; Shedler 1993). In general, sequences of regeneration points for GSSMCs cannot be directly constructed as for Markov chains having a discrete state space, since the probability that a GSSMC hits a given state is often 0.

In the case of delays, it can often be shown (Haas 2002, Sec. 8.2) that the delay sequence of interest is an od(one-dependent)-regenerative process. For such a process, the cycles are identically distributed and one-dependent, in that the ith and $(i + k)$th cycles are independent unless $k = 1$ (Henderson and Glynn 2001; Sigman 1990). The SLLN for regenerative process carries over unchanged to the od-regenerative setting.

The extended regenerative method for obtaining point estimates and confidence intervals looks almost like the standard regenerative method, but the variance constant appearing in the regenerative CLT contains a covariance term that involves adjacent cycles. Alternatively, one can apply a multiple runs method in which cycles are simulated independently and then "glued" together to form a (classically) regenerative process having the same time-average limit as the original process (Glynn 1994; Haas 2002). The standard regenerative method can then be applied to this latter process; if the cycle variables $Z_i = Y_i(f) - r(f)\tau_i$ are positively correlated, then the multiple runs method will have higher asymptotic efficiency than the extended regenerative method.

Analysis of GSSMCs, on the other hand, leads to the notion of an od-equilibrium process. Such a process satisfies all of the properties of an od-regenerative process and, moreover, the cycle lengths are i.i.d.. It follows that a SLLN holds (as with an od-regenerative process) and, in principle, the extended regenerative method and multiple runs methods may be applied to obtain point estimates and confidence intervals for steady-state means. Moreover, the regeneration points form a renewal process and – under appropriate aperiodicity and uniform integrability assumptions – the time-average limit can be interpreted as a steady-state and a limiting expected value. Thus estimation can proceed in essentially the same manner as for a classical regenerative process. The link to GSSMCs rests on a splitting argument, which shows that a GSSMC is an od-equilibrium process if it is Harris recurrent; see, e.g., Meyn and Tweedie (1993), Thorisson (2000), or Henderson and Glynn (2001) for details. Harris recurrence generalizes the notion of recurrence for a Markov chain with a discrete state space, and roughly asserts that a dense enough set of states is visited by the chain infinitely often with probability 1. The key impediment in practice is that actually identifying the od-equilibrium points (i.e., the cycle boundaries) appears to be extremely difficult in general; Henderson and Glynn (2001) explore this issue in detail. On the other hand, Glynn (1994) shows that all well-posed simulations have this type of regenerative structure, and there exist examples of Harris recurrent GSSMCs for which od-equilibrium points can be found.

If the definition of an od-equilibrium process is weakened by dropping the requirement that cycles be one-dependent (so that the cycles are merely stationary but the cycle lengths are i.i.d.), one obtains the class of equilibrium processes (Smith 1955), also called wide-sense regenerative processes (Thorisson 2000). Such processes are also related to the notion of renovating events in queueing networks (Foss and Kalashnikov 1991). Since renewal theory can be applied to such processes, results for steady-state means follow as for ordinary regenerative processes.

Conditions for Applicability

From a practical point of view, it is important to determine whether the regenerative method is applicable to a specific simulation of interest. Typically, some sort of modeling framework is used to specify a simulation model of the system under study, with either application-specific building blocks – such as robot arms and conveyor belts for manufacturing simulations – or general frameworks such as networks of queues, SPNs, event graphs, stochastic automata, and GSMPs. Thus the question is: what are the conditions on the building blocks of a simulation model under which steady state quantities are well defined and the regenerative method is valid?

For systems where the regenerative method is potentially applicable, it is often apparent that the underlying stochastic process probabilistically restarts, e.g., whenever the process is in a specified state and a specified event occurs (such as at an arrival to an empty $GI/G/1$ queue). It can be difficult, however, to verify that such restarts occur infinitely often with probability 1. It is even harder to determine whether the random time between successive regenerations has finite moments. Thus, establishing the validity of the regenerative method often amounts to establishing recurrence properties for the simulation model of interest.

Sufficient recurrence conditions for applicability of the regenerative method have been established in the specific setting of closed networks of queues – see, e.g., Kaspi and Mandelbaum (1992) – and in more general settings such as finite-state GSMPs and stochastic Petri nets. In these latter settings, one set of sufficient conditions for recurrence (Glynn and Haas 2006; Haas 2002) requires roughly that (1) the system be irreducible in that between any two states s and s' there exists a sequence of events that leads from s to s'

with positive probability, and (2) the clock-setting distributions used to stochastically schedule events have finite moments and densities that are positive on a common interval $(0, \varepsilon)$. In this case recurrence is established by first establishing Harris recurrence of the underlying GSSMC using arguments based on stochastic Lyapunov functions. An alternative approach based on geometric trials arguments (Haas 2002; Shedler 1993) avoids the positive density assumption but requires detailed knowledge of system behavior.

Relation to Other Methods

In general, many steady-state simulation methods can be viewed as exploring the behavior of the reward $r(f,t) = \int_0^t f(X(u))\,du$ as t becomes large. Under fairly general conditions, there exist constants $r(f)$ and $\sigma^2(f)$ such that $r(f,t)/t \to r(f)$ a.s. and $\mathrm{Var}[\mathrm{r(f,t)}]/\mathrm{t} \Rightarrow \sigma^2(\mathrm{f})$ as $t \to \infty$. The goal of the simulation is to estimate the time-average limit $r(f)$ and the time-average variance constant (TAVC) $\sigma^2(f)$ – given estimates $\hat{r}(f)$ and $\hat{\sigma}^2(f)$ of these quantities, the reward $r(f,t)$ and its variance can then be easily approximated as $r(f,t) \approx t\hat{r}(f)$ and $\mathrm{Var}[\mathrm{r(f,t)}] \approx \mathrm{t}\hat{\sigma}^2(\mathrm{f})$ when t is large. Examples of steady-state estimation methods include batch-means methods, spectral methods, the autoregressive method, and a variety of methods based on standardized time series, including the method of integrated paths (Calvin 2009).

Based on a simulation until time t, virtually all steady-state simulation methods estimate $r(f)$ by $\bar{r}(f,t) = r(f,t)/t$. The regenerative method essentially uses this estimator also. Indeed, the estimator of $r(f)$ based on simulation until time t is $\hat{r}(n(t))$, where $n(t)$ is the number of regenerative cycles completed by time t and $\hat{r}(n)$ is given by (2). This estimator differs from $\bar{r}(f,t)$ by a (random) remainder term that becomes negligible for large t. The key difference between estimation methods lies in how they estimate the TAVC.

When $\{X(t) : t \geq 0\}$ is a regenerative process, it can be shown that, under appropriate moment and regularity conditions, the TAVC has the representation $\mathrm{Var}[\mathrm{Y_1(f)} - \mathrm{r(f)}\tau_1]/\mathrm{E}[\tau_1]$ – see Henderson and Glynn (2001) – and can thus be consistently estimated by $s^2(n(t))/\bar{\tau}(n(t))$, where the quantities $\bar{\tau}(n)$ and $s^2(n)$ are defined as in (3) and (4). Note that the TAVC and the variance term in the previous CLT for regenerative process differ slightly, because the CLT is expressed in terms of number of cycles rather than simulated time. As discussed in Henderson and Glynn (2001), the mean squared error (MSE) of the regenerative estimate of the TAVC typically decreases at a rate of $O(t^{-1})$, whereas the MSE for all other known methods decreases at a strictly slower rate. On the other hand, these other methods can often be applied in practice to simulations for which regeneration points of sufficient frequency cannot be found.

Concluding Remarks

The standard regenerative method can only be applied to simulations having a sequence of identifiable regeneration points that occur with sufficient frequency. When applicable, however, the method provides a clean and simple solution to the problems of initialization bias and autocorrelation that are fundamental to steady-state analyses. For this reason, the regenerative method was the first mathematically rigorous method proposed for steady-state simulation analysis. Moreover, the point estimates and confidence intervals obtained from the regenerative method often have superior asymptotic properties relative to other output-analysis methods. Virtually all well-posed steady-state simulations have a form of regenerative structure, namely, the od-equilibrium property, making extensions of the standard regenerative method to this setting an important research area.

Regression Analysis

Irwin Greenberg
George Mason University, Fairfax, VA, USA

Introduction

In almost all fields of study, the researcher is frequently faced with the problem of trying to describe the relation between a response variable and a set of one or more input variables. Given data on input (predictor, independent) variables labeled x_1, x_2,. . ., x_p and the associated response (output, dependent) variable y, the objective is to determine an equation relating output to input. The reasons for developing such an equation include the following:

1. To predict the response from a given set of inputs.
2. To determine the effect of an input on the response.
3. To confirm, refute, or suggest theoretical or empirical relations.

To illustrate, the simplest situation is that of a single input for which a linear relation is assumed. Thus, if the relation is exact, it is given for appropriate values of β_0 and β_1 by

$$y = \beta_0 + \beta_1 x. \tag{1}$$

The determination of β_0 and β_1 in this case is easy, requiring only two distinct pairs of observations (x_1, y_1) and (x_2, y_2).

In general, the problem is more complex in that the response is not given exactly by (1). This may be true because, although the relation is theoretically given by (1), the observations are not measured without error. Alternatively, there may be no theoretical justification for an exact linear relation but it is used as an approximation.

A model, commonly used in both cases, is

$$y = \beta_0 + \beta_1 x + e. \tag{2}$$

Here e denotes the measurement error or other random fluctuations in y which cause the response to depart from (1); it is assumed that the input variables are either specified by the user or measured without error.

The appropriate analysis of (2) is dictated by the assumptions made on the distribution of errors. Typically, it is assumed that the errors have mean zero and variance σ^2 and that the errors associated with distinct observations are uncorrelated. That is, if a very large number of pairs (x_i, y_i) were observed for a situation modeled by (2), then (a) the errors

$$e_i = y_i - \beta_0 - \beta_1 x_i \tag{3}$$

would average to zero; (b) the error associated with one observation would in no way influence any other error; and (c) the mean of the squares of the errors would be σ^2.

Based on n pairs of observations (x_i, y_i), $i = 1,\ldots,n$, the objective of the analyst is to estimate β_0, β_1, and σ^2 and to make inferences about these parameters. In addition, it may be desirable to indicate the precision of a prediction obtained for a given input when the estimates b_0 and b_1 of β_0 and β_1 are used in (1). These inferences require further specification of the distribution of the errors. The classical results are developed assuming a Gaussian (or normal) distribution.

A generalization of this simple model is the multiple linear regression model

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_p x_p + e. \tag{4}$$

Here the assumption on the errors is the same as given above and the analysis is to be based on $n(p+1)$- tuples $(x_{1i}, x_{2i},\ldots,x_{pi}, y_i)$, $i = 1,\ldots, n$. The sense in which (4) is a linear model must be emphasized. As written, the average response in (2) is a linear function of x and in (4) is a linear (planar) function of $x_1,\ldots,x_p$, but this is not the essential linearity. The critical feature is that the average response is a linear function of the coefficients β_0, β_1, $\ldots$, β_p The variables indicated by y and x_i, $i = 1, \ldots, p$ may represent functions of the variables which are actually observed as long as these functions do not depend on unknown parameters. For example, the model

$$\log\ z = \beta_0 + \beta_1/w + e \tag{5}$$

does not represent z as a linear function of w, but by letting $y = \log z$ and $x = 1/w$ this model is seen to be equivalent to (2). Similarly, the polynomial model

$$y = \beta_0 + \beta_1 x + \beta_2 x^2 + e \tag{6}$$

is a special case of (4) with $x_1 = x$ and $x_2 = x^2$.

Classical Least-Squares Analysis

The estimation of the unknown parameters in the general linear regression model is most frequently achieved by the method of least squares. Given n observations (or cases) $(x_{1i}, x_{2i},\ldots,x_{pi}, y_i)$, $i = 1, \ldots, n$, let the ith residual be

$$e_i = y_i - \beta_0 - \sum_{j=1}^{p} \beta_j x_{ij}.$$

The method of least squares determines values, b_j, as estimates of β_j so as to minimize the sum of squared residuals. The estimated regression function (predicted value) for the ith set of inputs, $\hat{y}_i$, and the estimated residual r_i are given by

$$\begin{aligned} \hat{y}_i &= b_0 + \sum_{j=1}^{p} b_j x_{ij} \\ r_i &= y_i - \hat{y}_i \end{aligned} \tag{7}$$

There are essentially two major advantages of this method. The first is computational, since the method only requires the solution of a system of linear equations. The second is statistical, in that the estimates possess desirable small sample properties. In particular, the b_j are unbiased estimates of the β_j which have minimum variance in the class of estimators which are unbiased. Further, the assumption of normality allows for simple inferences on the β_j The estimate of σ^2 is also unbiased and minimum variance.

Note that these properties refer to the $(x_1, x_2,\ldots, x_p, y)$ relationship and not to the underlying variables. For example, the b_0 and b_1 values derived to estimate the β_0 and β_1 of (5) provide unbiased estimators of $\log z$, not of z, and minimize the sum of the squares of the deviations from the linear plot of $\log z$ vs. $1/w$, not from the curvilinear plot of z vs. w.

With the advent of high-speed computing, the computational advantage is less compelling than in the past. This has encouraged a study of alternatives to least squares, some of which will be described subsequently.

Departures from the Classical Assumptions

The standard analysis assumes that the model is correct and that the data are good. In practice, this is rarely the case and it is essential that the violations be detected and evaluated. Some of the main problems are the following:

1. Incorrect functional form for the regression function. Additional variables and/or different functions of the variables may be required.
2. Violations of the assumptions of independence, constant variance, and normality of errors.
3. Outliers and extreme points. The former are observations in which the response is abnormally large or small and the latter are cases in which the inputs are different from the rest of the data.
4. Multicollinearity among the input variables, that is, nearly exact linear relations among subsets of the input variables. This includes the case where one of the inputs is nearly constant.

One or more of these problems may completely invalidate the analysis. Several additional indicators have been proposed to address these possibilities. Unfortunately, there are no guaranteed solutions to any of the problems cited. The following remedies are typical but must be used with caution.

1. Nonuniform residual plots may suggest nonlinear functions. Individual points that are outstanding may suggest other variables that could be included, especially categorical variables defining subgroups of cases.
2. The most common cause of variance inhomogeneity is that the variance is proportional to one of the inputs. Division of the equation by this variable, or some power of it, will help. Normality may be achieved by transformations.
3. Outliers and extreme points may be deleted from the analysis but care must be taken, as these may be valid, informative observations. Alternatively, one of the robust procedures might be used.
4. An eigenvector analysis may identify the multicollinearity, but the action to be taken depends on the cause. If the linear relation is inherent in the system being modeled and the relation is strong, it may be appropriate to eliminate one of the variables in the relation. If the apparent linear relation is due to the peculiarities of the particular sample, then, if possible, additional data should be taken which are more uniformly spread over the sample space. Alternatively, one might simulate this by using ridge regression or a related method.

Alternatives to Classical Least Squares

Since least-squares analysis is vulnerable to departures from the basic assumptions, several alternatives have been suggested.

One of best known of these alternatives is robust regression, where the basic idea is that observations with large residuals are given less weight and hence become less influential.

When multicollinearities are present, least squares estimates of the coefficients may be abnormally large or even have the wrong sign. Ridge regression is the method that effectively adjoins fictitious data.

One of the oldest modifications of least squares is that of eliminating variables. This has been a confusing and controversial topic primarily because it has often applied indiscriminately to data that have not been subjected to proper diagnostics. Variable elimination only should be applied after the data have been examined for extremes, outliers, and multicollinearities, and appropriate action has been taken. Variables that are then not contributing to the description of the response may be eliminated.

An alternative to eliminating variables, implemented in most of the popular statistical software packages, is stepwise regression. The most significant of the x_i are determined and the parameters of (1) are estimated. New x variables are added to the equation until the resulting decrease in the portion of the variance of errors not explained by the regression becomes statistically insignificant.

Relaxed Problem

The term given to a constrained optimization problem in which some of the constraints have been weakened or relaxed. In particular, it is applied to an integer-programming problem in which the variables are no longer restricted to be integer. The objective function of the relaxed problem serves as a bound for the original problem.

See

► Integer-Programming Problem

Reliability

The ability of a component or system to be operable when called upon to do its intended job. Reliability is most often quantified as the probability that the component or system has not failed (is alive) at a particular time: $R(t) = \Pr\{\text{ lifetime} > t\} = 1 - F(t)$, where F is the cumulative distribution function of the lifetime of the component or system. This reliability function is often also called the survival function.

Reliability of Stochastic Systems

Donald Gross
George Mason University, Fairfax, VA, USA

Introduction

Quality is a ubiquitous concept, from newer developments such as quality circles and total quality management to old standbys such as quality control and quality assurance. Intricately related to quality,

in fact, a necessary ingredient, is reliability, loosely defined as the probability that a system, subject to random failures, will perform properly over some time span of interest. This definition shall be made more precise in the following. One might be able to have reliability without quality, but one can never have quality without reliability.

The major issue here is a consideration of the probability structure of systems made up of individual components, each with a known lifetime density, say, $f_i(t)$. The two basic combinations of system design are the series and parallel systems, with more complex structures built up from these. By series it is meant the arrangement whereby any single item's failure leads to total system failure. For the parallel case, all component devices must fail for total system failure.

There are a number of important variations on the parallel theme. They differ in the manner in which the set of devices are permitted to operate simultaneously and if not, what form of switch is necessary to call upon any alternative. When all are going together, such a system is called parallel redundant. When items are not in use but waiting to be switched to use if needed, and the items not in use do not deteriorate with age, the structure is said to be a cold standby system. The hybrid combination which finds the standby elements possibly aging at a slower pace than if they were in use is called a warm standby system. If items not in use age at the same rate as they do when in use, then the system is often referred to as a hot standby system and is equivalent to a parallel redundant system as long as the switching mechanism which brings the standby item on line when the operating item fails is itself 100% reliable (zero probability of failing).

Lifetime Probabilities

The direct application of the basic laws of probability permits the easy derivation of the lifetime probabilities associated with each of these fundamental structures. The cumulative distribution function (CDF) for the simple series system without maintenance is

$$F(t) = 1 - \prod_{i=1}^{n} [1 - F_i(t)]$$

where $F_i(t)$ is the lifetime CDF of the ith component. This result is made slightly more compact by defining a reliability function $R(t)$ as the complementary CDF, $1 - F(t)$, namely, the probability of a lifetime longer than t. Then the system reliability may be written in terms of the component device reliabilities as

$$R(t) = \prod_{i=1}^{n} R_i(t).$$

In the special case where each component's life follows the exponential distribution with parameter λ_i,

$$R(t) = \exp\left(\sum_{i=1}^{n} \lambda_i t\right).$$

For the parallel redundant (or hot standby with a 100% reliable switch) case, the system lifetime CDF is

$$F(t) = \prod_{i=1}^{n} F_i(t)$$

and thus, its reliability function is

$$R(t) = 1 - \prod_{i=1}^{n} F_i(t).$$

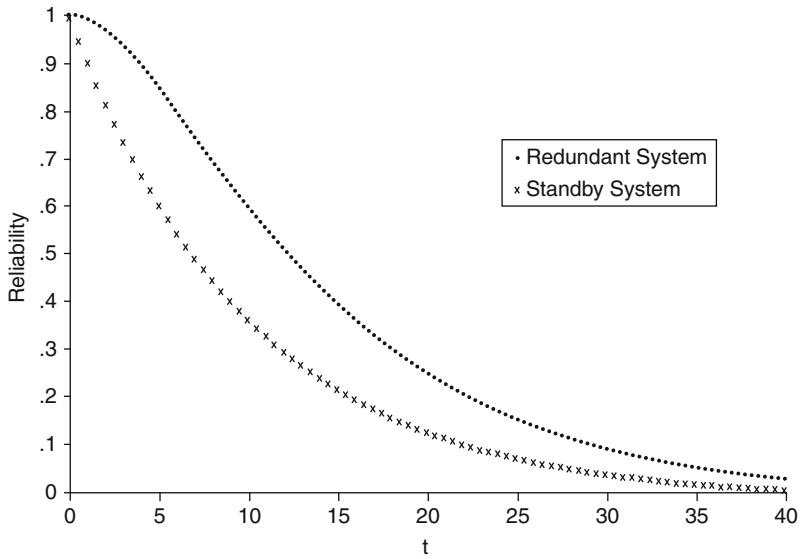
In the event that the devices are independent and identically distributed exponential distributions with parameter λ, then

$$F(t) = [1 - \exp(-\lambda t)]^n.$$

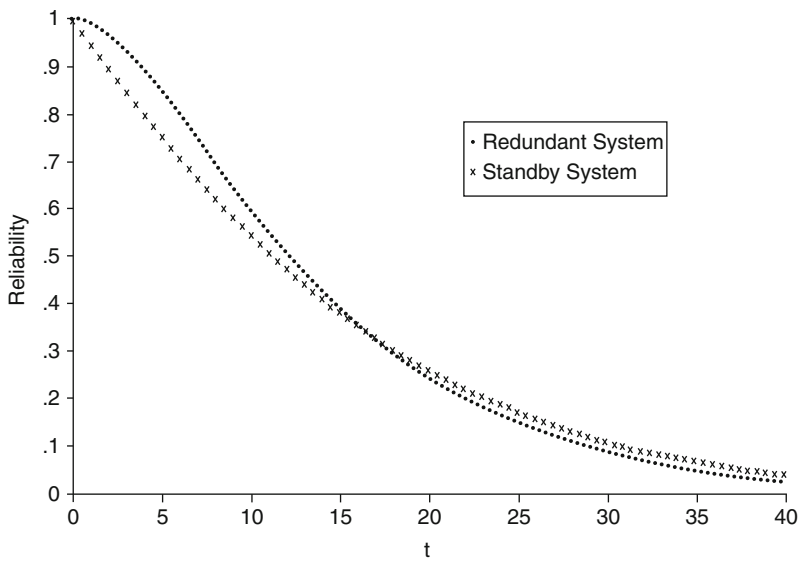
In the special case where $n = 2$, the exponential system has reliability function

$$R(t) = \exp(-\lambda t)[2 - \exp(-\lambda t)].$$

It is interesting then to compare this result to that for the two-unit exponential parallel cold standby 100% reliable switch system. The latter can be derived as the sum of two probabilities: the probability that the original component lives past time t plus the probability that the original component fails in some time v, $0 \le v \le t$, and the standby component lives longer than $t - v$, integrated over v from 0 to t.

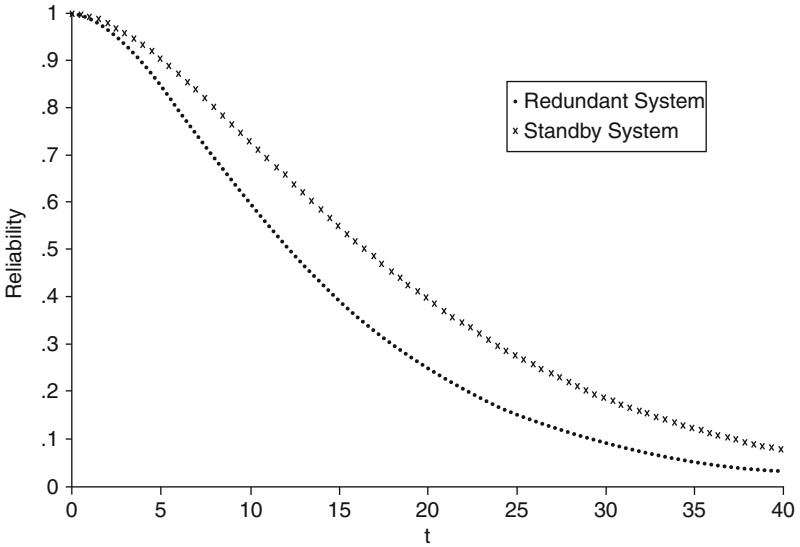


Reliability of Stochastic Systems, Fig. 1 Reliability Function for Redundant & Standby Parallel Systems (switch probability = 0)



Reliability of Stochastic Systems, Fig. 2 Reliability Function for Redundant & Standby Parallel Systems (switch probability = 0.5)

This cold-standby reliability, which, for the case of identical exponential components, turns out to be $R(t) = (1 + \lambda t)\exp(-\lambda t)$, is greater than that of the redundant structure for all values of λ. This result can be easily extended to general n. One can also build in a probability of switch failure for the standby case and observe the effects of an unreliable switch on the relative merits of standby versus redundant systems. If p is the probability that the switch will work, the reliability is adjusted to $R(t) = (1 + p\lambda t)\exp(-\lambda t)$. Figures 1, 2, and 3 show plots of $R(t)$ versus t for $p = 0.5$ and 1, respectively. When the probability of the switch working is zero, the graph shows that the parallel redundant case is superior. When the probability of the switch working is 1, the cold standby case is superior, as seen above. However, when the switch probability is between 0 and 1, as it is for the 0.5 case, there is a point of time where the reliabilities of the parallel redundant and the cold standby cases cross.



Reliability of Stochastic Systems, Fig. 3 Reliability Function for Redundant & Standby Parallel Systems (switch probability = 1)

N-Out-of-K Systems

The parallel redundant system is generalized to define failure if more than $n - k$ of the n components are not working (less than k working). So $R(t) = \Pr\{\text{at least } k \text{ of } n \text{ are up}\}$. Let $p = \Pr\{\text{component works until } t = \exp(-\lambda t)\}$. Then, from the binomial probability law,

$$R(t) = \sum_{i=k}^{n} \binom{n}{i} \exp(-\lambda t i)[1 - \exp(-\lambda t)]^{n-i}.$$

Maintained Systems

In the typical reliability application, failed units are often put into repair. As a first illustration of such a maintained system, consider a single device with time-to-failure exponential, mean $1/\lambda$, and the time to repair exponential, mean $1/\mu$. It then turns out in this simple single-component system that the probabilities that the system is operating or is down at time t, respectively, are

$$p_0(t) = \frac{\mu + \lambda \exp[-(\lambda + \mu)t]}{\lambda + \mu}$$

and

$$p_1(t) = \frac{\lambda\{1 - \exp[-(\lambda + \mu)t]\}}{\lambda + \mu}.$$

The quantity $p_0(t)$ is often called the system availability (written as $A(t)$ since it is the probability that the system is available at time t). The long-run average availability is computed from $A(t)$ as $t \to \infty$ to be $A = \mu/(\lambda + \mu)$.

Next, consider a two-item series system with identical exponential failure distributions and one exponential repair facility. The time-dependent probabilities are found as the solution to a 3×3 system of difference/differential equations; here, only the limiting probabilities are treated. The steady-state availability is the limiting fraction of time no devices are down and is given by $A = \mu^2/(2\lambda^2 + 2\lambda\mu + \mu^2)$. The limiting probabilities that one and two units are down are respectively given as

$$p_1 = \frac{2\lambda\mu}{2\lambda^2 + 2\lambda\mu + \mu^2}$$
$$p_2 = 1 - p_1 - A$$

The final maintained system discussed is the simple two-item exponential parallel redundant structure with repair. Here

$$A = \frac{\mu^2 + 2\lambda\mu}{2\mu^2 + 2\lambda\mu + 2\lambda^2}$$

which is clearly larger than that just presented for the series system.

The Structure Function

For more complicated systems of components, what is commonly called the structure function is a convenient vehicle for characterizing the reliability. First, for any component i, define a binary indicator random variable X_i as 1 if the device is operating and 0 otherwise. The structure function of a system of n components is then written as $\phi(X_1,\ldots, X_n)$ and will likewise be 1 if the system is operating and 0 otherwise. If all the components are queried at time t, then the system reliability $R(t)$ at that point is the probability that $\phi = 1$.

For a full series system then, all X_i must be 1 for ϕ to be 1, so that

$$\phi(X_1,\ldots,X_n) = \prod_{i=1}^{n} X_i.$$

In the pure parallel case, $\phi = 1$ if any $X_i = 1$, so that

$$\phi(X_1,\ldots,X_n) = 1 - \prod_{i=1}^{n} (1 - X_i).$$

The beauty of the structure function is its ability to model the most complex of systems in a fairly natural Boolean way. For example, consider a structure of five components with 1 and 4 in series, parallel with 2 and 5 in series, and also allowing the combination 1, 3, 5 for operation (together called a bridge structure). The system operates as long as at least one of these three combinations is up. Thus

$$\phi(X_1,\ldots,X_n) = 1 - (1 - X_1X_4)(1 - X_2X_5)(1 - X_1X_3X_5).$$

As a general rule, attention is limited to structures that make sense. A system is coherent if

(a) its structure function ϕ is increasing in each argument (that is, ϕ improves as X goes to 1 from 0); and
(b) each component is relevant (that is, its reliability affects system performance).

A fairly complete theory has been developed and is given in Barlow and Proschan (1975).

There is quite an extensive literature on systems reliability and related problems. Barlow and Proschan (1975) and Barlow (1998) are key references, and further material of special importance on systems problems may be found in Kaufmann et al. (1977). Introductory material on systems reliability may also be found in Chapter 12 of Hillier and Lieberman (1990) and Chapter 9 in Ross (2010), with a more advanced treatment in Chapter 9 of Crowder et al. (1991).

Renewal Equation

▶ Renewal Process

Renewal Process

Igor Ushakov
Qualcomm Inc., San Diego, CA, USA

A renewal process is a stochastic point process $\{N(t),\ t \geq 0\}$, where $N(t)$ = number of occurrences by time t, which describes the appearance of a sequence of instant random events where the times between occurrences (e.g., called interarrival times in queueing theory) are a sequence of independent and identically distributed (i.i.d.) non-negative random variables. It is common to write the interoccurrence distribution function as $F(t)$ and its density (if it exists) as $f(t)$, with expected value $1/\mu$. The Poisson process represents a particularly important renewal process in which the intervals between occurrences are exponentially distributed (Cox 1960; Cox and Isham 1980; Feller 1966; Ross 1996; Smith 1955; Wolff 1989).

The renewal equation for the process expectation (or renewal function) $H(t) = \boldsymbol{E}[N(t)]$, plays a fundamental role in all renewal problems:

$$H(t) = F(t) + \int_0^t H(t-x)\, dF(x).$$

The derivative of $H(t)$, $h(t) = dH/dt$, is often called the intensity function and has a simple interpretation: $h(t)dt$ is the approximate probability of an occurrence within the time interval $[t, t + dt]$.

One can write an equation for the intensity function similar to the one above:

$$h(t) = f(t) + \int_0^t h(t-x)\, dF(x).$$

With t increasing, it follows that

$$\lim_{t\to\infty} \frac{H(t)}{t} = \frac{1}{\mu}$$

In a physical sense, this means that, over a large interval of size t, the mean number of events is inversely proportional to the expected interarrival time. This is usually referred to as the elementary renewal theorem (Ross 1996; Wolff 1989).

Very close to the previous statement is the following. If the renewal process is formed by continuous random variables, then

$$\lim_{t\to\infty} h(t) = \frac{1}{\mu}$$

This reflects the fact that with increasing t, the renewal process becomes stationary and its intensity becomes independent of the current time.

A further generalization comes from Blackwell's Theorem, which states for continuous interrenewal-time random variables and an arbitrary interval width $\tau \geq 0$ (Feller 1966; Ross 1996; Wolff 1989):

$$\lim_{t\to\infty} [H(\tau + t) - H(t)] = \frac{\tau}{\mu}$$

The next important result is contained in Smith's Theorem (1955), also known as the key renewal theorem (Ross 1996; Wolff 1989). If the renewal times random variables are continuous and $V(t)$ is a monotone non-increasing function, integrable on $(0, \infty)$, then

$$\lim_{t\to\infty} \int_0^t V(t-x)\, dH(t) = \frac{1}{\mu} \int_0^\infty V(t)\, dt.$$

The actual choice of the function $V(t)$ depends on the particular problem of concern.

Another special point process can be formed by two independent subsequences of random variables that alternate, where a realization of such a process has the sequence $X_1, Y_1, X_2, Y_2, \ldots$. Such a process is called an alternating renewal process when the X and Y subsequences are themselves ordinary renewal processes. An example of such a process is the modeling of equipment failure and repair over time.

Introduction

Products and services have a finite life cycle, and the speed with which they go through their life cycle stages has been continuously increasing. Through the functions in an organization called research and development (R&D), new products and services are developed, existing ones are improved, and the respective transformation processes are improved to increase efficiency and minimize cost.

The worldwide distribution of R&D performance is highly concentrated in several industrialized nations, but large emerging economies like China, India and Brazil have been added to the countries engaged in R&D performance. Part of the R&D activity is aimed at pure research, i.e., research meant for pursuit of knowledge. This research takes place mainly in research laboratories of universities, research centers, government agencies, and major corporations. The other part of R&D activity is made on applied research, in which existing knowledge is used to design new products, services and processes, as well as on development, i.e., the conversion of the results of applied research into the actual transformation systems that will produce the new products and services.

In industry, ideas for R&D projects originate primarily in a firm's R&D department. However, other departments such as marketing, production and engineering are frequent contributors, as is top management. In some cases, suppliers, clients/customers, and government departments are sources of ideas. R&D project management is often difficult, due to the high degree of uncertainty involved, and OR/MS has developed several approaches to help R&D managers. OR/MS has addressed mainly two major problems in R&D management: (1) project evaluation, selection and resource allocation; and (2) project planning and control.

R&D Project Selection

The R&D project evaluation, selection and resource allocation problem deals with the evaluation of candidate R&D projects, and the selection of a subset of such projects to which available R&D resources (manpower, funds, equipment and facilities) will be allocated. Because of the investment commitment, the uncertainties involved, and the impact of the decisions upon the future of the organization, project selection is a very important and difficult problem. As a result, hundreds of papers have been published discussing the problem and suggesting various approaches for its

solution. Early approaches to the solution of the project selection problem were reviewed in several literature survey papers (Augood 1973; Baker and Pound 1964; Baker 1974; Baker and Freeland 1975; Liberatore and Titus 1983; Souder 1972; Souder and Mandakovic 1986). Since then, researchers have proposed several other approaches that introduce improvements over the earlier approaches. Only a small number of all the approaches that have been proposed can be discussed here, indicating the evolution of this area of OR/MS.

Before World War II, the project selection problem was non-existent. Companies were relatively small and competition was limited, which resulted in a limited need to develop new products. There was no distinction between "research" and "development," and the relevant function was not viewed as important. Usually, the chief technical officer would come up with a production related project and pursue it through its implementation. It was after World War II that the business environment changed, increased competition resulted in increased demand for new products/services and improved processes, and R&D project selection became a problem.

Project evaluation and selection methods started appearing in the mid-1950s. The first methods used, called checklists or profile charts, are based on a checklist of criteria. The checklist consists of factors considered to be important to the success or failure of the project, and is used as the basis on which each project is subjectively rated by one or more individuals. The checklist may include both economic and non-economic factors, such as social impacts and environmental concerns. The degree of favorableness of each criterion is checked for each project, with the objective to derive an overall pattern for each project and determine its degree of favorableness.

Because this method does not differentiate among the importance of different criteria and is based on qualitative judgment, scoring models were later developed. These models use weights assigned to both the different criteria and the degree of favorableness of each of them for each project. As a result, a weighted score is computed for each project. For the project scores to be comparable, similar criteria have to be used for all the projects. Different methods have been proposed for deriving the set of weights representative of the preference function of the particular decision maker, such as having the decision maker rank order the criteria or make comparisons of different pairs of projects.

Since these methods give dimensionless results, benefit-cost ratio approaches were developed. The different costs and benefits associated with a project, including non-economic costs and benefits, are expressed in terms of a common measure and their present value computed and expressed as a ratio. Risk factors can also be included in terms of probabilities of research, development and market success. For a project to be considered, its benefit-cost ratio should be greater than one.

The above methods, usually called classical methods, have been used extensively in R&D project evaluation and selection due to their simplicity and ease of use. They can prove useful in preliminary project analysis and screening. However, they cannot solve the project selection problem because they ignore several key aspects. For example, that projects are selected in sequences rather than individually, where the outcome of one affects that of another. Other ignored aspects include the dynamic nature of the R&D environment in terms of project funding at different levels, in which case the value and preferability of a project is a function of its funding level; dynamic resource constraints; and that the set of candidate projects continuously changes over time.

Decision trees were then introduced to deal with sequences of interrelated projects. A decision tree consists of decision nodes and event nodes from which alternative decisions and events, respectively, are branched out. Economic consequences expressed in monetary or utility values for decisions, and probabilities for events are added and, starting at the end of the branches and working backwards, the expected payoff for a sequence of decisions is computed. The optimum sequence of decisions (optimum sequence of projects/sub-projects) can thus be identified. Since the number of events that can be branched out of an event node is limited, stochastic decision trees were developed, where the event nodes are represented by a probability distribution. However, resource constraints cannot be included in a decision tree, which is a serious drawback, amongst others.

With the advent of OR/MS and the wide availability of computers, different portfolio models were developed to overcome the shortcomings of the above methods. Several types of mathematical programming (linear, integer, mixed integer,

zero-one, nonlinear, dynamic, goal, multi-objective, and stochastic) have been used to select a subset of projects that maximizes a particular objective without violating a set of constraints. The objective is usually to maximize the expected net present value of the subset of projects. In addition to providing the optimum portfolio of R&D projects and allocating the budget among them, mathematical programming presents the additional advantage of making sensitivity analysis easy, suggesting ranges of solutions, and answering what-if types of questions. However, the optimality of the portfolio is a function of the assumptions associated with each particular type of mathematical programming and the estimates used in the input data. This, combined with the difficulty on the part of decision-makers in understanding the mathematical aspects of the models, has resulted in limited reported successes of the portfolio models in terms of actual implementation.

During the 1970s, issues regarding the usefulness of the existing methods for solving real life R&D project selection problems and their acceptability by R&D managers were widely discussed. Two studies by Baker (1974) and Baker and Freeland (1975) identified several limitations of the methods that had been proposed up until that time. Such limitations included the inadequate treatment of uncertainty and risk with respect to benefit contribution and parameter estimation; project and parameter relationships with respect to both benefit contribution and resource utilization; multiple, interrelated decision criteria; the time variant property of data and criteria; and the problems associated with the continuity in the research program and the research staff.

Further limitations were the lack of explicit recognition of the experience and knowledge of the R&D manager; the non-monetary aspects such as establishing and maintaining a balance between basic and applied research, product and process development, in-house and contracted projects, improvement and breakthrough work, and different levels of risk-pay-off opportunities; the perceptions held by R&D managers that the models are difficult to understand and use; and the importance of certain individuals in the R&D organization.

Other limitations include the failure to treat the problem as an intermittent stream of investment alternatives and as a hierarchical diffuse decision process; to include in the model the timing of decisions, the generation of additional alternatives, and project recycling by gathering new information, reformulating criteria, variables and constraints, and defining new alternatives; and to recognize the diversity of projects from basic research to engineering.

Several OR/MS researchers tried to develop approaches that do not have these limitations. As a result, different models have been proposed which take into consideration a particular aspect of the shortcomings of the existing methods. Among the approaches that have been developed, the emphasis has been on multi-objective mathematical programming methods. In this respect, goal programming methods have been developed, where several goals are considered and expressed as constraints, with deviational variables used to express under-achievement or over-achievement of the goals. The objective function minimizes these deviations. The goals can be prioritized, so that their achievement is considered according to their priority sequence.

As difficulties arise in setting the aspiration levels of the goals and in including tradeoffs among goals, multi-objective linear programming methods were used, including multi-attribute utility theory (Ringuest and Graves 1989; Mehrez et al. 1982). In applying multi-attribute utility theory, utility values are assigned to each possible subset of projects for each of the goals and, using integer programming, a list of all non-dominated solutions is generated, consisting of solutions in which the performance in one goal cannot be improved without sacrifice in one or more other goals. One drawback is that the list of non-dominated solutions can be very large in a real life situation, creating a complex selection problem for the decision-maker. Screening methods that have been developed could provide some help in selecting one of the non-dominated solutions.

Several researchers have proposed multi-criteria and multi-objective approaches. Stewart (1991) developed a multi-criteria decision support system for R&D project selection. Medaglia, Graves and Ringuest (2007) have proposed an evolutionary method with partially funded projects, multiple (stochastic) objectives, project interdependencies (in the objectives), and a linear structure for resource constraints. Stewart and Mohamed (2002) have developed a decision-making framework for senior

executives when selecting innovative IT/IS projects, based on the multi-criteria utility theory combined with information economics principles. Guikema and Milke (2003) have proposed a multi-attribute optimization model based on a combination of multi-attribute utility theory, mixed-integer optimization, and statistical analysis. Gabriel et al. (2006) have developed a multi-objective, integer-constrained optimization model using probability distributions to describe costs and the Analytic Hierarchy Process to determine the criterion rank; it integrates multi-objective optimization, Monte Carlo simulation, and the Analytic Hierarchy Process.

Most of the suggested models that are based on mathematical programming techniques have almost exclusively dealt with R&D activities at the micro-level. Oral et al. (1991) have proposed a methodology for collective evaluation and selection of R&D projects at the macro-level (sectorial or national), where the experts participating in the evaluation and selection process are also stakeholders. The evaluation and selection process is based on the "relative values" of a given R&D project from the viewpoint of the other R&D projects, determined through mathematical programming. Oral et al. (2001) have developed a methodology for an international organization which has more than a dozen country members whose units or divisions have different values and preferences; the methodology is based on a multi-criteria disaggregative approach used as an instrument rather than as a descriptive tool that provides a platform to maximize the level of consensus among the member countries.

As projects may depend upon each other with respect to several factors such as cost and technology, cross impact may be significant. Cho and Kwon (2004) have developed an extended model of the Analytic Hierarchy Process called Cross-Impact Hierarchy Process through which a number of dependent technological alternatives are ranked. Kwon et al. (2004) have constructed a model which evaluates R&D projects considering cross impact among them, and selects proper projects to utilize resources efficiently as well as to maximize efficacy of investments. Wey and Wu (2007) have proposed a project selection methodology that reflects interdependence among evaluation criteria and candidate projects using the Analytic Network Process within a zero-one goal programming model.

Mittal and Kanda (2009) use two-phase heuristics based on a two-stage prioritization process of activities for resource allocation. At any decision point the projects are first prioritized as per project selection rule and eligible activities in the projects are then prioritized as per activity selection rule. These heuristics are categorized into look-ahead and non-look-ahead type based on the project selection rules used.

Mohanty et al. (2005) have applied a Fuzzy Analytic Network Process along with fuzzy cost analysis in selecting R&D projects. Fuzzy set theory has been incorporated to overcome vagueness in the preferences of the various stakeholders in an organization, which can differ and often hinder the attainment of consensus and coordination.

A different philosophy in approaching the problem of R&D project selection and resource allocation has been proposed by including in the decision making process the people at every level of the organization who would influence the project selection process. As a result, Behavioral Decision Aids (BDA) have been proposed, that use the output of project selection models, not as a solution to the problem, but as aids to communication and interaction among the parties involved to achieve a consensus. One such approach is Q-Sorting, where each individual is given a stack of cards, each bearing the title or number of one project. Through a series of sorting operations and the use of a specific criterion, the projects are sorted into five piles ranging from very high level of the criterion to very low. Another BDA approach is the Nominal Interactive Decision Process, used in combination with various other methods depending on the type of the project, where consensus is built using a modified Delphi approach.

The Analytic Hierarchy Process has also been used in what is called Decentralized Hierarchical Modeling, where the involved parties communicate electronically until they reach a consensus on the project portfolio. The dialogue takes place among the different hierarchical levels. Top management initiates the process through budgetary guidelines sent to the divisional managers; the divisional managers then send the guidelines, maybe modified, together with suggested prioritized program areas to the R&D

managers; and the R&D managers and their staff propose an R&D portfolio and send it up the hierarchy. The R&D people, in coming up with the portfolio, may use any of the available OR/MS techniques. This process may be repeated several times. Back and forth communication among the different hierarchical levels may take place at any stage of the process.

Another multi-criteria decision approach to R&D project selection has been applied by Henig and Katz (1996). It is based on an objective investigation into the impact of alternatives (portfolios of projects) on attributes and to the subjective evaluation of the decision-maker's preference system. The main stages of this application are: identifying the initial set of projects, their important attributes, and criteria associated with them; consolidating or revising attributes based on the criteria; and evaluating existing and searching for new alternatives based on the reevaluated attributes. This process goes through several iterations and helps the decision-maker to better understand the nature of the problem. The "objective hierarchy" (Keeney and Raiffa 1976) of the decision maker is thus generated and the best alternative can then be found.

There have been a few approaches that have been proposed for large-scale R&D program planning. Such programs involve multiple interdependent technologies. They are initially defined in terms of broad, qualitative policy directives, serve broad constituencies of sponsors, and R&D is performed at separate external organizations or at remote sites within an organization. Decisions regarding resource allocation among projects, establishment of objectives, assignment of projects to program sub-divisions, and scheduling of the projects need to be made. For a decision-support approach and pertinent bibliography see Mathieu and Gibson (1993).

Hueth et al. (2008) have proposed a mixed integer programming model that selects projects worthy of investment in a public utility company (a major Latin America water and sewage company). It maximizes the weighted sum of normalized economic and financial net present values and a social impact index. Buchanan and Vanderpooten (2007) describe a project selection methodology which incorporates a decision support tool (ELECTRE III), developed by a New Zealand electric generator, used in ranking and selecting projects.

Project Planning and Control

The second major area of R&D management to which OR/MS has made a significant contribution is project planning and control. Several approaches have been developed in this area as well.

One of the first approaches is Program Evaluation and Review Technique (PERT), developed in 1958 for planning and controlling the Polaris Fleet Ballistic Missile project by the Navy Special Projects Office and Lockheed Aircraft Corporation, in cooperation with Booz, Allen and Hamilton. In using PERT, the project is represented by a network, consisting of events (nodes) standing for specific accomplishments at a point in time, or milestones, and activities (arrows) representing the actual performance of a task. The events and activities follow one another in their proper technological and logical sequence, and the PERT network, also called the precedence relationships network, has a beginning event and an ending event. Activities consume time and resources such as manpower, materials, equipment, funds, and so on, and each activity is represented by the beginning and ending nodes. This means that only one activity can connect two nodes and that the network cannot have a loop.

Activity times are assumed to follow the beta distribution and three time estimates are given for each activity: an optimistic standing for the practically minimum time, a most likely standing for the best estimate of time, and a pessimistic standing for the practically maximum time. On the basis of these estimates, the mean and variance for each activity time is computed, the longest time path is determined (critical path), and the probability of reaching an event or of completing the critical path by a certain scheduled time is computed. The latter is usually taken as the probability of completing the project. Other important information derived from PERT is the earliest start and finish time, the latest start and finish time, and the slack time for each activity. Activities with zero slack time are considered critical activities that require special monitoring to avoid delays in the completion of a project.

At about the same time of the PERT development, the Critical Path Method (CPM) was developed in 1957 at the du Pont Company, in consultation with Remington Rand, in scheduling maintenance

shutdowns of chemical processing plants. PERT is a probabilistic approach whereas CPM is deterministic. CPM uses normal and crash time estimates for each activity, and their associated costs. The normal time estimate would be equivalent to PERT's expected time, and the crash time would be the minimum possible time needed to complete the activity irrespective of cost increases. Aside from these differences, CPM is almost identical to PERT, and for this reason the two techniques are referred to as the PERT/CPM technique. PERT and CPM have generated several variations, modifications, and new techniques with added capabilities and wider applications.

A number of project management software have been developed and continue being developed and updated. Mellentien and Trautmann (2001) have evaluated the resource allocation capabilities of a few of them: Acos Plus 1.8.2, CA SuperProject 5.0a, CS Project Professional 3.0, MS Project 2000, and Sctor Project Scheduler 8.0.1. Among them, Acos Plus.1 and Project Scheduler showed the best resource allocation performance. Several other software have been mentioned in the OR/MS bibliography like P3, MATLAB, Expert Choice, Time Line, Primavera Project Planner, Milestone, and others. There is a long list of current software published in Wikipedia which have been evaluated according to their capabilities. It can be accessed by searching for project management software.

PERT and CPM have been used in a variety of project planning and control situations, including R&D project management. However, some of their underlying assumptions are not always valid. For example, the originally developed network may become irrelevant in the future because of the changed content of a project. Precedence relationships cannot always be specified as they sometimes depend on the outcome of previous activities. Project completion time is not always determined by the longest time path, as a delay in a non-critical activity may result in a longer completion time of the project. The beta distribution is not the only distribution that could be used, the formulae used to estimate its mean and variance may give erroneous estimates compared with the original beta distribution formulae, and the three time estimates may include a high degree of subjectivity (Chase et al. 1998).

In addition to the criticisms of PERT and CPM, their use in R&D project planning and control includes some additional limitations (Clayton and Moore 1972; Pritsker et al. 1989). One of them is that branching from the nodes is deterministic, that is, each activity must be completed before the project is completed. In R&D projects, however, branching is usually probabilistic, for example, successful test and performance of the next stage, failure and abandonment of that part of the project, inconclusive results and repeat of the test. All the activities leading to a node must be realized before the relevant event can be realized, while in R&D projects, given the probabilistic nature of branching, not all activities leading to a node can be realized. Looping is not allowed, though an activity in an R&D project may have to be repeated, for example, a test. Activity times are assumed to be solely described by a beta distribution, while R&D activities may follow different other distributions. One terminal node is allowed (completion of the project) while in R&D one of several end events can be realized, for example, successful completion, failure and abandonment, redesign of the project.

It is obvious that these limitations render PERT inflexible in modeling complex R&D projects. To overcome PERT's limitations, the Graphical Evaluation and Review Technique (GERT) was developed under the assumption that each activity has an associated probability of being selected, ranging from zero to one. As a result, the nodes are constructed differently to denote their nature as deterministic or probabilistic. The realization of a node may be specified to occur upon the realization of one or more of the activities leading to it, it may be realized one or more times, and the first time it is realized the number of activities to be completed may be different from subsequent repeats. Looping in simple or complex forms is allowed. The network can have more than one source node and/or sink node. Modifications of the network following the completion of certain activities can be incorporated. Several types of probability distributions can be used to represent activity times. Cost can be assigned to each activity in terms of a fixed part and a variable per unit time component. Statistics on time, cost, and activity counts for specified activities can be collected for the sink as well as other designated nodes. GERT is a network-simulation approach that has been further

improved into a more powerful version, *Q-GERT*, that allows the inclusion and the simulation of more than one project, can model queues at nodes and route projects through teams based on user established decision rules (Taylor and Moore 1980; Pritsker et al. 1989).

In decision models for GERT networks, cost or time minimization is achieved under the assumption that the selection procedure of activities and the stopping rule are imposed exogenously into the model. However, in classical R&D projects, the activities and technological specifications are selected dynamically throughout the project's duration, and the stopping time of the project is unknown in advance. Granot and Zuckerman (1991) have constructed a model in which the selection procedure of activities and the stopping rule are defined as decision variables to be determined endogenously.

Another network-simulation based technique that was developed after GERT is Venture Evaluation and Review Technique (VERT). VERT, like GERT, has been developed as a technique for analyzing potential outcomes of projects, expected values of various project parameters, and criticality indices rather than for scheduling projects. It is used in assessing the risks involved in undertaking new ventures and in resource planning, control monitoring, and overall evaluation of on-going projects with respect to time, cost, and performance. It is considered to be more powerful than GERT due to the fact that performance enters the network in numerical terms. It can be modeled in terms of any unit of measurement or a dimensionless index. VERT introduced six new types of node logics and the capability of establishing a mathematical relationship between an arrow's parameter values (time, cost, performance) and any other arrow or node's parameter values, as well as mathematical relationships between the time, cost, and performance variables of a given arrow.

There have been several studies that have tried to provide solution approaches to the different complexities of the real R&D project planning and control problem. Hans et al. (2007) have looked into several viewpoints on the management of the planning complexity of multi-project organizations under uncertainty. They proposed a positioning framework to distinguish between different types of project driven organizations and thus aid project management in the choice between the various existing planning approaches. They also introduced a generic hierarchical project planning-and-control framework that serves to position planning methods for multi-project planning under uncertainty.

PERT assumes that activities are independent and they occur in linear sequence. However, R&D activity networks are recursive, reversing to earlier stages for rectification or to incorporate changes. Hardie (2001) has modeled such a network as a Markov process, where the probability of a reversion to an earlier stage is claimed to be the main factor determining project length.

Managing R&D projects under resource constraints is a usual case. Tormos and Lova (2001) have extended the concepts of activity slack and defined a new activity criticality index to classify the activities of the resource constrained project scheduling and control context. These new concepts have been integrated into standard project management software. Pantouvakis and Manoliadis (2006) have developed a heuristic method based on traditional CPM scheduling calculations and leveling algorithms for the resource constrained projects, which can be applied using normal scheduling software such as P3 and MSProject.

As a project is being implemented, it is necessary at some points that management evaluates the progress of the plan, analyze deviations and take appropriate corrective action. Falco and Macchiaroli (1998) have provided a quantitative determination of the optimum control points, based on the definition of an Effort Function. Raz and Erel (2000) have presented an analytical framework for determining the optimal timing of project control points, based on maximizing the amount of information generated by the control points. This depends on the intensity of the activities carried out since the last control point and on the time elapsed since their execution. They have used dynamic programming to solve the optimization problem. Given the uncertainty involved in planning an R&D project, Badri et al. (1997) have developed a simulation based decision support system to analyze the effect of delays in individual activities on the whole project.

A project may have to be terminated, due to technological risks, before completion, with each stage having a specific likelihood of success. Reyck and Leus (2008) have proposed an approach of scheduling projects in order to maximize their

expected net worth value when the project activities have a probability of failure and when an activity's failure leads to overall project termination. Managerial flexibility with respect to the option of abandonment of a project or taking corrective action is referred to as real option value. Huchzermeier and Loch (2001) have identified five example types of R&D uncertainty: in market payoffs, project budgets, project performance, market requirements, and project schedules. They have developed a model based on options pricing theory, which builds intuition for R&D managers as to when it is and when it is not worthwhile to delay commitments.

Al Subhi Al-Harbi (2001) presents the Analytic Hierarchy Process as a potential decision making method in project management using as an example the contractor prequalification problem. A hierarchical structure is constructed for the prequalification criteria and the contractors wishing to prequalify for a project. Then the prequalification criteria are prioritized and a descending-order list of contractors is made in order to select the best contractors. A sensitivity analysis can be performed to check the sensitivity of the final decisions to minor changes in judgments.

Kablan and Dweiri (2006) identify three criteria that may be considered as project management internal measures of efficiency: project cost, project time, and project quality. They present an approach that employs fuzzy decision making to combine these three measures into one measure they name project management internal efficiency, representing an overall estimate of how well the project was managed and executed.

Lova et al. (2000) have dealt with the problem of managing various projects that share a pool of constrained resources. They have developed a multi-criteria heuristic algorithm that improves lexicographically two criteria, each chosen by the user from two types: time type (mean project delay, multi-project duration increase), and no time type (project splitting, in-process inventory, resource leveling, idle resources). The multi-criteria heuristic consists of several algorithms based on the improvement of multi-project feasible schedules.

Wiley et al. (1998) have looked at the application of optimization techniques to the initial design and development of multi-project programs. The classic work breakdown structure is used as a framework to provide an aggregate model to investigate the effects of funding levels, resource allocation, and program, project, and component durations. Decomposition, sensitivity analysis, and parametric programming are utilized to provide the decision maker detailed information for establishing program parameters, conditions, and bounds.

Concluding Remarks

In summary, there are hundreds of OR/MS models that have been proposed for R&D management. The evolution of the field continues through newly proposed models that appear in the references, which try to improve upon existing ones by including additional aspects of the problem situation. The trend has been to recognize the multi-criteria and multi-objective nature of real world R&D projects as well as their interdependency with respect to resources, technologies, and other factors. The usage of these approaches is expected to increase in the future due to the wider exposure of R&D managers to OR/MS approaches, the wider availability of computers and user-friendly software, and the emphasis on using them "as a laboratory for testing policies, sharing opinions, asking 'what-if' types of questions and simulating interdepartmental interactions throughout the organization" (Souder and Mandakovic 1986).

Williams (2003) looked at the contribution that mathematical modeling has made to project management over the past 50 years (at the time of his study), and the contribution it is currently making and can make in the future. He maintains that project management started with well-defined foundations and modelers played an essential role in offering solutions. Since then, he concludes that much of the mathematical-modeling world continued producing ever more complex solutions to ever more complex models that did not help in solving real-world problems. However, several of the models built during the last couple of decades are systemic and dynamic and explain many of the behaviors of R&D projects.

Resource Aggregation

In a project network, a method of scheduling activities within their available float times according to a specific rule, for example, at their earliest start times, and determining the consequent total units of each resource required in each time period.

See

▶ Network Planning

Resource Leveling

A method of scheduling activities of a project to meet a limit in the amount of a resource that is available. This may mean that the project completion date is allowed to slip.

See

▶ Network Planning
▶ Project Management

Resource Smoothing

A method of scheduling activities of a project within their available float times to minimize fluctuations in day-to-day resource requirements. This approach would be used when the project completion time is not allowed to slip.

Response Surface Methodology

Russell R. Barton
The Pennsylvania State University, University Park, PA, USA

Introduction

Response surface methodology (RSM) is a technique to determine design factor settings to improve or optimize the performance or response of a process or

product. It combines design of experiments, regression analysis and optimization methods in a general purpose strategy to optimize the expected value of a stochastic response. In their landmark paper, Box and Wilson (1951) describe the development and application of this sequential method to chemical process design, in which yields of particular compounds were maximized. Since that time the method has been applied successfully in many areas. Recent texts devoted to RSM include Myers et al. (2009) and del Castillo (2007).

Problem Setting and Background

Mathematically, RSM solves:

$$\max f(x) \equiv \mathrm{E}(Y(x))$$

where Y is a random variable whose mean is an unknown function of the d-dimensional factor vector x and whose variance (arising from experimental error) is an unknown constant value, denoted σ^2; and where the maximization is over x in some region R. Generally the constraints describing R are not modeled, so the setting is usually considered an unconstrained optimization problem. RSM fits a sequence of local regression models, at first linear, and later quadratic. The models are fitted to experimental data based on a set of prescribed x vectors – also called the experiment design. The linear model has the form:

$$Y(x_i) = \beta_0 + \sum_{j=1}^{d} \beta_j x_{ij} + \varepsilon_i, \{\varepsilon_i\} \sim i.i.d.N\left(0,\sigma^2\right) \quad (1)$$

where i indexes the experimental run and j the component of the x_i vector. The fitted model is represented as

$$E(Y(x_i)) = \hat{y} = b_0 + \sum_{j=1}^{d} b_j x_{ij} = b_0 + b' x_i. \quad (2)$$

The quadratic model has the form:

$$Y(x_i) = \beta_0 + \sum_{j=1}^{d} \beta_j x_{ij} + \sum_{j=1}^{d} \sum_{k=j}^{d} \beta_{jk} x_{ij} x_{ik} + \varepsilon_i, \{\varepsilon_i\} \sim i.i.d.N\left(0,\sigma^2\right) \quad (3)$$

with fitted model

$$E(Y(x)) = \hat{y} = b_0 + \sum_{j=1}^{d} b_j x_j + \sum_{j=1}^{d} \sum_{k=j}^{d} b_{jk} x_j x_k = b_0 + b' x + x' B x. \quad (4)$$

The fitted coefficients b_0, b_j and b_{jk} are usually calculated via least squares. Note that in equation (4), the off-diagonal elements of B are half the magnitude of the b_{jk} values, i.e. $B[j,k] = B[k,j] = b_{jk}/2$. Also, $\{\varepsilon_i\} \sim i.i.d.N(0,\sigma^2)$ can be represented in multivariate form. If the experiment consists of n instances or runs, then ε is assumed to be a normally distributed random n-vector with mean the zero vector and covariance matrix $\Sigma_\varepsilon = \sigma^2 I$. Each fitted local model is used to determine a search direction or subregion in R where an increase or optimum of $\mathrm{E}(Y(x))$ is expected.

RSM is preferred over a simple grid search over R under the following conditions:

1. The response function f is complex: it is not well approximated by a single quadratic over all of R.
2. Experimental error (hence σ^2) is small enough to permit local characterization of f with relatively few experiment runs.
3. Derivatives of f are continuous.
4. Experiments can be carried out sequentially without undue delay or cost.

The first condition means that a grid search over d variables would require a fine rather than coarse grid. With l levels for each variable, the total number of experiments for a grid search would be l^d, i.e., a large number of different experimental conditions or *points*. The second condition says that a small number of experiment points will be sufficient to provide local approximation of the response by a low-order polynomial, without requiring many *replications* (repeated experiments under the same experimental conditions). The third condition permits local characterization of the response function by a low-order polynomial, typically linear or quadratic. The fourth condition allows each local approximation to be used to identify a next local subregion to explore. Since this sequential approach avoids local subregions that are not promising, fewer experiments are required to characterize the optimum subregion, compared with a grid search that characterizes all of R.

RSM Algorithm

At the highest level, RSM has four activities: scaling and transforming, screening, Phase 1 modeling and search, and Phase 2 modeling and search.

1. Scale the x variables (for example, to provide comparable units of change), and transform Y values (for example, to provide responses with homogeneous variance across different x values).
2. Screen for important components of the x vector (called factors - explained below).
3. Phase 1:
   a. Select an experiment design appropriate for fitting a first-order regression model.
   b. Conduct the experiment, fit the appropriate model, assess significance and fit.
   c. If the model is satisfactory, identify a search direction and conduct a sequence of experiments in this direction.
   d. Return to step 3a.
4. Phase 2:
   a. Select an experiment design appropriate for fitting a second-order regression model (this may be an augmentation of an existing first-order design).
   b. Conduct the experiment, fit the appropriate model, assess significance and fit.
   c. If the model is satisfactory, identify whether an optimum, saddle point or a ridge has been identified.
   d. If a ridge or optimal solution is contained in the experimental range, continue to step 5.
   e. Otherwise, identify a search direction and conduct a sequence of experiments in this direction.
   f. Return to step 4a.
5. Communicate the optimum settings or a ridge of near-optimum settings in the original units of x.

Scaling of the x variables is equivalent to determining the size of the local region for each variable, since the low and high values in a local region are generally scaled to +/− 1 for regression model fitting and analysis. The steepest ascent direction depends on this scaling. Transformation of Y values can be helpful in stabilizing the variance of $Y(x)$ across different x values, i.e., when $\mathrm{Var}(Y(x)) = \sigma^2(x)$. Since the models imply $\mathrm{Var}(Y(x)) = \mathrm{Var}(\varepsilon(x))$, transforming Y for homogeneous variance ($\sigma^2(x) = \sigma^2$ for every x) permits the use of statistical methods that assume $\{\varepsilon_i\} \sim i.i.d.N(0,\sigma^2)$, given independence of experimental runs. Nonhomogeneous variance is common in simulation settings, often having a power relationship with components of x. The Box and Cox (1964) power transformations are useful in this case. The family of transformations is parameterized by λ:

$$y(\lambda) = \begin{cases} \dfrac{y^\lambda - 1}{\lambda} & \lambda \neq 0 \\ \ln(y) & \lambda = 0 \end{cases}$$

where the natural log function provides continuity at $\lambda = 0$ and the parameter λ can be chosen by maximum likelihood or estimated as one minus the slope of a plot of the ln(estimated standard deviation of $Y(x)$) on the vertical axis vs. ln(estimated mean of $Y(x)$) on the horizontal axis (Montgomery 2009). Selecting a member of this transformation family requires replicated experiments at each design point. Transformation of Y can produce an additional benefit: the response surface is often less complex after the variance stabilizing transformation. This is because the nonlinearity of the response and the nonhomogeneity of the variance are often related, and so they are both removed or reduced by the same transformation. This allows the size of the local region to be increased, which permits faster progress for the optimization.

Alternatively, to achieve homogeneous variance, it is possible to conduct replications at each x point in the design, with the number or replications proportional to the variance at that x value. For large differences in the variance of $Y(x)$, many replications could be required, increasing the experimental costs of RSM.

Since the number of design points needed to fit a first-order (second-order) regression model increases linearly (quadratically) with the number of factors, screening out unimportant factors at the start of the response surface optimization can significantly reduce experimental effort. Screening experiment designs are typically fractional factorial designs, and often have $d + 1$ or fewer points for d factors. These designs are discussed by Satterthwaite (1959), Plackett and Burman (1946) and Lin (1993). Screening is performed by examining the regression equation. If fewer than $d + 1$ runs are conducted, this can be done using stepwise regression or other strategies described in Li and Lin (2003). Sequential screening methods

group factors together in setting their high and low values, to eliminate large numbers of factors in a relatively small number of runs. This strategy requires a priori knowledge of the sign of the factor, which is practical in some physical settings and uncertain in others. Sanchez et al. (2009) describe a strategy for dealing with uncertain signs, and summarize the original developments in this area by other researchers, including Bettonvil, Cheng and Kleijnen.

Phase 1 consists of building and exploiting local linear approximations to the response function. Typically a factorial or fractional factorial design is used for experimentation, along with a center point, with replications that allow a statistical test of lack of fit of the first-order model. The region for experimentation is local rather than all of R. The local region must be chosen small enough so that a linear approximation is likely to be adequate, but large enough so that the linear effects can be detected as statistically significant without large numbers of replications. The results of the regression analysis ideally provide a statistically significant model with no significant lack of fit. In this case a sequence of experiments are conducted, from the design center in the direction of the gradient. The increment between experimental points along this line is usually chosen to give a magnitude of 1 for the largest gradient component, so the increment in this direction would be $b/\max\{|b_j|\}$. Steps continue until the observed response decreases, but various rules have been proposed to use additional steps to ensure that random error does not cause premature termination. These rules include i) using multiple replications and testing for statistical significance of the change from one step to the next, ii) fitting a univariate polynomial to the responses observed along the search direction and stopping when the fitted maximum lies within the scope of the search, iii) stopping after three consecutive failures to increase the response. These and other stopping rules are compared in del Castillo (2007).

Outcomes other than a statistically significant model with no significant lack of fit are possible in Phase 1. Table 1 summarizes the possibilities and the corresponding actions as presented in Barton and Meckesheimer (2006).

Entry to Phase 2 is based on lack of fit in Phase 1. The local region then usually remains the same, since the Phase 1 factorial or fractional factorial design is usually retained, and augmented with design points at +/-δ on the factor axes. A design having a full factorial augmented by center and axis points is called a central composite design. For central composite designs, δ can be chosen to make the design rotatable. Rotatable designs give regression models with equal prediction variance at all points a fixed distance from the center of the design, and have some advantages, as discussed by Box and Wilson (1951) and others. Other types of rotatable (or near-rotatable) designs have been used, for example, Box-Behnken designs (Box and Behnken 1960). Donohue et al. (1995) construct designs that minimize sensitivity to model misspecification. These designs provide coefficient estimates that are least sensitive to the presence of higher-order terms in the true local response. As for Phase 1, the results of a Phase 2 regression analysis ideally provide a statistically significant quadratic model with no significant lack of fit. In this case, a canonical analysis is usually performed. This analysis transforms x-space to be centered at the zero slope of the fitted quadratic: $x_0 = -1/2\ B^{-1}b$ and a transformed factor vector $w = M'(x\text{-}x_0)$, where M is the matrix of normalized column vectors corresponding to the eigenvectors of B. When the fitted quadratic has all negative eigenvalues, the location of the origin for w is x_0, the maximum of the fitted quadratic, and the w axes correspond to the major and minor axes of the ellipsoidal contours of the quadratic. The canonical model is:

$$E(Y(w)) = \hat{y} = w_0 + \sum_{j=1}^{d} \lambda_j w_j,$$

Response Surface Methodology, Table 1 Phase 1 Assessment of Significance and Fit Results and Actions

	Linear Effects Not Significant	Linear Effects Statistically Significant
Lack of Fit of Linear Regression	Augment design and fit quadratic regression model, go to Phase 2.	Augment design and fit quadratic regression model, go to Phase 2.
No Significant Lack of Fit	Choose a larger local region for experimentation or increase the number of replications at each design point. Go to step 3a.	Go to step 3c: identify a search direction and conduct a sequence of experiments in this direction.

Response Surface Methodology, Table 2 Phase 2 Assessment of Significance and Fit Results and Actions

	Quadratic Effects Not Significant	Quadratic Effects Statistically Significant
Lack of Fit of Quadratic Regression	Unlikely. If this occurs, one could select a higher-order model (cubic) but instead one would usually reduce the size of the local region and go to step 4a.	Reduce the size of the local region and go to step 4a.
No Significant Lack of Fit	Unlikely. If this occurs, increase the number of replications and go to step 4b.	Perform canonical analysis. If result is an optimum within the range of the local design, go to step 5. Otherwise, conduct a search or identify a best value within a fixed distance from the center of the design, then go to step 4a.

where the λ_j are the eigenvalues corresponding to the eigenvectors of B. Canonical analysis allows easy identification of the nature of the fitted quadratic. If all λ_j are positive, a local minimum has been fitted; if all are negative, a local maximum. When some are positive and some negative, a saddle point is identified. In this case, a search proceeds in a direction that will increase the objective, for example by the largest amount for a given step length, r.

Small eigenvalues correspond to directions of little change in the objective, usually called ridges. The ridges identified through canonical analysis provide a set of alternative factor settings (along the ridge) that provide nearly the same response. When a ridge exists, the decision maker has added flexibility in choosing among factor settings along the ridge based on secondary criteria.

Confidence regions for the optimal value x^* and optimal value of $E(Y(x^*))$ can be constructed from the fitted regression model. These are presented in the original paper by Box and Wilson (1951) and the discussion accompanying the paper. Subsequent enhancements to these methods, in particular to the constrained case, are explained in detail in del Castillo (2007).

As for Phase 1, outcomes other than a statistically significant model with no significant lack of fit are possible in Phase 2. Table 2 summarizes the possibilities and the corresponding actions as presented in Barton and Meckesheimer (2006), which also contains a completely executed example of RSM.

Application of RSM to Discrete-Event Simulation

The output of discrete-event dynamic simulations are stochastic responses, and RSM was recognized as a tool for simulation optimization in the early development of that field (Mihram 1970). In discrete-event simulation, random variation is introduced using pseudorandom number generation. This control permits deliberate introduction of correlation in responses across design points, which was exploited by Schruben and Margolin (1978) for the case where the design can be decomposed into orthogonal blocks. For the central composite design, for example, inducing positive correlation across factorial points, positive correlation across axis points, and negative correlation between these blocks, greater precision is possible in the regression model. This advantage depends on the ability to induce correlation in the output values based on common and antithetic input pseudorandom number streams, which can be hard to achieve. Successful correlation-induction strategies are discussed in simulation texts, for example Law and Kelton (2000) and Banks et al. (2009). Statistical issues associated with common and antithetic variate strategies for response model fitting were examined by a number of researchers, including Nozari et al. (1987), Tew and Wilson (1992, 1994) and Donohue (1995).

Variants and Properties

Many variants have been proposed to the RSM structure described above. Many recent contributions have come from research in the discrete-event simulation community, but with broad applicability to RSM outside the simulation domain, so they are not identified separately.

A number of modifications relate to the models and estimators in equations (1–4). A general variance structure implying $\Sigma_\varepsilon \neq \sigma^2 I$ occurs for the correlation-induction strategies developed for simulation applications, but can also occur in

physical experimentation. In this case, weighted least squares or generalized least squares can be used to estimate the regression coefficients in equations (2) and (4). Independent nonhomogeneous variance is a special case of general variance. In this case Σ_ε is diagonal but with unequal diagonal values. Consequently weighted least squares provides an alternative to the strategies of transformation of Y or differential replication that were described above. Bayesian estimation can be used to determine regression coefficients (Cheng and Currie 2004; del Castillo 2007). This can be applied in physical or computer experimentation if prior experience or theory suggest appropriate ranges for β_j values.

The models in (1) and (3) can be replaced by generalized linear models which provide more flexible distribution forms for the random component and more general modeling terms as well. Staum (2009) describes weighted least squares, generalized least squares and generalized linear models for RSM. A broad class of model-based optimization methods use global approximations, for example, Kriging, splines, or neural networks. Barton and Meckesheimer (2006) review global model-based optimization and contrast it with RSM.

If the Phase 1 search is repeated several times, one can use a modified search direction to avoid the zigzagging that may occur. Conjugate gradient directions from nonlinear optimization were applied in the RSM setting by Joshi et al. (1998). The Phase 1 design is often not rotatable, and so the prediction variance in the gradient direction may increase more rapidly than in other directions. Kleijnen et al. (2004) used this concept to develop a search direction different from b and an interval different from $b/\max\{|b_j|\}$. For a fitted first-order model, they identify the point x^+ that maximizes a lower 1-α confidence interval for the predicted mean. This "adapted steepest ascent" search direction and interval is invariant to the scaling of the x components, unlike steepest descent, and the authors find that the performance is usually improved over steepest ascent.

Although the original form of RSM does not consider explicit constraints on the value of x, constraints must usually be taken into account (see Kleijnen 2008). When constraints are linear, linear programming may be used in Phase 1 optimization, and quadratic programming in Phase 2. For nonlinear constraints, other techniques have been proposed. Biles (1974) used a gradient projection search for RSM applied to the optimization of discrete-event simulation output. Robust design methods present an RSM situation with constraints that are themselves based on a model (del Castillo 2007). For this setting Bettonvil et al. (2009) developed statistical tests based on the Karush-Kuhn-Tucker conditions for nonlinear programming to check for optimality.

Box, in the discussion section of Box and Wilson (1951) warned against automating RSM. He felt that the specifics of each application would require the judgment of statisticians and process experts as decisions were made on experiment design choice, search direction choice and model choice. Nonetheless it is tempting, when applying RSM to the optimization of a computer simulation response function, to formalize and code the RSM process to permit an automated algorithm. Formal RSM algorithms were described by Neddermeijer et al. (2000), Nicolai et al. (2004), and Barton and Meckesheimer (2006). A formal structure naturally leads to a question of the convergence properties of the method. No convergence results were available for RSM until recently. Chang and Wan (2009) developed a version of RSM that chooses the step size and direction based on a trust region for the approximating model. They prove convergence under assumptions related to boundedness of the expected value of the maximum response, a mean response that is twice differentiable, bounded below and has uniformly bounded Hessian and gradient, and that for sufficiently small region the quadratic regression model (3) holds (possibly with nonhomogeneous variance). Convergence in this case means that with probability 1 the norm of the gradient of the $E(Y(x))$ with respect to x will go to zero as the number of successful iterations goes to infinity.

Response Time

Often used to describe the time between the arrival of a new queueing customer (e.g., as in the receipt of a call by an emergency dispatcher) and the initiation of service (as in the arrival of the emergency unit at the scene of the call), thus equal to the queueing delay.

Restricted-Basis Entry Rule

In the adaptation of the simplex algorithm for solving separable-programming problems in which variables are approximated by a set of grid variables, the restricted basis entry rule only allows, for each original variable, no more than two such neighboring grid variables to be in a solution. Such a rule is also used in solving quadratic-programming problems to force certain complementarity conditions to hold.

Retailing

Hiroaki Sandoh[1] and Kaoru Tone[2]
[1]Osaka University, Toyonaka, Osaka, Japan
[2]National Graduate Institute for Policy Studies, Minato-ku, Tokyo, Japan

Introduction

Retailing can be seen as the third phase in the flow of goods, following production and logistics. Retail shops are traditionally and historically classified into several categories: independent stores, department stores, supermarkets, discount stores and convenience stores. The advent of the Internet had a drastic impact on retailing, as it has alleviated restrictions in relation to time as well as space on the globe. As a result, online stores with global reach have led to even more intense competition between retailers.

Retailing has a wide variety of decision-making phases, and therefore OR/MS has been applied in many aspects with a view to obtaining scientific solutions to such areas as store location problems, product assortment along with shelf-space allocation, inventory control and advertising/sales promotion. Since the mid-1980s, applications of scientific methods have increased in retailing against growing competition among retailers in pursuit of larger profit. Many useful software packages have also been developed for the purpose of surviving in these extremely competitive environments.

Retail Store Location Problems

Decisions regarding store location are preliminary but vital for the retail management. Traditionally, OR/MS has addressed this problem along with general facility location problems. Models for a facility location problem often confine themselves to obtaining an optimal solution assuming the attractiveness of the facilities is known. For store location problems, however, how attractiveness can be measured is a critical concern, since development of accurate sales forecast is central to successful retail-site selection (Kotler 1984). For this reason, the following gravitational models are mainly used for retail store location problems.

Huff (1963) utilizes the conceptual properties of the gravity model, which is from the laws of Newtonian physics, to provide a probability that a customer patronizes a specific retail store. This gravity-based formula suggests that the probability is proportional to the attractiveness of the retail store and inversely proportional to the distance from it. More precisely, the attraction felt by customer i towards retail store $j(= 1, 2, \cdots, n)$ is expressed by S_j / T_{ij}^{λ}, where S_j denotes the selling space devoted to the sale of a specific class of goods by store j, T_{ij} the travel time of a customer S_j to retail store j, and λ a parameter which is to be estimated empirically to reflect the effect of travel time on various kinds of shopping trips. Then the probability that customer i chooses store j is given by $\left(S_j / T_{ij}^{\lambda}\right) \Big/ \sum_{k=1}^{n} \left(S_k / T_{ik}^{\lambda}\right)$. Once such

a probability is obtained, it serves as a useful index to determine the location of a new store. This model is called a gravitation model.

Nakanishi and Cooper (1974) generalize this gravitational model to include other properties of stores by suggesting techniques to estimate the attractiveness of stores, and since then retail location problems have been studied extensively. The gravitational models and, more generally, spatial interactions models receive more interest as more data and global information system technologies are becoming available (Birkin et al. 2002).

Prediction of the Number of Customers Visiting a Store

The number of customers visiting a retail store will influence the sales volume of individual goods at the store. If management can predict with a fair degree of accuracy the future number of customers, be it 1 day, a week or a month in advance, it then becomes possible to map out an efficient operations program. Regular and part-time employees can be scheduled effectively to reduce operating costs and improve customer service. On the product side, stock orders can be gauged more accurately, reducing the risk of lost sales due to shortages and wastage due to an overstocking of goods.

The number of customers is usually affected by the day of the week, weather, temperature, sales campaigns and economic conditions. Multiple regression analysis can be used to arrive at a formula that explains the volume and distribution of customers; see Chatterjee and Price (1991) for details of statistical methods. By using new data, the formula can be updated on a daily or weekly basis, or when the difference between the predicted number and the actual number falls out of a predetermined range.

Classification of Goods by Sales Volume

In an average size supermarket, several thousands of goods are displayed. They can be divided into three classes according to sales (or gross sales). This is known as ABC analysis or the Pareto chart. Class *A* goods, while accounting for around 50% of sales, constitute only a small portion of the entire range of goods, usually about 10%. Class *B* comprise approximately 40% of both the range of goods and sales value. Class *C* goods comprise about half of the goods available but only around 10% of the sales.

Empirical studies have shown that the sales of Class *C* goods reflect a Poisson-type distribution, while that of Class *B* goods is represented by a normal or log-normal distribution. The sales of Class *A* goods are well explained by regression analysis using causal models (including price and sales campaigns).

Retailers, wholesalers and producers will be able to get valuable information by classifying goods in this way and extend their understanding of their characteristics as represented by the set of parameters. This information can then be used to make appropriate choices for items in the store. For Class *A* goods, the effects of price and sales campaigns in the regression formula provide useful information for strategic management. In addition, as will be discussed below, goods procurement and inventories will be more efficiently controlled.

Product Assortment and Shelf-Space Allocation

One of the primary concerns of retail management involves determining the variety of products to offer, and the allocation of limited shelf-space among the selected products so as to maximize the store's profit. Most of the shelf-space research indicates that the proportion of total product shelf-space received by a particular product is important since it influences the brand's aggregate sale and market share.

Anderson and Amato (1974) develop a model for simultaneous decision making for a brand assortment and shelf-space allocation problem, assuming the shelf-space large enough to contain at least one facing of each available brand. Let B and S, respectively, denote a set consisting of all the available brands and a subset of B. In addition, let n_b ($b \in S$) signify the number of facings of brand b to be displayed. For a subset S of B, seeking an optimal value for n_b is a knapsack problem. They also provide a method for obtaining an optimal set of brands to be displayed.

However, their model does not take into account the cross-effect among products within the store. For this reason, Corstjens and Doyle (1981) develop a more

comprehensive model, considering the main effects and the cross-effect of demand with the cost effects, which is a generalized geometric programming problem. Hansen et al. (2010), furthermore, propose a retail shelf-space decision model that incorporates a nonlinear profit function, vertical and horizontal location effects, and product cross-elasticity together with comprehensive survey of shelf-space decision models.

Inventory Control

Future sales can be estimated with a certain degree of accuracy based on the results of the type of data analysis described before. The estimated values relate to the buying-in amount and the inventory of goods. It is especially important to predict and control the inventories of non-durable goods delivered daily, such as fresh foods and dairy products.

A basic inventory policy for a retail store can be described as follows. Let Z denote the remaining amount of a commodity at the store's closing time, of which a part, D, is to be scrapped due to expiration. Then, the stock at the end of the day is $U = Z - D$. If the predicted sales for the following day is Y, and the leadtime for buying-in is one night, then the order volume, P, is determined by $P = \max\{Y - U + \alpha, 0\}$, where α corresponds to the safety stock, the slack which prevents opportunity loss. The safety stock α relates directly to the trade-off between the probability of loss and the holding cost. An inventory simulation can be applied using past data to estimate an adequate α. It should be noted that the classical inventory control problem where the remaining amount Z should always be disposed, i.e., $D = Z$ or $U = 0$, is called a newsboy problem.

Inventory control for a retail store is significantly relevant to that for a warehouse as well as a manufacturer in the context of supply chain management.

Analysis of Movement of Customers

Although a point-of-sales (POS) record of a customer tells what kinds of goods were purchased, his or her movements through the store are not clear from the record alone. However, by comparing the layout of the store and the POS record, it becomes possible to deduce the route taken via a 'traveling salesman' scenario. By superimposing the solutions for a given number of customers, the congestion likely in each pathway of the store can be estimated. In addition, changing the distance table to correspond with the new assignment makes it much easier to analyze the effects of display changes on congestion. Traditional methods, such as the use of video and first-hand observations, are less efficient in terms of cost and precision. Using analysis such as that described above will result in less dead corners and fewer busy corners.

Pricing Strategies for Consumer Sales Promotion

Since the mid-1980s, consumer sales promotion has particularly been emphasized in retailing due to severe competition. Under these circumstances, retailers have actively introduced a variety of scientific models, mainly through software packages, for pricing strategies for consumer sales promotion with a view to attracting more customers to their shops.

Research on pricing strategies has been conducted by economists, marketing scientists, and operations researchers from a wide range of perspectives. Eliasberg and Steinberg (1993) present a comprehensive survey on this topic, and Nagle et al. (2002) develop excellent overview of decision makings for pricing management.

Markdown

Markdown pricing is one of the simplest and most popular pricing strategies for consumer sales promotion. Retailers of fresh foods use markdown pricing to sell out excess inventory before their expiration date. Retailers of apparel and seasonal goods likewise rely on markdown pricing. When goods have low salvage values once the sales season is over, retailers have incentive to sell the remaining goods while they can even at a low price due to their low salvage values.

Markdown pricing is advantageous when retailers are uncertain which products will be popular with customers. Retailers set high prices for all items initially to identify which products are popular for which customers have high reservation prices since

popular products sell out at the high initial price. The retailers then notice the remaining products as low-reservation price products and mark them down. These observations reveal that markdown pricing is a learning process of the market for retailers to sell a new item (Lazear 1986). Markdown pricing can also be interpreted as a segmentation mechanism since customers purchasing early have higher willingness to pay (Talluri and van Ryzin 1994). Heching et al. (2002) show significant improvements in revenues using model-based markdown optimization.

Decisions in markdown pricing involve optimization of the timing and magnitude of a markdown. It is essential for these decision models to identify a demand function, which explains the relationship between the price and the demand quantity. Usually, retailers themselves or related software packages seek a suitable form for the demand function by fitting historical POS data involving inventory transitions. Regression analysis will be effective when a linear demand function can be assumed.

Dynamic Pricing

Dynamic pricing is a flexible and efficient extension of markdown pricing. Under a dynamic pricing strategy, retailers of fashion and seasonal products, for example, reduce the selling price of items gradationally over time according to customers' reservation prices. Compared with markdown pricing described above, dynamic pricing is advantageous since it can explore the market in more detail with more accurate segmentation. However, dynamic pricing does not always introduce cost reduction, as airlines often raise prices over time.

There is an extensive literature on dynamic pricing. Bitran and Caldentey (2003) and Elmaghraby and Keskinocak (2003) provide an excellent survey on dynamic pricing in academic fields. Talluri and van Ryzin (2004) extensively discuss dynamic pricing within the framework of revenue management.

In the research literature, various models have been proposed for dynamic pricing from a wide range of perspectives. They are, first of all, categorized according to the level of competition of retail stores, monopoly, duopoly, oligopoly or perfect-competition. They are also classified depending on the population size, finite or infinite. Most important for theoretical understanding of dynamic pricing is a model of how demand responds to changes in price. Demand models can be for individual customers or for more aggregate classes, and can also be classified according to whether they are continuous or discrete, deterministic or stochastic, static or dynamic, without replenishment or with replenishment, etc. (Talluri and van Ryzin 2004). For example, a logit model or a discrete choice model (see Anderson et al. 1995) is a useful tool for describing demands by individual consumers under stochastic demand.

Revenue Management

Costis Maglaras
Columbia University, New York, NY, USA

Introduction

Revenue management focuses on how a firm should set and update pricing and product availability decisions across its various selling channels in order to maximize its profitability. A familiar example comes from the airline industry, where tickets for the same flight may be sold at many different fares, the availability of which is changing as a function of purchase restrictions, the forecasted future demand, and the number of unsold seats. Indeed, the airline deregulation act in the late 1970s motivated the rapid development and deployment of revenue management tools to manage the sales process of airline tickets, and such systems have been adopted and have transformed the transportation and hospitality industries, and is increasingly important in retail, telecommunications, entertainment, financial services, health care and manufacturing. In parallel, pricing and revenue optimization has become a rapidly expanding practice in consulting services, and a growing area of software and information technology (IT) development.

Revenue management, or yield management, as it was originally called focused on tactical optimization of capacity allocation decisions. This was motivated by the airline industry, where ticket prices – or fare classes – were determined early in the sales horizon, but where airlines could tactically decide which fare classes to make available to consumers at different points in time. The implementation of such systems was facilitated from the presence of industry-wide electronic reservation systems that allowed airlines to "push" their capacity allocation decisions to the travel agents that used to interact with potential passengers. Similar models and systems were applied in many other industries successfully starting with hotels and car rental companies in the late 1980s and the 1990s.

In other application settings, such as retailing, instead of tactical capacity allocation decisions, revenue management systems focus on tactical pricing and markdown decisions. Specifically, in retailing, such systems are used to choose which product pricing decisions to change, either through temporary promotions or permanent markdowns, so as to optimize the overall profitability of a product, a store, or a chain of stores. The same product may be offered at different initial prices at different geographic locations, reflecting local demand conditions, and can be differentially priced throughout its sales season across stores. Moreover, the initial inventory and product assortments at each store may themselves be optimized using to a large extent inputs from such a revenue management system. Revenue management systems have been widely adopted in retailing after their introduction around 2000, and similar tactical price optimization systems have been applied in many other settings such as sports event pricing, entertainment,

telecommunications, and financial services. And while most of the above applications are typically concerned with the interface between businesses and consumers, similar techniques have been adopted in many business-to-business (B2B) settings in customized pricing of B2B transactions.

In all of the above settings, some common characteristics can be identified, such as the large scale of potential transactions; markets with imperfect competition that allows firms to at least partially discriminate potential customers via differential pricing or capacity allocation decisions; the availability of data that is used to quantify market response and estimate demand models, form demand forecasts, characterize consumer choice behavior, etc.; and the use of quantitative methods and IT systems to implement and deploy such solutions.

Consider a firm that owns a fixed capacity of a certain resource that is consumed in the process of producing or offering multiple products or services over a finite time horizon. The firm's problem is to maximize its total expected revenues by dynamically selecting the price of each of its products over time. Four variants will be considered. In the first two, the prices of the products are assumed to be fixed and the firm controls the allocation of capacity at the different price levels. The first variant will focus on the basic setting of Littlewood's problem of a low-fare and a high-fare demand class that arrive sequentially over time, and the firm controls how much capacity to protect for the high-fare class. The second variant assumes that there are more than two demand classes, and where demand requests are not sequenced in time from lower to higher fare, but instead arrive stochastically over time. In such a setting the firm needs to dynamically control which set of fare class requests to be accepted at any point in time. In the next two variants, the firm controls the pricing of the product. In one case the firm offers just one product and is assumed to be a monopolist or to operate in a market with imperfect competition, and thus to have power to influence the demand for each product by varying its price. In this setting, the firm's problem is to choose a dynamic pricing strategy for its product in order to optimize expected revenues. In the second case, the firm offers many products that consume capacity of the same scarce resource, and again has pricing power and seeks to optimize its expected revenues by choosing a multi-dimensional dynamic pricing policy. Finally, the first two are referred to as capacity control problems, and the last two as dynamic pricing problems.

The approach taken here will highlight how the last three problems can be reduced to a common formulation, thus connecting prior results that have appeared in the literature under a unified framework, and explores some of the consequences of this formulation. Specifically, it is shown that the multi-product dynamic pricing and the capacity control problems can be recast within this common framework, and be treated as different instances of a single-product pricing problem for appropriately selected concave revenue functions. Broadly speaking, this is done by decoupling the revenue maximization problems in two parts: first, at each point in time the firm selects an aggregate capacity consumption rate from all products, and second, it computes the vector of demand rates to maximize instantaneous revenues subject to the constraint that all products jointly consume capacity at the aforementioned rate. The latter is akin to the basic microeconomics problem of resource allocation subject to a budget constraint, and gives rise to an appropriate aggregate revenue rate function in each case.

Adopting this common formulation, it will be straightforward to review some of the key structural results regarding the monotonicity properties of the value function and the associated controls, which were derived in the literature (Gallego and van Ryzin 1994, 1997; Lee and Hersh 1993; Lautenbacher and Stidham 1999; Zhao and Zheng 2000; Maglaras and Meissner 2006). Subsequently, the deterministic and continuous (fluid) approximations of the dynamic pricing problems described above are presented, reviewing their solution, the pricing heuristics that can be gleaned from them, and the performance bounds that they offer for the expected revenues of the stochastic and discrete revenue maximization of original interest.

The next section formulates and solves Littlewood's two-fare-class capacity control problem, and briefly discusses its extension to multiple fare classes. After that, the single product dynamic pricing problem is formulated, some known structural results are reviewed, and the deterministic and continuous (fluid) analog of the dynamic pricing problem presented. Multi-product variants and extensions to a network setting are then each described in separate sections.

Single-Resource Capacity Control with Two Fare Classes

Model

In its simplest form, this model can be described as follows: an airline has a fixed capacity for a flight to sell to the market; there is a low-fare and a high-fare class, and low-fare demand is realized before the high-fare demand; the key decision is to select how many units of capacity to reserve for the high-fare demand (i.e., make them unavailable for the low-fare demand that gets realized first), so as to maximize the total expected revenue per flight.

A firm has C identical units of a good to sell over two time periods to two demand classes indexed by $i = 1, 2$. The class-2 demand, denoted by D_2, arrives first and pays a price of p_2, followed by the class-1 demand, denoted by D_1, which pays $p_1 > p_2$. The salvage value is assumed without loss of generality to be 0. The two demands are discrete random variables that are independent of each other, and independent of any capacity control decisions made by the system manager, drawn from some distributions F_i for $i = 1, 2$. The firm controls whether to accept or reject each class- i request for one unit of its capacity, and its objective is to allocate the available capacity to the two demand streams described above so as to maximize its total expected revenue over the entire selling horizon. It is well known that the structure of the firm's optimal policy takes the form of a threshold, or protection level, denoted by L, which sets the number of units of capacity to be reserved for the high-fare class demand, D_1, i.e., class 2 demand requests are accepted as long as it the remaining capacity left for period 1 for the high-fare demand stream is greater than L, and are rejected otherwise. In summary, the firm's problem is to choose the protection level L to maximize its expected revenue:

$$\max_{0 \le L \le C} \mathbb{E}[p_1 \min(D_1,\ \max(C - D_2, L)) + p_2 \min(D_2, C - L)]. \tag{1}$$

where the expectation is taken with respect to the two demand distributions.

Littlewood's Formula

In the capacity control problem in (1), the term $\min(D_2,\ C - L)$ is the sales for the low-fare class, which arrives first; and consequently, the high-fare class sales is the minimum of demand D_1 and the remaining number of seats $C - \min(D_2,\ C - L) = \max(C - D_2,\ L)$. If D_1 and D_2 were continuous random variables and partial sales were allowed, then the optimal protection-level L^* would be given by the following equality:

$$\begin{aligned} p_1\, \mathbb{P}(D_1 \ge L^*) &= p_2 \\ \text{if and only if } \ F_1(L^*) &= \gamma := 1 - p_2/p_1. \end{aligned} \tag{2}$$

This condition is commonly referred to as Littlewood's rule. The left hand side of the above expression equates the marginal expected revenues from an immediate sale at price $\$p_2$ versus a potential sale in the next period at the higher price $\$p_1$. For discrete demand distributions, the optimal protection level satisfies

$$\begin{aligned} p_2 < p_1\, \mathbb{P}(D_1 \ge L^*) \ \text{ and } \ p_2 \ge p_1\, \mathbb{P}(D_1 \ge L^* + 1) \\ \Leftrightarrow\ \gamma > F_1(L^* - 1) \ \text{ and } \ \gamma \le F_1(L^*), \end{aligned} \tag{3}$$

i.e., the optimal protection level is given by

$$L^* = \inf\{L\ :\ F_1(L) \ge \gamma\}. \tag{4}$$

The above expression is known as Littlewood's rule, following Littlewood's 1972 paper that formulated and solved that problem. There is a natural connection between this problem and the well-known newsvendor problem in operations management.

Littlewood's rule has been extended into multiple fare classes, still under the assumption that lower fare demand is realized before higher fare demand. Two heuristics were developed in the literature under the EMSR(a) and EMSR(b), where the acronym EMSR stands for Expected-Marginal-Seat-Revenue. Both heuristics are based on recursive reductions of the multiple fare class problem into two fare classes looking at a marginal class against all downstream fare classes. The nature of the solution is a sequence of nested protection levels, where L_1 units are protected for class 1, L_2 are protected for the two highest fare classes 1,2, etc. The optimal solution of the multiple fare class problem is given in Brumelle and McGill (1993).

Single-Product Dynamic Pricing Problem

Model

Consider a firm endowed with C units of capacity of a product that is to be sold over a finite horizon τ, and where capacity cannot be replenished up to that time. The salvage value of remaining capacity at time τ is assumed to be zero. (A constant per-unit salvage value would also result to formulations similar to those developed below.) The firm is either a monopolist or is assumed to operate in a market with imperfect competition, and, in that, has power to influence the demand for each product by varying its menu of prices. Let $p(t)$ denote the price posted at time t. The demand process is assumed to be a non-homogeneous Poisson process with rate vector λ determined through a demand function $\lambda(p(t))$, where $\lambda : \mathcal{P} \to \mathcal{L}$, $\mathcal{P} \subseteq \mathbb{R}$ is the set of feasible prices, and $\mathcal{L} = \{x \geq 0 : x = \lambda(p),\ p \in \mathcal{P}\} \subseteq \mathbb{R}_+$ is the set of achievable demand rate vectors. Assume that $\mathcal{L}$ is a convex set. For ease of exposition the demand function $\lambda(\cdot)$ is assumed to be stationary. Consider regular demand functions that satisfy some additional conditions. In the sequel, x' denotes the transpose of any matrix x, for any real number y, $y^+ := \max(0, y)$, e is the vector of ones of appropriate dimension and a.s. stands for almost surely.

Definition 1. *A demand function is said to be regular if it is a continuously differentiable, bounded function, and (a) $\lambda(p)$ is strictly decreasing in p, (b) $\lim_{p\to\infty} \lambda(p) = 0$, and (c) the revenue rate $p\lambda(p)$ is bounded for all $p \in \mathcal{P}$ and has a finite maximizer $\hat{p}$.*

Assuming there exists a continuous inverse demand function $p(\lambda)$, $p : \mathcal{L} \to \mathcal{P}$, which maps an achievable demand rate λ to the corresponding price $p(\lambda)$, the demand rate can be taken as the firm's control, from which the appropriate price can be inferred using the inverse demand function. The expected revenue rate can be expressed as a function of the vector of demand rates λ as $R(\lambda) := \lambda p(\lambda)$, and is assumed to be continuous, bounded and strictly concave.

Ex.1 *Linear demand model:* the demand for the product at price p is given by $\lambda(p) = \Lambda - bp$, where $\Lambda > 0$ is the market potential for the product and $b > 0$ is the price sensitivity parameter. The inverse demand and revenue functions are $p(\lambda) = (\Lambda - \lambda)/b$ and $R(\lambda) = \lambda(\Lambda - \lambda)/b$, respectively.

Ex. 2 *Logit demand model:* $\lambda(p) = \Lambda e^{-bp}/(1 + e^{-bp})$, $p(\lambda) = (1/b)ln(\Lambda/\lambda - 1)$ and $R(\lambda) = (\lambda/b)$ $ln(\Lambda/\lambda - 1)$, respectively.

The problem addressed is roughly described as follows: given an initial capacity C, a selling horizon τ, and a demand function that maps a posted price to a corresponding instantaneous demand rate, the firm's goal is to choose a non-anticipating dynamic pricing strategy in order to maximize its total expected revenues.

A discrete-time formulation is adopted, i.e., one where time has been discretized in small intervals of length δt, indexed by $t = 1, \ldots, T$, such that $\mathbb{P}(\text{one product request in } [0, \delta t]) = \lambda\delta t + o(\delta t)$, $\mathbb{P}(\text{two product requests in } [0, \delta t]) = \lambda^2(\delta t)^2 + o((\delta t)^2)$, and so on, where the notation $f(x)$ is of order $o(x)$ implies that $f(x)/x \to 0$ as $x \to 0$. In addition, $T = \tau/\delta t$. With slight abuse of notation, write λ in place of $\lambda\delta t$, and refer to λ either as the demand or the buying probability. The random demand in period t, denoted by $\xi(t; \lambda)$, is Bernoulli with probability $\lambda(t) = \lambda(p(t))$, i.e., $\mathbb{P}(\xi(t; \lambda) = 1) = \lambda(p(t))$ and $\mathbb{P}(\xi(t) = 0) = 1 - \lambda(p(t))$. Treating the demand rate λ as the control variables (prices are inferred via the inverse demand relationship), the discrete-time formulation of the dynamic pricing problem of Gallego and van Ryzin (1994) is:

$$\max_{\{\lambda(t),\, t=1,\ldots,T\}} \left\{ \mathbb{E}\left[\sum_{t=1}^{T} p(\lambda(t))\xi(t; \lambda)\right] : \sum_{t=1}^{T} \xi(t; \lambda) \leq C \text{ a.s. and } \lambda(t) \in \mathcal{L}\ \forall t \right\}. \tag{5}$$

Analysis of the Dynamic Program

Let x denote the number of remaining units of capacity at the beginning of period t, and $V(x, t)$ be the expected revenue-to-go starting at time t with x units of capacity left. Then the Bellman equation associated with (5) is:

$$V(x, t) = \max_{\lambda \in \mathcal{L}} \{\lambda[p(\lambda) + V(x - 1, t + 1)] + (1 - \lambda)\, V(x, t + 1)\}, \tag{6}$$

with the boundary conditions

$$V(x, T + 1) = 0\ \forall x \quad \text{and} \quad V(0, t) = 0\ \forall t. \tag{7}$$

Letting $\Delta V(x,t) = V(x,t+1) - V(x-1,t+1)$ denote the marginal value of one unit of capacity as a function of the state (x,t), (6) can be rewritten as

$$V(x,t) = \max_{\lambda \in \mathcal{L}} \{R(\lambda) - \lambda \Delta V(x,t)\} + V(x,t+1), \quad (8)$$

and the optimal control $\lambda^*(x,t)$ is given by

$$\lambda^*(x,t) = \operatorname*{argmax}_{\lambda \in \mathcal{L}} \{R(\lambda) - \lambda \Delta V(x,t)\},$$

where $R(\cdot)$ is a concave increasing revenue function. Using the properties of $R(\cdot)$, one can show that $\lambda^*(x,t)$ is decreasing in $\Delta V(x,t)$, which using a backwards induction argument in t gives that $\Delta V(x,t)$ is decreasing in x and t. These monotonicity results are the key structural properties that one can extract from the dynamic program and are summarized in the following results.

Proposition 1. *(Talluri and van Ryzin 2004b, Prop. 5.2 Ch. 4) For the problem defined in (5):*

1. $\lambda^*(x,t)$ is decreasing in the marginal value of capacity $\Delta V(x,t)$, and
2. $\Delta V(x,t)$ is decreasing in x and t.

The dynamic program in (6) and (7) admits a closed-form solution for the special case of the exponential demand model, and is fairly easy to solve numerically in other cases. The optimal policy takes the form of a two-dimensional table that specifies a price for each (remaining inventory, time) pair. The optimal price path continuously decreases price between sales, and jumps up at every sales epoch.

The Fluid Model

The fluid model has deterministic and continuous dynamics, and in broad terms is obtained by replacing the Poisson demand process with non-homogeneous rate $\lambda(t)$, where demand requests arrive stochastically over time and require discrete units of capacity, by a deterministic and continuous process where demand for the product arrive continuously at the deterministic rate $\lambda(t)$. The resulting inventory dynamics (in discrete time) are given by

$$X(t+1) = X(t) - \lambda(t), \;\; x(0) = C, \;\; X(T) \geq 0.$$

This deterministic analog is a simplification of the discrete and stochastic model from the previous subsections. It can be rigorously justified as a limit under a law-of-large-numbers type of scaling as the potential demand and the capacity grow proportionally large, and, as such, one would expect to provide more useful analysis and policy recommendations in settings where the firm has many units to sell and operates in a market with high demand. For example, one would expect that the discrete and stochastic nature of the pricing problem to be relevant when selling four newly constructed single family homes over the course of 24 weeks, but it may be less critical when selling 4000 pairs of skis over a similar time duration from, say, October to March.

The fluid model formulation of the dynamic pricing problem is one where the firm selects a demand rate $\lambda(t)$ (or a price) at each time t to:

$$\max_{\{\lambda(t),\, t=1,\ldots,T\}} \left\{ \sum_{t=1}^{T} R(\lambda(t))dt \;:\; \sum_{t=1}^{T} \lambda(t)dt \leq C \text{ and } \lambda(t) \in \mathcal{L} \; \forall t \right\}. \quad (9)$$

Optimal policy for fluid pricing problem. An important result derived in Gallego and van Ryzin (1994) is that a constant price (and thus a constant demand rate) is optimal for (9). Specifically, let $\hat{\lambda} = \operatorname{argmax}\{R(\lambda) : \lambda \in \mathcal{L}\}$ and $\hat{p} = p(\hat{\lambda})$ be the demand rate and price that maximize the revenue rate disregarding any capacity considerations, respectively. Also, let $\lambda^0 = C/T$ be the run-out rate that depletes capacity at time T, and $p^0 = p(\lambda^0)$.

Proposition 2. *(Talluri and van Ryzin 2004b, § 5.2.1.2) The optimal solution for (9), denoted by $\bar{\lambda}$ and $\bar{p}$, are given by*

$$\bar{\lambda}(x,\, t) = \min(\lambda^0,\; \hat{\lambda}), \;\; \bar{p} = \max(p^0,\; \hat{p}), \quad t = 1, \ldots, T. \quad (10)$$

Intuitively, the firm uses the revenue-maximizing price $\hat{p}$ unless this would deplete the capacity too soon, in which case it increases its unit price to p^0 and sells its capacity by time T, while accruing higher total revenues. The proof is simple and exploits the structure of (9) that seeks to maximize a concave function over the capacity constraint; the first-order

optimality conditions set the marginal revenue rates at each time t to be equal, which in turn is achieved via a static pricing policy.

The static nature of the optimal policy for the fluid control problem is simple and intuitive, but also lacks the capability of corrective action against stochastic fluctuations. This does not arise in the fluid formulation, where the capacity is drained along the optimal deterministic trajectory, but it is relevant for the stochastic problems of original interest. Alternatively, $\bar{\lambda}$ can also be expressed in feedback form. Note that the deterministic trajectory of the fluid model is such that $x/(T-t) = C/T$ for all t if $\hat{\lambda} \geq C/T$, and $x/(T-t) = (C-\hat{\lambda}t)/(T-t) \geq C/T$ if $\hat{\lambda} < C/T$. Given this observation, $\bar{\lambda}$ can be expressed as

$$\bar{\lambda}(x,t) = \min\left(\hat{\lambda}, \frac{x}{T-t}\right). \tag{11}$$

Equation (11) illustrates that the optimal pricing policy extracted from the fluid model is essentially a tracking or feedback policy that continuously re-optimizes its decision so as to achieve a sales rate that is given by the minimum between the capacity unconstrained revenue maximizing rate and the rate that would deplete all inventory exactly at time T. This interpretation motivates the common practical heuristic that periodically resolves the fluid model so as to adjust its prevailing price, which according to (11) is exactly what the fluid model prescribes; it is worth noting that the resolving heuristic is one of the most practical and widely adopted approaches to price optimization.

An upper bound on achievable performance. Apart from good policy recommendations, the fluid model offers a useful upper bound on the achievable expected revenue in the underlying stochastic and discrete problem in (5). Specifically, Gallego and van Ryzin (1994) showed the following:

Proposition 3. *(Talluri and van Ryzin 2004b, §5.2.2.3)* $V(C,1) \leq (\bar{\lambda}\bar{p})T$.

This result establishes a tractable limit for the best achievable performance that is useful in establishing sub-optimality gaps for heuristics that one may wish to use, and to prove asymptotic optimality results of candidate policies.

Multiple Products, Single Resource

This section studies multi-product dynamic pricing and capacity control problems.

Problem Formulations

Dynamic pricing problem. The basic elements of the problem as similar to those in the previous section, with the key difference that the firm is now selling multiple products or services, indexed by $i = 1, \ldots, n$ that consume the capacity C. Each product i request requires one unit of capacity. Let $p(t) = [p_1(t), \ldots, p_n(t)]$ denote the vector of prices at time t. The demand process is assumed to be n -dimensional non-homogeneous Poisson process with rate vector λ determined through a demand function $\lambda(p(t))$, where $\lambda : \mathcal{P} \to \mathcal{L}$, $\mathcal{P} \subseteq \mathbb{R}^n$ is the set of feasible price vectors, and $\mathcal{L} = \{x \geq 0 : x = \lambda(p),\ p \in \mathcal{P}\} \subseteq \mathbb{R}^n_+$ is the set of achievable demand rate vectors, assumed to be a convex set. As in the previous section, the demand function $\lambda(\cdot)$ is assumed to be stationary. The definition of regular demand functions is as follows:

Definition 2. *A demand function is said to be regular if it is a continuously differentiable, bounded function, and (a) for each product i,* $\lambda_i(p)$ *is strictly decreasing in* p_i*, (b)* $\lim_{p_i \to \infty} \lambda_i(p) = 0$ *(i.e., consumers have bounded wealth), and (c) the revenue rate* $p'\lambda(p) = \sum_{i=1}^n p_i \lambda_i(p)$ *is bounded for all* $p \in \mathcal{P}$ *and has a finite maximizer* $\bar{p}$.

Assuming there exists a continuous inverse demand function $p(\lambda)$, $p : \mathcal{L} \to \mathcal{P}$, which maps an achievable vector of demand rates λ into a corresponding vector of prices $p(\lambda)$, allows one to view the demand rate vector as the firm's control, and infer the appropriate prices using the inverse demand function. The expected revenue rate can be expressed as a function of the vector of demand rates λ as $R(\lambda) := \lambda' p(\lambda)$, and is assumed to be continuous, bounded and strictly concave.

Ex. 1 *Linear demand model:* the demand for product i is given by

$$\lambda_i(p) = \Lambda_i - b_{ii}p_i - \sum_{j \neq i} b_{ij}p_j,$$

$$\text{or (in vector form) } \lambda(p) = \Lambda - Bp,$$

where Λ_i is the market potential for product i and b_{ii}, b_{ij} are the price and cross-price sensitivity parameters. The inverse demand and revenue functions are $p(\lambda) = B^{-1}(\Lambda - \lambda)$ and $R(\lambda) = \lambda' B^{-1}(\Lambda - \lambda)$, respectively. Definition 1 requires that $b_{ii} > 0$ for all i. To ensure that the inverse demand function is well defined and the revenue function is concave, it is required that either $b_{ii} > \sum_{j \neq i} |b_{ji}|$ or $b_{ii} > \sum_{j \neq i} |b_{ij}|$ for all i; both conditions guarantee that B is invertible and that its eigenvalues have positive real parts (Horn and Johnson 1994, Thm. 6.1.10). The linear demand model has the obvious shortcoming that for some prices it may generate negative demand values. This could be corrected by taking $\lambda(p) = (\Lambda - Bp)^+$, but such a change does not preserve the concavity of the revenue function. In practical applications, it is appropriate to use the linear demand model in settings where the set of reasonable prices would ensure that the demand rates are positive, or in applications where the pricing manager can constrain the prices so as to ensure this property.

Ex. 2 *Multinomial Logit (MNL) model:* Potential customers arrive with rate Λ and have utilities for each product i given by $v_i - p_i + \xi_i$, where v_i is the deterministic portion that is common to all customers, p_i is the price, and ξ_i is the random term (that differentiates customers) that is drawn from a Gumbel distribution with mean zero and parameter one (the latter is assumed w.l.o.g.), and is IID across products and customers. The no-purchase option has utility $u_0 + \xi_0$, ξ_0 is IID with the ξ_i's and $u_0 = 0$. The demand rates for product i is given by

$$\lambda_i(p) = \Lambda \frac{e^{v_i - p_i}}{1 + \sum_j e^{v_j - p_j}}.$$

Adopting again a discrete-time formulation, the random demand vector in each period t, denoted by $\xi(t;\lambda)$, is Bernoulli with probabilities $\lambda(t) = \lambda(p(t))$, and $\mathbb{P}(\xi_i(t;\lambda) = 1) = \lambda_i(p(t))$ and $\mathbb{P}(\xi_i(t;\lambda) = 0) = 1 - \lambda_i(p(t))$ for all i. Treating the demand rates λ_i as the control variables (prices are inferred via the inverse demand relationship), the discrete-time formulation of the dynamic pricing problem of Gallego and van Ryzin (1997) is:

$$\max_{\{\lambda(t),\, t=1,\ldots,T\}} \left\{ \mathbb{E}\left[\sum_{t=1}^{T} p(\lambda(t))' \xi(t;\lambda)\right] : \sum_{t=1}^{T} e' \xi(t;\lambda) \leq C \text{ a.s. and } \lambda(t) \in \mathcal{L}\ \forall t \right\}. \tag{12}$$

Capacity control problem. The next variant considered is the one studied by Lee and Hersh (1993), where the price vector p and the demand rate vector $\lambda = \lambda(p)$ are fixed, and the firm optimizes over capacity allocation decisions. For this problem and without any loss of generality it is assumed that products are labelled such that $p_1 \geq p_2 \geq \cdots \geq p_n$. The firm has discretion as to which product requests to accept at any given time. This is modeled through the control $u_i(t)$ that is equal to the probability of accepting a product i request at time t. It is customary to assume that the firm is "opening" or "closing" products, thus considering controls $u_i(\cdot)$ that are 0 or 1, but this need not be imposed as a restriction. The dynamic capacity control problem is the following:

$$\max_{\{u(t).t=1,\ldots,T\}} \left\{ \mathbb{E}\left[\sum_{t=1}^{T} p' \xi(t;u\lambda)\right] : \sum_{t=1}^{T} e' \xi(t;u\lambda) \leq C \text{ a.s. } 1 \text{ and } u_i(t) \in [0,1]\ \forall t \right\}, \tag{13}$$

where $u\lambda$ above denotes the vector with coordinates $u_i\lambda_i$.

The remainder of this section describes how to reduce (12) and (13) into dynamic optimization problems where the control is the (one-dimensional) aggregate capacity consumption rate. The reduced problems can be studied through a unified analysis.

A Common Formulation in Terms of the Aggregate Capacity Consumption

Dynamic pricing problem. Let x denote the number of remaining units of capacity at the beginning of period t, and $V(x,t)$ be the expected revenue-to-go

starting at time t with x units of capacity left. Then, the Bellman equation associated with (5) is:

$$V(x,t) = \max_{\lambda \in \mathcal{L}} \left\{ \sum_{i=1}^{n} \lambda_i [p_i(\lambda) + V(x-1,t+1)] + (1 - e'\lambda)\, V(x,t+1) \right\}, \tag{14}$$

with the boundary conditions

$$V(x,T+1) = 0 \ \forall x \quad \text{and} \quad V(0,t) = 0 \ \forall t. \tag{15}$$

Letting $\Delta V(x,t) = V(x,t+1) - V(x-1,t+1)$ denote the marginal value of one unit of capacity as a function of the state $(x,\ t)$, (14) can be rewritten as

$$\begin{aligned} V(x,t) &= \max_{\lambda \in \mathcal{L}} \left\{ R(\lambda) - \textstyle\sum_{i=1}^{n} \lambda_i \Delta V(x,t) \right\} \\ &\quad + V(x,t+1) \\ &= \max_{\rho \in \mathcal{R}} \{ R^r(\rho) - \rho \Delta V(x,t) \} \\ &\quad + V(x,t+1), \end{aligned} \tag{16}$$

where $\rho := \sum_{i=1}^{n} \lambda_i$ is the aggregate rate of capacity consumption, $\mathcal{R} := \left\{ \rho : \sum_{i=1}^{n} \lambda_i = \rho,\ \lambda \in \mathcal{L} \right\}$ is the set of achievable capacity consumption rates, and

$$R^r(\rho) := \max_{\lambda} \left\{ R(\lambda) : \sum_{i=1}^{n} \lambda_i = \rho,\ \lambda \in \mathcal{L} \right\} \tag{17}$$

is the maximum achievable revenue rate subject to the constraint that all products jointly consume capacity at a rate ρ. Note that (17) is a concave maximization problem over a convex set, and its solution is readily computable, often in closed form. The aggregate revenue function $R^r(\cdot)$ is concave and satisfies the conditions of Definition 1. The optimal vector of demand rates, denoted by $\lambda^r(\rho)$, is unique and continuous in ρ.

Ex. 1 *Linear demand model:* For $\lambda(p) = \Lambda - Bp$, the associated aggregate revenue function $R^r(\rho)$ defined through (17) can be expressed as

$$R^r(\rho) = -\alpha_i \rho^2 + \beta_i \rho + \gamma_i \quad \text{for} \quad \rho \in [r_{i-1}, r_i),$$

for $0 = r_0 \le r_1 \le r_2 \le \cdots \le r_I$, and constants $(\alpha_i, \beta_i, \gamma_i)$ and r_i that depend on the model parameters Λ, B, μ, and are such that $R^r(\rho)$ is continuous, almost everywhere differentiable, and increasing for all $\rho \le \hat{\rho} := \text{argmax}_{\rho} R^r(\rho)$. The value of r_{i-1} is that of the smallest capacity consumption rate above which it is optimal to start offering the i most profitable products. The derivation of the constants $(\alpha, \beta, \gamma, r)$ can be found in the Appendix of Maglaras (2005).

Ex. 2 For the MNL model, straightforward manipulations show that

$$R(\rho) = \rho \ln\left(\sum_j e^{v_j} \right) - \rho \ln(\rho/(\Lambda - \rho)),$$

$$\lambda_i(\rho) = \rho \frac{e^{v_i}}{\sum_j e^{v_j}} \quad \text{and} \quad p_i(\rho) = \ln\left(\textstyle\sum_j e^{v_j} \right) - \ln(\rho/(\Lambda - \rho)).$$

Proposition 4. *The dynamic pricing problem (12) can be reduced to the dynamic program (15)/(16) expressed in terms of the aggregate consumption rate. In particular, if $\rho^*(x,t)$ denotes the associated optimal control and $\lambda^*(x,t)$ and $p^*(x,t)$ denote the respective optimal demand rate and price vectors associated with (12), then, $\lambda^*(x,t) = \lambda^r(\rho^*(x,t))$ and $p^*(x,t) = p(\lambda^r(\rho^*(x,t)))$.*

The capacity control problem. Similarly, the Bellman equation associated with (13) is

$$V(x,t) = \max_{u_i \in [0,\ 1]} \left\{ \sum_{i=1}^{n} \lambda_i u_i [p_i + V(x-1,t+1)] + (1 - u'\lambda)\, V(x,t+1) \right\} \tag{18}$$

with the boundary condition (15), which using the marginal value of capacity ΔV becomes

$$\begin{aligned} V(x,t) &= \max_{u_i \in [0,\ 1]} \left\{ \textstyle\sum_{i=1}^{n} \lambda_i u_i p_i - u'\lambda \Delta V(x,t) \right\} \\ &\quad + V(x,t+1) \\ &= \max_{0 \le \rho \le \sum_{i=1}^{n} \lambda_i} \{ R^a(\rho) - \rho \Delta V(x,t) \} \\ &\quad + V(x,t+1), \end{aligned} \tag{19}$$

where $\rho = u'\lambda$ and $R^a(\rho) = \max_u \{\sum_{i=1}^n u_i\lambda_i p_i : u'\lambda = \rho,\ u_i \in [0,\ 1]\}$ is the maximum revenue rate when the capacity is consumed at rate equal to ρ, and $u^a(\rho)$ is the corresponding control.

Proposition 5. *The capacity control problem (13) can be reduced to the dynamic program (15)/(19) expressed in terms of the aggregate consumption rate ρ. In particular, if $\rho^*(x,t)$ denotes the optimal solution of (15) and (19) and $u^*(x,t)$ denote the optimal policy for (13), then $u^*(x,t) = u^a(\rho^*(x,t))$.*

A similar result was derived by Talluri and van Ryzin (2004a) for a capacity control problem for a model with customer choice.

A Unified Analysis of the Pricing and Capacity Control Problems

The preceding analysis illustrates that both problems can be reduced to appropriate single-product pricing problems, highlighting their common structure and enabling a unified treatment. As a starting observation, for both (16) and (19), the optimal control $\rho^*(x,t)$ is computed from

$$\rho^*(x,t) = \underset{\rho\in\mathcal{R}}{\text{argmax}}\ \{R(\rho) - \rho\Delta V(x,t)\}.,$$

where $R(\cdot)$ is a concave increasing revenue function. Using Proposition 1 and the properties of $R(\cdot)$, one gets that $\rho^*(x,t)$ is decreasing in $\Delta V(x,t)$, which using a backwards induction argument in t gives that $\Delta V(x,t)$ is decreasing in x and t.

Structural results for the pricing and capacity allocation policies follow from the properties of R^r, λ^r and R^a, u^a, respectively. For example, consider the pricing problem for the case where the products are non-substitutes, i.e., the demand for product i is only a function of the price for that product p_i. In that case, the Lagrangian associated with (17) is $L(\lambda,x,y) = R(\lambda) + x(\rho - \sum_{i=1}^n \lambda_i) - y'\lambda$, with first order conditions given by $\partial R(\lambda)/\partial\lambda_i = x + y_i$, for some $x \geq 0$ and $y_i \leq 0$ with $y_i = 0$ if $\lambda_i > 0$. It is easy to show that x is decreasing in ρ (i.e., the shadow price for the capacity consumption constraint decreases as ρ increases), and that $\lambda_i^r(\rho)$ is decreasing in x.

Corollary 1. *Consider the problem specified in (12) and further assume that the products are non-substitutes, i.e., $\lambda_i(p) = \lambda_i(p_i)$ for all i. Then, $\lambda_i^*(x,t)$ is non-decreasing in $\rho^*(x,t)$ (and non-increasing in $\Delta V(x,t)$).*

A similar result can be obtained when products are substitutable provided that the demand model satisfies certain conditions analogous to those of the sensitivity matrix B of the linear model described earlier in this section.

For the capacity control problem, it is easy to recover some well-known structural properties of the optimal policy (e.g., Lee and Hersh (1993)). The derivation based on the capacity consumption rate offers new intuition as to why they hold. Specifically, $R^a(\cdot)$ is a knapsack solution for which

$$\begin{aligned} R^a(\rho) &= \min_i\ c_i + p_i, \\ u_k^a(\rho) &= \min\left(\frac{(\rho - \sum_{i<k}\lambda_i)^+}{\lambda_k}, 1\right), \end{aligned} \tag{20}$$

where $c_1 = 0$ and $c_i = \sum_{k<i}\lambda_k(p_k - p_i)$, and for any $x \in R$, $x^+ := max(x,0)$, and the optimal control $\rho^*(x,t)$ reduces to the solution to $\max\{\min_i c_i + (p_i - \Delta V(x,t))\rho\ :\ 0 \leq \rho \leq \sum_{i=1}^n \lambda_i\}$. Let $i^*(x,t) = \max\ \{i \geq 1 : p_i \geq \Delta V(x,t)\}$. Then, by inspecting the form of the piecewise linear objective function involved in the calculation of $\rho^*(x,t)$, it follows that $\rho^*(x,t) = \sum_{i\leq i^*(x,t)}^n \lambda_i$, i.e., the solution is "bang-bang" in the sense that the form of the optimal control is such that $u_i^*(x,t)$ is 0 if $i > i^*(x,\ t)$ and 1 if $i \leq i^*(x,\ t)$. In addition, from Proposition 1 part 1, $i^*(x,t)$ is decreasing in the marginal value of capacity $\Delta V(x,t)$. Therefore:

Corollary 2. *For the capacity control problem (13) or equivalently, (15)/(19), the optimal allocation policy is nested, in that $u_i^*(x,t) = 1$ if $i \leq i^*(x,t)$, and $u_i^*(x,t) = 0$ otherwise, and $i^*(x,t)$ is decreasing in the marginal value of capacity $\Delta V(x,t)$.*

Efficient frontier. The subproblem of computing the optimal revenue subject to a constraint on the aggregate capacity consumption rate specified in (17) and (20) defines an efficient frontier $(\rho,\ R^r(\rho))$ and $(\rho,\ R^a(\rho))$ for the dynamic pricing and capacity allocation problems, respectively. As in the context of portfolio optimization, the efficient frontier provides a systematic framework for comparing different policies and highlights the structure of the respective optimal controls. Some of the direct insights extracted form the efficient frontier calculation is that the optimal

capacity control policy in a multi-product setting is nested, and that the optimal dynamic pricing policy is the solution of a problem that strives to equalize the marginal revenue rates across products.

It may also lead to computational improvements if this subproblem can be solved efficiently, which is indeed the case for some common demand models such as the linear and the multinomial logit. The preceding discussion is from Maglaras and Meissner (2006); see also Feng and Xiao (2000, 2004) and Talluri and van Ryzin (2004a). Finally, note that the structure of the dynamic programs studied in this section has been observed in other papers, such as Lin et al. (2003) and their study of single-resource capacity control problems where each arrival may request multiple units of capacity, and Vulcano et al. (2002) and their analysis of optimal dynamic auctions. The latter involves an analysis of a discrete-time, batch demand analog to the dynamic program studied here.

Solution to the Deterministic Multi-product Pricing Problem

As before, the fluid model has deterministic and continuous dynamics, and is obtained by replacing the discrete stochastic demand process by its rate, which now evolves as a continuous process. The realized instantaneous demand for product i at time t is deterministic and given by $\lambda_i(t)$. It is allowed for product i requests to consume capacity at a rate of $a_i > 0$ units per unit of demand, and denote by a the vector $[a_1, \ldots, a_n]$. This is a generalization of the model considered thus far that assumed uniform capacity requirements (all equal to 1). With a general capacity requirement vector a, the capacity consumption rate is defined by $\rho = a'\lambda$, and the definitions of R^r and λ^r can be appropriately adjusted to reflect that change. The system dynamics are given by $X(t+1) = X(t) - \sum_{i=1}^{n} a_i \lambda_i(t), \quad X(0) = C$, together with the boundary condition that $X(T) \geq 0$. The firm selects a demand rate $\lambda_i(t)$ (or a price) at each time t. The fluid formulation of the multi-product pricing problem is the following:

$$\max_{\{\lambda(t), t=1,\ldots,T\}} \left\{ \sum_{t=1}^{T} R(\lambda(t))dt \;:\; \sum_{t=1}^{T} a'\lambda(t)dt \leq C \text{ and } \lambda(t) \in \mathcal{L}\ \forall t \right\}. \tag{21}$$

Gallego and van Ryzin (1997, §4.5) partially extended their single product results to multiple products, but without providing such a succinct solution as the one presented in the previous section. An alternative approach that exploits the action space reduction described earlier was described in Maglaras and Meissner (2006) and is reviewed below. Specifically, recalling the definitions of the aggregate revenue function $R^r(\rho)$ and optimal demand rate vector $\lambda^r(\rho)$ in (17) adjusted for the fact that $\rho = a'\lambda$, (21) can be rewritten as:

$$\max_{\{\rho(t),\, t=1,\ldots,\, T\}} \left\{ \sum_{t=1}^{T} R^r(\rho(t))dt : \sum_{t=1}^{T} \rho(t)dt \leq C,\ \rho(t) \in R\ \forall t \right\}. \tag{22}$$

Note that (22) is identical to a single-product problem with revenue function R^r, and thus is solvable using the approach described above. Let $\rho^0 := C/T$ and $\hat{\rho} = \text{argmax}_\rho R^r(\rho)$. Then, the optimal solution to (22) is to consume capacity at a constant rate $\bar{\rho}$ given by

$$\bar{\rho}(t) := \min(\hat{\rho}, \rho^0) \quad \forall t, \tag{23}$$

the corresponding vector of demand rates is $\lambda^r(\bar{\rho})$, while the price vector is $p(\lambda^r(\bar{\rho}))$. A direct verification that this solution satisfies the optimality conditions for (21) establishes the following:

Proposition 6. *Let $\bar{\lambda}(\cdot)$ and $\bar{p}(\cdot)$ denote the optimal vectors of demand rates and prices for (21). Then, $\bar{\lambda}, \bar{p}$ are constant over time and are given by $\bar{\lambda}(t) = \lambda^r(\bar{\rho})$ and $\bar{p}(t) = p(\lambda^r(\bar{\rho}))$.*

Asymptotically Optimal Heuristics Extracted from the Deterministic Model

Finally, three heuristics for the revenue management problems studied in this section are presented. For each of these policies, one could show that they achieve the optimal asymptotic performance (Maglaras and Meissner 2006).

a. **The static pricing (make-to-order) heuristic of Gallego and van Ryzin (1997).** This policy implements the static prices $\bar{p}$ specified in Proposition 1.

b. **A List Price Capacity Control (LPCC) heuristic.** One way to implement (3) is by introducing capacity control capability on top of the static prices given in (a), specifically,
   1. price according to $\bar{p}$ and label products such that $\bar{p}_1/a_1 \geq \bar{p}_2/a_2 \geq \cdots \geq \bar{p}_n/a_n$, and
   2. compute $\bar{\rho}(x,t)$ and use the capacity controls $u_1(x,t) = 1$ if $x > 0$, $u_1(0,t) = 0$, and for $i \geq 2$,

$$u_i(x,t) = \begin{cases} 1 & \text{if } \bar{\rho}(x,t) - \sum_{j<i} a_j \bar{\lambda}_j \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{24}$$

   Note that this policy can only reduce the aggregate capacity consumption rate from its nominal value of $\sum_{i=1}^{n} a_i \bar{\lambda}_i$, but can never increase it. A product is made available only if the fluid solution starting from that state would choose to sell this product in all future time periods, and closes the product if the fluid solution would dictate only partial acceptance of the associated demand.
   This policy was described in Maglaras and Meissner (2006). It is a refinement of the static pricing policy in (a) and the make-to-order heuristic of Gallego and van Ryzin (1997). Other examples of joint pricing and capacity controls include Vulcano et al. (2002), Lin et al. (2003), and Feng and Xiao (2004).

c. **A dynamic pricing heuristic.** The solution of the fluid pricing problem studied earlier can be described in feedback form as

$$\bar{\rho}(x,t) = \min\left(\hat{\rho}, \frac{x}{T-t}\right), \tag{25}$$

where x is the remaining capacity at time t. The third heuristic translates the aggregate control $\bar{\rho}(x,t)$ into product-level rates (and prices) through

$$\begin{aligned} \lambda(x,t) &= \lambda^r(\bar{\rho}(x,t)) \quad \text{and} \\ p(x,t) &= p(\lambda(x,t)), \end{aligned} \tag{26}$$

where the mapping $\lambda^r(\cdot)$ was the maximizer in (17) and it is continuous in ρ. This corresponds to the idea of resolving the fluid problem while stepping through time. This is widely applied in practice, where, however, the resolving occurs at discrete points in time, e.g., daily or weekly, depending on the application setting. These resolving policies seem to have been first analyzed in Maglaras and Meissner (2006), which show that the idea of resolving applied in the context of the dynamic pricing or the LPCC heuristics is fluid-scale asymptotically optimal, as is the static policy (a). The single-product version of this feedback pricing policy has also been studied by Reiman (2002). These result show that the suboptimal behavior demonstrated by a resolving policy in the negative example studied in Cooper (2002) does not persist in systems with large capacity and large demand. Intuitively, resolving is nothing but implementing the fluid policy in feedback form. Numerical experiments documented in many papers (e.g., Maglaras and Meissner (2006)) demonstrate that such feedback heuristics tend to outperform policies that are static.

Dynamic Pricing Network Revenue Management Problems

This section offers a glimpse of network revenue management problems, and specifically a brief review of its associated fluid model formulation; see Gallego and van Ryzin (1997) and Talluri and van Ryzin (2004b) for a more detailed treatment. Suppose that the firm is operating a network of resources, indexed by $j = 1, \ldots, m$, and that each product i request consumes A_{ij} units of resource j capacity. Let $A := [A_{ij}]$ denote the associated capacity consumption matrix, and assume that the initial capacity for each resource j is C_j. Then, the fluid model formulation of the network dynamic pricing problem is:

$$\max_{\{\lambda(t),\ t=1,\ldots,\ T\}} \left\{ \sum_{t=1}^{T} R(\lambda(t))dt : \sum_{t=1}^{T} A\lambda(t)dt \leq C \text{ and } \lambda(t) \in \mathcal{L}\ \forall t \right\}. \tag{27}$$

As before, this problem can be expressed in terms of ρ, which is defined by $\rho := A\lambda$. Specifically, let

$$R^r(\rho) := \max_{\lambda} \{R(\lambda) : A\lambda = \rho,\ \lambda \in \mathcal{L}\}, \tag{28}$$

be the maximum achievable revenue rate when resource capacity is consumed at a rate ρ, and $\lambda^r(\rho)$

denote the corresponding vector of optimal demand rates. Then, (27) can be reduced to

$$\max_{\{\rho(t),\ t=1,\ldots,\ T\}} \left\{ \sum_{t=1}^{T} R^r(\rho(t))dt : \sum_{t=1}^{T} \rho(t)dt \le C \text{ and } \rho(t) \in \mathcal{R}\ \forall t \right\}. \quad (29)$$

Let $\bar{\rho}$ denote the solution to (29). Then, $\lambda^r(\bar{\rho})$ is the vector of optimal demand rates for (27). This reduction could prove computationally beneficial, since as is often the case the number of products (e.g., the number of fare-class and origin–destination pairs) tends to be greater than the number of resources (e.g., number of flights in a hub-and-spoke network). However, unlike the treatment of the single-resource models in the previous section, this reduction need not necessarily apply to the discrete and stochastic formulation of the underlying revenue management problem.

Concluding Remarks

The papers by Elmghraby and Keskinocak (2003), Bitran and Caldentey (2003), and McGill and van Ryzin (1999), and the book by Talluri and van Ryzin (2004b) provide comprehensive overviews of the areas of dynamic pricing and revenue management. The modeling framework adopted here closely matches that of Gallego and van Ryzin (1994, 1997). Additional references on the capacity control formulation are Brumelle and McGill (1993) and Lautenbacher and Stidhman (1999). The reduction of the multi-product and capacity control problems to single-product pricing problems and their subsequent solutions are from Maglaras and Meissner (2006). The asymptotic analysis that is briefly reviewed here builds on the setup used in Gallego and van Ryzin (1994, 1997) and Cooper (2002), and the results reviewed here are adopted from Maglaras and Meissner (2006). The idea of efficient controls and that of a notion of an efficient frontier on how to choose the product level pricing and capacity control decisions to achieve a desired capacity absorption rate is from Maglaras and Meissner (2006). Related ideas have appeared in slightly different settings in Talluri and van Ryzin (2004a), in the context of a capacity control problem for a model with customer choice among products, and in Feng and Xiao (2000, 2004), while studying pricing problems with a predetermined set of price points; the presentation of this topic here follows Maglaras and Meissner (2006). The pricing and capacity control heuristics have appeared in many references such as Gallego and van Ryzin (1994, 1997), McGill and van Ryzin (1999), Feng and Xiao (2004), Lin et al. (2003), and Maglaras and Meissner (2006). The feedback form of the static pricing policy that is optimal for the deterministic and continuous (fluid) analog of the stochastic and discrete dynamic pricing problem and the property of asymptotic optimality of the resolving pricing heuristic that is based on that feedback policy are both from Maglaras and Meissner (2006).

The are several extensions, generalizations, and new directions of work in the area of revenue management that were not reviewed here. Some may be the result of practical considerations. For example, one may want to consider pricing policies where the feasible price grid is discrete, say in $10 increments. Another extension would incorporate costs incurred when the price is changed. Other important research directions include revenue maximization problems for which the seller does not have accurate information about the underlying demand model, where in such settings, the seller uses its pricing decisions to simultaneously learn the demand and optimize revenues; the effect of strategic consumer behavior on revenue maximization practices, such as intentional waiting for sales to make retail purchases; and multi-product and multi-firm pricing problems under competition.

Reversible Markov Chain/Process

A stationary Markov process whose infinitesimal generator (rate matrix) has elements given by

$$q(k,j) = \frac{\pi_j q(j,k)}{\pi_k} \quad \text{for } j,k \in E,$$

where π_j is the steady-state probability that the chain is in state j and $q(j, k)$ is the rate at which the chain goes from state j to k, i.e., the mean flow rates or probability flux satisfies detailed balance equations for every pair of nodes.

Risk

The risk of a decision d is the expected value of the loss incurred using d taken over all possible states of nature. A risk-averse person is one who prefers to behave conservatively. A decision maker (DM) is said to be risk averse if the DM prefers the expected consequence of a nondegenerate lottery to that lottery (a nondegenerate lottery is one where no single consequence has a probability of one of occurring). A DM is risk averse if and only if the DM's utility function is concave. In contrast, a risk-prone (or risk-seeking) person is one who does not prefer to behave conservatively. A DM is said to be risk prone (or risk seeking) if the DM prefers any nondegenerate lottery to the expected consequences of that lottery. A DM is risk prone if and only if the DM's utility function is convex. Finally, a DM is risk neutral if and only if the DM's utility function is linear.

Risk Assessment

Clyde G. Chittister[1] and Yacov Y. Haimes[2]
[1]Carnegie Mellon University, Pittsburgh, PA, USA
[2]University of Virginia, Charlottesville, VA, USA

Introduction

To the layman, risk is often quantified in terms of probabilities, whereby it might be said that gambling on any event with a low probability of occurring is a risky proposition. Or, the mere existence of a catastrophic event with non-zero probability exposes those involved to risk. The risk of nuclear plant failure, global warming, or the depletion of the ozone layer are examples. One might say that the risk of not carrying an automobile insurance policy is not worth the risk. One result of these simple considerations is that the standard components of risk are the chance of a loss, the possible magnitude of the loss, and the exposure to that loss.

Public interest in the field of risk analysis has grown and expanded in leaps and bounds since 2000. Furthermore, since 1990, risk analysis has emerged as an effective and comprehensive procedure that supplements and complements the overall management of almost all aspects of people's lives. Managers of health care, the environment, and physical infrastructure systems (e.g., water resources, transportation, and electric power) all incorporate risk assessment in their decision-making processes. The omnipresent adaptation of risk analysis by many disciplines and its deployment by industry and government agencies in decision making have led to an unprecedented development of theory, methodology, and practical tools. Technical articles on risk assessment address concepts, tools, and technologies that have been developed and practiced in such areas as design, development, system integration, prototyping, and construction of physical infrastructure; in reliability, quality control, and maintenance; and in the estimation of cost and schedule and in project management (Haimes 2009).

Risk, a measure of the probability and severity of adverse effects, is a concept that many find

difficult to comprehend, and its quantification has challenged and confused lay persons and professionals alike. There are myriad reasons for this state of affairs. One of the fundamental elements that causes so much confusion and misunderstanding of the concept of risk is that it is composed of two diverse constructs. It is a complex composition and amalgamation of two components, one real (the potential damage, or unfavorable adverse effects and consequences), the other an imagined, mathematical human construct, termed probability. Probability, per se, is intangible, yet its omnipresence in risk-based decision making is indisputable. Furthermore, the measure of the probability that dominates the measure of risk is itself uncertain, especially for rare and extreme events, e.g., when there exists an element of surprise. Furthermore, what is meant by the terms probability (or likelihood) and adverse effects? Consider the interpretation of the term likelihood in isolation (for now) of its probable consequences: Is it the likelihood of the occurrence of any kind of threat (or other initiating event), at any level or magnitude, and when, and of what duration? Or, is it the likelihood of the level and magnitude of the consequences (for every element of the vector of consequences)? Thus, the phrase "*probability and severity of adverse effects*" can be interpreted in two ways at the same time: (1) in terms of the probability of the occurrence of adverse effects, and (2) in terms of the probability of the severity of adverse effects, given their occurrence. Both interpretations are valid; however, each represents varied conceptual and theoretical challenges (Haimes 2009).

In the first issue of *Risk Analysis*, Kaplan and Garrick (1981) set forth the following "set of triplets" definition of risk, R:

$$R = \{<S_i,\ L_i,\ X_i>\} \tag{1}$$

where S_i denotes the ith risk scenario, L_i denotes the likelihood of that scenario, and X_i the "damage vector" or resulting consequences. This definition has served the field of risk analysis well since then, and much early debate has been thoroughly resolved about how to quantify the L_i and X_i, and the meaning of probability, frequency, and probability of frequency in this connection (Kaplan 1993).

In Kaplan and Garrick (1981), the S_i themselves were defined, somewhat informally, as answers to the question, "What can go wrong?" with the system or process being analyzed.

Subsequently, a subscript "c" was added to the set of triplets by Kaplan (1991, 1993):

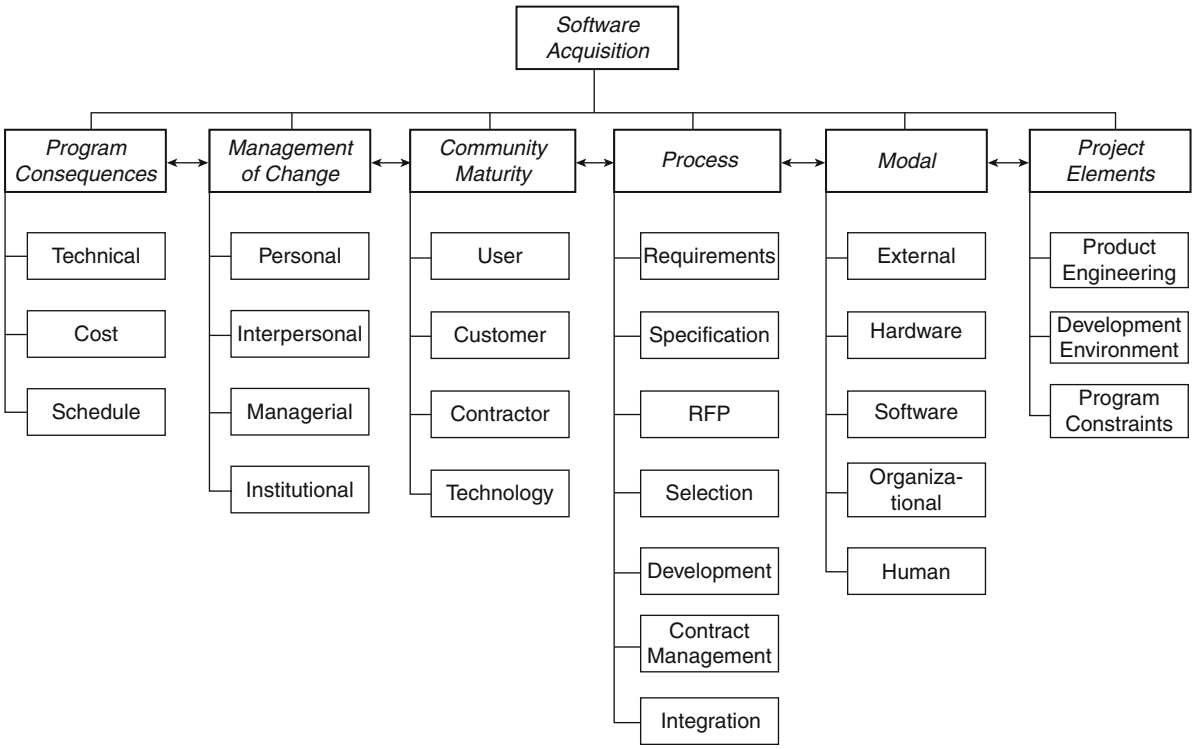
$$R = \{<S_i,\ L_i,\ X_i>\}_c \tag{2}$$

to denote that the set of scenarios, $\{S_i\}$, should be complete, meaning it should include all the possible scenarios, or at least all the important ones.

Also in Kaplan (1991, 1993), the idea of the "success," or "as-planned," scenario was introduced and denoted by S_0. The risk scenarios S_i could then be visualized as deviations from S_0. Thus the idea began to gel that the various risk analysis methods used in different industries (e.g., failure mode and effects analysis (FMEA), fault trees, and event trees) could be viewed as just different systematic ways of identifying and categorizing these deviations, S_i. When these methods became generalized and when the Russian method of anticipatory failure determination (AFD) was added, this idea matured into what is now called the theory of scenario structuring (TSS) (Kaplan et al. 2001).

At about the same time that the definition of risk article (Kaplan and Garrick 1981) was published, so too was the first article on hierarchical holographic modeling (HHM) (Haimes 1981). Central to the HHM method is a particular form of diagram, which is particularly useful for the analysis of systems with multiple, interacting (perhaps overlapping) subsystems such as a regional transportation or water supply system (Haimes 2009). Figure 1 presents an HHM for software acquisition (Schooff et al. 1997; Haimes 2009). The different columns in the diagram reflect different perspectives on the overall system.

The HHM methodology recognizes that most organizational as well as technology-based systems are hierarchical in structure, and thus the risk management of such systems must be driven by and responsive to this structure. The intent is that from this perspective, multiple methods can be compared, and thus be better understood. The risk analyst then can be more confident and flexible when choosing, mixing, and designing the method applicable to a specific problem.



Risk Assessment, Fig. 1 HHM for software acquisition (Schooff et al. 1997; Haimes 2009)

HHM can be seen as part of the TSS and vice versa. Under the sweeping generalization of the HHM method, the different methods of scenario structuring can lead to seemingly different sets of scenarios for the same underlying problem. This fact is a bit awkward from the standpoint of the set-of-triplets definition of risk (Kaplan and Garrick 1981). To eliminate this awkwardness, this definition of risk is refined to make explicit what was only implicit before: The set of risk scenarios used in a quantitative risk analysis should be (1) complete, (2) finite, and (3) disjoint. These three properties can be achieved by first noting that in realistic problems, there is always an underlying continuum of possible scenarios; this continuum is then divided into a finite set of nonoverlapping subsets. Thus, recognizing that each such subset is itself a scenario leads to a complete, finite, and disjoint set. The mathematical term for this dividing process is partitioning.

The HHM approach divides the continuum but does not necessarily partition it. In other words, it allows the set of subsets to be overlapping, i.e., non-disjoint. It argues that disjointedness is required only when the likelihood of the scenarios is going to be quantified, and even then, only if these likelihoods are going to be added up (in which case the overlapping areas would end up counted twice). Thus, if the risk analysis seeks mainly to identify scenarios rather than to quantify their likelihood, the disjointedness requirement can be relaxed somewhat, so that it becomes a preference rather than a necessity.

With this understanding, the risk identification and scenario structuring dimensions of HHM take their place within the TSS as an extremely general scenario identification process, alongside the other well-known but more specific processes: FMEA, hazard and operations analysis (HAZOP), fault and event trees, and AFD (Haimes 2009).

In seeing how HHM and TSS fit within each other, one key idea is to view the HHM diagram as a depiction of the success scenario S_0. Each box in the diagram may then be viewed as defining a set

of actions or results required of the system, as part of the definition of success. Conversely then, each box also defines a set of risk scenarios; the set of scenarios in which there is failure to accomplish one or more of the actions or results defined by that box. The union of all these sets of risk scenarios is then "complete" in that it contains all possible risk scenarios.

In (1) the choice of the subscript i, on the S_i, carries with it, by conventional usage, the implicit assumption that the set of scenarios is denumerable (i.e., countable). Moreover, because (1) is intended to describe the result of an actual risk analysis, there is the further implicit assumption that the number of scenarios in the set $\{S_i\}$ is finite. To release both these assumptions, revise (2) to read:

$$R = \{<S_\alpha,\ L_\alpha,\ X_\alpha>\}, \alpha\, \varepsilon\, A \tag{3}$$

where the index α now ranges over a set A, which in general is non-denumerable. The set A is therefore infinite and non-denumerable. It has the same order of infinity as the real number continuum.

From the perspective of this framework, TSS can now be viewed as a study of the various techniques for achieving such a partitioning. Having defined the success scenario S_0, the process of finding the risk scenarios, S_i, consists of decomposing S_0 into parts or components. Then, putting a magnifying glass over each part in turn, it is asked, "What could go wrong in this part?" In this way the S_i is generated.

Now (2) and (3) can be connected by recalling the principle that every scenario, S_i, that can be described with a finite number of words is itself a set of scenarios (Kaplan 1991, 1993). Thus, each S_i in (2) can be visualized as a subset of S_A. For practical purposes, the set of scenarios in the risk analysis, $\{S_i\}$, should be

1. Complete, in the sense that $\cup_i S_i = S_A$;
2. Finite; and
3. Disjoint, meaning that $S_i \cap S_j, = \emptyset$ for all $i \neq j$.

Such a set of subsets of S_A is termed a partitioning, P, of S_A. Thus, the goal of risk analysis can be viewed as identifying a partitioning of the underlying risk space S_A. The individual sets in this partitioning are the scenarios S_i, which are finite in number, disjoint, and together cover the underlying space S_A. It may then be written

$$R_P = \{<S_i,\ L_i,\ X_i>\}_P \tag{4}$$

R_P is thus an approximation to R based on the partition P:

$$R_P \approx R \tag{5}$$

Within the field of risk assessment, TSS and HHM aspire to be a comprehensive treatment of the process of finding, organizing, and categorizing the set of risk scenarios. As such, each should include within itself the well-known standard methods of scenario identification such as fault trees, FMEA, and failure mode, effects, and criticality analysis (FMECA) (Haimes 2009).

Risk Management for Software Engineering

Clyde G. Chittister[1] and Yacov Y. Haimes[2]
[1]Carnegie Mellon University, Pittsburgh, PA, USA
[2]University of Virginia, Charlottesville, VA, USA

Introduction

Most, if not all, engineering systems are conceived, designed, constructed, marketed, and maintained under great unknowns and immense uncertainties. This lack of knowledge is not limited to technological issues such as strength of material, functionality, performance, accuracy, and quality of the components and the total product, but in fact spans a diversity of non-technical areas as well, such as predictions of customer, competitor, and market behaviors, or the anticipation of the product's impact on the organization that manufactures it. Thus, there are risks (measured by the probability and severity of adverse effects) associated with engineering systems; these risks must be managed. Computer software plays a critical role in the operation of engineering systems, due to the pervasive nature of computers in society, plus the integrality of software to the business of OR/MS.

Because software has its foundation in mathematics and logic and not in physical laws, the ability of a software engineer to introduce uncertainty into a software system is greater than in any other field. Only through very stringent management can those uncertainties introduced during the software development cycle be effectively controlled. The increased influence of software in decision making has introduced a new dimension to the way business is done in engineering quarters: many of the used-to-be-engineering decisions have been or transferred and transformed, albeit in a limited and controlled manner, to the software function. This power shift in software functionality, the explicit responsibility and accountability of software engineers, and the expertise required on the job of technical professionals, has interesting manifestations, implications, and challenges for the software engineers to adapt to new realities and to change — all of which affect the assessment and management of risk associated with software development (Chittister and Haimes 1994; Haimes and Chittister 1996).

Perhaps one of the most striking manifestations of this power shift relates to real-time control systems. Quality control in the manufacture of an engineering component, for example, is no longer primarily the responsibility of the operator; instead, the software controlling the process also controls the quality. Thus, in many respects, the software, which is designed and developed by software engineers, actually controls the process, not the engineers who originally designed the product. This implies that a shift has taken place from a strictly hardware-engineering perspective to a hardware-and software-engineering perspective. Software now fundamentally influences the design of the system. For example, the C-17 transport aircraft has been called the most computerized, software-intensive transport aircraft ever built (General Accounting Office 1992). Similarly, the Space Station has "on-board computers . . . critical to space craft safety and mission" (General Accounting Office 1989). Likewise, neither the A320 Airbus nor a number of high technology civilian and military systems can perform their functions without software. Such examples illustrate the difference between software as amanufacturing or implementation mechanism and software as a system-design component. A comprehensive discussion of software acquisition is presented by Boehm and Lane (2007) and Haimes and Chittister (1996).

For example, the decision to update or change operating parameters or entire algorithms based on real-time sensor data received from other sources is now embedded in the software system design. As another example, the data selected to be displayed on one system may be based on information received from other systems. Indeed, the types of changes or updates being implemented by software today would have, in the past, required either system hardware modification or a fundamental redesign of the system. In spite of these examples and others like them, software risk assessment and management, as a specialized entity, with all its importance and implications on other engineering systems and humans, remains an emerging rather than a well-understood activity.

Since software development, in the majority of cases, is an ad hoc process (Humphrey 1990), it is

not surprising that the risk identification and management process has been by and large ad hoc also. That process, however, can be made systematic and structured even if the software development process is not. The advances in hardware technology and reliability and the seemingly unlimited capabilities of computers render the reliability of most systems to be more heavily dependent on the integrity of the software used. Thus, software failure must be scrutinized with respect to its contribution to overall system failure and with the same diligence and tenacity that have been devoted to hardware failure.

Software Risk

In the software development process, the following three basic questions must be posed and answered at each stage regarding risk: (1) What can go wrong? (2) What is the likelihood that it will go wrong? (3) What are the consequences? (Kaplan and Garrick 1981). Now it can be added: what is the time frame? (Haimes 2009a). Only after these questions have been answered can the final question be asked: What can be done? Determining what can be done entails developing alternative design options; evaluating trade-offs; selecting one or more acceptable options (in terms of cost, reliability, performance, total quality, and safety); and evaluating the impact of current policies on future options. To answer the first three questions in the risk assessment process, however, one may benefit from knowledge of the four major sources of failure of systems in general, as well as in software development (Haimes 1991, 2009a, b):

1. Hardware failure
2. Software failure (which includes software used in the development of software)
3. Organizational failure
4. Human failure

The evolving role of the software engineer in decision making has created and continues to create enormous new challenges. The risk of not meeting specified product quality has also shifted. What was once solely the responsibility of traditional engineers who had technical know-how, expertise, and experience is now responsibility shared with software engineers, who design and develop the controlling software (Haimes and Chittister 2005, 2006; Chittister and Haimes 2004).

Although all engineering managers practice risk management in one way or another, only a minority follow this systemic process by looking for sources of failure across the entire system. The intricacy and complexity of the risk assessment and management process (when applied to complex engineering systems) and the need for quantitative analysis (which requires knowledge in probability and statistics, and frequently other content knowledge) have contributed to the emergence of the subspecialization of risk management in engineering. Thus, seeds for two seemingly distinct groups — engineers as managers of risk, and risk experts as managers of engineering systems — have been sown. In a parallel way, one may trace the distinction between (a) the engineer as a technical expert, one primarily concerned with the technical aspects of a project and to a lesser degree with managerial issues; and (b) the manager, one primarily concerned with management (in the broader and more encompassing sense of the term) and to a lesser degree with technical aspects.

Here again, the engineer (as a local manager) and the manager (as a more global manager with a broader vision and perspective) share responsibilities, tools, and methodologies, yet at the same time, each performs distinct functions, matures in different professional cultures, often uses a different jargon, and communicates with a different language. Understanding this emerging paradigm surrounding the three entities — software engineering, management, and risk analysis — is at the heart of understanding the emergence of software technical risk management.

Furthermore, to appreciate the connectedness among the three elements of this paradigm, one must also understand the hierarchical managerial structure and the consequences of its divisions:

1. *Upper management*: This group views risk almost exclusively in terms of profitability, schedule, and quality. Risk is also viewed in terms of the organization as a whole, and the effect on multiple projects or a product line.
2. *Program management*: Although this group is concerned with profitability, it concentrates more on cost, schedules, product specificity, quality, and performance, usually for a specific program or project.

3. *Technical staff* (software engineers, hardware engineers, etc.): This group of professionals concerns itself primarily with technical details of components, subassemblies, and products for one or more projects.

Clearly, differences among the risk managers at each level of this hierarchical decision making structure are caused by numerous factors, including the scope and level of responsibilities, time horizon, functionality, as well as requirements of skill, knowledge, experience, and expertise. Consequently, these differences determine, to a large extent, the tools and methodologies employed by risk managers at various levels. The management of risk associated with the development of software is governed by the same hierarchical decision making structure and by the same interconnected engineering-management-risk subspecialization paradigm.

Technical vs. Non-technical Risk

The increase in the influence and dominance of software on the system necessarily accompanies an increase in the elements of risk and uncertainty. Although no single classification of risk associated with software development has been developed, a dichotomous model of software technical risk vs. software non-technical risk is adopted here (Chittister and Haimes 1994).

This dichotomy between software technical and non-technical risk is introduced not for the purpose of distinguishing between two types of software products; rather, this classification distinguishes various functions in the developmental process of software, and thus, is concerned with the expertise required to deliver each function. Clearly, software technical and non-technical risks are dependent on and influence one another. For example, during a systems integration phase, the developed software may not meet some performance criteria or requirements. In this case, management has several options, including fixing the product and thus delaying the delivery time (and possibly exceeding the budgeted cost) or shipping the product as-is on time. In either case, however, the sources of software technical risk have not changed: only the consequences have been altered.

Software technical risk is defined as a measure of the probability and severity of adverse effects inherent in the development of software that does not meet its intended functions and performance requirements. Thus, software technical risk connotes the risk associated with those aspects in the software developmental process that are concerned with the quality, precision, accuracy, and performance over time of the developed software. In other words, software technical risk connotes the risk associated with building a software product that meets intended functions and performance.

On the other hand, software non-technical risk connotes the risk associated with the programmatic aspects in the developmental process of software that are concerned with general management, that is, with personnel, contractor selection, scheduling, budget, and marketing.

Software non-technical risk is defined as a measure of the probability and severity of adverse effects that are inherent in the development of software and are associated with the programmatic aspects in the development process of software. Although each type of risk may have an impact on the other, this distinction is still useful because it improves the process of risk assessment and management by establishing causality. Indeed, the distinction between software technical risk (e.g., noncompliance with expected product quality) and software non-technical risk (e.g., cost overruns and delays in scheduled delivery of the product) is helpful in many ways. Indeed, cognizance of the differences between the types of risks should improve their assessment and management, not serve as a detriment to dealing with them. In other words, while the distinction among the multifarious sources and types of risks is important only to the extent that the totality of these sources and type can be accounted for through their inherent differences, the successful management of risk can be achieved only through an integrated and holistically-based approach. Since software development is an intellectual, labor-intensive activity, the role of humans and human factors must be carefully understood to properly assess and manage software technical risk.

The sources of risk associated with software development are many and varied. Indeed, at each stage of the software life-cycle (design, development, testing, installation, integration into a larger system,

and its ultimate use), one can identify numerous sources of risk.

The road to building a software system is full of surprises. Software often goes through numerous changes, upgrades, fixes, recompiles, and system builds, etc., to address problems; nevertheless, new problems invariably arise. These changes take place because requirements change, people make mistakes, hardware manufacturers make changes to the system in response to marketing information, engineers introduce improvements, and software vendors upgrade their tools. In addition, often there is a break in communication, all these changes necessarily introduce uncertainties into the software development process and into the road to building software.

The ability to predict software problems before-hand has three major components:

1. Identifying and anticipating problems before they happen.
2. Determining the magnitude of potential or existing problems or risks.
3. Communicating the problems or risks to the appropriate people (people who cause, fix, are affected by, or are responsible for the problems).

The Role of Software in a Larger System

To understand what software development risk is, and to contribute to its assessment and management through the transfer of knowledge from the hardware engineering field to the software engineering field, one must (a) recognize the salient features and differences between the development processes of hardware engineering and software engineering; (b) understand the role of software engineering within the entire system; (c) appreciate, in the context of design and development, the uniqueness of software failure as juxtaposed against hardware failure, recognizing the importance of all four sources of system failure — hardware, software, organizational, and human; and (d) be familiar with the process of risk assessment and management from a total systems viewpoint.

There would be, in general, a finite and unambiguous number of fundamentally different paths or design options for hardware development to meet a given set of design specifications. Indeed, the extensive use of fault-tree analysis builds on this premise of finiteness. This is not so in the case of the architectural design of software; the number of significantly distinguishable paths or design options of software, for any given specifications, is significantly larger, more ambiguous, and broader. This inherently large number of degrees of freedom in design defies attempts to rely on historical statistics in predicting potential defects, faults, and errors in the development of software. A case in point is the development of high performance computing technology (Chittister and Haimes 2010). Significant challenges are facing the following three different groups within the professional community that support the development of large-scale scientific and engineering software applications. The first of the groups encompasses the application developers of large-scale scientific and engineering software systems, especially those requiring high-performance computing (HPC). The second group covers the HPC software development and run-time environments. The third consists of the integrators of the first two groups, with a focus on the systems engineers whose task is to bridge the technical and cultural gap between the other two. These challenges reside in several areas, the most important being the educational and cultural backgrounds that are reflected in the knowledge, expertise, and experience of the principals involved (Chittister and Haimes 2010).

The design and development of software do not typically follow well-established protocol and commonly accepted procedures. Indeed, in most cases, each software development is envisioned as a unique and distinct product. This lack of a well-developed and acceptable protocol has major implications on several dimensions for the assessment of software development risk.

Hardware has been increasingly taking the component role, whereas software has been forcefully assuming the overall systems role. Clearly, however, this is not the case in all organizations. This seemingly pivotal development has significant implications for the evolving influence of software engineers on important and critical decisions concerning product design, development, and marketing. The coordination of myriads of components in one system can often be accomplished more cost effectively and with higher reliability through software; this is a marked departure from

past practices. This fact has also brought the role of systems engineers to greater prominence in formulating policy affecting product design and development. Furthermore, the software engineers' evolving role in implementation, more than the knowledge that they bring into the project, constitutes another important force in the power shift from hardware to software engineers. Indeed, the last step in the development of a system always involves software engineers, a fact that carries with it more responsibility and implied authority in final product development. It is important to recognize, however, that both hardware and software engineers play an equally important role in the over all system design. In this sense, in the evolution of the power shift from hardware to software one must keep in mind that software development is an intellectually intensive activity where human factors are central. In his chapter on cognitive ergonomics, Sage (1992) makes a forceful argument about the centrality of human interaction with various aspects of the system throughout all phase so fa systems engineering life cycle. Therefore, to assess and manage software technical and non-technical risks, one must explicitly address the human element. Sage argues that "a systematic study of human error and approaches to ameliorate the effects of human error in systems and in organizations" is essential in this regard.

As the role that software is assuming in meeting system requirements grows, the impact of software on system risk grows. To be effective and meaningful, risk management must be an integral part of overall system management. This is particularly important in the management of technological systems, especially software-intensive systems, where the failure of a system can be caused by the failure of hardware, software, the organization, or its people.

Hierarchical Holographic Modeling for Risk Assessment

In the quest to develop an analytical framework for risk management of software engineering it is important to focus on the *sources and causes* of these problems, attempt to group them into a meaningful, yet manageable, number of categories, and then develop a comprehensive framework for dealing with the causes rather than the symptoms. To streamline the discussion and add order to it, a hierarchical structure is adopted.

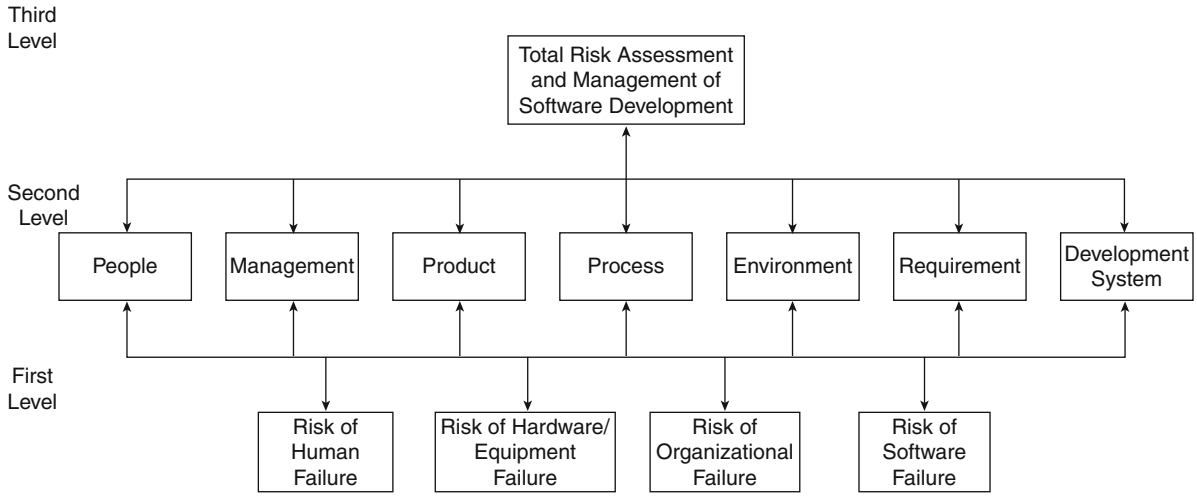
Indeed, it is impossible to do justice to a comprehensive framework for the risk assessment and management of software development by boxing it into one planar structure (model). By allowing cross-representations and overlapping models of the various facets and dimensions of the process, hierarchical holographic modeling (HHM) alleviates some of the limitations of a single schema or a single vision of the complex system (Haimes 1981, 2009a, b; Haimes et al. 1990).

Fundamentally, HHM is grounded on the premise that large-scale and complex systems, such as software development, should be studied and modeled by more than a single representation, vision, or schema. And, because such complexities cannot be adequately modeled or represented through a planar or a single vision, overlapping among these visions is not only unavoidable, but can be helpful in a holistic appreciation of the interconnectedness among the various components, aspects, objectives, and decision makers associated with such systems.

The stratagem presented here for risk identification evolves around three hierarchical levels (Chittister and Haimes 1994; Haimes 2009a, b). The three major decompositions, visions, or perspectives include: the functional perspective, the source-based perspective, and the temporal perspective.

From a functional perspective, the software development process may be decomposed into the following seven subsystems: requirement, product, process, people, management, environment, and the development system (Fig. 1). These terms may be defined as follows:

1. *Requirement*: The highest-level definition of what the product is supposed to do: what needs it must meet, how it should behave, and how the customer will use it. It corresponds to the production perspective.
2. *Product*: The output of the project that will be delivered to the customer. It includes the complete system: hardware, software, and documentation.
3. *Process*: The way by which the contractor proposes to satisfy the customer's requirement. The process is the sequence of steps — their inputs, outputs, actions, validation criteria, and monitoring activities — that leads from the initial requirement



Risk Management for Software Engineering, Fig. 1 Total risk assessment and management of software engineering: Functional-based hierarchical holographic structure

to the final delivered product. It includes such phases as requirements analysis, product definition, product creation, testing, and delivery. It includes both general management processes, such as costing, schedule tracking, and personnel assignment, and project-specific processes, such as feasibility studies, design reviews, or regression testing.

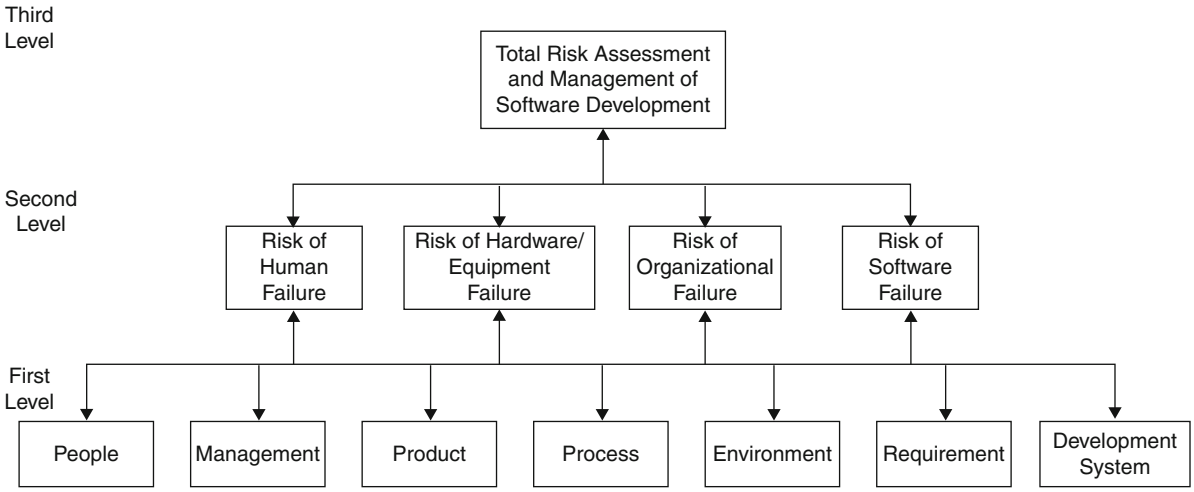
4. *People*: All those who will be associated with the technical work on the project and all the support staff. It also includes the technical advisers, overseers, and experts, whether in the chain of command or matrixed.
5. *Management*: The line managers at every level who have authority over the project, including those responsible for budget, schedule, personnel, facilities, and customer relations.
6. *Environment*: The "externals" of the project: the factors that are outside the control of the project but can still have major effects on its success or be sources of substantial risk.
7. *Development system*: The methods, tools, and supporting equipment that will be used in the product development. This includes, for instance, CASE tools, simulators, design methodologies, compilers, and host computer systems.

Another vision of the HHM can be obtained through the four sources of system failure discussed earlier (Fig. 2):

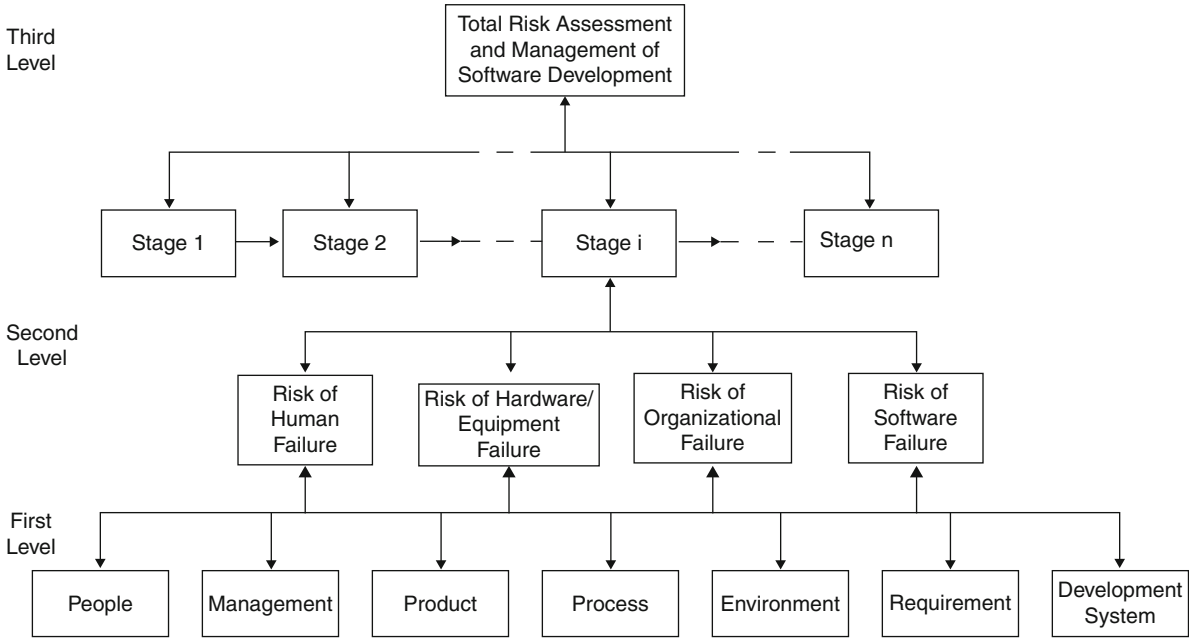
1. Hardware failure
2. Software failure (software used in the development of software)
3. Organizational failure
4. Human failure

These four sources of failure are not necessarily independent of each other. Just as the distinction between software and hardware is not always straightforward, neither is the separation between human and organizational failure. Nevertheless, these four categories of sources of failure provide a meaningful foundation upon which to build the decision-making hierarchy for the proposed framework. Note that software development is an intellectual, labor-intensive activity that must be streamlined through a well-managed organizational infrastructure and nurtured by an organizational culture and vision that are conducive to and driven by a continuous improvement philosophy.

The third vision of the HHM relates to the evolution of software development over time. Each of the various stages of software development, although often not sharply distinguishable, overlapping, and iterative, constitutes a subsystem in the temporal decomposition (Figs. 3 and 4). For purposes of this section, the temporal stages are identified as in Humphrey (1990) as: (1) system requirements; (2) software requirements; (3) analysis; (4) program design; (5) coding; (6) testing; and (7) operations.

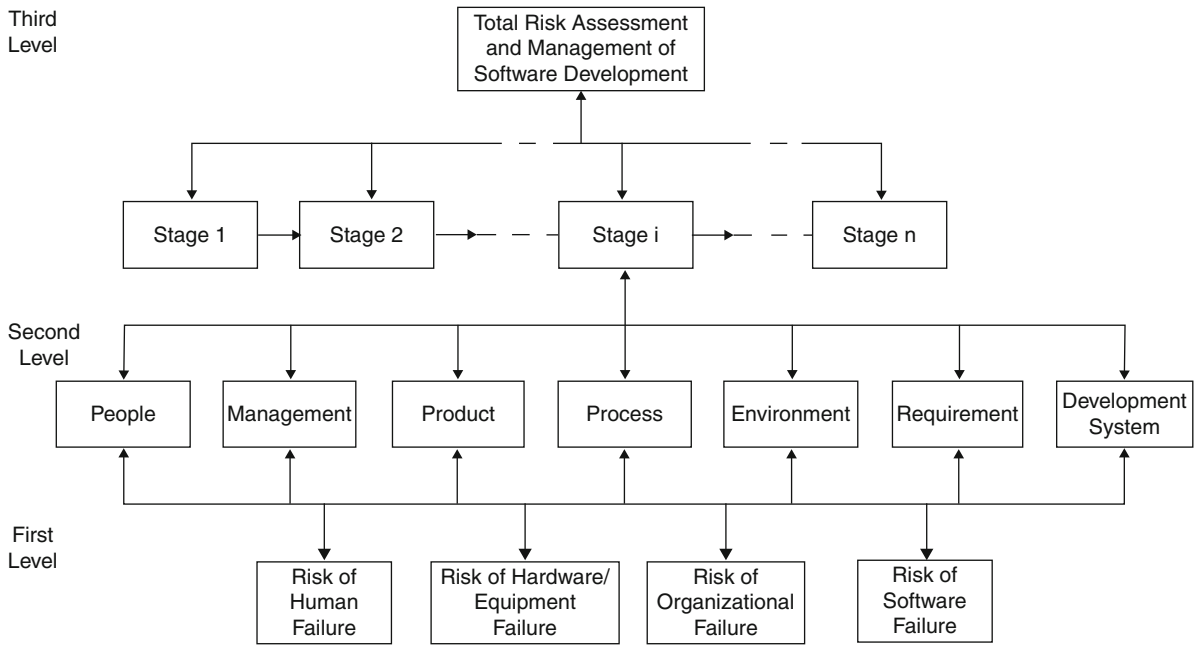


Risk Management for Software Engineering, Fig. 2 Total risk assessment and management of software engineering: Source-based hierarchical holographic structure



Risk Management for Software Engineering, Fig. 3 Total risk assessment and management of software engineering: Temporal-based hierarchical holographic structure

Each stage (subsystem) in the temporal decomposition can be viewed as one frame in a fixed time (e.g., testing) during the software development process. It is at this fixed-time frame that risks associated with the functional decomposition (e.g., requirement) and with the source-based decomposition (e.g., organizational failure) are identified and articulated. As another example, consider the following four risks that are common during each stage of software development: cost overrun, time delay, not meeting requirements, and not meeting technical quality specifications.



Risk Management for Software Engineering, Fig. 4 Total risk assessment and management of software engineering: Temporal-based hierarchical holographic structure

The temporal domain has significance far beyond the schedule of the project; it articulates how risks change and evolve over time.

Each of the three hierarchical holographic (HH) submodels developed here contributes to the identification of risk associated with software development. The overlaps among these HH submodels mimic the fuzziness that characterizes the real world of software development with respect to the inability to make a clear distinction among the various causes of failures. Figure 1, which is an inverted image of Fig. 2, presents an entirely different perspective in answering the set of triple questions: What can go wrong? What is the likelihood that it will go wrong? And what would the consequences be? Since a central objective of risk assessment is to identify, to the extent possible, everything that can go wrong, then a hierarchical holographic modeling structure is superior to a planar single model in this respect. Note, for example, that in Fig. 1, the four sources of risk (human, hardware, organizational, and software) are investigated for each subsystem of the functional decomposition (people, management, product, process, environment, requirement, and development systems). On the other hand, Fig. 2 depicts a different perspective; namely, the seven functional de-compositions are investigated for each of the four sources of risk of failure. Figures 3 and 4 incorporates the temporal decomposition that captures the stage-wise evolutionary process of software development, and thus the risk associated with each stage and for each subsystem of the functional and source-based decompositions. In particular, Figs. 3 and 4 extend Figs. 1 and 2 by incorporating the temporal domain into the HHM.

Bases for Variances in Software Cost Estimation

Most developers of large complex software systems use cost models to estimate their costs and to assess the risk of cost overrun. These models are structured on a set of relationships based on such parameters as the size and complexity of the software, the experience level of the software developer, and the type of application within which the software will be used. Different models generate different weights or levels of importance for these parameters, and not all models

use the same parameters. Radically different cost estimates can result merely on the basis of which parameters are used in the models and how they are implemented. Even when the parameters are consistent, different developers will probably not agree on the value or weight of the parameter in the first place. In fact, many organizations consider their interpretations of these parameters to contribute to their "competitive edge" because the definition affects their ability to determine costs accurately. For example, an organization that has little experience in developing space system software may not have the same perception of difficulty when developing a complex avionic software system as would an organization that has significant experience in that area. Their understanding of space systems, however, will alter their definition of the avionic system parameters. Do developers with little experience overestimate or underestimate the complexity of the task because of how they define these parameters? The central questions are, "What are the sources of risk associated with project cost estimation? How can such risk be quantified?" (Schooff 1996; Schooff et al. 1997; Haimes 2009a, b).

Although creating, maintaining, and updating project cost-estimation metrics and parameters are extremely important for an organization, it is nevertheless unlikely that a future project will be similar enough to previous projects to merit directly importing these metrics or parameters; such metrics and parameters may not be directly applicable without appropriate modifications. Indeed, cost estimators must use judgment when applying these parameters to a new project requirement. Furthermore, cost estimation constitutes a critical area with regard to the sources of risk for software development, which is without parallel to other fields. An analogy would be a contractor estimating the cost to construct a 50-story building. If the contractor had previously built only structures with a maximum of ten stories, he would not just increase the estimate five-fold. In fact, the contractor would probably question the basic foundations and relevance of extending the 10-story model to the new structure parameters. In software, however, it is not uncommon to increase estimates for new projects by a factor of five from previous projects of one-fifth the size and complexity. Many new systems have size estimates of over 1,000,000 lines of code even though the developers have little experience with systems of this size (Schooff et al. 1997; Haimes 2009a, b).

Another example is in the use of commercial off-the-shelf (COTS) software. The original assumption that a commercial database management system (DBMS) can be used to meet customer requirements may change if the customer requires features not supported by DBMS suppliers. Such changes may have serious ramifications for the cost estimate, depending on how the developer plans to solve the problem. If the developer chooses to deal with a subcontractor in a way similar to dealing with the DBMS vendor, there will be risk associated with the subcontractor. The alternative is for the developer to undertake the development of its own DBMS. This requires an additional set of assumptions, design parameters, and judgments regarding the architecture, size, experience level, domain knowledge, software engineering knowledge, and the support environment needed to develop the DBMS. Each of these assumptions, parameters, and judgments has some uncertainty associated with it, which contributes to the overall risk in the cost estimate. If the developer chooses to subcontract the DBMS development to an outside vendor, then the issue for the contractor is understanding and accounting for the set of assumptions that are made by the subcontractors on the DBMS and on the system architecture.

The ability of the developer to make valid assumptions and design decisions is usually based on a set of metrics; these metrics can either be based on current measurements or on past performance. Either way, however, there has to be an agreed-upon set of measures that is being evaluated (such as the number of lines of code needed to accomplish specified tasks, or productivity rates in terms of lines of code per hour). The difficulty with software development is that the community has not agreed upon basic measures, such as how to count lines of code or how to measure productivity. Using performance history is difficult because the systems under development are sufficiently different such that history may not adequately reflect the new parameters accurately.

There are many models for software acquisition (Schooff et al. 1997). In the spiral model of software development (Boehm 1988), the process consists of multiple repetitions of primary stages and often

extends over a great length of time. Lederer and Prassad (1993) reported that in practice, software estimation is most often prepared at the initial project proposal stage; then, with declining frequency, at the requirements, systems analysis, design, and development stages. However, as the software development community continues to move away from the traditional waterfall development process model to the spiral-type models, demand has increased for cost-estimation models that account for the dynamics of changing software requirements and design (and the always-present uncertainty) over multiple time periods (Schooff et al. 1997; Haimes 2009a, b). Bell's survey of software development and software acquisition professionals indicates that a vast majority believe a dynamic software-estimation model would be most applicable for their estimation requirements (Bell 1995).

At each stage of the acquisition process, decisions are made that affect the events and decision opportunities of subsequent phases. Software estimation is a required activity in every stage of the process. Applying the probabilistic cost-estimation method with multiple objective risk functions described in Schooff and Haimes (1997) and in Haimes (2009a, b) constitutes a multiple-objective decision problem that is solved over the multiple stages of the acquisition life cycle.

Concluding Remarks

Software will continue to grow in size, complexity, and importance as it assumes more functionality in large, complex systems. If engineers and managers working in the community do not embrace a risk management ethic for software development, then software problems will continue to grow as well. Although practicing risk management does not guarantee fewer problems, it does provide a structure with which to make better decisions about the uncertainty and impact of future events. If risks can be measured, then contingency strategies can be provided; however, if risks are unknown, then surprise is likely when it is least convenient (Haimes 2009a).

Although software engineering is different from other engineering disciplines, the management of risk in the developmental process is critical for all engineering disciplines. The framework for identifying and assessing risk in the software development process is grounded on the premise that software development is an intellectual, labor-intensive activity, thus making the human factor central to the assessment and management of risk.

As systems become larger and more complex, the assessment and management of risk must be a team effort. The team has to include, among others, the system developers, support staff from the organization, and management. Risk management is neither just the program manager's job nor just a technical issue. Financial and quality risks are as important as software technical risk.

The more diversified the team, the more important it is to have a common and agreed-upon risk assessment and management process. The members of the team will have their own technical jargon and their own frames of reference. If each subgroup identifies and manages risks differently, there will be no common ground for communication or measurement. A systematic and structured process that is used by everyone will provide a foundation for discussion and for mitigation strategies. This process will also greatly reduce confusion caused by misunderstanding, which is itself a source of risk in large complex systems.

Indeed, modeling and managing software technical risk must be an activity that recognizes the intricacy of the internal and external environment within which software development is practiced. Depending on the forces exerted and on the software development practice itself, two types of risks are likely to emerge — software technical and non-technical risks. Indigenous to these forces is the power shift from hardware to software; consequently, such change must be recognized and managed. In *Changed Agents*, London (1990) summarized his views on organizational change, as follows:

Incremental change merges the new with the old. It requires a willingness to be open to new ideas and to continuously refine and possibly extend the goals of the organization. Frame-breaking change is dramatic and often sudden. Though resistance is likely, the organization's survival depends on re-creating the organization's mission, structure, staff, and modes of operation.

Indeed, the risks of not meeting product quality and performance, cost, and schedule can be successfully

identified, quantified and measured, evaluated, and managed only when a systemic and holistic process of assessment and management is employed. Such a process is an organizational recipe for long-term sustainable development. Toffler (1990) best articulated the imperative of properly coping with technological change. The software engineering community is traveling in unexplored terrain; the success of its journey depends, to a large extent, on its ability to bring the larger systems community into the realization that acknowledging and responding to the power shift in the software area is a first and critical step in a successful management of software technical and non-technical risk.

No one would argue that the best way to manage problems is to keep them from happening. A risk ethic that is embraced and practiced by an entire organization will significantly reduce the chaos created by unknown risks and crisis situations.

► Block-Angular System

Robust Optimization

Optimization that takes into account data uncertainty without using probability by considering only the ranges of possible values of parameters, e.g., "best case" and "worst case" scenarios. For example, in the standard linear programming problem $\min_{\boldsymbol{x}} \boldsymbol{c}^{\boldsymbol{T}}\boldsymbol{x}$ subject to $\boldsymbol{Ax} \leq \boldsymbol{b}$, the robust counterpart formulation would consider the input data $\boldsymbol{A}$, $\boldsymbol{b}$, and $\boldsymbol{c}$ in a given range comprising the uncertainty set for the parameters. This approach is contrasted with stochastic programming, which takes into account uncertainty explicitly by using probability distributions on scenarios.

Robustness Analysis is a method for evaluating initial decision commitments under conditions of uncertainty, where subsequent decisions will be implemented over time. The robustness of an initial decision is an operational measure of the flexibility which that commitment will leave for useful future decision choice.

The definition of the robustness of an initial commitment is:

> *the number of acceptable options at the planning horizon that are compatible with that commitment, as a ratio of the total number of acceptable options.*

In more formal notation, if
$\underline{S}$ is the set of all options at the planning horizon with acceptable performance;
$\underline{S}_i$ is the subset of $\underline{S}$ that is compatible with initial commitment d_i;
and n (.) denotes the number of elements in a set
then the robustness of commitment d_i is given by

$$r(d_i) = n(\underline{S}_i)/n(\underline{S})$$

All robustness scores lie in the range (0, 1). Higher scores are preferred to lower ones.

The same basic logic can be used where there is a particular concern to avoid access to future options that are assessed as likely to perform unacceptably badly. The mirror image concept of debility is defined as above, where now both numerator and denominator refer to *un*acceptable options. Lower debility scores are preferred.

A variant of the approach is multi-future robustness analysis. In this case the acceptability of an option may vary between futures, and the analysis produces a vector of robustness scores for each commitment. For a fuller description of Robustness Analysis, see Rosenhead (2001).

To employ Robustness Analysis it is necessary to:

- Identify the initial commitments to be evaluated;
- Select a planning horizon (typically 5–10 years, depending on the speed of change in the environment and the time lag in implementing decisions);
- Clarify the range and variety of future options that could result at the planning horizon;
- Establish which commitments are compatible with, ie leave available, which options; and
- Determine the acceptability of future options in the projected future(s)

The evaluations of 'acceptability' and of 'compatibility' may be model-based, or may be elicited from stakeholders. When employed in a workshop format Robustness Analysis is a member of the Problem Structuring Methods family. The conceptual simplicity of Robustness Analysis makes it easy to grasp intuitively.

It is not suggested that decision-makers should automatically select and implement the commitment that has the highest robustness score. The balance between flexibility and more short-term factors will depend on circumstances. The advantage that Robustness Analysis brings to the decision table is a language in which flexibility can participate systematically in the conversation.

Safety

Igor Ushakov
Qualcomm Inc., San Diego, CA, USA

Safety is a property of a system that permits the system to operate without dangerous consequences for people (including serving personnel) and the environment. For many systems (as aircraft, submarines, chemical plants, nuclear power stations, etc.), some kinds of failures can lead to catastrophic results. In these cases, the safety indices coincide with reliability

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

indices after the choice of the appropriate criteria for defining failure. These might be the (complementary) probability of successful operation without accident, the mean time to accident appearance, etc.

Sometimes the safety of systems (as for dams of hydro-power stations, constructions in seismic zones, etc.) is considered to be only under the influence of nature. In this case, probabilistic measures may be insufficient and one should instead consider conditional safety under some specified levels of external influence.

But many systems may be harmful even under ideal conditions, without accidents. Examples are various chemical and metallurgical technological processes, power stations, and other objects polluting the environment with various toxic substances.

To quantify, begin by letting $f(t)$ be the poisonous emission function in time. One useful index of safety of such a system is the condition that, for some specified time interval of width Δ,

$$\int_t^{t+\Delta} f(t)dt \le f^0$$

where the threshold f^0 is given.

If there is some reduction process $\phi(t)$ which lowers the harmful consequences described by $f(t)$, then an appropriate index could be

$$\int_t^{t+\Delta} [f(t) - \phi(t)]_+ dt \le f^0$$

where $[\cdot]_+$ denotes the positive part of the number in brackets.

Many harmful processes (radioactive emission, dioxide pollution, etc.) exponentially calm down (recover) with time. In this case, a good safety criterion might be

$$\int_t^{t+\Delta} f(t)e^{-\alpha t}\, dt \le f^0$$

where α is the intensity of the recovery.

For more complete discussions of the issues outlined here, see Ushakov (1994), particularly for the relationship of classical reliability modeling to the analysis of safety.

Sample Average Approximation

Alexander Shapiro
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Consider the following optimization problem

$$\operatorname*{Min}_{x\in\chi} f_0(x) \text{ subject to } f_i(x) \le 0,\ i = 1, \ldots, q. \quad (1)$$

In stochastic optimization (stochastic programming), the objective and/or constraint functions are given in the form of expected values:

$$f_i(x) := \mathbb{E}[F_i(x, \xi)],\ i = 0, \ldots, q, \quad (2)$$

where " := " means "equal by definition", the set $\chi \subset \mathbb{R}^n$ is deterministic, $\xi \in \mathbb{R}^d$ is a vector representing uncertain parameters of the problem and $F_i(x, \xi), i = 0, \ldots, q$, are explicitly defined real-valued functions. In this formulation it is assumed that the parameter vector ξ is modeled as random with a specified probability distribution P, and the expectations in (2) are computed with respect to this distribution. (The same notation ξ will be used to denote a random vector and its particular realization; which one of these two meanings will be used in a particular situation will be clear from the context.)

By writing the objective function $f_0(x)$, say a cost of a certain procedure, as an expected value with respect to the probability distribution of involved random parameters, the optimization (minimization) is supposed to be performed on average. In some situations where the same procedure is repeated many

times, this can be justified by the Law of Large Numbers. On the other hand, modeling constraints as expectations could be quite different. It does not make sense trying to maintain on average power supply in a large city. Nevertheless there are some cases where expectation constraints appear naturally. One such example is given by problems with chance (probabilistic) constraints.

Suppose that it is desirable to enforce constraints $G(x, \xi) \leq 0$, where $G(x, \xi)$ is a given function depending on parameter vector ξ, for all possible realization of vector ξ varying in a specified uncertainty set $\Xi \subset \mathbb{R}^d$. However, this could be too costly or even impossible to maintain for all $\xi \in \Xi$, and one settles for a less restrictive constraint

$$\Pr\{G(x, \xi) \leq 0\} \geq 1 - \alpha, \tag{3}$$

where parameter vector ξ is modeled as random, $\Pr\{G(x, \xi) \leq 0\}$ denotes probability of the event "$G(x, \xi) \leq 0$" and $\alpha \in (0, 1)$ is a small specified number. Constraints of the form (3) are called chance (or probabilistic) constraints and $1 - \alpha$ is often referred to as the corresponding confidence level. Chance constraints were introduced by Charnes et al. (1958) and thoroughly discussed in Prékopa (1995). Recall that probability of an event A can be written as the expectation $\mathbb{E}[1_A]$, where 1_A denotes the corresponding indicator function, i.e., chance constraint (3) can be written as the expectation constraint $\mathbb{E}[H(x, \xi)] \geq 1 - \alpha$, where

$$H(x, \xi) := \begin{cases} 1 & \text{if } G(x, \xi) \leq 0, \\ 0 & \text{if } G(x, \xi) > 0. \end{cases} \tag{4}$$

A problem with the above formulation is that the function $H(x, \xi)$ is not everywhere continuous.

Monte Carlo Sampling

The expected value functions $f_i(x)$, $i = 0, \ldots, q$, are given by integrals $\mathbb{E}[F_i(x, \xi)] = \int F_i(x, \xi) dP(\xi)$. If the probability distribution P of ξ is discrete, say ξ can take values $\xi_1, \ldots, \xi_K$ with respective (positive) probabilities $p_1, \ldots, p_K$, then these integrals can be written as sums

$$\mathbb{E}[F_i(x, \xi)] = \sum_{k=1}^{K} p_k F_i(x, \xi_k), \ i = 0, \ldots, q, \tag{5}$$

and for not too large values of K could be computed in a straightforward way. On the other hand, for continuous distributions these expectations become multivariate integrals which could be evaluated in a closed form only in rather specific cases. Numerical computation of these integrals can be approached by discretization, i.e., by using approximations of the form (5). Suppose, for example, that components of the random vector ξ are distributed independently of each other, and r points are used for discretization of marginal distribution of each component of ξ. Then the total number of discretization points is $K = r^d$ and this number quickly becomes astronomically large with increase of the dimension d of ξ even for moderate values of r.

A way of dealing with exponential growth of discretization points is by using randomization based on Monte Carlo sampling techniques. Suppose that it is possible to generate in the computer a random (or rather pseudo-random) sample $\xi^1, \ldots, \xi^N$ of N independent realizations of the random vector ξ (see, e.g., Fishman 1999), i.e., $\xi^1, \ldots, \xi^N$ is an independent identically distributed (iid) sample of the random vector ξ. Then the expected value functions can be approximated by the respective sample averages $\hat{f}_{iN}(x) := N^{-1} \sum_{j=1}^{N} F_i(x, \xi^j)$. The employed sample can be viewed as a randomized discretization with each discretization point ξ^j taken with equal probability $p_j = N^{-1}$. Consequently the "true" problem (1) can be approximated by the optimization problem

$$\operatorname*{Min}_{x \in \chi} \hat{f}_{0N}(x) \text{ subject to } \hat{f}_{iN}(x) \leq 0, \ i = 1, \ldots, q. \tag{6}$$

Once the sample is generated, each $\hat{f}_{iN}(x)$ becomes an explicitly defined function of the decision vector x and (6) becomes a deterministic problem which could be solved by an appropriate deterministic algorithm. Although the sample average functions $\hat{f}_{iN}$ also depend on the generated sample, for the sake of simplicity, this dependence is suppressed with only the sample size appearing in the notation.

It is difficult to point to an exact origin of such Monte Carlo sampling approach to solving stochastic optimization problems. The idea is rather simple and natural, and the method and its variants were discovered and rediscovered by many authors under different names in various contexts and applications. In the stochastic optimization literature, it can be pointed, for example, to Rubinstein and Shapiro (1990)

and Robinson (1996), where this approach was called the stochastic counterpart method and sample-path optimization, respectively; in statistics, this type of approach was used in Geyer and Thompson (1992); in the machine learning literature, some specific forms of this approach are referred to as the empirical mean optimization. In the recent stochastic programming literature, it is often called the sample average approximation (SAA) method, the term coined in Kleywegt et al. (2001). Interestingly, only relatively recently it was realized that the SAA method can be reasonably efficient in solving certain classes of stochastic optimization problems. This was motivated by development of statistical inference of the SAA method and supported by numerical experiments.

Statistical Properties of SAA Estimates

The SAA problem (6) depends on the corresponding random sample and hence its optimal value and optimal solutions can be viewed as random (statistical) estimates of their counterparts of the "true" problem (1). The notation ϑ^* and $\hat{\vartheta}_N$ will be used for the optimal values of the true (1) and SAA (6) problems, respectively, and $\mathcal{S}$ and $\hat{\mathcal{S}}_N$ for respective sets of optimal solutions. Statistical properties of the optimal value $\hat{\vartheta}_N$ and optimal solutions $\hat{x}_N \in \hat{\mathcal{S}}_N$ of the SAA problem are discussed, e.g., in Shapiro et al. (2009). Below is presented a somewhat informal discussion of the main implications of that theory.

By the Law of Large Numbers (LLN), it follows that sample averages $\hat{f}_{iN}(x)$ converge with probability one (w.p.1) to their expected values $f_i(x)$ as the sample size N tends to infinity. The classical LLN ensures such pointwise convergence w.p.1, i.e., it holds for a fixed x provided that the expected value $f_i(x)$ is well defined and finite valued. Under mild additional conditions, it is possible to show that this convergence is uniform on any bounded subset of $\mathbb{R}^n$ (uniform LLN). It follows, under certain regularity conditions, that $\hat{\vartheta}_N$ and $\hat{x}_N$ converge to their true counterparts w.p.1 as $N \to \infty$. In the statistical terminology this means that $\hat{\vartheta}_N$ is a consistent estimator of ϑ^*. For optimal solutions $\hat{x}_N \in \hat{\mathcal{S}}_N$ of the SAA problem the convergence issue is more delicate. Assuming that the true problem has unique optimal solution $\bar{x}$, i.e., $\mathcal{S} = \{\bar{x}\}$, under mild regularity conditions it holds that $\hat{x}_N \to \bar{x}$ w.p.1 as $N \to \infty$. This, however, does not imply that $\hat{x}_N$ is a feasible point of the true problem for any sample size N. If the problem does not have expectation constraints, i.e., is of the form

$$\operatorname*{Min}_{x \in \chi} \{f(x) := \mathbb{E}[F(x, \xi)]\}, \tag{7}$$

then the (deterministic) feasible set χ of the true and the corresponding SAA problems is the same.

Next the rate of convergence is considered. For a given x, the Central Limit Theorem (CLT) implies that $N^{1/2}[\hat{f}_{iN}(x) - f_i(x)]$ converges in distribution to a normal distribution with zero mean and variance $\sigma_i^2(x) = \operatorname{Var}[F_i(x, \xi)]$. In particular, this implies that the error $\hat{f}_{iN}(x) - f_i(x)$ of the sample average estimator is of stochastic order $O_p(N^{-1/2})$. In other words in order to improve the accuracy of the sample average estimator by one digit (i.e., 10 times) the sample size should be increased by 100 times. There are some variance reduction techniques which are aimed at reducing variance of the corresponding estimators (e.g., Fishman 1999), but the rate $O_p(N^{-1/2})$ of convergence of Monte Carlo sampling estimates cannot be changed. It also could be mentioned that Quasi-Monte Carlo methods have theoretically better rates of convergence and in some cases, especially when the dimension of the parameter vector ξ is relatively small, can outperform the straightforward Monte Carlo methods (e.g., Niederreiter 1992). However, in principle it is not possible to evaluate multidimensional integrals with a high precision.

There are CLT-type results for the optimal value and optimal solutions of the SAA problems. Consider problem (7) and let $\hat{f}_N(x)$ be the sample average estimate of $f(x)$ and $\hat{\vartheta}_N$ be the optimal value of the corresponding SAA problem. Under mild regularity conditions, in particular if $F(\cdot, \xi)$ is Lipschitz continuous, then

$$\hat{\vartheta}_N = \inf_{x \in \mathcal{S}} \hat{f}_N(x) + o_p(N^{-1/2}). \tag{8}$$

Moreover, if the true problem (7) has unique optimal solution $\bar{x}$, then

$$\hat{\vartheta}_N - \vartheta^* = \hat{f}_N(\bar{x}) - f(\bar{x}) + o_p(N^{-1/2}), \tag{9}$$

and hence $N^{1/2}(\hat{\vartheta}_N - \vartheta^*)$ converges in distribution to a normal distribution with zero mean and variance $\sigma^2(\bar{x}) = \operatorname{Var}[F(\bar{x}, \xi)]$ (Shapiro 1991). For the

problems of the form (7) (i.e., without expectation constraints), it also holds that $\mathbb{E}[\hat{\vartheta}_N] \leq \vartheta^*$ and the bias $\vartheta^* - \mathbb{E}[\hat{\vartheta}_N]$ is monotonically decreasing to zero with increase of the sample size N (Norkin et al. 1998). By (9) it follows that if problem (7) has unique optimal solution $\bar{x}$, then this bias is of order $o(N^{-1/2})$ and $\hat{\vartheta}_N$ converges to ϑ^* more or less at the same rate as $\hat{f}_N(\bar{x})$ converges to $f(\bar{x})$. On the other hand, if the problem (7) has a large set $\mathcal{S}$ of optimal solutions, then the bias tends to become bigger and is of order $O(N^{-1/2})$.

Consider now problem (1) with expectation constraints. Suppose that the true problem (1) has unique optimal solution $\bar{x}$ and unique corresponding Lagrange multipliers $\bar{\lambda}_i \geq 0, \quad i = 1, .., q$. Then under certain regularity conditions, in particular if the set χ is convex and functions $F_i(\cdot, \xi)$, $i = 0, \ldots, q$, are either convex or continuously differentiable, it follows that

$$N^{1/2}(\hat{\vartheta}_N - \vartheta^*) \xrightarrow{d} \mathcal{N}(0, \sigma^2), \tag{10}$$

where $\sigma^2 = \mathrm{Var}\left[F_0(\bar{x}, \xi) + \sum_{i=1}^{q} \bar{\lambda}_i F_i(\bar{x}, \xi)\right]$ (Shapiro 1991) and $\xrightarrow{d}$ denotes convergence in distribution and $\mathcal{N}(0, \sigma^2)$ denotes normal distribution with mean 0 and variance σ^2.

There is an interesting implication of this result. In the formulation (6) of the corresponding SAA problem, the same sample is used in estimation of the objective and constraint functions. An alternative will be to employ different, independent of each other, samples for estimation of the involved functions. In the first case, the asymptotic variance of $\hat{\vartheta}_N$ is given by N^{-1} times $\mathrm{Var}\left[F_0(\bar{x}, \xi) + \sum_{i=1}^{q} \bar{\lambda}_i F_i(\bar{x}, \xi)\right]$, and this variance is equal to the sum of variances $\mathrm{Var}[F_0(\bar{x}, \xi)]$ and $\mathrm{Var}\left[\bar{\lambda}_i F_i(\bar{x}, \xi)\right]$, $i = 1, \ldots, q$, and the corresponding covariance terms. On the other hand, in the second case of independent samples, a similar formula holds but without the covariance terms. It could be expected for the covariance terms in the first case to be positive. In such situation it would be preferable to use the independent samples strategy in order to reduce variability of the SAA estimators.

Evaluation of the Sample Size and Validation of Optimality

Consider problem (7) (without expectation constraints). For an $\varepsilon > 0$ it is said that a feasible point $\bar{x} \in \chi$ is an ε -optimal solution of problem (7) if $f(\bar{x}) \leq \vartheta^* + \varepsilon$. A natural question is how large should be the sample size N to ensure that an ε' -optimal solution of the corresponding SAA problem is an ε-optimal solution of the true problem. Recall that the SAA method is not an algorithm; the constructed SAA problem still has to be solved numerically. Clearly the computational effort in solving the SAA problems grows with increase of the sample size N. (For convex problems coupled with good algorithms, this computational effort is more or less proportional to N.) Therefore, this question is directly related to computational complexity of stochastic programming problems.

Suppose for the moment that the feasible set χ is finite (i.e., the true problem is discrete), although its cardinality $|\chi|$ can be very large. The following estimate of the required sample size is given in Kleywegt et al. (2001): for $\varepsilon > 0$, $\varepsilon' \in [0, \varepsilon)$, $\alpha \in (0, 1)$ and sample size N satisfying

$$N \geq \frac{2\sigma^2}{(\varepsilon - \varepsilon')^2} \ln\left(\frac{|\chi|}{\alpha}\right), \tag{11}$$

it follows with probability at least $1 - \alpha$ that any ε'-optimal solution of the SAA problem is an ε-optimal solution of the true problem, i.e., for any sample size satisfying (11), there is a guarantee with confidence $1 - \alpha$ that by solving the SAA problem with accuracy $\varepsilon' < \varepsilon$, an ε-optimal solution of the true problem is recovered.

The constant σ^2 in (11) measures, in a sense, variability of the objective function $F(x, \xi)$. An important feature of the estimate (11) is that the cardinality of the set χ and significance level α are under the logarithm sign. This indicates that the required sample size is not very sensitive to increase of the cardinality of the considered combinatorial problem and a desirable confidence level. On the other hand, for say $\varepsilon' = \varepsilon/2$, the sample size N is of order $O(\varepsilon^{-2})$. Such dependence of the sample size on the required accuracy is unavoidable for Monte Carlo sampling estimates. This type of sample size estimates can be extended to general (bounded) sets $\chi \subset \mathbb{R}^n$ with similar conclusions (Shapiro (2001); see also Shapiro et al. (2009) for a discussion of such estimates).

Although important from the theoretical point of view, sample size estimates of the type (11) are far

too conservative for practical applications. The following procedure for validation of optimality of a candidate feasible point $\bar{x} \in \chi$, and hence for controlling the corresponding sample size, was suggested in Norkin et al. (1998) and developed in Mak et al. (1999). Since $\bar{x} \in \chi$ is a feasible point of the problem (7), it follows that $f(\bar{x}) \geq \vartheta^*$. Value $f(\bar{x})$ can be estimated by a direct Monte Carlo sampling.

An iid random sample ξ^j, $j = 1, \ldots, N'$, is generated, and $f(\bar{x})$ is estimated by the average $\hat{f}_{N'}(\bar{x})$. Note that the employed sample should be independent of sample(s) used in construction of the candidate solution $\bar{x}$. Also since it does not require solving large optimization problems, the sample size N' can be relatively large here. At the same time, the sample variance

$$\hat{\sigma}^2(\bar{x}) := \frac{1}{N'-1} \sum_{j=1}^{N'} \left(F(\bar{x}, \xi^j) - \hat{f}_{N'}(\bar{x})\right)^2$$

is computed. Consequently the upper bound $\hat{f}_{N'}(\bar{x}) + z_\alpha \hat{\sigma}(\bar{x})/\sqrt{N'}$ of the corresponding confidence interval gives an upper bound, with confidence of $1 - \alpha$, for the value $f(\bar{x})$, and hence for the optimal value ϑ^*, where z_α is the $(1-\alpha)$-quantile of the standard normal distribution.

Construction of a lower bound for the optimal value is based on the inequality $\mathbb{E}[\hat{\vartheta}_N] \leq \vartheta^*$, where the expectation $\mathbb{E}[\hat{\vartheta}_N]$ can be estimated by averaging optimal values of several SAA problems. Let $\hat{\vartheta}_N^1, \ldots, \hat{\vartheta}_N^M$ be optimal values of SAA problems based on independent samples each of size N. Then $\hat{v}_{N,M} := M^{-1} \sum_{m=1}^{M} \hat{\vartheta}_N^m$ is an unbiased estimate of $\mathbb{E}[\hat{\vartheta}_N]$, and $\hat{v}_{N,M} - t_{\alpha,M-1}\, \hat{\sigma}_{N,M}/\sqrt{M}$ can be used as a lower bound for ϑ^*, where $\hat{\sigma}^2_{N,M}$ is the sample variance of $\hat{\vartheta}_N^1, \ldots, \hat{\vartheta}_N^M$, and $t_{\alpha,M-1}$ is the $(1-\alpha)$-critical value of t-distribution with $M-1$ degrees of freedom (since M is typically not large, say in the range of 5–10, critical values of t-distribution, rather than standard normal, are used here). This procedure requires solving SAA problems M times, which involves considerable additional computational effort. For some ideas of reducing the computational burden of solving several SAA problems, see Bayraksan and Morton (2006).

Consider now problem (1) (with expectation constraints), and the corresponding Lagrangian $L(x, \lambda) := f_0(x) + \sum_{i=1}^{q} \lambda_i f_i(x)$. Of course,

$$\vartheta^* = \inf_{x \in \chi} \sup_{\lambda \geq 0} L(x, \lambda),$$

and hence $\vartheta^* \geq \inf_{x \in \chi} L(x, \bar{\lambda})$ for any $\bar{\lambda} \geq 0$. The equality $\vartheta^* = \inf_{x \in \chi} L(x, \bar{\lambda})$ holds, under mild regularity conditions, if the problem is convex and $\bar{\lambda}$ is a Lagrange multipliers vector, given by an optimal solution of the dual problem. By fixing $\bar{\lambda} \geq 0$ and solving SAA problems associated with the minimization of $L(x, \bar{\lambda})$ over $x \in \chi$, it is possible in a way described above to construct a lower bound for the optimal value of the true problem (1). In order to construct an upper bound for ϑ^*, it is needed to find, say with confidence $1 - \alpha$, a feasible point $\bar{x}$ of the true problem and then to estimate value $f(\bar{x})$ of the objective function.

Concluding Remarks

It is possible to apply the SAA method to chance-constrained problems. For a generated sample $\xi^1, \ldots, \xi^N$, the probability $p(x) := \Pr\{G(x, \xi) \leq 0\}$ can be estimated by the average $\hat{p}_N(x) := N^{-1} \sum_{j=1}^{N} H(x, \xi^j)$, where function $H(x, \xi)$ is defined in (4), i.e., $\hat{p}_N(x)$ is given by frequency of the event "$G(x, \xi^j) \leq 0$", $j = 1, \ldots, N$. Consequently the chance constraint (3) can be approximated by the constraint $\hat{p}_N(x) \geq 1 - \gamma$. The confidence level $1 - \gamma$ of the SAA problem does not need to be the same as for the true problem, i.e., γ does not need to be equal to α. The constructed SAA problem could be a difficult combinatorial problem. Recently some progress was made in solving such type of problems (Luedtke and Ahmed 2008). It is also possible to construct statistical upper and lower bounds for optimal values of chance constrained problems (Nemirovski and Shapiro 2006).

The SAA method can also be applied in a dynamic setting to multistage stochastic programming problems. However, the complexity of constructed SAA problems, in terms of the number generated scenarios, grows exponentially with increase of the number of stages (Shapiro and Nemirovski 2005; Shapiro 2006).

This poses a question whether multistage stochastic programming problems could be solved with a reasonable accuracy by randomization techniques.

Sand Table Battle Model

A model or game with a physical representation of the geography and units. The classical sand table used sand because it could be molded into a model of the terrain's relief. The tin soldiers were used to represent the troops.

Satisficing

In a decision problem, the selection by the decision maker (DM) of a satisfactory alternative as opposed to the selection of an "optimal" alternative. Here, the DM sets aspiration levels or acceptable levels on the outcomes and chooses the (first) alternative that satisfies these levels. This compromise selection is due to the DM's inability to encompass all the complexities of the decision problem and/or lack of a method that can determine an optimal solution. The concept is due to Herb Simon (1955, 1957).

Scaling

The pre-solution transformation of the data of a problem that attempts to make the magnitudes of all the data as close as possible. Such scaling is important for mathematical-and linear-programming problems as it helps to reduce roundoff error. Most mathematical-programming systems have a SCALE command that automatically adjusts the magnitudes of the data in the rows and columns. This can be done by multiplying the technological coefficient matrix $\boldsymbol{A}$ by suitable row and column transformation matrices. A frequently used scaling algorithm is to divide each row by the largest absolute element in it, and then divide each resulting column by the largest absolute element in it. This ensures that the largest absolute value in the matrix is 1.0 and that each column and row has at least one element equal to 1.0.

Scenario

The set of conditions and characteristics that define the situation or environment under which a system or policy has to perform. There is often a baseline scenario (what will happen if trends continue) and an ideal scenario (what future one would like to have). In stochastic programming, a scenario represents a possible future uncertain outcome (or sample path).

Scheduling and Sequencing

Nicholas G. Hall[1] and Michael Magazine[2]
[1]The Ohio State University, Columbus, OH, USA
[2]University of Cincinnati, Cincinnati, OH, USA

Introduction

Scheduling is the allocation of limited resources over time to perform a given set of jobs or activities. The focus here is on scheduling models with applications to factory and computer systems. Other common uses of the term scheduling include:

1. Project scheduling – the determination of activity times and project duration for complex projects composed of multiple activities with precedence relations;
2. Workforce scheduling – the determination of the number of workers and their duty cycles to meet certain labor restrictions; and

3. Timetabling – the determination of the matching of participants with each other and with resources, such as sports scheduling or student/room exam assignments.

Scheduling problems have been studied informally for centuries. The Gantt Chart, developed in World War I for logistics purposes, is a graphical representation of tasks and resources over time, and was the first formal model used for scheduling purposes. Critical path methods were developed after World War II for project management and are still widely used. The 1950s saw the first analyses of machine scheduling problems using mathematical models. Further research interest was provided by the computational complexity paradigm of the early 1970s. More recently, modern manufacturing environments and supply chain coordination issues have attracted the attention of scheduling researchers.

The reason for this continuing activity is the amount of time and value that manufacturing organizations necessarily invest in the scheduling function. This function typically takes place at the operational level, after completion of the planning phases concerned with which tasks are to be performed and which resources are to be made available. Examples of such planning phases include forecasting, aggregate planning, inventory control and materials requirements planning.

In spite of all the research in this area, there is little unifying theory (McKay et al. 1988; Pinedo 1995). This is apparently because of the very difficult and diverse mathematical structure of these problems, due for example to the wide variety of special constraints that arise in applications. Nevertheless, there are some results that have had a major impact. These, along with some of the basic tools of scheduling will be described, following some useful definitions.

Textbooks and surveys reviewing the scheduling literature include Conway et al. (1967); French (1982); Lawler et al. (1993); Morton and Pentico (1993); Baker (1995); Pinedo (1995); Pinedo and Chao (1998); and Potts and Strusevich (2009).

Preliminaries

Scheduling involves the determination of two types of decisions:

- Allocation decisions – which resources (here called machines) will be assigned to perform each of a given set of jobs; and
- Sequencing decisions – in what order and when are each of these jobs performed.

Although many applications involve the determination of a schedule that is simply feasible with respect to scarce resources, most mathematical models use some economic objective that requires comparison of different schedules.

These objectives typically represent some measure of throughput, customer satisfaction or costs. In general, the problems focus on a single objective at a time, although there are some results on multicriteria problems (Hoogeveen 2005).

The constraints or considerations that are relevant in these models include precedence relations among jobs, job priorities, setup times on machines, and preemption capabilities. McKay et al. (1988) identified over 600 types of constraints present in manufacturing environments. The machine environment also affects the ability to solve these problems. Considered here are single-machine problems, several machines in parallel, flow shops that involve several machines in series, and job shops that involve several machines through which jobs follow various routings.

Also influencing the difficulty of solving these problems and the techniques that can be used to solve them is the precision in the problem data. Most models and results assume that the data is deterministic, although there exist some results for stochastic or probabilistic environments (Righter 1994), as well as some models that protect against uncertainty in the data (Daniels and Kouvelis 1995).

Solution Techniques

Since most scheduling problems have economic objectives and constraints, it is natural to use optimization methods to solve these problems. However, the number of feasible schedules grows quickly with problem size, making almost all such problems extremely difficult to solve. Consider the simplest problem with n jobs on a single machine, with no additional constraints. There are $n!$ sequences that must be considered, and even for relatively small problems, for example of size $n = 100$, the enumeration task is virtually impossible. In the mid 1970s, many scheduling problems were classified by complexity theory as intractable. More formally, as optimization problems, they are

NP-hard (Garey and Johnson 1979), and thus optimal solution procedures that are substantially more efficient than enumeration are unlikely to exist.

Traditional optimization techniques such as mathematical programming, enumeration methods, and dynamic programming have had limited success. Quite often, it is necessary to resort to heuristic techniques, which do not guarantee an optimal solution. These techniques have been of two types: limit the space of search by only considering schedules that meet some specified criteria, or search in a limited neighborhood of some known feasible schedule. These heuristics have shown some success, but unfortunately much of this work considers only their worst-case performance, which is not necessarily a true measure of the average performance of a heuristic. Recent advances in heuristics, including constraint satisfaction (Fox and Smith 1984), simulated annealing (Matsuo et al. 1989), tabu search (Widmer and Hertz 1989) and genetic algorithms (Storer et al. 1992) have extended the ability to find good solutions. Anderson et al. (1997) provided a comprehensive discussion of local search methods for scheduling problems.

Surprisingly, it is a simple principle that has given some of the most significant scheduling results. This principle is pairwise interchange (Baker 1995). This neighborhood search technique starts with a feasible schedule for the problem and interchanges the sequence of two already scheduled jobs according to some rule. For some classes of simple problems, this procedure always results in an optimal solution. For other classes, it routinely results in a computationally good, although not necessarily optimal, solution.

In problems with stochastic data, some of these same combinatorial techniques can be used. In some simple problems, it is possible to take advantage of queueing theory results or of stochastic analogs of the pairwise interchange rules discussed above. However, in most cases, simulation becomes the technique of choice. Often, the complicated environment or simply the highly combinatorial nature of the problem is enough to make simulation the only viable method of analysis.

Scheduling Results

Next some results are described, which are key building blocks to scheduling theory and applications. These arise from problems with a single, continuously available machine; with independent, one-operation, and deterministic jobs; and with machine setup times that are negligible or are not sequence-dependent.

Single-Machine Models – it is assumed that there are n jobs with the following data:

p_j = the processing time required by job j;

r_j = the ready time of job j, i.e., the earliest time at which the job can begin processing;

d_j = the time job j is due to have processing completed.

Once a schedule has been determined, the following variables can be evaluated:

C_j = the completion time of job j;

F_j = the flowtime of job $j = C_j - r_j$;

L_j = the lateness of job $j = C_j - d_j$;

T_j = the tardiness of job $j = \max\{0, L_j\}$.

The simplest models assume criteria that are nondecreasing in the completion time of jobs, i.e., in all the above variables. These are called regular measures, and include:

$$\text{Total Flowtime} = \sum_{j=1}^{n} Fj;$$

$$\text{Total Lateness} = \sum_{j=1}^{n} Lj;$$

$$\text{Maximum Lateness} = L_{\max};$$

$$\text{Total Tardiness} = \sum_{j=1}^{n} T_j; \text{ and}$$

$$\text{Maximum Tardiness} = T_{\max}.$$

In these problems, optimal schedules exist in which job preemption and machine idle time do not occur. Thus, a solution is completely characterized by a sequence of the jobs.

The following is an important result in scheduling theory (Smith 1956): *Shortest Processing Time (SPT) sequence*, i.e., *sequencing the jobs from shortest to longest processing time, minimizes total flowtime when* $r_j = 0$ *for all jobs.*

This is proved by interchange arguments and can be extended to include jobs of different importance, or weights, by using weight-to-processing-time ratio.

For customer service measures, due date information is included. Perhaps counterintuitively, SPT also minimizes Total Lateness. The most important result using due date measures is:

Earliest Due Date (EDD), i.e., sequencing the jobs from earliest to latest due date, minimizes both $L_{\max}$ and $T_{\max}$ (Jackson 1955).

In many other problems with due-date measures, EDD provides useful guidance towards an optimal, or close to optimal, solution.

There are several other single machine results. The presence of nonzero ready times creates problems with due date measures unless jobs can be preempted without penalty. If this is not the case, it is necessary to look ahead to jobs not yet in the system, causing simple dispatching rules that do not consider the current partial sequence, such as SPT or EDD, to yield suboptimal solutions.

Another condition imposed on jobs may be precedence relations. They represent a partial ordering of the jobs, which is imposed for technological reasons. These relationships (which can be represented by graphs where job i precedes job j if there is an arc from i to j), may under certain conditions still yield relatively simple algorithms. When the graph is composed of chains or is series–parallel, many problems can be solved optimally. However, general precedence relationships between jobs typically prevent the finding of optimal solutions quickly (Monma 1981).

As noted, these simple models ignore setup times. When setup times are present and sequence-dependent, many simple problems become very difficult to solve. For example, minimizing makespan, i.e., $C_{\max}$ = completion time of the last job, is equivalent to solving a traveling salesman problem.

Thus far only regular measures of performance were considered. One important non-regular measure that represents another attribute of customer service is a job earliness penalty, where a job's earliness is $E_j = \max\{0, d_j - C_j\}$. When there are many jobs and a common due date, minimizing a combination of earliness and tardiness penalties is still possible (Baker and Scudder 1990; Hall and Posner 1991). When the due dates are distinct for each job, these problems are difficult to solve.

Multiple Parallel-Machine Models – Fast optimal algorithms for scheduling problems with several machines are scarce. The existence of several machines requires not only sequencing decisions, but also allocation decisions. The simplest environment assumes there are n jobs available at time zero and m identical machines for processing them.

The simplest model in this environment attempts to minimize makespan, i.e., the time to complete all n jobs. Since changing the sequence of jobs allocated to a particular machine does not affect the makespan, the only decision is allocating jobs to machines. If preemption is permitted, McNaughton (1959) showed that there is a simple algorithm to perform this allocation. When preemption is not permitted, the problem is *NP*-hard even for $m = 2$. However, a computationally reasonable (pseudo-polynomial time) algorithm provides optimal solutions.

Here, a reasonable heuristic seems to be to list the jobs in some prespecified order, placing the next job in the list onto the first machine that becomes available. By cleverly ordering the jobs, list-scheduling heuristics provide acceptable performance guarantees. For example, a simple rule such as longest processing time first (LPT) guarantees a solution within 33% of the optimal makespan (Graham 1969). Graham also found several interesting anomalies in list scheduling, such as that increasing the number of machines or reducing the processing time of the jobs can increase makespan.

If the objective is to minimize total flow time on m identical machines, an SPT list-scheduling algorithm gives an optimal solution. Unfortunately almost all other problems that can be generalized from the single machine case fail to yield optimal solutions in polynomial time.

The next important class of problems is flow shop models. The simplest instance assumes there are m machines and each job requires processing on each machine, i.e., each job has m operations. In addition, processing moves from machine to machine in a prespecified order that is the same for each job. These problems are much more difficult to solve than single-machine problems. One additional consideration is that inserted idle time may be desirable. This was not the case for single machines with regular performance measures. In addition, if there are more than three machines, different permutations of the jobs must be considered for each machine, giving rise to $(n!)^m$ possible sequences.

When $m = 2$, however, Johnson (1954) provided an efficient algorithm for minimizing makespan. When there are more than two machines, the makespan problem becomes *NP*-hard. There are several special cases, however, when $m = 3$ that use variations of Johnson's algorithm to guarantee optimal solutions.

Johnson's theorem is stated using his notation. Here,

A_i = the processing-time (including setup, if any) of the first operation of the ith job;

B_i = the processing-time (including setup, if any) of the second operation of the ith job.

Johnson's algorithm is applied to the following problem: sequence an arbitrary number of jobs in a two-machine flow shop to minimize the makespan. It is assumed that all jobs are simultaneously available.

Johnson's Theorem

An optimal schedule for a two-machine flow shop that minimizes the make-span is obtained when job j precedes job $j + 1$if

$$\min\{A_j, B_{j+1}\} \leq \min\{A_{j+1}, B_j\}.$$

Under certain conditions, the processing of an operation of job j can start before the completion of the previous operation. This overlapping of operations can improve the makespan. Trietsch and Baker (1993) discussed a variety of these lot-streaming problems.

One variation of the flow shop model requires that the processing of a job cannot be interrupted once it has started. A survey of applications, algorithms and complexity results for these no-wait models, and for related models with machine blocking, was given by Hall and Sriskandarajah (1996). Another extension of the flow shop model allows the job to pass through the machines in any order. This is referred to as an open shop and, except for the case of two machines with makespan objective, the problems are essentially all very hard to solve optimally.

Job shop scheduling models cover a significant portion of all factory scheduling problems. In a job shop, the number and order of operations for each job may differ. These problems are virtually intractable because of the large number of possible schedules. The notorious 10-job, 10-machine problem of Fisher and Thompson (1963) provided the benchmark for the computational difficulty of these problems. It took 25 years of research for its optimal solution to be verified (Carlier and Pinson 1988). Many heuristic procedures use dispatching rules. These heuristics choose, according to some rule, the next job from those available to start on a machine when that machine becomes idle. A successful and widely used heuristic for the job shop problem was described by Adams et al. (1988).

Research Directions

Scheduling Families or Groups – Modern manufacturing facilities contain flexible machines that can produce or assemble a variety of products. When products are similar, switching between them requires no setup time. These groups of products are called product families. Switching between different product families is possible, but requires a setup. Here a batch represents a set of items that are produced following a single setup. The difficulty in scheduling these environments arises from the tradeoff between scheduling large batches, which cause delays to jobs in other families, and scheduling small batches, which incur many setups. The issues to be resolved include sequencing items within families, the determination of the batch sizes and the sequencing of the batches from different families (Monma and Potts 1989; Santos and Magazine 1985). A useful survey is provided by Potts and Kovalyov (2002).

Modern Manufacturing Environments – The requirements of modern manufacturing impose new demands on the scheduling function and the theory that supports it. Lee et al. (1992) considered burn-in problems that arise in semiconductor manufacturing, where the processing time required by a batch of jobs is the length of the longest job rather than the total processing time. Automated manufacturing systems, particularly those which require the coordination of computer-controlled material handling devices with production schedules, generate a variety of interesting scheduling problems, as discussed by Crama (1997). For example, Hall et al. (1997) considered robotic cells, in which a robot serves several production machines. Also in accordance with modern manufacturing principles are manufacturing environments with limited storage buffers (Hall et al. 1998). Deterministic scheduling, with an emphasis on modern manufacturing problems, is extensively reviewed by Lee et al. (1997).

Online Scheduling – In various practical situations, information about arriving jobs is not know at the start of the planning horizon. In online scheduling, this information is revealed

over time. A standard performance measure for online algorithms is the competitive ratio, which bounds the performance ratio of online and optimal offline schedules. Online scheduling models have application to purchasing and ordering systems that use the Internet. Pruhs et al. (2004) provide a thorough review of the research in this area. One of the key ideas in online scheduling is to delay the processing of jobs until more information about the future is available. Hall et al. (2009) consider an environment where jobs can only arrive at known future times. This environment interpolates between the classical offline and online environments.

Supply Chain Scheduling – One of the most active research areas within operations management starting in the 1990s has been supply chain management, i.e., the consideration of integration and coordination issues, and incentives, within manufacturing systems. Much of this research has been strategic in nature, but the supply chain scheduling area focuses on operational level decisions. Examples of this research include the coordination of manufacturing and distribution (Hall and Potts 2003), and the coordination of component delivery from multiple suppliers (Chen and Hall 2007). Issues that are discussed include the classical one of computational solvability, evaluation of the cost of conflict if one powerful supply chain member imposes their preferred schedule on others, and evaluation of the benefit of cooperation that results if all supply chain members agree on a common schedule. A comprehensive survey of related results is provided by Chen (2010).

Scheduling with Machine Availability Constraints – Although classical scheduling models typically assume that all processing resources are continuously available from the start of the planning horizon, there are practical situations where this assumption is incorrect. For example, resources may be allocated to outsourcing contracts at particular times, or downtime for maintenance may be planned in advance. Unavailable times may either be known in advance or not. Moreover, jobs that are interrupted by resource unavailability may either be resumable, or may need to be restarted. As the surveys by Schmidt (2000) and Lee (2004) reveal, most scheduling problems in this area are intractable. Consequently, the design of approximation algorithms and approximation schemes (Ng and Kovalyov 2004) is an active research area.

Safe Scheduling – Safe scheduling (Baker and Trietsch 2009) is an approach to stochastic scheduling problems that explicitly considers the role of safety time to meet service levels. These problems are analogous to safety stocks in inventory problems. A key element of safe scheduling is the inclusion of service levels, defined as the probability that a job completes by its due date. Safety time is the difference between the expected completion time and the due date. Safe scheduling problems are formulated with either explicit service level constraints or as an objective function that considers costs associated with not meeting due dates. To completely specify the problem either decisions have to be made as to which jobs (with known release date and due date) to choose or to decide on release dates and due dates and minimizes total cost. Results are often not analogous to the deterministic version of the problem.

Introduction

Many complex real world systems can be modeled as discrete-event systems (DES). Examples are computer-communication networks, flexible manufacturing systems, probabilistic fracture mechanics models, PERT-project networks and flow networks. In view of the complex interactions within a DES, they are typically studied via stochastic simulation.

In the design and analysis of a DES, the interest is not only in performance evaluation, but also in sensitivity analysis and optimization. Consider for example manufacturing systems. Here (1) the performance measure may be the average waiting time of an item to be processed at several work stations (robots) according to a given schedule and route; (2) the sensitivity and decision parameters may be the average rate at which the work-stations (robots) process the item. In such a system, the goal may be to minimize the average makespan consisting of the processing time and delay time with allowance for some constraints (e.g., cost).

Alternatively, consider failure probability models for mechanical passive components (such as pipes or vessels). Here (1) the performance measure may be cumulative failure or leakage probability of a passive component over some time; (2) the sensitivity and decision parameters may be the geometry of the component (thickness of the walls), fracture toughness of the material and stress intensity factors. In such a system, failure probability is a function of the sizes of defects (cracks) and their time dependent stochastic development.

Methods for sensitivity analysis and optimization of a DES include infinitesimal perturbation analysis (IPA) and the score function (SF) method, also called the likelihood ratio (LR) method (Rubinstein 1976; Reiman and Weiss 1989; Glynn 1990; L'Ecuyer 1990; Ho and Cao 1991; Glasserman 1991; Rubinstein and Shapiro 1993; Asmussen and Glynn 2007). The SF method allows one to evaluate, *simultaneously* from a *single* sample path (simulation experiment) not only the performance and all its sensitivities, (gradient, Hessian, etc.), but to solve an entire optimization problem as well. An alternative approach, called analytic perturbation analysis, for calculating the sensitivities of discrete-event systems using analytical formulas for the expectations of indicator functions, has also been proposed by Uryasev (1995, 1997).

Estimation and Sensitivity Analysis of Discrete-Event Static Systems

Let $l(\boldsymbol{\theta})$ be a real-valued function represented in the form $l(\boldsymbol{\theta}) = E_{\boldsymbol{\theta}}[L(\boldsymbol{Y})]$. Here $\boldsymbol{Y}$ is a random vector whose cumulative distribution function (CDF) $F(\boldsymbol{y}, \boldsymbol{\theta})$ depends on the parameter vector $\boldsymbol{\theta} \in \ominus$ with $\ominus$ being a subset of a finite dimensional vector space, say $\ominus \subset \mathrm{R}^n$. The function $L(\boldsymbol{Y})$ can be viewed as a sample performance driven by the input vector $\boldsymbol{Y}$. The notation $E_{\boldsymbol{\theta}}$ stands for the expectation with respect to the CDF $F(\boldsymbol{y}, \boldsymbol{\theta})$.

In order to estimate the expected value $l(\boldsymbol{\theta})$ by simulation (Monte Carlo) techniques, one can proceed as follows. Generate a sample $\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_N$ from N the CDF $F(\boldsymbol{y}, \boldsymbol{\theta})$ and set the sample mean $N^{-1}\sum_{i=1}^{n} L(Y_i)$ as the corresponding estimator. Of course, this procedure requires generation of a new sample every time the expectation $l(\boldsymbol{\theta})$ should be estimated for a different value of the parameter vector $\boldsymbol{\theta} \in \ominus$. In order to overcome this difficulty, consider the following procedure based on a change

of probability measure techniques. Suppose that the random vector $\boldsymbol{Y}$ has a probability density function (PDF) $f(\boldsymbol{y}, \boldsymbol{\theta})$ corresponding to the CDF $F(\boldsymbol{y}, \boldsymbol{\theta})$. For a PDF $g(\boldsymbol{y})$ such that the outcome space of $f(\cdot,\boldsymbol{\theta})$ lies in the outcome space of $g(\cdot)$:

$$l(\boldsymbol{\theta}) = \int L(z)\,[f(z, \boldsymbol{\theta})/g(z)]g(z)dz = E_g[L(Z)W(Z, \boldsymbol{\theta})], \tag{1}$$

where $W(\boldsymbol{z}, \boldsymbol{\theta}) = f(\boldsymbol{z}, \boldsymbol{\theta})/g(\boldsymbol{z})$. Note that the integration variable $\boldsymbol{y}$ was replaced by $\boldsymbol{z}$ when the involved densities were changed from $f(\cdot,\boldsymbol{\theta})$ to $g(\cdot)$, and the integrals are over the outcome spaces of the corresponding density functions. Formula (1) suggests the following way for estimating $l(\boldsymbol{\theta})$. Generate a sample $\boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_N$, from the PDF $g(\boldsymbol{z})$ and estimate $l(\boldsymbol{\theta})$ by

$$\hat{l}(\boldsymbol{\theta}) = N^{-1} \sum_{i=1}^{N} L(Zi)W(Zi, \boldsymbol{\theta}) \tag{2}$$

The function $W(z, \boldsymbol{\theta})$ is called the likelihood ratio (LR) function and $g(\boldsymbol{y})$ is the dominating density. Typically one takes $g(\mathrm{z}) = \mathrm{f}(\boldsymbol{z}, \boldsymbol{\theta}_0)$ for a particular value $\boldsymbol{\theta}_0 \in \ominus$ of the parameter vector. The chosen $\boldsymbol{\theta}_0$ is referred to as the reference value of the parameter vector.

The LR function is given explicitly through the corresponding density functions and is typically smooth (differentiable) in $\boldsymbol{\theta}$. As soon as the sample $\boldsymbol{Z}_1,\ldots, \boldsymbol{Z}_N$ is generated, the obtained LR estimator $\hat{l}_N(\boldsymbol{\theta})$ becomes an analytical function of $\boldsymbol{\theta}$ and provides an estimate of the entire function (response surface) $l(\boldsymbol{\theta})$. Moreover, under mild regularity conditions ensuring interchangeability of the integration and differentiation operators, it follows that derivatives of the expected performance $l(\boldsymbol{\theta})$ can be taken inside the expected value representation given in the right-hand side of (1). Consequently, the gradient $\nabla\hat{l}_N(\boldsymbol{\theta})$ of the sample estimate, as defined in (2), provides an unbiased estimator of the corresponding gradient of $l(\boldsymbol{\theta})$. The Hessian matrix can be similarly estimated (Rubinstein and Shapiro 1993).

In particular, for $g(\cdot) = f(\cdot, \boldsymbol{\theta})$, the gradient of the LR function $W(\boldsymbol{y}, \boldsymbol{\theta})$ is called the score function (SF) and can be written in the form $\boldsymbol{S}(\boldsymbol{y}, \boldsymbol{\theta}) = \nabla \log f(\boldsymbol{y}, \boldsymbol{\theta})$. Then, given a random sample $\boldsymbol{Y}_1,\ldots, \boldsymbol{Y}_N$ from $f(y, \boldsymbol{\theta})$, the gradient $\nabla l(\boldsymbol{\theta})$ can be estimated by

$$\bar{\nabla} l_N(\boldsymbol{\theta}) = N^{-1} \sum_{i=1}^{N} L(Y_i)S(Y_{i,}\boldsymbol{\theta}). \tag{3}$$

High-order derivatives can be handled in a similar way. Note that gradient $\nabla W(\boldsymbol{z}, \boldsymbol{\theta})$ of the LR function can be written in the form $W(\boldsymbol{z}, \boldsymbol{\theta})\boldsymbol{S}(\boldsymbol{z}, \boldsymbol{\theta})$ and is called the generalized score function.

A word of caution is due. Although the generalized SF estimators typically are unbiased and consistent, their accuracy is determined by the corresponding variances and can be quite sensitive to the choice of the dominating PDF $g(\boldsymbol{y})$ (reference value $\boldsymbol{\theta}_0$). The problem of an optimal choice of $g(\boldsymbol{y})$ is closely related to the importance sampling method in simulation. A detailed discussion of this problem and relevant variance reduction techniques may be found Rubinstein and Shapiro (1993).

Example 1 (System Reliability). Consider the sample performance function:

$$L(Y) = \max_{l\le k\le p} \min_{j\in\Im} Y_j,$$

where $\Im_1,\ldots, \Im_p$ are the complete paths from a source to a sink and Y_j are durations (lifetimes) of the components in the system. Suppose that the random variables $Y_1,\ldots, Y_m$ are independent and each distributed as a gamma. Given the (vector) random sample $\boldsymbol{Y}_1,\ldots, \boldsymbol{Y}_N$, the gradient of the corresponding expected performance $l(\lambda)$ can be estimated by the SF estimator

$$\bar{\nabla} l_N(\lambda) = N^{-1} \sum_{i=1}^{N} L(\boldsymbol{Y_i})(\beta\lambda^{-1} - \boldsymbol{Y}_i).$$

Estimation and Sensitivity Analysis of Discrete-Event Dynamic Systems

The SF approach presented in the previous section can be extended to dynamic systems as well. Consider a Discrete Event Dynamic System (DEDS) driven by

an input sequence of iid random vectors $\boldsymbol{Y}_1, \boldsymbol{Y}_2, \ldots$, generated from a PDF $f(\boldsymbol{y}, \boldsymbol{\theta})$ depending on the parameter vector $\boldsymbol{\theta} \in \ominus$. Let $L_1, L_2, \ldots$, be an output process driven by this input sequence. That is, $L_t = L_t(\boldsymbol{Y}_t), t = 1, 2, \ldots$, where vector $\boldsymbol{Y}_t = (\boldsymbol{Y}_1, \ldots, \boldsymbol{Y}_t)$ represents a history of the input process up to time t, and $\boldsymbol{L}_t(\cdot)$ is a sequence of real valued functions.

Suppose that $\{L_t\}$ is a discrete-time regenerative process with the regenerative cycle of length τ. For example, consider a GI/G/1 queue with FIFO discipline. In that case, the input sequence is represented by the two-dimensional vector $\boldsymbol{Y}_t = (Y_{1t}, Y_{2t})$, with Y_{1t} being the service time of the tth customer, Y_{2t} being the interarrival time between the $(t-1)$stand tth customers, and τ is the number of customers served during the busy period. The output process L_t can be, for example, the system waiting time of the tth customer.

Consider the expected long-run average $l(\boldsymbol{\theta})$ of the process L_t. It is well known in the theory of regenerative processes that $l(\boldsymbol{\theta})$ is equal to the expected steady-state performance of L_t and can be represented as the ratio $l(\boldsymbol{\theta}) = l_1(\boldsymbol{\theta})/l_2(\boldsymbol{\theta})$ of the expectations $l_1(\boldsymbol{\theta}) = E_{\boldsymbol{\theta}}[\sum_{t=1}^{\tau} L_t]$ and $l_2(\boldsymbol{\theta}) = E_{\boldsymbol{\theta}}[\tau]$, respectively. Note that the above expectations and hence the expected performance $l(\boldsymbol{\theta})$ are functions of the parameter vector $\boldsymbol{\theta} \in \ominus$.

The SF approach can again be used to derive an estimate of the expected performance $l(\boldsymbol{\theta})$ and its sensitivities $\nabla l(\boldsymbol{\theta})$ for different values of $\boldsymbol{\theta}$, i.e.,, for a chosen dominating PDF $g(\boldsymbol{y})$, the expected value functions $l_1(\boldsymbol{\theta})$ and $l_2(\boldsymbol{\theta})$ can be written in the form

$$l_1(\boldsymbol{\theta}) = E_g\left[\sum_{t=1}^{t} L_t(Z_t)\tilde{w}_t(\boldsymbol{Z}_t, \boldsymbol{\theta})\right] \text{ and}$$
$$l_2(\boldsymbol{\theta}) = E_g\left[\sum_{t=1}^{t} \tilde{w}(\boldsymbol{Z}_t, \boldsymbol{\theta})\right], \tag{5}$$

where $\tilde{w}(\boldsymbol{Z}_t, \boldsymbol{\theta}) = f_t(\boldsymbol{Z}_t, \boldsymbol{\theta})/g_t(\boldsymbol{Z}_t)$ with $f_t(\mathbf{z_t}, \boldsymbol{\theta}) = \prod_{i=1}^{t} f(\mathbf{z_t}, \boldsymbol{\theta})$ and $g_t(\mathbf{z_t}) = \prod_{i=1}^{t} g(\mathbf{z_i})$. The latter term is the density function of the random vector $\boldsymbol{Z}_t = (\boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_t)$, with the random vectors $\boldsymbol{Z}_1, \ldots, \boldsymbol{Z}_t$ drawn according to the PDF $g(\cdot)$.

Under standard regularity conditions, the derivatives of $l_1(\boldsymbol{\theta})$ and $l_2(\boldsymbol{\theta})$ can be taken inside the expectation. Consequently, by generating a random sample of N regenerative cycles based on the PDF $g(\cdot)$, one can estimate the above expectations by the corresponding sample means (averages), and hence can estimate $l(\boldsymbol{\theta})$ and $\nabla l(\boldsymbol{\theta})$.

Example 2 (Queueing Delays). Let L_t be the system waiting time of tth customer in a GI/G/1 queue driven by the input sequences of the service times Y_{1t} and the interarrival times Y_{2t} with respective density functions $f_1(y_1, \boldsymbol{\theta}_1)$ and $f_2(y_2, \boldsymbol{\theta}_2)$. By Lindley's equation, it follows:

$$L_t = Y_{1t} + [L_{t-1} - Y_{2t}]+, \quad t = 1, 2, \ldots$$

Let τ be the number of customers served in the first busy period. Then the expected long-run average waiting time of a customer can be written as

$$l(\boldsymbol{\theta}) = \frac{E\left[\sum_{t=1}^{\tau} L_t\right]}{E_{\boldsymbol{\theta}}[\tau]} = \frac{E\left[\sum_{t=1}^{\tau}\sum_{j=1}^{\tau} Y_{1j} - \sum_{t=2}^{\tau}\sum_{j=2}^{\tau} Y_{2j}\right]}{E_{\boldsymbol{\theta}}[\tau]},$$

where $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ and $f(\boldsymbol{y}, \boldsymbol{\theta}) = f_1(y_1, \boldsymbol{\theta}_1) f_2(y_2, \boldsymbol{\theta}_2)$. By generating N regenerative cycles (busy periods) of the service and interarrival times according to the PDF $f(z, \boldsymbol{\theta}_0)$ for a chosen value $\boldsymbol{\theta}_0$ of the parameter vector, one can estimate $l(\boldsymbol{\theta})$ and $\nabla l(\boldsymbol{\theta})$ for various values of $\boldsymbol{\theta}$.

Optimization

Consider the following (unconstrained) optimization problem involving the expected performance function of a static or dynamic system:

$$(\mathbf{P}_0) \ \text{minimize}\, l(\boldsymbol{\theta}), \quad \boldsymbol{\theta} \in \ominus$$

Let $\boldsymbol{\theta}^*$ be an optimal solution of the program $(\mathbf{P}_0)$. The optimal solution $\boldsymbol{\theta}^*$ can be estimated from a single simulation using the SF approach, i.e., let $\hat{l}_N(\boldsymbol{\theta})$ be the LR estimator of $l(\boldsymbol{\theta})$ calculated via the corresponding LR function (process). Consider the optimization problem:

$$(\hat{\mathbf{P}}_N) \ \text{minimize}\ \hat{l}_N(\boldsymbol{\theta}), \quad \boldsymbol{\theta} \in \ominus$$

where the program $(\hat{P}_{\mathrm{N}})$ is referred to as the stochastic counterpart of the program $(\mathbf{P}_0)$.

The LR estimator $\hat{l}_N(\boldsymbol{\theta})$ and, hence, the program $\hat{P}_N(\boldsymbol{\theta})$ depend on the generated random sample and in that way are stochastic. However, as soon as the sample is generated by the function $\hat{l}$, its derivatives are given explicitly through the corresponding density functions and can be calculated for various values of $\boldsymbol{\theta}$. Consequently, $(\hat{P}_N)$ becomes a deterministic optimization program and can be solved by standard methods of mathematical programming. Rubinstein and Shapiro (1993) showed that, under mild regularity conditions: (i) The optimal solution $\hat{\boldsymbol{\theta}}_N$ of the program $(\hat{P}_N)$ converges with probability one as $N \to \infty$ to its true counterpart $\boldsymbol{\theta}^*$, i.e., $\hat{\boldsymbol{\theta}}_N$ is a consistent estimator of $\boldsymbol{\theta}^*$; (ii) $N^{1/2}(\hat{\boldsymbol{\theta}}_N - \boldsymbol{\theta}^*)$ converges in distribution to multivariate normal with zero mean vector and covariance matrix $B^{-1}\sum B^{-1}$, where $B = \nabla^2 l(\boldsymbol{\theta}^*)$ and $\sum$ is the asymptotic covariance matrix of $N^{1/2}\nabla \hat{l}_N(\boldsymbol{\theta}^*)$, i.e., $\hat{\boldsymbol{\theta}}_N$ is asymptotically normal $N(\boldsymbol{\theta}^*, N^{-1}B^{-1}\sum B^{-1})$. Extensive simulation studies with the SF approach, as well as extension of the above simulation-based approach to constrained optimization, can be found in Rubinstein and Shapiro (1993).

Search Theory

Lawrence D. Stone
Metron Inc., Reston, VA, USA

Introduction

Search theory is the study of how to effectively employ limited resources when trying to find an object whose location is not precisely known. The goal is to deploy search assets to maximize the probability of locating the search object with the resources available. Sometimes this goal is stated in terms of minimizing

the time to find the search object. Search theorists seek to find methods, procedures, and algorithms that describe how to achieve these goals. In search theory, the search object is called the target even when the target is neutral or friendly, such as a person lost at sea.

In 1942 work on search theory began in the U. S. Navy's Antisubmarine Warfare Operations Research Group (ASWORG) (1942) in response to the German submarine threat in the Atlantic (Morse 1982). A summary of the work done by this group from 1942 to 1945 is given in Sternhell and Thorndike (1946).

Bernard Koopman joined ASWORG in 1943, and at George Kimball's suggestion, Koopman, James Dobbie, and a few others were given the job of assembling the existing results on search into a coherent theory. Morse (1982) credits Koopman with providing the basic probabilistic foundation of the subject and finding the first results on optimal allocation of search effort, specifically the optimal allocation of a fixed amount of search effort to detect a stationary target with a bivariate normal distribution of possible locations and an exponential detection function.

Koopman defined the elements of the basic problem of optimal search: a prior probability distribution on target location; a function relating search effort and detection probability; a constrained amount of search effort; and an optimization criterion of maximizing probability of detection subject to the constraint on effort. This is called the optimal detection search problem: finding an optimal allocation of a fixed amount of search effort to maximize probability of detection.

The resulting synthesis of search theory by Koopman and his colleagues was published in *Search and Screening* (Koopman 1946), which defines many of the basic search concepts such as lateral range function, sweep width, sweep rate, detection function, and kinematic enhancement.

Search and Screening provided methods for designing barrier searches (bow tie searches) and antisubmarine warfare screens. It presented models for radar and visual search. This report and its updated version, Koopman (1980), are still the classic references on basic search theory. Washburn (1981b) provides an excellent and very readable introduction to search and detection problems.

Types of Search Problems

The work of Koopman and his colleagues in the ASWORG (later the Operations Evaluation Group (OEG)) laid the groundwork for the development of search theory and the applications that followed. It is convenient to categorize this subsequent work according to the type of search problem involved. A detailed bibliography and discussion of the types of search problems can be found in Benkoski, Monticino, and Weisinger (1991).

One-Sided Search Problems

The simplest type of search problems are those in which the searcher can choose his strategy, but the target neither chooses a strategy nor reacts to the search in any way. These are called one-sided search problems. The simplest one-sided problems involve search for a stationary target.

Stationary Targets. A stationary target is one that does not move. The searches for the sunken treasure ship, *SS Central America* (Stone 1992), the missing submarine *USS Scorpion* (Richardson and Stone 1971), and the H-bomb lost off the coast of Spain in 1964 (Richardson 1967) are examples of searches for stationary targets. Other examples include searches for downed aircraft, hidden natural resources (gas, oil, minerals, etc.), searches for archeological sites and artifacts, and even searches for something as mundane as lost car keys.

These are one-sided search problems because the target has not chosen its location and it does not react to the searcher's efforts.

Moving Targets. Search for a life raft adrift in the ocean is an example of a one-sided moving target search problem. The movement of the raft is not (substantially) under the control of the people in the raft, and the people are not able to react to the search effort except perhaps by trying to signal an aircraft or a passing vessel. The U. S. Coast Guard's Search and Rescue Optimal Planning System (SAROPS) employs search theory to plan searches for people and vessels lost at sea (Kratzke et al. 2010). Searches for submarines can be considered one-sided searches when the searching platform or system is covert, i.e., when the target submarine is unaware of the searcher's presence. During the Cold War, the U. S. Navy used a computer system that employed search theory to plan passive sonobuoy searches by Anti-Submarine

Warfare Patrol Aircraft for Soviet Nuclear submarines. Use of the system doubled the success probability of the searches.

Two-Sided Search Problems

In two-sided search problems, both the target and the searcher are allowed to choose their strategies. Two-sided problems can involve either stationary or moving targets. An example of a two-sided stationary target problem occurs when the target chooses a place to hide and stays there. The searcher then has to find the target. Most two-sided problems involve moving targets. Two-sided search problems divide into cooperative and non-cooperative searches.

Cooperative. An example of a two-sided cooperative search is a rendezvous search. In these searches two people are trying to find one another. For example, when two people have become separated and wish to find one another again, one has a cooperative search problem.

Another example is searching for an intelligent person lost in the woods. That person may be trying to move to a place where he can be found more easily or to cooperate in some way by leaving or giving signals to indicate his position.

Non Cooperative. Many two-sided searches are non-cooperative. An example is one submarine searching for another submarine when each is aware of the other's presence. Another example is law enforcement officers searching for drug smugglers.

Optimal Search for Stationary Targets

Koopman (1956a, b, 1957) published three articles that summarized, in an unclassified fashion, the theoretical aspects of the work reported in *Search and Screening* (Koopman 1946),which was classified at that time. In these papers Koopman showed how to find optimal allocations of search effort when the target is stationary and the detection function is exponential. He was able to solve explicitly for the optimal effort allocation for a bivariate normal target location distribution.

Lateral Range Function and Sweep Width. Koopman characterized a sensor's detection capability by the use of a lateral range function defined as follows. Consider a sensor that passes by a stationary target on long a straight path. The range r of the target from the sensor at the point of closest approach is called the lateral range of the target for that path. Let

$$\alpha(r) = \text{probability the sensor detects the target on a path having lateral range } r \text{ to target.} \tag{1}$$

Positive lateral ranges indicate ranges on right hand side of the sensor. Negative ones indicate ranges on the left-hand side.

Sweep Width. The sweep width W of a sensor is defined as

$$W = \int_{-\infty}^{\infty} \alpha(r)dr. \tag{2}$$

If one imagines the sensor moving through space on straight line of length l, then $l\,W$ is the effective (expected) area swept by the sensor.

Exponential Detection Function. Suppose that one is searching with a sensor that has sweep width W and moves at speed v. If the search is uniform in a region of area A with the effectiveness of "random" search, then the probability of detecting the target by time t given it is located in the region is

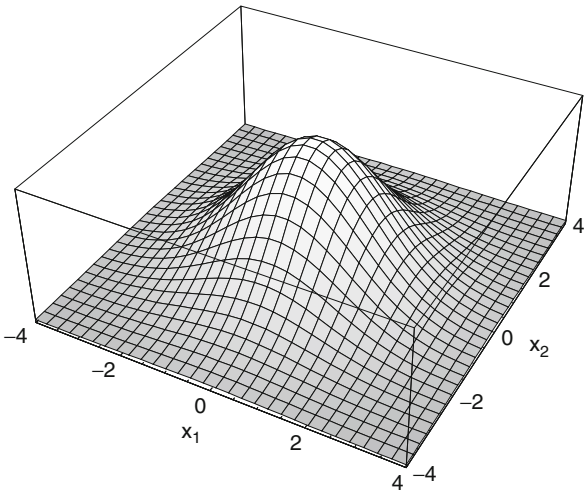
$$P(t) = 1 - \exp\left(-\frac{Wvt}{A}\right). \tag{3}$$

The fraction Wvt/A is the density of search effort in the region. Equation (3) is called the random search formula. This typically gives a lower bound on the effectiveness of a systematic search that tries to spread its effort uniformly over the search region. The term random searchmust not be taken too literally. With completely random searching, one can obtain very non-uniform coverage of the search area, and as a result obtain a lower probability of detection than that given by the random search formula.

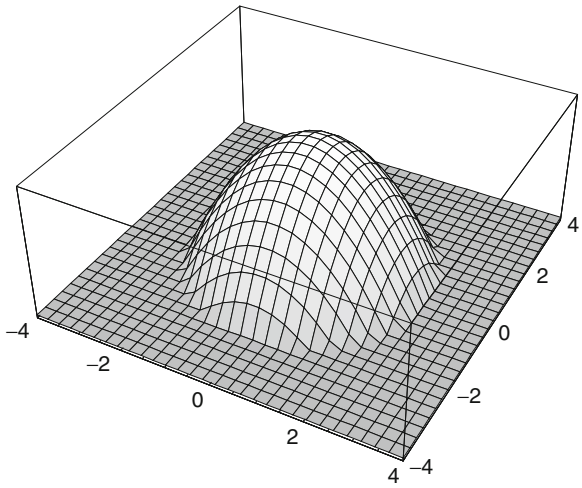
Suppose that $f(x)$ is the density of search effort in the neighborhood of the point x in the search space, X, the plane. Let

$$b(x,f(x)) = \text{probability of detecting the target given it is located at } x \text{ and the search density is } f(x).$$

The function b is called a detection function. If $b(x,f(x)) = 1 - \exp(-f(x))$, then b is an exponential detection function.



Search Theory, Fig. 1 Probability density function for a circular normal distribution



Search Theory, Fig. 2 Optimal search density for a circular normal distribution

Target Location Distribution. Suppose that the target is stationary and located in the plane X. Knowledge of the target's location is given by a bivariate normal probability distribution with its mean at $(0,0)$. This knowledge may have been obtained from a navigational fix with uncertainty where the uncertainty in the fix is modeled by a bivariate normal distribution.

The density function, p, for this distribution is given by

$$p(x_1,x_2)=\frac{1}{2\pi\sigma_1\sigma_2}\exp\left[-\frac{1}{2}\left(\frac{x_1^2}{\sigma_1^2}+\frac{x_2^2}{\sigma_2^2}\right)\right].$$

A graph of this density function is shown in Fig. 1 for the case where $\sigma_1=\sigma_2$. This is called a circular normal distribution. In Fig. 1, the probability density is highest at the center of the distribution (0,0) and decreases as distance from the center increases. In theory, this distribution covers an infinitely large area since the probability density approaches, but never actually reaches, zero. In practice some reasonable cutoff is applied.

Optimal Search Density. Suppose that the search sensor has sweep width W, travels at speed v, and has an exponential detection function. If there are T hours of search time available, then Koopman (1946) showed that the optimal search density f^* is

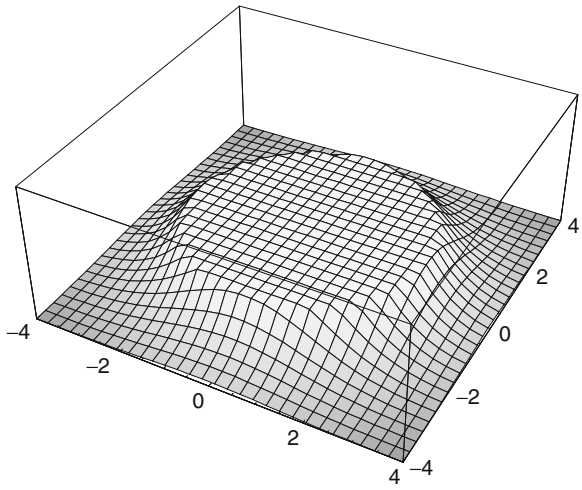
$$f^*(x_1,x_2)=\begin{cases}\left(\frac{WvT}{\pi\sigma_1\sigma_2}\right)^{\frac{1}{2}}-\frac{1}{2}r^2(x_1,x_2) & \text{for } r^2(x_1,x_2)\le 2\left(\frac{WvT}{\pi\sigma_1\sigma_2}\right)^{\frac{1}{2}}\\ 0 & \text{for } r^2(x_1,x_2)>2\left(\frac{WvT}{\pi\sigma_1\sigma_2}\right)^{\frac{1}{2}}\end{cases}$$

where

$$r^2(x_1,x_2)=\frac{x_1^2}{\sigma_1^2}+\frac{x_2^2}{\sigma_2^2}.$$

Figure 2 shows an example of the optimal search effort density for the circular normal location density in Fig. 1 based on a specific amount of search effort. The optimal effort density is highest at the center where the location probability density is also highest. The optimal density decreases with distance from the center until at a certain radius the effort density becomes zero. All the available search effort is expended within a certain radius (depending on the amount of effort available) and none is expended outside that radius even though there is some probability of the target being outside the circle inscribed by this radius.

Posterior Target Location Density. Suppose that the optimal search has been applied as shown in Fig. 2 and failed to detect the target. What is the target location distribution given this unsuccessful search effort? This distribution is computed by employing the form of probabilistic reasoning called



Search Theory, Fig. 3 Posterior Target Location Distribution given Failure to Detect

Bayes' rule. The result is shown in Fig. 3. This is the posterior target location density given the search has been unsuccessful. The posterior density is flat inside the circle where search effort has been applied. As more and more effort is applied (in an optimal fashion), the posterior density becomes flatter and flatter, and the radius of the circle of search increases.

Koopman (1957) extended his optimal allocation results from normal distributions to a more general class of probability distributions

Non-exponential Detection Functions

Koopman's original results have been extended in two important directions to allow one to find optimal allocations of search effort when the detection function is not exponential and when the target location distribution is not bivariate normal. Target location distributions that are not bivariate normal occur often in operational problems. For example, cellular target location distributions commonly arise in both land and maritime search and rescue situations. The use of detection functions that are not exponential is also common in operational search problems. For example the U. S. Coast Guard uses inverse-cube detection models in SAROPS (Kratzke et al. 2010). This detection function was initially postulated by Koopman (1946) as a model for visual search.

The exponential detection function has an important property. It is exhibits a decreasing rate of return. This means that the probability of detection increases more and more slowly as the amount of search effort increases. This effect is seen clearly in Fig. 4.

In mathematical terms, this property is expressed by saying the detection function has a decreasing derivative or rate of return. A decreasing rate of return is a common property in economic situations in which effort may be measured in dollars, time, or manpower and return is in dollars. Most detection functions have the decreasing rate of return property. DeGuenin (1961) extended Koopman's results by finding the optimal allocation of search effort for a stationary target for any detection function with a decreasing rate of return. Let $b'(x,z)$ denote the derivative of detection function $b(x,z)$ with respect to z. If $b'(x,z)$ is decreasing in z, then b has the decreasing rate of return property.

Regular Detection Functions. A detection function is regular if $b(x,0) = 0$ and $b'(x,\cdot)$ is continuous, positive, and strictly decreasing for $x \in X$. Let

$$\rho_x(z) = p(x)b'(x,z) \text{ for } x \in X \text{ and } z \geq 0. \quad (4)$$

If one has applied z effort density at x, then $\rho_x(z)$ is the marginal rate of return (in terms of increase in probability of detection) for applying additional search effort density at x when density z has already been applied.

Optimal Allocations for Continuous Target Location Distributions

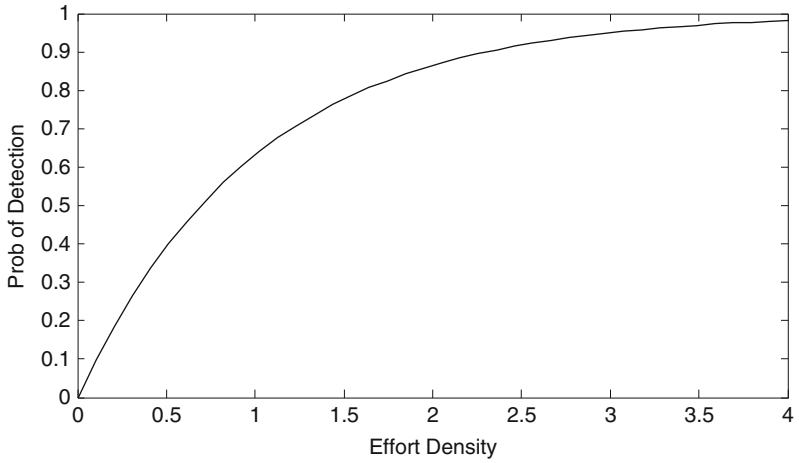
A search plan is a non-negative function f defined on the search space X which is a subset of Euclidean n-space. Typically, $n = 2$ or 3. The probability of detection, $P[f]$ and cost $C[f]$ of the plan f are computed as follows.

$$P[f] = \int_X b(x,f(x))dx \text{ and } C[f] = \int_X f(x)dx. \quad (5)$$

A search plan f^* is optimal for cost K if

$$P[f^*] \geq P[f] \text{ for all search plans } f \text{ such that } C[f] \leq K. \quad (6)$$

Stone (1989, section 2.2) showed that the following is a necessary and sufficient condition for a search plan f^* to be optimal for cost K.



Search Theory,
Fig. 4 Exponential detection function

Optimality Condition for Stationary Target Search. If the detection function b is regular, then a search plan f^* is optimal for cost $C[f^*]$ if and only if there exists $a\ \lambda > 0$ such that for $x \in X$

$$\begin{aligned}\rho_x(f^*(x)) = p(x)b'(x,f^*(x)) = \lambda \text{ if } f^*(x) > 0\\ \leq \lambda \text{ if } f^*(x) = 0.\end{aligned} \tag{7}$$

Observe that the optimal plan searches in a way to level the marginal rate of returns to some value λ in all locations where search effort is allocated and to be less than or equal to λ in all locations where no search is effort is allocated.

In the case where b is an exponential detection function, $\rho_x(f(x)) = p(x)\exp(-f(x))$. Let $\tilde{p}$ denote the density function of the posterior target location distribution given failure of plan f to detect the target. By Bayes' rule,

$$\begin{aligned}\tilde{p}(x) \propto \Pr\{\text{ plan } f \text{ fails to detect target}|\text{target at } x\}p(x) =\\ \exp(-f(x))p(x) = \rho_x(f(x)).\end{aligned}$$

Thus for an exponential detection function, the optimal plan searches the highest probability areas in a way that levels the posterior distribution where search takes place as one can see from Fig. 3.

Computing Optimal Stationary Target Search Plans. The optimality condition provides a method of computing the optimal search plan for a given cost K. The assumption that b is a regular detection function insures that ρ_x has an inverse for any x such that $p(x) > 0$. For $\lambda > 0$ define

$$\begin{aligned}f_\lambda(x) = \begin{cases}\rho_x^{-1}(\lambda) & \text{if } \lambda \leq \rho_x(0)\\ 0 & \text{otherwise}\end{cases} \text{ and}\\ U\ (\lambda) = \int_X f_\lambda(x)dx \text{ for } \lambda > 0.\end{aligned} \tag{8}$$

One can check that U is a function that decreases continuously from ∞ to 0 as λ increases from 0 to ∞. This means that for any $K \geq 0$, one can find a $\lambda^* > 0$ such that $C[f_{\lambda^*}] = K$. By (8), f_{λ^*} satisfies

$$\begin{aligned}\rho_x(f_{\lambda^*}(x)) = \lambda \text{ if } f_{\lambda^*}(x) > 0\\ \leq \lambda \text{ if } f_{\lambda^*}(x) = 0.\end{aligned} \tag{9}$$

By the optimality condition, f_{λ^*} is optimal for cost K.

Optimal Allocations for Cellular Distributions

In the above examples, the probability distributions have density functions that vary smoothly over space. However, there are many situations in which the search space is divided into cells. This occurs in Coast Guard maritime search and rescue problems, land search and rescue problems, and in many others.

Suppose there are J cells with

$$\begin{aligned}p_j &= \text{probability the target is in cell } j\\ A_j &= \text{area of cell } j\\ W_j &= \text{sweep width in cell } j\\ v_j &= \text{search speed in cell } j\\ t_j &= \text{time spent searching in cell } j.\end{aligned} \tag{10}$$

The optimal search problem is to divide the total search time T over the cells to maximize probability of detection.

Charnes and Cooper Algorithm. Suppose the detection function in the jth cell is

$$b(j,t) = 1 - \exp\left(-\frac{W_j v_j t}{A_j}\right). \tag{11}$$

For this case, Charnes and Cooper (1958) presented the following algorithm for computing the optimal distribution of search effort over these cells to maximize probability of detection by search time T.

The problem solved by Charnes and Cooper arises often in land search and rescue. The probability distribution for the location of the target, say a lost boy, is often cellular with cells of varying size. Because of variations in terrain, both the sweep width and the speed at which one can search may vary from cell to cell.

Optimal Allocation f^* of T Search Time for a Cellular Distribution

Set $\alpha_j = \dfrac{W_j v_j}{A_j}$ for $j = 1, \ldots, J$

Index cells so that $\alpha_1 p_1 \geq \alpha_2 p_2 \geq \ldots \geq \alpha_J p_J$

Set $S(0) = 0$ and $y_J = 1$

For $i = 1$ to $J - 1$

$$y_i = \ln \frac{\alpha_i p_i}{\alpha_{i+1} p_{i+1}} \text{ and } S(i) = S(i-1) + y_i \sum_{j=1}^{i} \frac{1}{\alpha_j}$$

End

If $S(j^*) \geq T$ for some $j^* < J$,

then

$$a = \frac{T - S(j^* - 1)}{S(j^*) - S(j^* - 1)}$$

otherwise

$$j^* = J \text{ and } a = \frac{T - S(j^* - 1)}{\sum_{j=1}^{J} \frac{1}{\alpha_j}}$$

End

Set

$$f^*(j) = \begin{cases} \dfrac{1}{\alpha_j}\left(\sum_{i=j}^{j^*-1} y_i + a y_{j^*}\right) & \text{for } 1 \leq j \leq j^* \\ 0 & \text{for } j > j^* \end{cases}$$

Uniformly Optimal Search Plans

The search plans described above maximize the probability of detecting the target with a fixed amount of effort K or time T. They tell the searcher the total effort to put into each cell or region, but they say nothing about how the effort should be put into cells over time. Suppose that one wants a plan that tells the searcher how to allocate search effort in space and time so that at each time t between 0 and T, he has done as well as possible. In fact, one would like the result after time t of search to be *optimal* for time t. A plan with this pleasing property is called uniformly optimal. Uniformly optimal plans also minimize the mean time to detect the target.

Koopman showed that when the detection function is exponential, a uniformly optimal plan exists. In fact, the way to obtain a uniformly optimal plan is to organize the search effort so that by time t one has allocated search effort to be optimal for that time. One then continues on to a plan that is optimal for time $T > t$ by distributing the additional effort that it is required by the time T plan over the time t plan. Stone (1989) showed that uniformly optimal plans exist and may be constructed in a similar fashion whenever the detection function is regular.

Uniformly Optimal Plans for a Continuous Search Space. The family of optimal plans defined in (8) provides a method for finding uniformly optimal plans. Let $M(t)$ be the cumulative amount of search effort available by time t for $0 \leq t \leq T$. Consider the class of search plans φ which are defined over space and time so that

$$\varphi(x,t) \geq 0,\ \varphi(x,\cdot) \text{ is increasing for } x \in X \text{ and } C[\varphi(\cdot,t)] = M(t) \text{ for } 0 \leq t \leq T.$$

Let U^{-1} be the inverse of the function U defined in (8). Set

$$\lambda(t) = U^{-1}(M(t)) \text{ and } \varphi^*(x,t) = f_{\lambda(t)}(x) \text{ for } x \in X \text{ and } 0 \leq t \leq T. \tag{12}$$

Then $\varphi^*(x,t)$ specifies the cumulative effort density to be applied to point x by time t. One can check that λ is a decreasing function and that as a result $\varphi^*(x,\cdot)$ is an increasing function of t for $x \in X$. Furthermore, $C[\varphi^*(\cdot,t)] = M(t)$, and $\varphi^*(\cdot,t)$ satisfies the optimality conditions in (7). Thus, $\varphi^*(\cdot,t)$ is optimal for cost $M(t)$ for $0 \le t \le T$, and φ^* is a uniformly optimal search plan.

Incrementally Optimal Plans. Usually one allocates search effort in discrete increments rather than continuously. So one might first design and implement a plan to be optimal for $M(t_1)$, the amount of effort available by t_1. If this search fails, one might decide to add an additional increment Δ of effort by time t_2 to obtain a total effort of $M(t_2) = M(t_1) + \Delta$. *Question:* How does one allocate this increment Δ optimally and will this allocation produce a plan that is optimal for the total effort $M(t_2) = M(t_1) + \Delta$? The uniformly optimal plan in (12) provides the answer to both of these questions. First, the allocation of the initial increment is specified by $\varphi^*(\cdot,t_1)$. Then the allocation of the increment Δ is given by $\varphi^*(\cdot,t_2) - \varphi^*(\cdot,t_1)$ and the resulting total effort allocation $\varphi^*(\cdot,t_2)$ is optimal for $M(t_2) = M(t_1) + \Delta$.

Minimizing Mean Time to Detection. A common question is, can you design a search plan to minimize the mean time to detect the target? The answer is yes, and the plan that does this is the uniformly optimal plan. First one has to imaging extending to T to ∞ so that the detection probability will reach 1. The mean time to detect, $\mu[\varphi]$, for a plan φ can be calculated by

$$\mu[\varphi] = \int_0^\infty (1 - P[\varphi(\cdot,t)])\,dt. \tag{13}$$

Since φ^* is uniformly optimal, it minimizes the integrand in (13) for all t and therefore produces the minimum mean time to detection. If $T < \infty$ and the probability of detection for the optimal plan is less than 1 by time T, then one can define the mean time to complete the search as follows

$$\mu[\varphi] = \int_0^T (1 - P[\varphi(\cdot,t)])\,dt + (1 - P[\varphi(\cdot,T)])T$$

and see that φ^* minimizes this as well as maximizing the probability of detection by time T.

Uniformly Optimal Plans for Cellular Distributions. Stone (1989, Section 2.2) finds uniformly optimal plans for cellular distributions and regular detection functions.

Suppose there are J cells with probability p_j of the target being cell j and that the detection function b is regular. Let $M(t)$ be the cumulative search effort available by time t. Define

$$\rho_j(z) = p_j b'(j,z) \text{ for } j = 1,\ldots,J \text{ and } z \ge 0$$

$$f_\lambda(j) = \begin{cases} \rho_j^{-1}(\lambda) \text{ if } \lambda \le \rho_x(0) \\ 0 \quad \text{otherwise} \end{cases} \text{ and } U(\lambda) = \sum_{j=1}^J f_\lambda(j)$$

Let U^{-1} be the inverse of the function U, and set $\lambda(t) = U^{-1}(M(t))$. Then

$$f_{\lambda(t)}(j) = \rho_j^{-1}(\lambda(t)) \text{ for } j = 1,\ldots,J \tag{14}$$

is optimal for $M(t)$ effort for $t \ge 0$ and is uniformly optimal.

Optimal Search with Uncertain Sweep Width

In the detection problems discussed so far, such as the cellular search problems, it is assumed that the sweep width of the sensor is known with certainty. It is often the case that the sweep width is uncertain, particularly in cases where state of the target is uncertain. For example, if one is looking for a lost aircraft, one often does not know if the plane has landed in one piece of if there is wreckage scatter over an area. Maybe the planed burned after crashing. Each of these situations will yield a different value for the sweep width of a visual search from the air.

Richardson and Belkin (1972) and Stone (1989, section 2.3) show how to find optimal plans when the sweep width has a probability distribution on its value.

Search in Presence of False Targets

Often searches are performed with a sensor such as a side-looking sonar which is used in underwater searches for lost objects. This type of sensor is excellent for covering large areas with high detection probability. However, these broad search sensors can generate a large number of false targets, i.e., detections on real objects which are not the target. Thus detections have to be investigated, perhaps by a visual sensor, to determine whether the objects detected are targets or not. Thus, a search plan in the presences of false targets must specify not only the

allocation of the broad search effort but a strategy for investigating detections. Chapter 6 of Stone (1989) develops models of search in the presence of false targets, introduces a number of classes of search plans in presence of false targets, and finds plans that minimize expected cost to detect the target.

Optimal Search for Moving Targets

Prior to Brown (1980), optimal allocation results for moving targets were limited to very special cases. Most moving target problems were approached by freezing the target motion over some increment of time, allocating effort as though the target were stationary during that time increment, and then repeating the process for the next time increment. For example, the U. S. Coast Guard's Computer Assisted Search Planning (CASP) System (Richardson and Discenza 1980) used this technique. Brown discovered an efficient algorithm for finding optimal search allocations for moving target problems when the target distribution is cellular, the target motion is Markovian, and the detection function is exponential. Brown's algorithm maximizes detection probability at time T. This algorithm was applied to great effect by the U. S. Navy in searching for Soviet Submarines.

Washburn (1983) generalized Brown's algorithm to the class of forward and backward (FAB) algorithms that apply to a more general class of payoff functions. Algorithms for non-exponential detection functions and non-Markovian motions are given in Stone (1979) and Stromquist and Stone (1981).

Optimal One-Sided Search for a Moving Target

The target's location and motion through X are specified by the stochastic process $X = \{X_t; t \geq 0\}$ where $X_t \in X$ gives the target's position at time t. A time horizon $[0, T]$ is specified and the goal is to maximize the probability of detecting the target by time T. For this discussion, time will be discrete so that $t = 0, 1, \ldots, T$.

A search plan ψ specifies the allocation of search effort in space and time. Specifically $\psi(x, t) =$ effort density placed at point x at time t for $x \in X,\ t = 0, 1, \ldots, T$. Search effort is constrained by the rate at which effort can be applied. Specifically there is a function m such that $m(t) =$ effort available for search at time t for $t = 0, 1, \ldots, T$, and search plans ψ must satisfy

$$\int_Y \psi(x, t)\, dx \leq m(t) \text{ for } t = 0, 1, \ldots, T, \tag{15}$$

$$\psi(x, t) \geq 0 \text{ for } x \in X,\ t = 0, 1, \ldots, T. \tag{16}$$

Let Ψ be the set of search plans satisfying (15) and (16). For each sample path ω of the process X, the probability of detecting the target by time t, given that it follows that path, is a function of the weighted total effort density,

$$\zeta(\psi, \omega, t) = \sum_{s=0}^{t} W(X_s(\omega), s)\psi(X_s(\omega), s),$$

which accumulates by time t on the target over the course of the path. The weight $W(x, s)$ represents the relative detectability or sweep width against the target given it is located at point x at time s. There is a detection function $b : [0, \infty] \to [0, 1]$ such that $b(\zeta(\psi, \omega, t))$ is the probability of detecting the target by time t given that it follows sample path ω and that search plan ψ is executed. Letting E denote expectation over the sample paths of X, it follows that

$$P[\psi] = E[b(\zeta(\psi, \cdot, T))]$$

is the probability of detecting the target by time T with plan ψ. In the remainder of this discussion, the argument ω is suppressed.

The optimal detection problem for a moving target is to find a plan $\psi^* \in \Psi$ such that $P[\psi^*] \geq P[\psi]$ for all $\psi^* \in \Psi$. Such a plan is called *T-optimal*.

Brown's Algorithm for Continuous Space. For an exponential detection function and a target moving in discrete time and space, Brown's algorithm solves the problem of finding a T-optimal allocation by solving a sequence of stationary target problems. The following paragraphs present an extension of Brown's algorithm to continuous search spaces and relate this extension to the original discrete-space algorithm. The continuous space algorithm is based on the following necessary and sufficient condition for a T-optimal search plan proved by Stone (1979).

Define

$$g_t^{\psi}(x) = \Pr\{X_t = x | \text{failure to detect at all times other than } t \text{ using plan } \psi\}$$

$$\text{for } x \in X,\ \psi \in \Psi,\ \text{and } t = 0, 1, \ldots, T.$$

The function g_t^{ψ} is the posterior target location density given failure to detect by the search effort at all times other than t. If the detection function b is exponential, i.e., $b(z) = 1 - \exp(-z)$ for $z \geq 0$, then $g_t^{\psi}(x)$ is proportional to

$$\mathrm{E}\left[\exp\left\{-\sum_{s \neq t} W(\mathrm{X}_s, s)\,\psi(\mathrm{X}_s, s)\right\} \middle| \mathrm{X}_t = x\right]$$

where p_t is the prior probability density function for X_t

Necessary and Sufficient Condition for T-Optimality. Assume that the detection function b is exponential. A necessary and sufficient condition for $\psi^* \in \Psi$ to be T-optimal is that $\psi^*(\cdot, t)$ maximizes the probability of detecting a stationary target with distribution $g_t^{\psi^*}$ using effort $m(t)$ for $t = 0, 1, \ldots, T$.

Description of Algorithm. For time $t = 0$, the algorithm allocates $m(0)$ effort optimally to the target distribution p_0. For $t = 1, \ldots, T$, the algorithm calculates the posterior target distribution at time t given failure to detect by the effort prior to time t and allocates $m(t)$ effort in a manner that is optimal for the stationary target problem with target distribution given by g_t^{ψ}. The plan that results from this first pass is the incrementally optimal or myopic search plan. It maximizes the increment in detection probability at each time t but does not produce a T-optimal plan.

Subsequent passes proceed as follows for $t = 0, 1, \ldots, T$. The algorithm computes g_t^{ψ} based on the allocation ψ obtained up to that point in the iteration, redistributes the effort $m(t)$ at time t to be optimal for g_t^{ψ}, and changes ψ to reflect the reallocation. The algorithm continues in this iterative fashion until a convergence criterion is met.

To use this algorithm, one must be able to calculate g_t^{ψ} and find the optimal allocation of effort for a stationary target problem when the detection function is exponential. The methods described in the section on *Optimal Search for Stationary Targets* provide efficient algorithms for doing this. If one can find an efficient method of computing g_t^{ψ}, then one can implement the above algorithm for the case of a discrete or continuous search space. For the case where X is a discrete time and space Markov process, Brown (1980) devised a very efficient algorithm for computing g_t^{ψ} and used it along with the Charnes-Cooper algorithm described above to produce an algorithm for calculating T-optimal search plans. By making use of the upper bound discovered by Washburn (1981a), one can tell when his solution has come within a specified tolerance of the detection probability of the T-optimal plan. When using Brown's algorithm, the convergence is usually very rapid.

Stone et al. (1978) present a generalization of Brown's algorithm to arbitrary discrete time and space target motions.

Generalized Search Optimization

Stromquist and Stone (1981) found a set of necessary and sufficient conditions for maximizing a class of functionals with search theory applications. Using these conditions, they were able to unify the solutions to a number of previously solved search problems including the following.

Multistate Target Search. A generalization of the detection search described above is the multistate target search. In this case the target's motion is given by $\{(X_t, S_t); t = 0, 1, \ldots, T\}$ where X_t is the target's position at time t and S_t is the target's state at time t. The target may change state as well as location stochastically, and the target's state can affect the target's motion as well as its detectability. As an example, consider a case where there are K states and the sweep width is a function of location, state, and time, so that cumulative effort ζ becomes

$$\zeta(\psi, T) = \sum_{t=0}^{T} W(X_t, S_t, t)\psi(X_t, t)$$

and

$$P[\psi] = E[b(\zeta(\psi, T))]$$

as before. Observe that effort cannot be allocated to states but only to locations. Discenza and Stone (1981) developed algorithms for solving these multistate target search problems.

Optimal Survivor Search is a special case of multistate target search. In the search problems discussed above, the goal is to maximize the probability of detecting the target by some time. In the case of search and rescue problems, a more appropriate goal may be to maximize the probability of detecting the target alive. A search with this goal

may apply the initial effort in some lower probability areas that are particularly hazardous to the target in order to recover a survivor quickly if he or she is located there. This may involve some sacrifice of overall detection probability. As an example, one might want to concentrate initially on search areas where a survivor would be located if he is immersed in the water and delay somewhat searching areas that would be likely only if he is still in his boat.

Defensive Search is another special case of multistate target search. In defensive search, one is trying to detect an attacker before it launches a weapon. In this case the target has two states, weapon launched and not launched. Once the attacker launches a weapon, the sweep width is set to zero and the target remains in the launched state for the remainder of the problem. In this case, maximizing P is maximizing the probability of detecting the attacker before it launches an attack

Surveillance Search. Tierney and Kadane (1983) have developed a technique for solving surveillance problems which builds on the optimal detection search results discussed above. The surveillance problem is to maximize the probability of being in contact (i.e., having a detection on the target) at time T. In contrast to the detection search problem, a detection before time T does not end the problem. It merely helps to obtain a detection at time T. For problems where the target's motion is modeled by a discrete-time-and-space Markov chain, Tierney and Kadane have shown that the optimal surveillance problem can be solved by solving a series of optimal detection search problems. In their method, one starts at time T and works his way backward in time in a fashion similar to dynamic programming. At each time t, one must solve what Tierney and Kadane call a general detection search problem given knowledge of the target's position at time t.

In the general detection problem, the searcher receives a payoff or return $r(j,t)$ if he detects the target in cell j at time t. The search stops the first time the target is detected, and the objective of the general detection problem is to maximize the expected payoff.

Whereabouts Search. Stone and Kadane (1981) solve the problem of optimal whereabouts search for a moving target. In a whereabouts search one can succeed either by detecting the target or guessing its location. When $X = \{1, \ldots, J\}$, Stone and Kadane show that solving a whereabouts problem is equivalent to solving J detection search problems

Constraints on the Searcher

In the search problems considered above, it is assumed that effort can be distributed over the search space any way one chooses. Sometimes this is a reasonable approximation. A visual search by aircraft over a region where the time to travel from one part of the region to another is small is an example. Sometimes the constraints on the movement of the search platforms require that one consider special types of search plans. Usually there are two of types of constraints that are considered – path constraints and simplicity constraints.

Path Constraints. If the search platform is a boat or a person walking on land, then the place where the platform is searching now constrains the places where it can search in the next increment of time. In these cases, one has an optimal searcher path problem. Instead of finding an optimal allocation of search effort, the problem is to find an optimal path for the searcher. The set of paths from which the optimum is chosen is restricted to those that obey the physical constraints on the movement of the search platform. This is a difficult class of problems, especially for moving targets, but there has been some progress in solving them.

Stewart (1979, 1980), Eagle (1984), and Eagle and Yee (1988) have applied integer programming approaches to finding efficient algorithms for solving these problems.

Simplicity Constraints. In executing actual searches, it may be desirable to restrict the search patterns to a class of searches the are simple to execute operationally. A typical example is to restrict search plans to be composed of searches consisting of a set of rectangles each with a uniform search density or coverage. Such plans can be approximated by searches that employ equally spaced, parallel search paths in the rectangles.

Single Rectangle Searches. In the case of search for a stationary target with a bivariate normal location distribution, Richardson and Discenza (1980), show how to find optimal rectangle plans. For an optimal rectangle plan, one chooses a single rectangle and spreads his search effort uniformly over that rectangle. Richardson and Discenza show that it is always possible to pick an optimal rectangle plan that

comes quite close to (within 3% of) the detection probability of the optimal plan.

Multiple Rectangle Searches. Discenza (1980) developed an algorithm for finding optimal multiple rectangle searches for the cellular target location distributions generated by CASP. These multiple rectangle searches consist of non-overlapping rectangles. In each rectangle the search effort is spread uniformly over the rectangle. Furthermore, each search asset (say an aircraft) is assigned to search one and only one rectangle. The solution method proposed by Discenza involves some additional restrictions on the choices of rectangles to allow an efficient solution of this problem.

Kratzke, Stone, and Frost (2010) describe the methodology used in the SAROPS program to find optimal non-overlapping rectangles for Coast Guard Search and rescue problems. The optimization approach is numerical, but it does account for the movement of the search object during the search.

Search and Evasion Problems

A classic two-sided search problem involves a target that is trying to evade a searcher. In one case the target's goal may be simply to avoid detection. In other cases, the target may have additional goals such as reaching a certain area undetected. This would be the goal for a smuggler or an infiltrator. The goal for the search theorist is to solve for the optimal strategy for both the searcher and the evader. These problems tend to have a game theory formulation. Although they are difficult to solve, there has been some progress made by Auger (1991), Dobbie (1975), Eagle and Washburn (1991), Gal (1980), Garnaev (2000), Stewart (1981), and Washburn (1980b).

Alpern and Gal (2003, Book I) present an excellent and highly readable summary of the main results in search games. Below is a sampling of the results presented by them.

Search Games in a Bounded Connected Region Q of Euclidean Space of dimension 2 or more with an Immobile hider.

Search in a Region. Let A be the area or volume of the region Q and R the search rate (area or volume per unit time) of the searcher.

Result. The (minimax) value of this game is $A/2R$. This is true whether the searcher's path is continuous or not, whether he chooses his initial search point or not, and whether or not his strategy is randomized.

Search on a Network: A network is defined to be a finite connected set of arcs that intersect only at their end points. Let the sum of the length of all the arcs be equal to L. The searcher moves through the network at unit speed.

Result: The value of the search game using pure strategies for an immobile hider on the network Q is L if Q is Eulerian. Note: A network Q is Eulerian if there is a tour (a path traversing all the arcs of Q and returning to its starting point) of length L. If mixed strategies are allowed the value of the game drops to $L/2$.

Mobile Hider in Bounded Connected Region:

Result*:* In the case where the searcher's path does not have to be continuous, the value of the game is A/R.

Mobile Hider in a Bounded Convex Region Q in Euclidean 2-Space. For these searches r is the detection radius (which is small compared to the diameter of Q), the searcher moves in continuous paths at a speed of 1, and the mobile hider moves on a continuous path with a speed that is "not too small." The searcher starts at specified point in Q, the hider chooses his starting point.

Result. Both the searcher and the hider can keep the probability of capture before time t close to $1 - \exp(-2rt/A)$ where A is the area of Q.

Note that $1 - \exp(-2rt/A)$ is probability of detection by time t for random search (as defined by Koopman) for a stationary target in a region of area A.

Second-order Conditions

Conditions Involving Second Derivatives.

Self-Dual Parametric Algorithm

A variation of the simplex method and parametric programming in which the given linear-programming problem is adjusted so that the same parameter is added

to each cost coefficient and each right-hand-side element. By using a sequence of primal and dual simplex transformations, the problem will be optimal for some value of the parameter, with the process continuing until a solution with a zero value of the parameter is found.

See

► Simplex Method (Algorithm)

Semi-Markov Process

A stochastic process that evolves via an embedded discrete-time Markov process, where the times spent in a state before making a transition are independent random variables following general distributions. Generalizes the continuous-time Markov process setting where the time spent in a state is exponentially distributed. Used for analyzing queueing and related systems.

Sensitivity Analysis

Andres Redchuk[1,2] and David Ríos Insua[3]
[1]Universidad Rey Juan Carlos, Mostoles, Madrid, Spain

Introduction

In operations research (OR), sensitivity analysis describes the methods and tools used to study how the output of a model varies with changes in the input data. The input data may refer to parameters affecting the objective functions and/or constraints or to the structure of the problem. Depending on the problem and model, the output could refer to:

- the optimal alternative and/or the optimal value, or,
- a set of alternatives with a certain property. Some examples include the non-dominated set in a multi-objective optimization problem; the set of alternatives satisfying certain constraints in a classification problem; or the set of the, say, five best alternatives.

Typical questions addressed within sensitivity analysis are whether a given optimal solution will remain as such if inputs are changed in a certain way, and, if not, which other alternatives may become

optimal. Finding the most critical directions for changes in inputs that may affect the model output are also relevant sensitivity analysis issues; see French and Ríos Insua (2000), Saltelli et al. (2000), and Saltelli et al. (2004) for reviews.

As motivating examples, consider the following problems:

1. Linear programming. One may be interested in checking how the costs (reduced costs) and/or the right hand side terms and/or the technological matrix terms impact over the optimal solution. A typical question would be: does the optimal solution change if one of the costs increases so much?
2. Decision analysis. One may be interested in checking the impact of the beliefs and preferences, modeled, respectively, through a probability distribution and a utility function, over the optimal alternative and its expected utility. For example, one could wonder how much arelevant binomial parameter and a risk tolerance parameter should be changed to make a certain alternative optimal.
3. Multi-objective decision making with a multi-attribute value function. One may want to check which alternatives become optimal when the weights vary within a range around the current weight settings.

An important, and occasionally controversial, issue in sensitivity analysis is the distinction between decision sensitivity and value sensitivity (Kadane and Srinivasan 1996). A variety of situations may hold. For instance, when performing sensitivity analysis, it may happen that value changes considerably with virtually no change in the optimal alternative.

Motivations

There may be many reasons to check the sensitivity of the output of an OR model to its inputs. A first reason may be the almost ubiquitous uncertainty in the inputs. One may not be willing or capable of assessing such uncertainty with a probability distribution. Then, baseline values for the inputs could be assessed and changes in how they affect the output are observed.

Similarly, the assessment of the inputs might be affected by inherent imprecision and output robustness may be checked. In relation with this, it may be interesting to check the robustness of the output under various input scenarios.

Note also that, since some of the inputs to an analysis may encode the subjective judgments of the decision maker (DM), their implications and possible inconsistencies should be explored. The need for sensitivity analysis is further emphasized by the fact that the assessment of such judgments could be a difficult task. For example, it is frequently mentioned that assessing a subjective probability distribution is involved. Consider the simplest case in which it is desired to elicit a prior over a finite set of states $\theta_i, i \in \{1, \ldots, I\}$. A common technique to assess a precise probability distribution $\pi(\theta_i) = p_i$ proceeds as follows, with the aid of a reference experiment: one progressively bounds $\pi(\theta_i)$ above and below until no further discrimination is possible and then takes the midpoint of the resulting interval as the value of p_i. Instead, one could directly operate with the obtained constraints $\alpha_i \leq \pi(\theta_i) \leq \beta_i$, acknowledging cognitive limitations. This is an especially important point, as the DM's judgments will evolve through the analysis until they are requisite. Sensitivity analysis may guide such process.

In relation with the limitations of elicitation, consider also the situation in which there are several decision makers and/or experts involved in the elicitation. Then it is not even necessarily possible theoretically to obtain a single model: one might be left with only classes of each, corresponding to differing expert opinions, and one may need to study the model under those various settings.

Finally, note that sensitivity analysis may be used to perform value of information calculations that allow one to compute how much to pay for information used to reduce uncertainty in an analysis.

To sum up, sensitivity analysis aims at increasing the confidence in an OR model and its output by providing an understanding of the responses of the model to changes in the inputs.

Foundations

A number of results show that imprecision in model inputs may be dealt with through a class of probability distributions and a class of utility functions. These results have two basic implications. First, they provide a qualitative framework for sensitivity analysis, describing under what conditions the standard and natural sensitivity analysis approach of perturbing the

initial input assessments within some reasonable constraints may be undertaken. Second, they point out to the basic solution concept of robust approaches, thus indicating a key computational objective in sensitivity analysis, as long as the interest is in decision analytic problems: that of non-dominated alternatives. An alternative a dominates another alternative b, if its evaluation is better for each potential input to the analysis. Then, an alternative a is non-dominated if no other feasible alternative dominates it. This corresponds to a Pareto ordering of alternatives based on inequalities on their evaluations.

To construct an appropriate framework for general sensitivity analysis, the standard decision-theoretic axiomatic foundations should be reconsidered to account for imprecision in model inputs. Although this approach does not lead to such well-rounded development as in the precise case, in which various axiomatizations essentially lead to the subjective expected utility model, various partial results do exist (e.g., Ríos Insua 1990 or Walley 1991), leading to, essentially, the same conclusion: imprecise beliefs and preferences may be modeled by a class of priors and a class of utility functions, so that preferences among alternatives may be represented by inequalities of the corresponding posterior expected utilities. The basic argument for such results assumes that the underlying preference relation, rather than being a weak order (complete and transitive), is a quasi order (reflexive and transitive).

Key Approaches to Sensitivity Analysis

Clearly, as there is a large variety of OR models, there is a comparatively large number of approaches to sensitivity analysis. Only a few of the approaches that may be applied to various OR models are described, without much dwelling into their numerical details.

Testing Alternative Inputs

One first generic approach refers to changing the inputs to the model and observe variations in the output. This may be done in several ways.

Trying Other Values

The first approach may be termed the informal one, which considers several inputs and compares the quantity of interest (e.g., the posterior mean, the difference in value between two alternatives, the optimal alternative) under them. The approach is very popular because of its simplicity. While this is a healthy practice and a good way to start a sensitivity analysis, in general this will not be sufficient and more formal analysis should be undertaken: the limited number of priors chosen might not include some which are compatible with the prior knowledge and could lead to very different values of the quantity. Sometimes, the alternative inputs considered are randomly generated.

Parametric Analysis

Another way of changing the inputs is through parametric analysis. Using a baseline input assessment, one determines a relevant direction to perturb the inputs and considers a parametric perturbation along such direction observing whether there is a change, or not, in, e.g., the optimal alternative (Gal and Greenberg 1997).

Global Robustness

Another popular approach in SA is called global sensitivity. All inputs compatible with the prior knowledge available are considered and robustness measures are computed as the inputs vary within that class. Computations are not always easy since they require the evaluation of suprema and infima of quantities of interest. The choice of the class of inputs should be driven by the following goals:

1. the class should be related with the elicitation method used;
2. the class should contain only reasonable inputs, avoiding unreasonable inputs which might erroneously lead to lack of robustness;
3. computation of sensitivity measures should be as simple as possible.

The robustness measures provides, in general, a number that should be interpreted in the following way:

- if the measure is small, then robustness is achieved and any input in the class can be chosen without relevant effects on the quantity of interest;
- if the measure is large, then new data should be acquired and/or further elicitation to narrow the class, recomputing the robustness measure and stopping as before;
- otherwise, if the measure is large and the class cannot be modified, then an input can be chosen in

the class but the relevant influence of the choice over the quantity of interest should be considered carefully.

Given a class of inputs, global sensitivity analysis will usually pay attention to the range of variation of a quantity of interest as the input ranges over the class. As an example, in a decision-theoretic problem, suppose a quadratic loss function is used in a problem. The optimal rule is the posterior expectation. If there is imprecision about the prior, the range of the posterior expectation as the prior ranges in the class would be computed.

Behavior of the Optimal Alternative

The other family of sensitivity analysis approaches studies the behavior of the output of interest under small input perturbations, either via differential approaches or convergence arguments.

Local Sensitivity

Local sensitivity analysis studies the rate of change in inferences and decisions, using functional analysis differential techniques, trying to assess how a small change in the input affects the quantity of interest. The two issues involved refer to choosing the derivative and the corresponding norm, over the appropriate class of inputs. For the first choice, Fréchet derivatives, total derivatives and Gateaux differentials have been used, among others. Divergence measures have been used as well. For the second choice, the total variation, Prohorov, Levy, and Kolmogorov metrics have been used among others. The direction providing the supremum norm is used as the most sensitive direction; alternatively, the average sensitivity is sometimes used integrating the norm along all possible relevant directions.

As an example, Ruggeri and Wasserman (1993) measured the local sensitivity of a posterior expectation with respect to the prior by computing the norm of the Fréchet derivative of the posterior with respect to the prior over several different classes of inputs.

Stability

Stability theory provides another unifying, general sensitivity framework, formalizing the idea that imprecision in elicitation of inputs should not affect the optimal decision greatly. When strong stability holds, a careful enough elicitation leads to decisions with optimal value close to the greatest achievable; when weak stability holds, at least one stabilized decision will have such property. However, when neither concept of stability applies, even small elicitation errors may lead to disastrous results in terms of large losses in value.

Stability theory studies the convergence of decisions, nearly optimal for input sequences converging to the baseline inputs, to the corresponding optimal alternative. The arguments involved refer to the continuity of the relevant operator, e.g., the posterior expected utility functional. Note that stability is not always guaranteed, even in standard problems, as shown e.g., in Kadane and Srinivasan (1996). Such counterexamples show a need for conditions which ensure stability. While these conditions simplify the task of verifying stability, it can still be hard to do so in practice.

An Operational Approach to Sensitivity Analysis

An operational approach to sensitivity analysis in OR models may be described as follows. At a given stage of the analysis, information on the DM's inputs is elicited, and the class of all inputs compatible with such information is considered. The set of non-dominated solutions is approximated. If these alternatives do not differ too much in their value, the analysis may be stopped; otherwise, additional information will be gathered. This would further constrain the class: the set of non-dominated alternatives will be smaller. It is hoped that this iterative process would converge until the non-dominated set is small enough to reach a final decision. It is conceivable in this context that at some stage it might not be possible to gather additional information yet there remain several non-dominated alternatives with very different values. In these situations, ad hoc approaches such as maximin solutions may aid as a way of selecting a single robust solution: each alternative is associated with its worst evaluation, given the current input imprecision. The alternative with best worst evaluation is suggested. Alternatively, a prior over the class of inputs could be built and base choice on expectations over evaluations.

The relevant steps are now described.

Non-dominated Alternatives

As mentioned, a key solution concept is the efficient set, i.e., the set of non-dominated alternatives. In most cases, it is not possible to compute the non-dominated set exactly, and thus approximation schemes are necessary. Typically, one would proceed by randomly sampling the set of alternatives, randomly sampling the set of inputs, and checking dominance among pairs of alternatives. Under appropriate conditions, this sampling scheme is such that the sample non-dominated set converges to the non-dominated set, as the sample size grows.

Extracting Additional Information

In some cases, non-dominance is a very powerful concept leading to a unique non-dominated alternative. However, in most cases the non-dominated set will be too large to imply a final decision. It may happen that there are several non-dominated alternatives and differences in expected utilities are non-negligible. If such is the case, additional information should be sought that would help to reduce the classes, and, perhaps, reduce the non-dominated set. Some tools based on functional derivatives to elicit additional information may be seen in Ríos and Ruggeri (2000). Tools based on distance analysis may be seen in Ríos Insua (1990).

Robust Solutions

When no additional information may be extracted from experts to reduce the set of inputs, and the set of alternatives is still too large, robust solution concepts should be sought. One is the maximin approach which may be considered as an automated method that allows the choice of actions that guard against catastrophic consequences. A maximin approach would be suitable after a sensitivity analysis has been unable to significantly narrow the range of variation, under changes in inputs of the quantity of interest.

Hyperpriors

Another approach to dealing with lack of robustness would be to place a hyperprior on the class of inputs. Indeed, if there were no possibility of obtaining additional information to deal with the lack of robustness, this technique would be recommended, with the hyperprior being chosen in some default fashion.

Misconceptions in Sensitivity Analysis

Some basic issues corresponding to a number of sensitivity analysis approaches are described. Their relevance stems from them corresponding to typical misconceptions.

- It is not enough to study changes in output by trying some other inputs.
- Partial sensitivity studies may not be sufficient: a problem may be insensitive to changes in utility and changes in probability, but sensitive to simultaneous changes in utility and probability.
- When performing sensitivity analysis, there are cases in which the optimal value may change a lot, with virtually no change in the optimal action, even if the utility is fixed.
- Alternatively, there are cases in which the optimal alternative varies widely, but the optimal value does not practically change.
- Big changes in optimal value do not necessarily correspond to big changes in consequences of interest.
- Standard global robustness studies, based for example on ranges of expected utilities of actions, may not be sufficient within a decision-theoretic perspective.

Concluding Remarks

Imprecise probability is a generic term used to describe mathematical models that measure uncertainty without precise probabilities. This is certainly the case with robust Bayesian analysis, but there are many other imprecise probability theories, including upper and lower probabilities, belief functions, Choquet capacities, fuzzy logic, and upper and lower previsions (Walley 1991). Some of these theories, such as fuzzy logic and belief functions, are only tangentially related to sensitivity analysis, whereas others are intimately related. For example, some classes of probability distributions that are considered in Bayesian sensitivity analysis, such as distribution band classes, can also be interpreted in terms of upper and lower probabilities (Ríos Insua et al. 2000). Also, classes of probability distributions used in sensitivity analysis robust Bayesian analysis will typically generate upper and lower previsions as their upper and lower envelopes (Berger et al. 1996).

Finally, sensitivity analysis is linked to uncertainty analysis, which aims at quantifying the uncertainty of the output as a function of the uncertainty in the model inputs.

Separable Function

A function $f(x_1, \ldots, x_n)$ is a separable function if $f(x_1, \ldots, x_n) = f_1(x_1) + \ldots + f_n(x_n)$. Certain nonlinear-programming problems that contain separable functions can be suitably represented by a linear approximation and solved by a variation of the simplex method.

Separable-Programming Problem

A nonlinear-programming problem in which some or all of the constraints and the objective function are separable functions of one variable. Using linear approximations to the separable functions, the problem can be approximated and solved by a variation of the simplex algorithm that uses a restricted-basis entry rule.

Service Science

James C. Spohrer[1] and Wendy M. Murphy[2]
[1]Almaden Research Center, San Jose, CA, USA
[2]IBM Corporation, Armonk, NY, USA

Introduction

Service science is the interdisciplinary study of service systems and value-cocreation phenomena in the human-made world. However, because the service science community brings together participants from many academic disciplines, industry sectors, and national governments, the community is still working to answer basic questions, such as: (1) what is service? What is a service system? What is value-cocreation? (2) What are the causes of the tremendous observed growth in service activities in both developed and emerging economies around the world? How are product-systems and service-systems alike and different? Is there any longer a meaningful distinction to be made? (3) What should the research agenda associated with service science be? (4) Where is the science in service science? (5) How is service science different from <name your favorite academic discipline that studies complex human-made systems>? (6) If service science is successful, how will the world be different/better?

Service science is an emerging area of research and practice for the interdisciplinary study and improvement of service system structures and value-cocreation mechanisms. Value-cocreation or non-zero-sum games have been growing in quantity and quality, and between more complex entities, throughout human history (Wright 2000). Service systems are human-made systems to improve customer-provider interactions. Service systems include the complex business and societal systems, in which customers, providers, and other stakeholders interact directly and indirectly to create mutual benefits (value-cocreation). Service systems include government, education, health, finance, retail, buildings, communications, energy, food, water, and transportation.

Many of the grand challenges facing the world's growing population, such as hunger, poverty, and discrimination can be framed as lack of access to resources and capabilities in a world of increasing abundance. For the last 50 years the economies of most developed nations and nearly all cities have been dominated by what traditional economists refer to as the service sector, and yet service has been understudied in academia relative to its economic importance (Chesbrough and Spohrer 2006). Economics, marketing and operations (including operations research) were three of the first disciplines to begin scientific study of service and service systems, and more recently management, engineering, computing, design, law, social and behavioral sciences, and other disciplines have applied their unique methods and also established service-oriented specializations. As the world's population shifts from rural to urban areas and as national economies become dominated by the what economist call the service sector, or the knowledge economy, interest in service science has grown.

Also, the service science community has become increasingly focused on the study of holistic service systems, such as cities, universities, luxury resort hotels, and cruise ships that are parts of a complex system of systems. As service science matures operations research is playing a central role and provides the mathematical models and optimization tools for the study of holistic service systems, in which local optimization does not necessarily lead to global optimization and in which small changes in one component system can lead to large consequences in other systems. These are familiar optimization challenges for operation researchers, especially in queueing theory, supply chain optimization, and total quality improvement.

Service Growth

The growing interest in the study of service and service systems can be traced to five factors:

1. Service Sector Growth (OECD 2005): Traditional economic measures of the overall relative percentage of and growth of economic output from service sector and knowledge economy in nations, often referred to as the intangible economy and contrasted with agriculture and manufacturing which create tangible output. This also includes the growth of manufacturing companies growing their service revenue (servitization). Servitization often results because of the growing complexity of manufactured goods, and the need for more customer service to help maintain the product and for users to get the full benefit from the products they purchase.
2. Urban and Knowledge Economy Growth (North 2005: 87–102): The increase in the percentage of the world's population that lives in urban areas as compared with rural areas. The growth of cities and the dependence of cities on universities to ensure skills needed to compete in a global knowledge economy, as well as to provide sustainable innovations that improve quality of life from one generation to the next.
3. IT-Enabled Service Growth (UK Royal Society 2009): The increase in IT enabled service, exemplified by both the rise of internet and web-based service delivery, but also what IBM calls "Smarter Planet" in which natural and human-made systems are becoming instrumented, interconnected, and intelligent. The potential for new types of service that IT-enables creates the possibility of continuous improvement by tapping into increasingly powerful IT, has resulted in the growth of areas such as service computing. This is also tied to the view that "nature's service" that access to resource and capability of the planet are increasingly in jeopardy if greener and more sustainable technology-enabled approaches are not implemented.
4. Grand Challenges Framing (Sen 2001): The increasing realization that grand challenges such as hunger, poverty, discrimination, etc. result from lack of access to resources and capabilities in a world of increasing abundance. Using traditional economist definitions of service, the challenge is not only about increasing the number of farms, factories, and law-enforcement/court-houses, but ensuring access to these resources. Other examples are the large percentage high school drop out rate in the US and other developed nations, especially in urban areas; or joblessness during economic cycles. Recovering from natural disasters can be seen as getting service systems back up and running. Even warfare these days may be viewed as nation-building and building up service systems.
5. Skills for Twenty-first Century (Hefly and Murphy 2008; Donofrio et al. 2010): In a knowledge economy, the challenge is there is too much to teach. Even with specialization, it is important that specialists be able to communicate with other specialists and work on teams together. Specialists or I-shaped people, who have good deep knowledge and problem-solving skills, become better team members when they have broad communications skills, and become what is known as a T-shaped person. T-shaped people are better at team-oriented projects, and in general are faster learners and more adaptable because they already have advanced organizers and knowledge of the main concepts in many domains.

For more on the growth of service and national responses to the need for scientific approaches to service innovation see (US Congress 2007) and (UK Royal Society 2009).

Academic Response: Discipline Growth

While many have argued convincingly that academic institutions have been slow to respond to service growth, nevertheless an ever increasing number of existing disciplines have established service-oriented sub-disciplines. Five of the major areas are:

1. Service marketing (Vargo and Lusch 2004; Zeithaml et al. 2006): Marketing was one of the first disciplines to establish a service-oriented sub-discipline, with service quality a primary measure of concern, largely from the customer perspective. Concepts include service-dominant-logic, the gaps model, linkage research relating employee and customer perceptions of quality, the service profit chain, customer equity, customer co-development of service innovations, and relationship marketing

2. Service engineering (Tien and Berg 2003; Chang 2010; Karwowski and Salvendy 2010): More recently, systems engineers have begun to study service systems, and textbooks have begun to appear. Service engineering is working to identify common building blocks or architectural components of service systems.
3. Service design (Glushko 2010): This is one of the fastest growing areas of service research. Service design has an architectural component like service engineering, but much more emphasis on customer and employee experience during service interactions.
4. Service computing (Demirkan and Goul 2006; Zysman 2006; Zhang 2007; Katzan 2008): Another fast growing area, the rise of service-oriented architectures, web services and smart phones have given a huge boost to this emerging service-oriented sub-discipline of computer science. IEEE and ACM have been collaborating on establishing a standard curriculum in this area.
5. Service operations (Fitzsimmons and Fitzsimmons 2007; Chase 2010; Sampson 2010; Daskin 2010): Operations, which includes operations management, service management, and operations research, was also one of the first discipline areas to establish a service-oriented sub-discipline, with service delivery productivity a primary measure of concern, largely from the provider perspective. Concepts include customer contact theory, unified service theory based on customer input to processes, modeling and optimization and much more.

Some Examples of Major Contributions of Operations Research in Services

- Supply chain; personnel staffing; scheduling
- Pricing optimization
- Layout (queues/waiting – Disney; banks)
- (Help desk) call flow optimization, forecasting
- Projects – critical path, resource constraints (could be inventory management for people)
- Models to assist in forecasting demand for services, regression, econometric, time series
- Managing demand
  - Incentives to affect demand (shifting demand, off peak demand)
  - Overbooking of airline seats
  - Sharing capacity
- Yield management
- Simulations
- Capacity planning
- Queueing models
- Vehicle routing (bus, train service)

Operations researchers are working to address the grand challenges mentioned above. Local optimization does not always lead to global optimization; and in highly interconnected system of systems, a small problem in one place can lead to large problems elsewhere. There are issues of stability and resilience in service networks to consider. Operations research benefits from the interdisciplinary framework of service science, and therefore contributions from operations research to service science, can also impact service marketing, service engineering, service design, and service computing as well. For example, consider some of the human-aspects of the following service system challenges:

1. Staffing. People aren't widgets and perhaps one doesn't *want* to do the assignment the tool "optimally" matched –them with according to existing criteria (skills, availability), or perhaps the customer doesn't like them and so the employee might better be assigned another place or another time.
2. Price optimization. Perhaps perception of service value is resistant to price incentives; maybe models take this into account, but can they be adjusted for each day's mass mental state (a la why the stock market rises and falls – emotion!)
3. Call routing. Maybe the person next on the call queue is tired of answering the same questions and wants a new challenge; is there a way to accommodate the human need to achieve and contribute?
4. Demand management. Overbooking of airline seats is today getting a great deal of customer unhappiness.
5. Queueing and routing. Tarmac waiting time has not been deemed illegal after certain limits.
6. Yield management. One of these days passengers are going to revolt against paying premium for business travel over leisure travel. Companies are eschewing travel for alternative means for people to meet face to face.

As additional disciplines, from management of information systems to areas of the social sciences,

add service-oriented sub-disciplines, there is a growing interest working together to establish a science of service (Ostrom et al. 2010).

Industry Response: Product-Service-Systems Growth

The servitization of traditional manufacturing businesses and the growth of self-service technologies in traditional service businesses have given rise to the concept of product-service-systems (IfM and IBM 2008; Spohrer et al. 2010). Industry practitioners and academic researchers are collaborating on public-private partnerships to engineer smarter product-service-systems in three main areas.

1. Systems associated with moving physical things: Transportation, supply chain, water, air, waste, food, products, energy, electricity, and information and communications technology deal with systems engineered to move physical things. Productivity is a primary concern.
2. Systems that support human activities: Buildings, construction, retail, hospitality, media, entertainment, tourism, sports, financial, business consulting, health, family life, education, and professional life deal with systems engineered to support human activities. Quality is a primary concern.
3. Systems that govern: Cities, security, states, economic development, nations, and the law deal with systems engineered to govern. Compliance and competitiveness are primary concerns.

As product-service-systems become smarter, or more instrumented, interconnected, and intelligent (using analytics to support decision making), there is an ever growing need to model and optimize networks or product-service-system value chains.

Service Science: An Emerging Framework

Service science is the interdisciplinary study of service systems and value-cocreation phenomena (Spohrer et al. 2007; Spohrer and Maglio 2008). A service system is a human-made system to improve customer-provider interactions, or value-cocreation. Service science is also an emerging community of academic researchers, industry practitioners, and government policy makers working together to study the entities, interactions, and outcomes associated with the growth of the service system ecology (Spohrer and Maglio 2009, 2010). The "systems and disciplines matrix" is used to visualize the areas of study that is service science, and is shown in Fig. 1 below:

Spohrer and Maglio (2009) describe the foundational concepts of service science (see Fig. 2). Spohrer et al. (2010) provides a glossary of the key terms.

Service science identifies three premises summarized in Fig. 3. Service system entities dynamically configure (transform) four types of resources: people, technology, organizations, and shared information. Service system entities calculate value from multiple stakeholder perspectives, including: customer, provider, authority, and competitor. Service system entities reconfigure access rights to resources by mutually agreed to value propositions, and include: owned-outright, leased-contracted, shared-access, and privileged-access. These concepts and premises allow service scientists to bridge across multiple disciplines that may use different vocabulary or take different perspectives when analyzing service system entity structure or interaction mechanisms.

Concluding Remarks

While the growth of the service science community has been accelerating, nothing is settled and much work remains to be done (Chesbrough and Spohrer 2006; Maglio et al. 2010). Members of the community from marketing refer to service systems entities as resource-integrators, consistent with Service-Dominant Logic of (Vargo and Lusch 2004; Lusch et al. 2008). Members of the community from operations and manufacturing companies may refer to service system entities as product-service-systems. What is clear is that the old distinction between product businesses and service businesses is gradually disappearing as result of the efforts of the service science community, and instead the focus is shifting to entities, interactions, and outcomes. Practitioners are concerned with practical tools and methods that apply service science to guide investments to improve quality, productivity, compliance, and sustainable innovation.

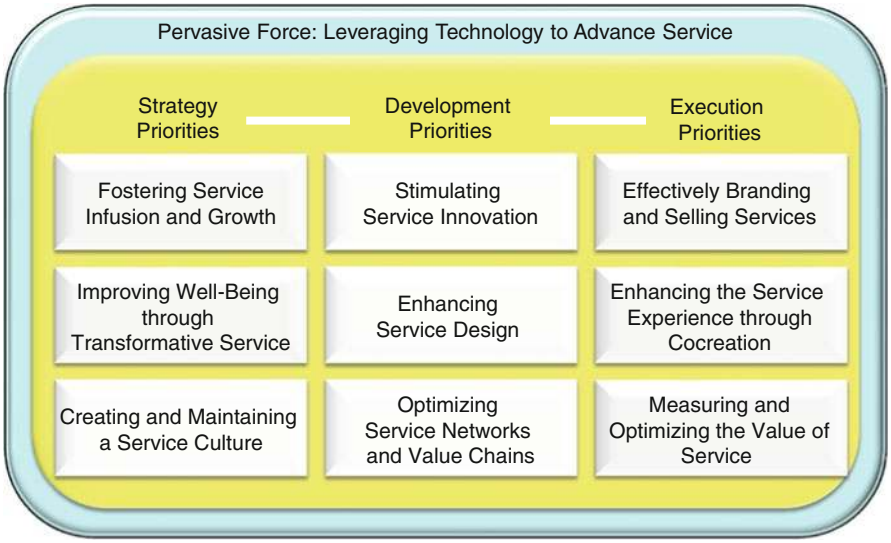
Operations research challenge: Analytic framework needed.

- What type of mathematical models can be constructed?
- What analytic tools exist to study and refine mathematical models?
- Analytic tools – mathematical tools and techniques

No single discipline provides the comprehensive view but by using an interdisciplinary approach, the service science community is making progress. Service science is not just the union of separate disciplines but a deeper integration that may lead to the formation of a service science transdiscipline someday. Mathematics and computer science are existing examples of transdisciplines because they can be used to model aspects of many types of systems. As service scientists develop new tools and methods to model a wide range of service systems and diverse types of value-cocreation phenomena, then service science will likely emerge as a transdiscipline.

The results of an Arizona State University (Ostrom et al. 2010) survey of the global service research community on research priorities for those working to develop a science of service are summarized in Fig. 4.

In sum, service science is an area of research and practice for the interdisciplinary study and improvement of service system structures and value-cocreation mechanisms. Service systems are complex business and societal systems the create benefits for customers, providers, and other



Service Science, Fig. 4 Research priorities for a science of service (Ostrom et al. 2010)

stakeholders, and include all human-made systems that enable and/or grant diverse entities access to resources and capabilities such as transportation, water, food, energy, communications, buildings, retail, finance, health, education, and governance. Many of the grand challenges facing the world's growing population, such as hunger, poverty, and discrimination can be framed as lack of access to resources and capabilities in a world of increasing abundance. For the last 50 years the economies of most developed nations and nearly all cities have been dominated by what traditional economists refer to as the service sector, and yet service has been understudied in academia relative to its economic importance. Economics, marketing and operations (including operations research) were three of the first disciplines to begin scientific study of service and service systems, and more recently management, engineering, computing, design, law, social and behavioral sciences, and other disciplines have applied their unique methods and also established service-oriented specializations. As the world's population shifts from rural to urban areas and as national economies become dominated by what economist call the service sector, or the knowledge economy, interest in service science has grown. Also, the service science community has become increasingly focused on the study of holistic service systems, such as cities, universities, luxury resort hotels, and cruise ships that are parts of a complex system of systems. As service science matures operations research is playing a central role and provides the mathematical models and optimization tools for the study of holistic service systems, in which local optimization does not necessarily lead to global optimization and in which small changes in one component system can lead to large consequences in other systems. These are familiar optimization challenges in for operation researchers, especially in queueing theory, supply chain optimization, and total quality improvement (Daskin 2010).

Service Systems

Systems in which the workers provide a service to customers, as opposed to manufacturing systems where workers produce or assemble products or goods. Examples of service systems include financial services (such as old-fashioned banks), healthcare systems, and call centers. Both manufacturing and service systems are modeled in operations research using queueing models.

Set-covering Problem

The set-covering problem is an integer-programming problem defined as follows:
- Minimze $\boldsymbol{cx}$
- subject to $\boldsymbol{Ex} \geq \boldsymbol{e}$

where the components of $\boldsymbol{E}$ are either 1 or 0, the components of the column vector $\boldsymbol{e}$ are all 1's, and the variables are restricted to be either 1 or 0. The idea of the problem is to find the minimum cost set of column from $\boldsymbol{E}$ such that the 1's in vector $\boldsymbol{e}$ are covered by at least one of the 1's in the selected set of columns. Note that multiple coverage is allowed.

- ▶ Set-partitioning Problem

Set-partitioning Problem

The set-partitioning problem is an integer-programming problem defined as follows:
- Minimize $\boldsymbol{cx}$
- subject to $\boldsymbol{Ex} = \boldsymbol{e}$

where the components of $\boldsymbol{E}$ are either 1 or 0, the components of the column vector $\boldsymbol{e}$ are all 1 s, and the variables are restricted to be either 1 or 0. It is similar to a set-covering problem except multiple coverage is allowed in that more general setting.

Shadow Prices

The optimal dual variables (marginal values) to a linear-programming problem. For an activity-analysis and similar problems, the shadow price associated with a constraint can be interpreted as the change in the value of the objective function per unit increase of the constraint's right-hand-side (resource).

Shortest Path Problem

- ▶ Shortest-route Problem

Shortest-route Problem

A network problem where the goal is to find the shortest route from a home (source) node to a destination node, or the shortest routes from a home node to all other nodes. This can be formulated as a linear-programming problem and solved by the simplex method, but special shortest route algorithms exist that are computationally more efficient.

Simple Upper-bounded Problem (SUB)

A linear-programming problem in which some or all of the variables x_j are constrained by upper-bound conditions of the form $x_j \leq u_j$, where u_j is a given finite bound. It can be solved by a special adaptation of the simplex method in which the upper-bounded constraints are considered implicitly.

See

- ▶ Linear Programming
- ▶ Simplex Method (Algorithm)

Simplex

A polyhedron of the form $x_1 + \ldots + x_n \leq 1$, $x_j \geq 0$. Also, a simplex is the convex hull of $n + 1$ points in general position in Euclidean n-space.

Simplex Method (Algorithm)

A computational procedure for solving linear-programming problems of the form: Minimize (maximize) $\boldsymbol{cx}$, subject to $\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} > \boldsymbol{0}$, where $\boldsymbol{A}$ is an $m \times n$ matrix, $\boldsymbol{c}$ is an n-dimensional row vector, $\boldsymbol{b}$ is an m-dimensional column vector, and $\boldsymbol{x}$ is an n-dimensional variable vector. The simplex method was developed by George B. Dantzig in the late 1940s. The method starts with a known basic feasible solution or an artificial basic solution, and, given that the problem is feasible, finds a sequence of basic feasible solutions (extreme-point solutions) such that the value of the objective function improves or does not degrade. Under a nondegeneracy assumption, the simplex algorithm will converge in a finite number of steps, as there are only a finite number of extreme points and extreme directions of the underlying convex set of solutions. At most, m variables can be in the solution at a positive level. In each step (iteration) of the simplex method, a new basis is found and developed by applying Gaussian elimination in a manner that preserves the nonnegativity of the solution. The elimination step replaces a variable in the current solution with a new one. The inverse of the basis (revised-simplex method) is used to develop a pricing vector for "pricing out" the variables not in the current basic solution and to select one to enter the solution if the current solution is not optimal. The optimal solution to the corresponding dual problem is also generated by the simplex method as part of the solution to the original, primal problem. The simplex method has been implemented on just about all major computer systems and a wide

range of simplex-based software is available for personal computers and in spreadsheets.

Simplex Tableau

A schematic, numerical representation that displays the transformed data set associated with a basic solution to a linear-programming problem. For the problem: Minimize $\boldsymbol{cx}$, subject to $\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$, if the $m \times m$ matrix $\boldsymbol{B}$ is a feasible basis and the $m \times 1$ row vector c_0 the ordered cost coefficients for the variables in the basis, then the simplex tableau displays the following information in an $(m + 1) \times (n + 1)$ rectangular matrix

$$\begin{bmatrix} \boldsymbol{B}^{-1}\boldsymbol{A} & \boldsymbol{B}^{-1}\boldsymbol{b} \\ \boldsymbol{\pi A} - \boldsymbol{c} & \boldsymbol{\pi b} \end{bmatrix}$$

where $\boldsymbol{\pi}$, the pricing vector, is equal to $\boldsymbol{c}_0 \boldsymbol{B}^{-1}$. The last or $(m + 1)$st, row of the tableau contains the reduced costs and the current value of the objective function, respectively. If the simplex method is in Phase I, then an additional row is added to the tableau, which contains the reduced costs associated with the artificial basis. In some arrangements of the tableau, the rows associated with the reduced costs are given at the top of the tableau; also, a reduced tableau is obtained by leaving out the columns that correspond to the columns in the basis as they transform to unit columns with reduced costs of zero. The simplex tableau is useful when solving small problems by hand and as an instructional tool. Computer-based simplex method software do not use the tableau as it is computationally inefficient, instead using some form of the revised simplex method.

Simulated Annealing

Balram Suman
Energy Technology Company, Chevron Corporation, Houston, TX, USA

Introduction

Simulated annealing (SA) is a compact and robust technique to solve single and multiple objective optimization problems with a substantial reduction in the computation time. The method is based on an analogy with the way metals cool and anneal. When a liquid metal is cooled slowly, its atoms form a pure crystal corresponding to the state of minimum energy for the metal. In contrast, when cooled quickly, the metal reaches a state with higher energy (imperfect crystal). Kirkpatrick et al. (1983) and Cerny (1985) showed that a model for simulating the annealing of solids, proposed by Metropolis et al. (1953), could be used for optimization where the objective function to be minimized corresponds to the energy of states of the metal. Since the late 1980s, SA has received significant attention to solve optimization problems where a desired global optimum is hidden among many poor local optima. Thus, SA has become one of the many heuristic approaches designed to give a good, not necessarily optimal solution.

Key Advantages of this Approach

(i) It is very simple to formulate and it can handle mixed discrete and continuous problem with ease.

(ii) The method is also efficient and has low memory requirement. (iii) It takes less CPU time than using a genetic algorithm because it finds the solution using a point-by-point iteration rather than a search over a population of individuals.

With the initiation of SA, the method has been used to solve combinatorial optimization problems. SA can be considered as one type of randomized heuristic approaches for combinatorial optimization problems. Many combinatorial problems belong to a class known as NP-hard problems, whose computation time increases with N as exp(constant $\times$ N). A well-known traveling salesman problem belongs to this class. The salesman visits N cities (with given positions) only once and returns to his city of origin. The objective is to make the route as short as possible. Later, SA was extended to solve single and multi-objective optimization problems with continuous N-dimensional control space. Summary of these approaches is presented in Van Laahoven and Aarts (1987). Surveys on single objective SA have been well documented (Collins et al. 1988; Rutenbar 1989; Aarts and Korst 1989; Eglese 1990, and Reeves 1993). While much of the work on SA to focused on combinatorial optimization (and integer programming) problems, there are also articles on the use of SA for continuous variables (Dekkers and Aarts 1991). A recent review on SA for single and multi-objective optimization problems was presented by Suman and Kumar (2006).

Applications of SA

SA has been greatly in use in operational research problems. Chen et al. (1988) reported a new approach to setup planning of prismatic parts using Hopfield neural net coupled with SA. Sridhar and Rajendran (1993) described three perturbation schemes to generate new sequences for solving the scheduling problem in cellular manufacturing system. Suresh and Sahu (1994) used SA for assembly line balancing. They only considered single objective problems. They found that SA performed at least as well as the other approaches. Meller and Bozer (1996) applied SA to facility layout problems with single and multiple floors. The facility layout problem is highly combinatorial in nature and generally exhibits many local minima. SA achieves low-cost solutions that are much less dependent on the initial layout than other approaches. Mukhopadhyay et al. (1998) used SA to solve the problem of Flexible Manufacturing system (FMS) machine loading with the objective of minimizing the system imbalance. Kim et al. (2002) considered a multi-period multi-stop transportation planning problem in a one-warehouse multi-retailer distribution system to determine the routes of vehicles and delivery quantities for each retailer. They suggested a two-stage heuristic algorithm based on SA as an alternative for large problems that can not be solved by the column-generation algorithm in a reasonable computation time to minimize the total transportation distance for product delivery over the planning horizon while satisfying demands of the retailers. Golenko-Ginzburg and Sims (1992) defined a priority list to be any permutation of a set of symbols where the symbol for each job appears the same number of times as its operations. Every priority list can be associated in a natural way with a feasible schedule and every feasible schedule arises in the same way. Therefore, priority lists are a representation of feasible schedules that avoid the problems normally associated with schedule infeasibility. Shutler (2003) presented priority list based Monte Carlo implementation of SA, which was competitive with the current leading schedule based SA and tabu search heuristics. New job sequences were generated with a proposed perturbation scheme called the modified insertion scheme (MIS), which has been used in the proposed SA algorithm to arrive at a near global optimum solution. The SA algorithm using the proposed MIS gave substantial improvement in system imbalance. Its other applications were presented by machine loading problem of FMS (Swarnkar and Tiwari 2004), part classification (Tiwari and Roy 2003), resource-constrained project scheduling (Cho and Kim 1997). McCormick and Powell (2004) described a two-stage SA algorithm to derive pump schedules for water distribution in a time short enough for routine operational use. They built the model based on automatic interaction with a hydraulic simulator, which deals with non-linear effects from reservoir-level variations.

Adaptive simulated annealing (ASA) offers a viable optimization tool for tackling these difficult nonlinear optimization problems (Chen and Luk 1999). Optimization of batch distillation processes, widely used in chemical industry can be solved using SA.

Hanke and Li (2000) showed the potential of SA for developing optimal operation strategies for batch chemical processes. SA was applied in antenna array synthesis (Girard et al. 2001), multimedia data placement (Terzi et al. 2004) molecular physics. Suman (2002, 2004, 2005) used SA-based multi-objective algorithms to optimize the profit and its sensitivity of a refinery model problem. Suman (2003) applied five simulated annealing based multi-objective algorithms to find a Pareto set of solutions of a system reliability multi-objective optimization problem in a short time. Kumral (2003) applied chance-constrained programming based on multi-objective SA to optimize blending of different available ores in a way that expected value and standard deviation of the cost of buying ores is minimized while satisfying the quality specifications.

Application of SA is not restricted to optimization of nonlinear objective function, it was also applied for many other purposes. Bell et al. (1987) used it to cluster tuples in databases. They attempted to use SA in circuit board layout design and it suggests that it would be advantageously applied to clustering tuples in database in order to enhance responsiveness to queries. SA has not only been applied for optimization but also for recognition of patterns and object classification (Liu and Huang (1998), Yip and Pao (1995), Starink and Barker (1995)). Liu and Huang (1998) proposed hybrid pattern recognition based on the evolutionary algorithms with fast SA that can recognize patterns deformed by transformation caused by rotation, scaling or translation, singly or in combination. Object recognition problem as matching of a global model graph with an input scene graph representing either a single object or several overlapping objects has been formulated. Chu et al. (1996) used SA to analyze the network of interacting genes that control embryonic development and other biological processes.

SA for Optimization

SA for Single Objective Optimization

A solution space (S) is a finite set of all solutions and the objective function (f) is a real-valued function defined for the members of S. The minimization problem can be formulated to find a solution or state, $i \in S$, which minimizes f over S.

A simple form of a local search algorithm, say a descent method, starts with an initial solution. In the neighborhood of this solution a new solution is generated using suitable algorithms and the objective function is calculated. If a reduction in the objective function is observed, the current solution is updated. Otherwise, the current solution is retained and the process is repeated until no further reduction in the objective function is obtained. Thus, the search terminates with a local minimum, which may or may not be the true global minimum. Due to this disadvantage, this algorithm is not relied on, though this is simple and easy to execute. In SA, instead of this strategy, the algorithm attempts to avoid being trapped in a local minimum by sometimes accepting even a worse move. The acceptance and rejection of the worse move is controlled by a probability function. The probability of accepting a move, which causes an increase δ in f, is called the acceptance function. It is normally set to $\exp(-\delta/T)$ where T is a control parameter, corresponding to the temperature in analogy with the physical annealing. This acceptance function implies that a small increase in f is more likely to be accepted than a large increase in f. With high T, most uphill moves are accepted, but at low T, fewer uphill moves get accepted. Therefore, SA starts with a high temperature to avoid being trapped in local minimum. The algorithm proceeds by attempting a certain number of moves at each temperature and decreasing the temperature slowly. The SA-based algorithm for a single objective optimization problem is illustrated in Table 1. Similar to other heuristic optimization techniques, there is a chance of revisiting a solution multiple times in SA, leading to extra computational time without any improvement in the optimal solution. A strategy of avoiding such moves would improve SA efficiency.

SA for Multi-objective Optimization

Real life problems are multi-objective in nature. Researchers have developed many multi-objective optimization procedures, which has a number of disadvantages and pitfalls. Increasing acceptance of SA and other heuristic algorithms is due to their ability to: (1) find multiple solutions in a single run, (2) work without derivatives, (3) converge speedily to Pareto-optimal solutions with a high degree of accuracy, (4) handle both continuous function and combinatorial

Simulated Annealing, Table 1 SA based Algorithm for single objective

1. Initialize the temperature.
2. Start with a randomly generated initial solution vector, X and generate the objective function.
3. Give a random perturbation and generate a new solution vector, Y, in the neighborhood of current solution vector, X, revaluate the objective function and apply a penalty function approach to the objective function, if necessary.
4. If the generated solution vector is archived, make it the current solution vector by putting $X = Y$. Update the existing optimal solution and go to step 6.
5. Else accept Y with probability $P = \exp(-\Delta s/T)$, (1) where $\Delta s = Z(Y) - Z(X)$. If the solution is accepted, replace X with Y.
6. Decrease the temperature periodically.
7. Repeat step 2 through 6 until stopping criterion is met.

optimization problems with ease, (5) be less susceptible to the shape or continuity of the Pareto front.

Acceptance of SA in a multi-objective framework is due to its simplicity and capability of producing a Pareto set of solutions in a single run with little computational cost. In addition, the method is not susceptible to the shape of the Pareto set, whereas these two issues are real concerns for mathematical programming techniques. The first multi-objective version of SA has been proposed by Serafini (1985, 1992). The algorithm is similar to the SA-based algorithm for single objective problems. The method uses a modification of the acceptance criterion of solutions in the original algorithm. Various alternative criteria have been investigated in order to increase the probability of accepting non-dominated solutions. A special rule given by the combination of several criteria has been proposed in order to concentrate the search almost exclusively on the non-dominated solutions. Thereafter, this method was applied by Ulungu and Teghem (1994). They only used the notion of the probability in the multi-objective framework. Serafini (1994) applied a simulated annealing algorithm on the multi-objective framework. A target-vector approach to solve a bi-objective optimization problem was used. Ulungu et al. (1999) proposed a complete MOSA algorithm which they tested on a multi-objective combinatorial optimization problem. A weighted aggregating function to evaluate the fitness of solutions was used. The algorithm worked with only one current solution but maintained a population with the non-dominated solutions found during the search. This method was further improved and extensively tested by Ulungu et al. (1998) and an interactive version of MOSA was used to solve an industrial problem (UMOSA method). Tuyttens et al. (2000) used the MOSA (multi-objective optimization simulated annealing) method for the bicriteria assignment problem.

Suppapitnarm and Parks (1999) proposed a different SA-based approach to tackle multi-objective problems (SMOSA method). The algorithm uses only one solution and the annealing process adjusts each temperature independently according to the performance of the solution in each criterion during the search. An archive set stores all the non-dominated solutions between each of the multiple objectives. An acceptance probability formulation based on an annealing schedule with multiple temperatures (one for each objective) was proposed. The acceptance probability of a new solution depends on whether or not it is added to the set of potentially Pareto- optimal solutions. If it is added to this set, it is accepted to be the current solution with probability equal to one. Otherwise, a multi-objective acceptance rule is used.

Czyżak and Jaszkiewicz (1998) proposed another way to adopt simulated annealing to a multi-objective framework, (PSA method). Czyżak et al. (1994) combined unicriterion simulated annealing and a genetic algorithm to provide efficient solutions of multicriteria shortest path problem. A population-based extension of simulated annealing proposed for multi-objective combinatorial optimization problems were used. The population of solutions explored their neighborhood similarly to the classical simulated annealing, but weights for each objective tuned in each iteration. The weights for each solution were adjusted in order to increase the probability of moving away from its closest neighborhood in a similar way as in the multi-objective tabu search.

Suman (2002 and 2003) proposed two different SA-based approaches (WMOSA and PDMOSA) to tackle the multi-objective optimization of constrained problems. Suman (2003) also tested five simulated annealing algorithms for the system reliability optimization problem. The goal of these methods

Simulated Annealing, Table 2 SA based Algorithm for Multi-objective Optimization

The basic steps involved in the SMOSA algorithm for a problem having N objective functions and n decision variables are as follows:
1. Start with a randomly generated initial solution vector, X (an n x 1 vector whose elements are decision variables) and evaluate all objective functions and put it into a Pareto set of solutions.
2. Give a random perturbation and generate a new solution vector, Y,in the neighborhood of current solution vector, X, reevaluate the objective functions and apply a penalty function approach to the corresponding objective functions, if necessary.
3. Compare the generated solution vector with all the solutions in the Pareto set and update the Pareto set, if necessary.
4. If the generated solution vector is archived, make it the current solution vector by putting $X = Y$ and go to step 7.
5. If the generated solution vector is not archived, accept it with the probability: $P = \min\left(1, \prod_{i=1}^{N} \exp\left\{\frac{-\Delta s_i}{T_i}\right\}\right)$, (2) where $\Delta s_i = f(z_i(Y) - z_i(X))$ with the function, f, depends on the choice of a SA based algorithm. If the generated solution is accepted, make it the current solution vector by putting $X = Y$ and go to step 7.
6. If the generated solution vector is not accepted, retain the earlier solution vector as the current solution vector and go to step 7.
7. Periodically, restart with a randomly selected solution from the Pareto set. While periodically restarting with the archived solutions, Suppapitnarm et al. (2000) have recommended biasing towards the extreme ends of the trade-off surface.
8. Reduce the temperature periodically using a problem dependent annealing schedule.
9. Repeat steps 2 to 8, until a predefined number of iterations is carried out.

was to generate a set of solutions, which are a good approximation to the whole set of efficient (non-dominated or Pareto-optimal) solutions in a relatively short time.

Suman (2005) further improved the SA based multi-objective algorithm so that the user does not need to give a predefined number of maximum iterations. All simulated annealing multi-objective algorithms have the advantage that they allow the full exploration of the solution space: because the starting temperature is high, any move is accepted. The move becomes selective as temperature decreases with an increase in the iteration number and by the end it accepts only the improving moves. Suman et al. (2010) proposed an OSA (orthogonal simulated annealing) algorithm incorporates an orthogonal based on experiment design (OED) with a simulated annealing based multi-objective algorithm aiming to provide an efficient multi-objective algorithm. A typical multi-objective algorithm based on SA is presented in Table 2.

Annealing Schedule

Parameters of an annealing schedule for the SA-based algorithm determine performance of the SA-based algorithm. A high cooling rate leads to poor results due to lack of representative states, while a low cooling rate requires a very high computation time to get the solution. The following choices must be made for any implementation of SA and they constitute the annealing schedule: initial value of temperature (T), cooling schedule, number of iterations to be performed at each temperature and stopping criterion to terminate the algorithm.

Initial value of temperature (T)

The initial temperature is chosen such that it can capture the entire solution space. One choice is a very high initial temperature to increase the solution space. But, at a high initial temperature, SA performs a large number of iterations, which may be even without generating better solutions. Therefore, the initial temperature is chosen by experimentation depending upon the nature of the problem. The range of change, Δf_0 in the value of the objective function with different moves is determined. The initial value of temperature should be considerably larger than the largest Δf_0 encountered. van Laarhoven and Aarts (1987) proposed a method to select the initial temperature based on the initial acceptance ratio χ_0, and the average increase in the objective function, Δf_0:

$$T = -\frac{\Delta f_0}{\ln(\chi_0)}, \tag{3}$$

where χ_0 is defined as the number of accepted bad moves divided by the number of attempted bad moves. A similar formula has been proposed by Sait and Youssef (1999) with the only difference being in the definition of χ_0. They defined χ_0 as the number of accepted moves divided by the number of attempted moves. A simple way of selecting initial temperature has been proposed by Kouvelis and Chiang (1992). They proposed to select the initial temperature by the formula:

$$P = \exp\left(\frac{-\Delta s}{T}\right) \tag{4}$$

where P is the initial average probability of acceptance and taken in the range of 0.50 to 0.95.

Cooling Schedule

The cooling schedule determines the functional form of the change in temperature required in SA. The earliest annealing schedules were based on the analogy with physical annealing. Therefore, they set the initial temperature high enough to accept all transitions, which means heating up substances until all the molecules are randomly arranged in liquid. A proportional temperature can be used i.e., $T\,(i+1) = \alpha T\,(i)$ where α is a constant known as the cooling factor and it can vary from 0.80 to 0.99. Finally, the temperature becomes very small and it will not search any smaller energy level. It is called the frozen state.

Three important cooling schedules are logarithmic, Cauchy and exponential (Azencott 1992). SA converges to the global minimum of the cost function if the temperature change is governed by a logarithmic schedule in which the temperature $T\,(i)$ at step i is given by $T\,(i) = T_o/\log i$ (Geman and Geman 1984). This schedule requires the move to be drawn from a Gaussian distribution. A faster schedule is the Cauchy schedule in which $T\,(i) = T_o/i$ converges to the global minimum when moves are drawn from a Cauchy distribution (Szu and Hartley 1987). It is sometimes called "fast simulated annealing". The fastest is exponential or geometric schedule in which $T\,(i) = T_o\exp(-Ci)$ where C is a constant. There is no rigorous proof of the convergence of this schedule to the global optimum although good heuristic arguments for its convergence have been made for a system in which annealing state variables are bounded (Ingber 1989).

A proportional temperature cooling schedule does not lead to equilibrium at low temperature. Therefore, there is a need for a small number of transitions to be sufficient to reach the thermal equilibrium. However, a serious attempt was made with adaptive simulated annealing (Gong et al. 2001). Annealing schedules use information about the cost function obtained during the annealing run itself. Such a schedule is called an adaptive cooling schedule (Ingber 1989; Azizi and Zolfaghari 2004). An adaptive cooling schedule tries to keep the annealing temperature close to the equilibrium as well as reducing the number of transitions to reach equilibrium. It adjusts the rate of temperature decrease based on the past history of the run. Otten and van Ginneken (1984) proposed the following cooling schedule:

$$T_{i+1} = T_i - \frac{1}{M_k}\frac{T_k^3}{\sigma^2(T_i)} \tag{5}$$

where σ^2 is the variance of the objective function at equilibrium and M_k is given by

$$M_k = \frac{f_{\max} + T_i \ln(1+\delta)}{\sigma^2(T_i)\ln(1+\delta)} T_i \tag{6}$$

where $f_{\max}$ is an estimated maximum value of the objective function.

Similar to equation (3.3), Van Laarhoven and Aarts (1987) proposed the following cooling schedule:

$$T_{i+1} = \frac{T_i}{1 + \frac{\ln(1+\delta)T_i}{3\sigma T_i}} \tag{7}$$

where δ is a small real number.

Another adaptive cooling schedules is the adaptive schedule of Lam. The Lam schedule (Lam and Delosme 1988a, 1988b) has been derived by optimizing the rate at which temperature can be decreased subject to the constraint of maintaining quasi-equilibrium. It is given as:

$$S_{k+1} = S_k + \lambda\left(\frac{1}{\sigma(S_k)}\right)\left(\frac{1}{S_k^2\,\sigma^2(S_k)}\right)\left(\frac{4\rho_o(S_k)(1-\rho_o(S_k))^2}{(2-\rho_o(S_k))^2}\right) \tag{8}$$

where $S_i = 1/T_i$ and T_i is the temperature at ith iteration of the cost function E. The quantity $\sigma(S_k)$ is the standard deviation of E at this step and $\rho_o(S_k)$ is the acceptance ratio; that is, the ratio of accepted to attempted moves. The following four factors play important roles:

(a) λ is a quality factor. Smaller λ improves the quality of the solution, but it also increases the computation time.

(b) $\frac{1}{\sigma(S_k)}$ measures the distance of the system from quasi-equilibrium.

(c) $\left(\frac{1}{S_k^2\sigma^2(S_k)}\right)$ is the inverse of the statistical specific heat which depends on the variance.

(d) $\left(\frac{4\rho_o(S_k)(1-\rho_o(S_k))^2}{(2-\rho_o(S_k))^2}\right)$ is equal to $\rho_2/2$ where ρ_2 is the variance of the average energy change during a move. This is a measure of how effectively the state space is sampled and was found to be at a maximum value when $\rho_o \approx 0.44$

Azizi and Zolfahgari (2004) used an adaptive annealing schedule that adjusts the temperature dynamically based on the profile of the search path. Such adjustments could be in any direction including the possibility of reheating. In their proposed method, an adaptive temperature control scheme was used to change temperature based on the number of consecutive improving moves. In the second method, a tabulist was added to the adaptive simulated annealing algorithm in order to avoid revisits to the solutions.

Triki et al. (2004) studied annealing schedules. They performed experiments to construct an optimum annealing schedule that showed that there was no clearly better annealing schedule than the logarithmic schedule to ensure convergence towards the set of optima with probability one. They developed software to calculate a practical and optimum annealing schedule for a given objective function. They also conducted experiments on adaptive annealing schedules to compare classical annealing schedules. They proposed the following cooling schedules:

$$T_{i+1} = T_i \exp\left(-\frac{\lambda T_i}{\sigma(T_i)}\right) \tag{9}$$

$$T_{i+1} = T_i\left(1 - T_i\frac{\Delta(T_i)}{\sigma^2(T_i)}\right) \tag{10}$$

They showed that several classical adaptive temperature decrement rules proposed in the literature, which have different theoretical foundations and different mathematical equations, were in fact the same practical rule. They calculated a new adaptive decrement rule for controlling and tuning the SA algorithm.

Other cooling schedules make a more direct appeal to the theoretical results on asymptotic convergence. Lundy and Mees (1986) proposed an annealing schedule where there is only a single iteration at each temperature. They used heuristic arguments to derive a temperature function of the form

$$T_{i+1} = \frac{T_i}{1 + BT_i} \tag{11}$$

where B is a constant. Equation (11) is equivalent to

$$T_i = \frac{C_1}{1 + iC_2} \tag{12}$$

where C_1 and C_2 are constants. SA proposed by Connolly (1987, 1988) suggested that the majority of the iterations should be conducted at a suitably fixed temperature.

The choice of decreasing the temperature is an important issue as there has been a conflict, since the early days of SA, between theory and practice. There is no universally valid conclusion in the literature. However, a general choice is to cool the system slowly at the stage where the objective function is rapidly improving.

Number of Iterations

The number of iterations at each temperature is chosen so that the system is sufficiently close to the stationary distribution at that temperature. Aarts and Korst (1989) and van Laarhoven and Aarts (1987) refered this as quasi-equilibrium. An enough number of iterations at each temperature should be performed if the temperature is decreased periodically. If a smaller number of iterations is performed, all represented states will not be searched and the solution will not be able to reach the global optimum. The value of the number of iterations depends on the nature of the problem and its complexity.

Stopping Criterion

Various stopping criteria have been employed with SA-based algorithms. First, prefix a total number of iterations and number of iterations to move at each temperature. This criterion leads to a higher computation time without much update in f sometimes leading to a local optimal due to a less number of iterations. The biggest issue with this method is the prerequisite of the setting the number of iteration, which may not be known beforehand. Second, set a minimum value of the temperature and the number of iterations at each temperature. This idea is generated by the fact that the chance of improvement in a solution is rare once the temperature is close to zero. At a very low temperature, moves will be trapped in the neighborhood of the current solution. Third, set a number of iterations to move at each temperature and a predefined number of iterations to get a better solution. SA-based algorithms are capable of solving single objective and multi-objective optimization problems where a desired global optimal is hidden among many local optima. These methods have attractive and unique features when compared with other optimization techniques. First, a solution does not get trapped in a local minimum or maximum by sometimes accepting even the worse move. Second, configuration decisions proceed in a logical manner in SA. As a result, SA-based algorithms have been popular and their applications have been expanded. However, the search for an efficient algorithm based on SA is still continuing.

Simulation Metamodeling

Linda Weiser Friedman
Baruch College, City University of New York, New York, NY, USA

Introduction

Simulation experiments may be conducted for many reasons, for example, optimization. Additionally, and not incidentally, an objective of any system simulation must be to achieve a certain measure of understanding of the nature of the relationships between the input variables and the output variables of the real system under study. The simulation model, although simpler than the real-world system, is still a very complex way of relating input to output. Sometimes, a simpler model may be used as an auxiliary to the simulation model in order to better understand the more complex model and to provide a framework for testing hypotheses about it. This auxiliary model is frequently referred to as a metamodel (Santos 2009; Cheng 2008; Santos and Santos 2007; Friedman 1996).

One simple metamodel favored by some simulation researchers, e.g., Kleijnen (1979), Kleijnen and Sargent (2000), Santos and Santos (2009), is the general linear model. For a univariate response experiment, this is

$$\mu = \beta_0 + \sum_{j=1}^{k} \beta_j x_j + \varepsilon.$$

When simulation-generated data are used to estimate the parameters of this first-order linear additive model, the resulting estimated metamodel is

$$y_i = b_0 + \sum_{j=1}^{k} b_j x_{ij} + e_i \, (i = 1, \ldots, n).$$

This general linear metamodel can provide additional information regarding the relative contribution of each input factor to a response variable of interest.

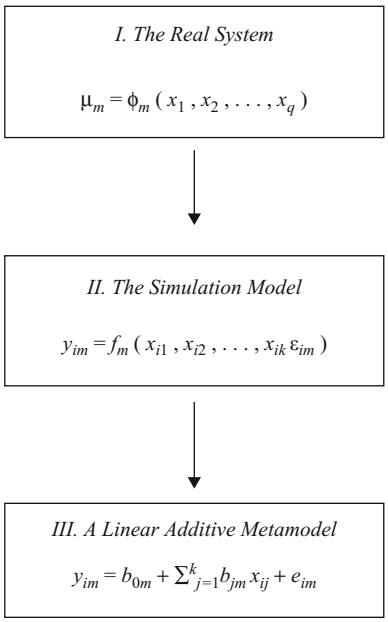
Most simulation experiments study more than one response variable, and so a multivariate metamodel (Friedman 1989) must necessarily be proposed. The multivariate general linear model

$$\mu_m = b_{0m} + \sum_{j=1}^{k} \beta_{jm} x_j + \varepsilon_m \, (m = 1, \ldots, p)$$

is estimated by

$$y_{im} = b_{0m} + \sum_{j=1}^{k} b_{jm} x_{ij} + e_{im} \, (i = 1, \ldots, n;\ m = 1, .., p).$$

Thus, the multivariate response metamodel is actually a series of regression-type equations, each representing the contributions of the criterion variables to the value of a response. This metamodel may be tested for significance via the multivariate



Simulation Metamodeling, Fig. 1 The simulation metamodel in context

general linear hypothesis (see, e.g., Hair et al. 2010), which was automated in Friedman and Friedman (1985a).

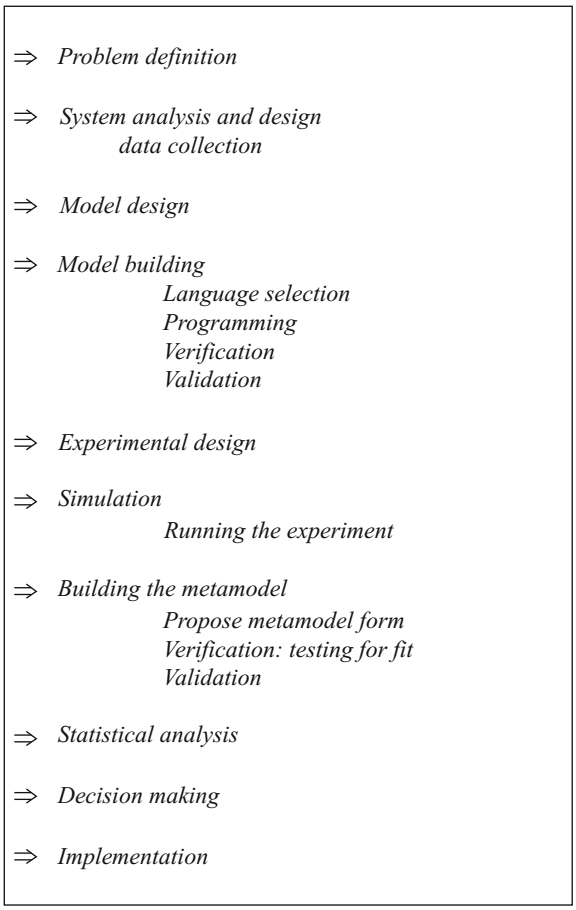
It can be shown that many multivariate statistical techniques as well as the univariate techniques of experimental design are specific cases of this general multivariate linear model. Thus, depending on the experimental layout, whether the factors are quantitative or qualitative, and the aim of the study, the general linear metamodel may be applied to regression analysis, analysis of variance, *t*-test, paired *t*-test, etc. In fact, whether a researcher explicitly says so or not, designing simulation experiments that will be analyzed via one of these statistical tests implies the use of a linear metamodel in one of its forms. The explicit use of a general linear metamodel enables one to interpret the simulated system more easily and more fully supporting model simplification; the enhanced exploration, optimization, and interpretation of the model; generalization to models of other systems of the same type; sensitivity analysis; etc.

Figure 1 is a pictorial representation of the three levels of explanation of the dynamics of a system simulation study. At the first level, the real system itself is unapproachable by the researcher, who can never hope to understand it completely. The system analysis and data collection functions take place here. At the second level, although the simulation model is leaner and more streamlined than the real system, it does attempt to replicate the real system at least with regard to the variables that are important to the goals of the researcher. The simulation model building, verification, and validation functions take place here. Finally, the analytic metamodel is at the leanest and most streamlined level. It attempts to approximate and aid in the interpretation of the simulation model and ultimately, of the real system itself. The experimental design and analysis function takes place here, and the multivariate general linear metamodel can often be used as a generalization of the various types of analyses performed on simulation output data.

Figure 2 displays the steps in a typical simulation study, with metamodeling included. During the metamodel construction phase, information uncovered during system analysis is used to propose one or more possible metamodel forms; use the simulation-generated data to fit the model, providing estimates of the parameters of the proposed metamodel; verify this metamodel by applying a statistical test for fit; and, validate the metamodel in the same manner that the simulation model was validated, for example, by comparing it to actual data from the system under study or a similar system. Overviews on the use of simulation metamodeling may be found in Madu and Kuei (1994), Barton (1994), Friedman (1996) and, more recently, Kuei et al. (2008), Iooss (2009), Santos and Santos (2009), and Zobel and Keeling (2008).

A Metamodeling Example

As an illustration, a multivariate general linear metamodel for the *M*/*M*/*s* queueing system is built and validated against known theoretical results (Friedman 1989). For this example, a simulation program was developed using SIMSCRIPT II.5 of the *M*/*M*/*s* queuing system with a single service facility and a single waiting line. The parameters λ, μ, and the number of identical service channels, *s*, were input as data to the simulation program, i.e., these were the factors in the simulation experiment. Twenty-five independent replications were generated for each of the six system variants displayed in Table 1. These system variants were selected judgmentally



Simulation Metamodeling, Fig. 2 Progress of a simulation study, metamodeling included

as being fairly congested, i.e., utilization factors ($\rho = \lambda/s\mu$) between 0.90 and 0.95. Three performance characteristics were output from each 15-week simulation run: average number of demands in the system, L; average system waiting time per demand, W; and average utilization per server, U.

The simulation model was validated by comparing the values of performance characteristics generated by the simulation program at the end of a 15-week run with the steady-state values expected using queueing theory. This comparison was done via the one-sample multivariate Hotelling T^2 test for the three measures of effectiveness. Validation results indicated that the simulation-generated estimates of the measures of performance were what one would expect as output from the *M*/*M*/*s* queuing system.

In developing the metamodel, the first impulse might be to fit a linear additive model with three

Simulation Metamodeling, Table 1 Experimental design

System	Arrival rate(λ)	Service rate (μ)	# Servers (s)
1	15	8	2
2	15	16	1
3	18	10	2
4	18	20	1
5	19	10	2
6	19	20	1

main effects (λ, μ, s) and some interaction effects. However, attempts to fit such a model resulted in a lack-of-fit test that showed that the model fit the data poorly. Poor fit of a linear regression model is a common problem in metamodels developed from queueing system simulation data since λ, μ, and s are actually intricately related in a nonlinear fashion.

The functional relationship next hypothesized for the *M*/*M*/*s* simulation metamodel was designed to take advantage of the fact that an important determinant in the behavior of queuing systems is the utilization factor, $\rho = \lambda/s\,\mu$. Thus, the proposed metamodel was

$$MOE_{im} = \alpha_m \frac{\lambda_i^{\beta_{1m}}}{\mu_i^{\beta_{2m}} s_i^{\beta_{3m}}} \eta_{im}$$
$$(i = 1, \ldots, n;\ m = 1, \ \ldots, p),$$

where i is the index for observations; m is the index for measurements and functions; MOE_m is the mth measure of effectiveness; α_m is a constant multiplier for the mth equation; and η_{im} represents an error factor in the hypothesized function. While this proposed metamodel is neither linear nor additive, it is a form of the intrinsically linear multiplicative model, namely,

$$MOE_{im} = \alpha_m \lambda_I^{\beta_{1m}}\ \mu_i^{\beta_{2m}}\ s_i^{\beta_{3m}}\ \eta_{im}$$

which may be transformed to a linear model by a logarithmic transformation

$$\ln MOE_{im} = \ln \alpha_m + \beta_{1m} \ln \lambda_i - \beta_{2m} \ln \mu_i - \beta_{3m} \ln s_i + \eta_{im}.$$

That this is the familiar multivariate general linear (regression) model

$$Y_{im} = \beta_{0m} + \beta_{1m} X_{1i} + \beta_{2m} X_{2i} + \beta_{3m} X_{3i} + \varepsilon_{im}$$

New Variable	←	Old Variable
Y_1	=	$\ln L$
Y_2	=	$\ln W$
Y_3	=	$\ln U$
β_{0m}	=	$\ln \alpha_m$
X_1	=	$\ln \lambda$
X_2	=	$\ln \mu$
X_3	=	$\ln s$
ε_m	=	$\ln \eta_m$

Simulation Metamodeling, Fig. 3 Change of variables for the regression metamodel

Simulation Metamodeling, Table 2 Multivariate regression metamodel estimates

	Y_1 (ln L)	Y_2 (ln W)	Y_1 (ln U)
Estimated regression coefficients			
$\boldsymbol{b}_0$	3.279	3.286	0.008*
$\boldsymbol{b}_1$	12.979	11.973	1.000
$\boldsymbol{b}_2$	−12.877	−12.874	−1.003
$\boldsymbol{b}_3$	−12.826	−12.823	−1.003

$\boldsymbol{b}_1$	0.445	0.433	0.024
$\boldsymbol{b}_2$	0.428	0.417	0.023
$\boldsymbol{b}_3$	0.429	0.418	0.023

*not significantly different from zero

is made clear by the change of variables listed in Fig. 3. The least-squares estimates for the vectors β_0, β_1, β_2, β_3 are, respectively, the vectors $\mathbf{b}_0$, $\mathbf{b}_1$, $\mathbf{b}_2$, $\mathbf{b}_3$. Applying this multivariate regression equation to the *M/M/s* simulation data produced the regression estimates presented in Table 2 along with their standard errors.

Metamodel Verification

As can be seen from Table 3, the multivariate linear regression model specified is indeed a significant effect in explaining the responses, as are the individual treatment effects. Further model exploration was not necessary, as the test for overall lack of fit was not significant, and the metamodel was accepted. (For further discussion of the Wilks' Λ statistic, and the

Simulation Metamodeling, Table 3 Tests of multivariate hypotheses

Source	Wilks'Λ	F	d.f.	p
Model	0.0001	9885.35	4,294	<0.001

X_2 (ln μ)	0.0356	1299.22	3,144	<0.001
X_3 (ln s)	0.0358	1292.60	3,144	<0.001
Lack-of-fit	0.9951	0.12	6,284	>0.990

F-test derived from it, see Hair et al. 2010). Table 4 displays the results of the regression analysis on each response variable individually, laid out in the familiar analysis of variance table.

In this case, estimation of the metamodel parameters by (say) linear regression analysis is not an end in itself. Inserting the regression estimates of the metamodel coefficients into the general linear model, and then taking antilogarithms of both sides of the set of regression equations, leads back to the original (predictive) functional relationships, i.e., the simulation metamodel:

$$L = e^{3.279} \frac{\lambda^{12.979}}{\mu^{12.877} s^{12.826}}$$

$$W = e^{3.286} \frac{\lambda^{11.973}}{\mu^{12.871} s^{12.823}}$$

$$U = \frac{\lambda}{\mu^{1.003} s^{1.003}}$$

Metamodel Validation

Once a metamodel is developed, there is naturally a great temptation to simply use it as is, but it is at least as important to validate the simulation metamodel as validating the simulation model. After all, the metamodel is two steps removed from the real-world system under study. Once built and verified to determine that the metamodel fits the data with which it was developed, the metamodel should then be tested for two types of validity: Internal validity reflects the degree to which the metamodel accurately approximates the simulation model; external validity reflects the degree to which the metamodel accurately approximates the real-world system.

Internal Validity — Regression analysis, used to develop the general linear metamodel, is very much a data-based technique in that it finds the model with the best possible fit to the data. Frequently, models built in this manner fail to perform as well on new data. Several appropriate, practical statistical validation techniques for the general linear simulation metamodel have been examined (see, e.g., Friedman and Friedman 1985b; Panis et al. 1994; Santos and Porta Nova 2007; Iooss 2009; Kleijnen and Sargent 2000).

In the cross-validation technique, the regression metamodel is developed using only a portion, say, two-thirds of the observations, selected randomly. The regression metamodel is then tested against the remaining third, the holdout group, to see how well this equation, developed on one set of data, explains the responses in the new data. In this procedure, the held-out data is used to predict a whole new set of values of the response variable, which is then used together with the "true" responses (the values in the simulation-generated data of the holdout sample) to find the coefficient of determination, R^2. When compared to the original R^2 in the first set of data, one can see how much deterioration there was from the original data used to develop the model to the new, fresh data of the holdout sample, for example, a very low R^2 for the unselected cases would indicate that the model lacks predictive validity since it does not sufficiently explain the variation in the new, held out data. In validating the *M*/*M*/*s* metamodel, the value of the R^2 statistic for the original set of data was .70 and the R^2 for the holdout sample was .80. This indicated that the metamodel developed does indeed have predictive validity.

Further insight into how well the model predicts may be obtained by examining the residuals — computed by taking the actual observations minus the values predicted by the metamodel equation — of the holdout sample. The mean absolute percentage error, whereabsolute percentage error is calculated as $100\% \times |Residual|/y$ was found to be 5.6%, indicating good predictive validity on the part of the simulation metamodel with respect to the simulation model.

External Validity: Methods used in testing a simulation metamodel for external validity are equivalent, and sometimes identical, to those used to validate the simulation model, for example, face validity or expert judgment. Just as simulation responses have been compared with historical data from the real (or similar) system, so metamodel responses may also be compared with historical observations from the real (or similar) system. For this simulation metamodel to be valid, it should be a useful approximation not merely to the simulation model, from which the data used in building the metamodel was drawn, but also to the real-world system, to which any inferences and conclusions will

Simulation Metamodeling, Table 5 Metamodel validation to the theoretical system

			Analytic			Metamodel		
λ	μ	*s*	*L*	*W*	*U*	*L*	*W*	*U*

				Avg. error:		1.69%	1.70%	0.81%

be applied. Since the *M*/*M*/*s* system has been widely studied, it can be used to test the metamodel developed here for validity to the real system which the simulation models. This would be equivalent to taking actual (historical) data from the real system, or a similar equivalent one, and validating the simulation model and the metamodel with portions of that data.

Towards this end, several additional *M*/*M*/*s* system variants were selected which were different from the six used to develop the metamodel yet still within the experimental space. These new system configurations also had fairly high utilization factors. Values computed for *L*, *W*, and *U* using the multivariate metamodel were compared with the actual steady-state values for these system measures of effectiveness. The average absolute error, used to measure metamodel validity, is obtained by means of the ratio $100\% \times |Metamodel - Analytic|/Analytic$. Given the results of Table 5, the multivariate metamodel is taken to have performed well in representing the *M*/*M*/*s* queueing system in the range of system configurations studied.

Using the Simulation Metamodel

It is obvious from the patterns evident in the estimated coefficients in Table 2 that the multivariate metamodel may serve as more than a predictive functional model relating dependent variables with the independent variables. When such patterns appear, they urge the researcher to examine the metamodel further for relationships that are not immediately obvious. In simplified form, the multivariate metamodel may be (after suitable testing of estimated coefficients) represented as:

$$L = e^{3.28}\left(\frac{\lambda}{\mu s}\right)^{12.85}$$

$$W = \frac{e^{3.26}}{\lambda}\left(\frac{\lambda}{\mu s}\right)^{12.85}$$

$$U = \frac{\lambda}{\mu s}$$

It turns out that the formula for *U* is, of course, simply a restatement of the analytic formula for utilization, ρ. Additionally, from the metamodel formulas for *L* and *W*, it can be concluded that $L = \lambda W$, which is (not coincidentally) the well-known relationship first demonstrated by Little. An example of another sort of simplified-form relationship derived from this simplified metamodel that might prove useful in a study of this nature is $L = e^{3.28}\, U^{12.85}$.

Thus, in addition to providing a vehicle for prediction, the multivariate metamodel may also be expected to provide a means of exploring relationships inherent in the real system and in the simulation model of the real system, but otherwise masked by the complexity of the system studied.

Simulation of Stochastic Discrete-Event Systems

Michael C. Fu[1] and Donald Gross[2]
[1]University of Maryland, College Park, MD, USA
[2]George Mason University, Fairfax, VA, USA

Introduction

One of the most powerful modeling tools in the operations research analyst's toolbox is stochastic (or Monte Carlo) simulation, which provides the ability to study complex stochastic systems in great detail using a computer program. Simulation models complement analytical models that require many simplifying assumptions, and in many situations, simulation provides the only way to analyze a system. Stochastic discrete-event systems are systems whose state changes upon the occurrence of discrete events, usually at stochastic times (Cassandras and Lafortune 2010). For example, in a queueing system, the state of the system includes the queue lengths, which change at discrete points in time when arrivals or departures occur. Discrete-event systems can be contrasted with continuous-time, continuous-state systems whose state changes continuously over time, with dynamics usually driven by differential equations, e.g., the motion of particles in a fluid. Discrete-event systems are ubiquitous in the man-made world, and thus simulation is widely used for modeling, analysis, and decision making in manufacturing, logistics and transportation, telecommunications, military operations, computer networks, health care, emergency response, finance, business processes, and many other service sectors. The following presents an overview of the key points in discrete-event stochastic simulation. For more details, refer to textbooks such as Banks et al. (2010), Law and Kelton (2000), and Fishman (1978), and the handbook on simulation edited by Henderson and Nelson (2006).

Elements of a Simulation Model

A simulation model contains three major components: input generation, process/event/sample path construction, and statistical output analysis. The input to the simulation model requires generation of the appropriate input processes. For example, a manufacturing system is generally modeled as a network of queues with a variety of different interarrival time and service time distributions. Random variates from these different distributions must be generated so that realizations or sample paths of the system "in action" can be constructed. Once these distributions are chosen, input random variates are generated, from which the next-event mechanism performs the simulation by advancing time upon occurrences of scheduled events, updating the system

state (e.g., queue lengths, idle/busy status of servers), and keeping track of various statistics through counters (e.g., number of customers served, waiting times, cumulative queue lengths) in order to calculate appropriate output performance measures. Output analysis employs the appropriate statistical techniques required to make valid statements concerning system performance based on the output performance measures obtained from the simulation runs.

The following simple hypothetical example illustrates the three basic elements described above.

> A small manufacturer of specialty items has signed a contract with a very prestigious customer for twenty orders of its premiere product. Management is concerned with current capacity and wishes to analyze the situation using discrete-event simulation. The customer will place orders at random times and would like them filled as soon as possible. Orders are placed only at the beginning of a month and could come as frequently as two months apart or as infrequently as seven months apart, or anything in between, all with equal probability (assumed independent). Currently, the production capability for this product is such that orders are shipped only at the end of a month and order filling time is equally likely between one and six months, inclusive (again, assumed independent). Only one order at a time can be processed, so that if a second order comes in while one is being prepared, it must wait until the order ahead of it is completed. For this capability, management would like to get an idea of the average number of orders in the system, the average time an order spends in the system, the maximum time an order spends in the system and the percentage of time the system is idle. The date of the first order is known and the production line will be set up just in time to receive the first order. The production line will be taken down after the last (20th) order is completed.

For this simple example, an easy way to generate the random input data would be to use independent rolls of a fair die. To generate the interarrival times, simply roll the die 19 times and add one to each value to get the times between successive orders after the first one. For the service times, the value of the roll itself suffices, requiring a roll of the die 20 more times. Table 1 below gives a sample of using a fair die to generate the input data, and Table 2 presents the (abbreviated) simulation table constructed from Table 1's input data. This would be called one simulation replication.

Table 2 was constructed from the interarrival and service-time input data as follows. At clock time 0, the first order (transaction) comes into the system, has a service time of 1 (month) and is due to depart at clock time 1 (month). At clock time 1, the next arrival, order 2, is due in at clock $0 + 7 = 7$, and since no order is in the system, will depart at its arrival time plus service time, i.e., $7 + 3 = 10$. The clock is advanced to time 7, and the next arrival (order 3) scheduled at $7 + 2 = 9$. Since order 3 arrives before order 2 leaves, the clock is advanced to time 9, the arriving order 3 enters the queue and order 2 is still in service, but due to depart at time 10. Order 4 is due in at $9 + 6 = 15$. The clock is then advanced to time 10, when order 2 leaves the system, order 3 enters service and is scheduled to depart at $10 + 2 = 12$. Order 4 is next to arrive and it is due in at 15, so the clock advances to 12. The simulated next-event mechanism continues in this fashion until the 20th order is processed.

The data in Table 2 can be used obtain the queue wait time and total time in system for each order. For example, order 1 entered the system at time 0, went right into service and left at time 1, spending zero time in queue and one month in the system. Order 2 arrived at time 7, also went directly into processing and left at time 10, spending 3 months in the system. Order 3, however, arriving at time 9, had to enter the queue since order 2 was still in process when it arrived. It left the queue for processing at time 10 and exited

the system at time 12 (not shown in the abbreviated table), spending 1 month in queue waiting for processing and 3 months total time in the system. Average waiting times and maximum waiting times can also be easily calculated, as well as average queue lengths and system utilization.

For the above example, the maximum number of orders in the queue was 1, the maximum number of orders in the system was 2, the maximum time an order spent in the system waiting to be processed was 4 months (order number 17), and the maximum time an order spent in the system was 9 months (also order number 17). The average queue length was 0.13, the average number in system was 0.81, the percent of the time the system was empty and idle was 32%, and the average waiting times in queue and system were 0.6 and 3.7 months, respectively.

Input Distribution Selection and Random Variate Generation

Keeping in mind the old acronym, GIGO (Garbage In, Garbage Out), care must be given to choosing the distributions that best describe the environment being modeled. This involves knowing as much about the modeling environment as possible and valid data analyses. There are some cases where data are not available nor can they be collected (e.g., design of a new system) and for these, only domain knowledge can be used. Sensitivity of output performance measures to specific input distributions is still an area of active research; some discussion is provided later.

Once the appropriate distributions are chosen (discussed in the entry on distribution selection for stochastic modeling), it is necessary to be able to generate representative samples from these distributions for running the simulation. Much study has been done in this area, as discussed in Banks et al. (2010), Fishman (1978), Law and Kelton (2000).

The basis for generating random variates from a desired probability distribution lies in being able to generate random numbers U_1, U_2, U_3,... which are independent and identically distributed (i.i.d.) on the interval [0,1], written as $U(0,1)$, where $U(a,b)$ denotes the uniform distribution on $[a, b]$. This is generally done via a pseudorandom number generator, which uses a mathematical recursion to generate a sequence of integers that statistically look as if they are random. These integers can then be normalized to the interval [0,1]. Perhaps the simplest generator is based on a linear congruence equation of the form

$$Y_i = (aY_{i-1} + c) \bmod m,$$

where a is called the constant multiplier, c is the increment, and m is the modulus in modulo arithmetic (the quantity in the parentheses is divided by m and only the remainder kept). Since the relation is recursive, a starting point called the seed, Y_0, is required. The numbers generated from this recursion will be in the interval $[0, m-1)$ and thus dividing by m normalizes the values to [0,1). When simulation was first used, these were the most reliable random number generators, but current practice employs much more sophisticated generators that are described in the random number generation entry; see also Chapters 3 and 6 of Henderson and Nelson (2006).

Using i.i.d. $U(0,1)$ random numbers, random variates from virtually any probability distribution (including empirical data) can be generated. One procedure for doing this is via the inverse (CDF) transform method. Given a random number $U \sim U(0,1)$ and the cumulative distribution function (CDF) F, the inverse transform method generates a random variate $X \sim F$ via

$$X = F^{-1}(U),$$

where F^{-1} denotes the inverse function (not $1/F$). The inversion algorithm can be viewed graphically as follows: find the U value on the y-axis, project horizontally to the CDF curve, and then project vertically down to the x-axis to read off the corresponding X value. As an example, to generate exponentially distributed random variates with mean θ, the CDF is given by $F(x) = 1 - e^{-x/\theta}$, so solving for X in $U = 1 - e^{-X/\theta}$ yields

$$X = -\theta \ln(1 - U).$$

Since (1- U) has the same distribution as U, the usual implementation is to use

$$X = -\theta \ln U,$$

since it saves one arithmetic operation. Another simple example is the algorithm for the general uniform

distribution, i.e., $X \sim U(a, b)$, which simply scales and shifts the random number:

$$X = a + (b - a)U.$$

The inverse transform method can be used for both discrete and continuous probability distributions, including empirical distributions. However, for most continuous distributions, the CDF F is not analytically invertible, e.g., the normal and most gamma distributions, though a simple numerical procedure can often be used. Other methods for generating random variates include acceptance-rejection, convolution, and composition. One advantage that the inverse transform has over other methods is that a single random number generates a single random variate, whereas in the other methods multiple random numbers may be needed to produce a single random variate; in the case of acceptance-rejection, the number of random numbers required is generally itself random. In addition to efficiency, the one-to-one correspondence can also be of great benefit when it comes to implementing variance reduction techniques, e.g., common random numbers. The entire volume of Devroye (1986), available online from the author's own Web site for free download, is devoted to input variate generation; see also Fishman (1996) and Chapters 4 and 5 of Henderson and Nelson (2006).

Simulation Programming Languages/ Modeling Software

The simulation modeler has a large variety of languages and packages from which to choose. These can be categorized into three main types: general-purpose languages, simulation languages, and simulation modeling software packages. General-purpose languages such as FORTRAN, BASIC, C, C++, Pascal, and Java allow the most flexibility in modeling but require the most effort to program. One can get a feel from the earlier very simple example of what might be involved in generating variates from the input probability distributions and programming the next-event routines and statistical calculations needed for obtaining output measures of performance. Numerical computing languages/environments such as MATLAB and R can also be used to program simulation models.

Simulation languages such as GPSS, SIMAN, SIMSCRIPT, and SLAM were developed to automatically include the components that stochastic discrete-event simulation models have in common, as illustrated by the simple example presented earlier, e.g., random variate generation, next-event logic execution, statistical counters, and output analyses. These simulation language packages make building a simulation model much easier, although some flexibility in modeling is sacrificed since the model must fit into the specific language environment being used. As a general rule, one can expect that the easier the programming becomes, the less flexibility there is in deviating from the language environment, although many software packages allow linkage to general purpose languages, thereby greatly increasing their modeling and analysis capabilities.

Even easier to use than simulation languages are simulation modeling software packages, the successors to what used to be called simulators. These are completely self-contained and require very little, if any, programming, as the model is generally built in a graphical user interface by choosing among icons in pull-down menus or from toolbars, and the software automatically includes animation capabilities that will allow the user to observe the system evolving over time. Well-known simulation software packages include Arena, SIMPROCESS, ProModel, WITNESS, Simio, SIMUL8, and AnyLogic. Examples of software packages tailored to a particular application area include AutoMod and SIMFACTORY.

Falling somewhere between self-contained simulation software packages and simulation languages are add-in packages that enable simulation modeling and analysis. Examples include SimEvents in MATLAB and SAS Simulation Studio for JMP. In addition, for stochastic (Monte Carlo, generally static) spreadsheet simulation, two of the most common add-in software packages are Crystal Ball and @RISK.

Output Analysis

Making valid conclusions from simulation output requires sound experimental design and statistical analysis. This section presents some basic procedures for analyzing simulation output.

There are two major types of simulation models: terminating and non-terminating. A terminating model

has a natural start and stop time, e.g., a bank opens its doors at 9:00 am and closes its doors at 3:00 pm. On the other hand, a non-terminating model does not have a start and stop time, e.g., a semiconductor manufacturing fabrication facility that essentially runs continually. In non-terminating simulations, steady-state results are usually of interest, and in simulating such a system, a determination must be made as to when the initial transients have dampened out and the simulation is in steady state.

For terminating simulations, ***Once is not enough***! In other words, a single replication does not provide enough information to make any statistical statements. For example, the maximum waiting time is a single observation, that is, a sample size of one. Multiple independent replications (repeated runs) of the experiment are required. For the example presented earlier, different random number streams (e.g., two dice rather than one) are used for the order arrival and processing times for each replication, which generates a sample of independent output observations to which classical statistics can be applied. Thus, n replications would generate n values for the maximum waiting times, say, $w_1, w_2, \ldots, w_n$. Assuming n is large enough to employ the central limit theorem, a $100(1-\alpha)\%$ confidence interval (CI) is formed by calculating the respective sample mean and sample standard deviation of the maximum waiting time by $\overline{w} = \frac{1}{n}\sum_{i=1}^{n} w_i$,

$$s_w = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(w_i - \overline{w})^2},$$

and then obtaining the CI as

$$\overline{w} \pm t_{n-1,1-\alpha/2}\frac{s_w}{\sqrt{n}},$$

where $t_{n-1,1-\alpha/2}$ is the upper $1-\alpha/2$ critical value for the t-distribution with $n-1$ degrees of freedom.

Non-terminating simulations aimed at steady-state estimation face two major challenges: initialization bias and serial correlation. The former has to do with determining when steady state is reached, and the latter has to do with how to carry out the simulations for the purpose of forming CIs. The main approaches in non-terminating simulations are independent replications, batch means, and the regenerative method. The first two approaches are the most commonly used and must address both challenges. The regenerative method can actually eliminate both major challenges but faces its own unique challenges.

Assume for the moment that the first challenge is solved, and the simulation is run for n transactions after reaching steady state to obtain n values for the time a customer spends waiting in a particular queue for service, again denoted by w_i (now these are actual waits, not maximum waits). It might be tempting to calculate the average and standard deviation of these n values and proceed as above to form a CI. However, these w_i are generally positively correlated, so that using the above formula for s_w would be a poor (biased low) estimate for the true variance. This is one version of the serial correlation problem.

One way around the serial correlation problem is to follow the same procedure as in the terminating simulation setting, and run m independent replications, as in the terminating case. For each independent replication, again calculate the mean of the w_i, denoting the mean for the jth replication by

$$\overline{w}_j = \sum_{i=1}^{n} w_{ij}/n$$

where w_{ij} is the waiting time for transaction i in replication j, $i = 1, 2, \ldots, n$ and $j = 1, 2, \ldots, m$. An approximate $100(1-\alpha)\%$ CI is given by

$$\overline{w} \pm t_{m-1,1-\alpha/2}\frac{s_{\overline{w}_j}}{\sqrt{m}}$$

where

$$\overline{w} = \frac{1}{m}\sum_{j=1}^{m}\overline{w}_j$$

and

$$s_{\overline{w}_j} = \sqrt{\frac{1}{m-1}\sum_{i=1}^{m}(w_i - \overline{w})^2}.$$

Both the run length (n) and the number of replications (m) influence the size of the standard error used in forming the CI. The standard error goes down by the square root of m, so that the more replications made, the tighter (narrower) the CI. As the run length n is increased, the computed value

of $s_{\overline{w}_j}$ itself will be smaller for a given number of replications, so that longer run lengths will also increase the precision of the CI. Thus for a fixed amount of computer running time, there is a trade-off between the sizes of n and m. CI coverage for steady-state simulation was first addressed in Schruben (1980).

The other major challenge in non-terminating simulations is the determination of the warm-up period, the initial amount of simulation time required to bring the process near steady-state conditions and hence eliminate initialization bias. Data are not collected until after the end of the warm-up period. A variety of procedures have been developed and the reader is referred to the basic simulation texts referenced previously for more details and further references.

In the procedure just described, the warm-up period is wasted in each of the m independent replications. The method of batch means (Law 1977; Schmeiser 1982) avoids this by using one single long run that is broken up into m segments (batches) of n transactions each, so that only a single warm-up period is discarded rather than m as in the independent replications procedure. However, this procedure brings back the earlier problem, since there is serial correlation between segments. However, the performance measures for each segment become statistically less correlated as the length of each individual segment increases, since the distance between transactions in each segment is further apart. If the segment length is sufficiently large, then the methodology for determining CIs is identical to that for m independent replications. The trade-off here is between the length of the batches (n) and the number of segments (m). Assuming the product mn is kept constant, larger m means tighter CIs but increased serial correlation, because the length of each segment is small.

The regenerative method can eliminate both problems of initialization bias and serial correlation. The main challenges for the regenerative method include finding regenerative points, which can be difficult for large systems, and the length of regenerative cycles, which are stochastic and can be long for large systems. Since these cycles are used to form CIs, with each cycle essentially corresponding to a replication, the efficiency of the method can be drastically reduced when regenerative cycles are long. See the accompanying entry for more details on the regenerative method. Other methods for steady-state simulation include autoregressive methods, spectral analysis, and standardized time series and time series analyses, which are summarized in Law and Kelton (2000); see Chapter 8 in Henderson and Nelson (2006) for an in-depth presentation of statistical techniques for simulation output analysis, including quantile and density estimation.

In comparing two alternative system designs, the technique most commonly used is a paired-t CI on the difference of a given performance measure. The number of replications for both designs must be the same, and the mean and sample variance are computed in the same manner as before, after forming the pairwise differences on the performance measure. The difference in performance of the two designs is considered statistically significant if the resulting CI does not contain 0 (zero); if it does contain 0, then it is generally desirable to carry out more replications to tighten the CI to be able to detect a statistical difference. Also, in forming pairwise comparisons, whenever possible the same random number stream(s) should be used for each design *within* a replication, so that the difference observed depends only on the design parameter change and not on the variation due to the randomness of the random variates generated. Different random numbers streams are still used between the replications. This is a variance reduction technique called common random numbers (CRN) and can be quite effective in tightening CIs. Critical to the success of CRN is the notion of synchronization, which intuitively means that as much as possible the same random numbers are used for the parts of the two system designs that are similar (or identical).

Comparing more than two designs necessitates using multiple comparison techniques. The most straightforward method would be comparisons in a pairwise fashion using the methodology for comparing only two systems. However, making all pairwise CIs among k designs would require $k(k\text{-}1)/2$ comparisons, and if the confidence level of a single pairwise CI is $1-\alpha$, and there are N CIs, the confidence associated with a statement concerning all the pairs simultaneously drops to a lower bound of $1-N\alpha$ (Bonferroni inequality). So, for example, if there are 5 designs being compared in all possible pairs (10 in all), and an overall 95% confidence level is desired, then each CI level should be 99.5%.

Since all pairwise comparisons is not very efficient if the number of alternatives is more than a few, it is better to consider other statistical ranking and selection procedures, such as selecting the best of k systems (or multiple comparisons with the best), selecting a subset of size r containing the best of the k systems, and selecting the r best of k systems. This topic is treated in detail in the entry on statistical ranking and selection; see also Law and Kelton (2000).

Variance Reduction Techniques

Unlike sampling from the real world, the simulation modeler has control over the randomness generated in the system. Often, purposely introducing correlation among certain of the random variates in a simulation run can reduce variance and provide tighter CIs. One example of this was shown above in forming a paired-t CI for the difference between two systems by using common random numbers within a replication, which introduces positive correlation between the two performance measures within a replication, yielding a smaller variance for the mean difference.

Another technique, called antithetic variates, introduces negative correlation between two successive replications of a given design with the idea that a large random value in one of the pairs will be offset by a small random value in the other. The performance measures for the pairs are averaged to give a single observed performance measure. Hence, if m replications are run, there are $m/2$ independent values being averaged for the CI calculation, but the variance of these values should be lower than m independent observations. Caution must be exercised when combining antithetic variates with common random numbers (see Law and Kelton 2000).

Indirect estimation is another simple approach for reducing variance, using known relationships between quantities whose performance is being estimated by the simulation model. For example, the mean time spent in the system is the sum of the mean time spent in queue and the mean service time. Since the latter is known exactly, it should be clear that for estimating the mean system time, it is better – in terms of obtaining tighter CIs – to estimate the mean queue time and add this to the known mean service time rather than directly averaging the individual system times. As another example, Little's Law relates mean queue time to the mean queue length, whereas again both can be estimated from the simulation. It turns out it is better in this case to estimate mean queue times directly and use Little's Law to obtain an indirect estimate for mean queue length (see Law and Kelton 2000).

Other effective, albeit more complicated, variance reduction techniques include control variates, conditioning, importance sampling, stratified sampling, and splitting, all of which are described in the variance reduction techniques entry in this Encyclopedia.

Sensitivity Analysis and Optimization

All good modelers appreciate the importance of sensitivity analysis in testing the utility of their model. For example, in the simple example presented earlier, one might be interested in the sensitivity of the average waiting time in queue to the mean service time of the orders. In simulation, the most direct brute-force way of carrying out sensitivity analysis is to perturb the parameter of interest and perform another simulation at the perturbed value of the parameter; in other words, resimulation. Clearly if the number of parameters is large, this becomes very inefficient. As a result, much research has been carried out since the 1970s to find efficient ways of estimating sensitivities, called stochastic gradient estimation (see Chapter 19 in Henderson and Nelson 2006). The two most common approaches are perturbation analysis and the likelihood ratio/score function method, both of which attempt to provide estimators that can be computed on a *single* simulation replication, i.e., *without resimulation*; see the corresponding entries in this Encyclopedia for details. In addition to sensitivity analysis, stochastic gradient estimation can be used in conjunction with the simulation model to carry out optimization for an objective function based on output measures of performance from the simulation model. Methods for doing this are described in the entries on simulation optimization and stochastic approximation.

Model Verification and Validation

Model validation is an essential step in a simulation study. Prior to developing a simulation model,

it behooves the simulation analyst to become very familiar with the system being studied, to involve the managers and operating personnel of the system, and thus to agree on the level of detail required to achieve the goal of the study. The appropriate level of detail is always the coarsest that can still provide the answers required. One problem with simulation modeling is that since any level of detail can be modeled, models are often developed in more detail than necessary, which can be very inefficient and counterproductive.

Validity is closely associated with verification and credibility. Verification has to do with program debugging to make sure the computer program does what is intended. This is generally the most straightforward of the triumvirate to accomplish, as there are well-known and established methods for debugging computer programs. The animation capability in simulation software can be helpful in verification, since the user can observe directly if the evolution is progressing as intended.

Validation deals with how accurate a representation of reality the model provides, and credibility deals with how believable the model is to the users. To establish validity and credibility, users must be involved in the study early and often. Goals of the study, appropriate system performance measures, and level of detail must be agreed upon and kept as simple as possible. A log book of assumptions should be kept, updated frequently, and signed off periodically by the model builders and users. Animation of the system can again be of help in the process of establishing credibility, by convincing users that the simulation model adequately mimics the true system.

When possible, simulation model output should be checked against actual system performance, if the system being modeled is in operation. If the model can duplicate (in a statistical sense) actual data, both validity and credibility are advanced. The model can be run under a variety of conditions and results examined by the users for plausibility. Most simulation texts have at least one chapter devoted to this important topic; see also Gass and Thompson (1980), Sargent (2011).

Other Simulation

For operations research analysts, the most well-known continuous-time simulation paradigm is probably system dynamics. In addition to purely discrete-event or continuous-time models, many systems are best modeled with a state that contains both a discrete-event and continuous-time component, e.g., a flow system that could be in one of many discrete modes (such as up or down) or a queueing system where customers possess characteristics with continuous-valued variables changing over time, giving rise to hybrid system simulations. Many of the simulation software packages can handle these, as well, either directly or through a combination (e.g., Simulink with SimEvents in MATLAB). Another important modeling paradigm is agent-based simulation, where the focus is on the agents in the system rather than the processes or events; these models are widespread not only in the operations research/management science community but also in economics and the behavioral sciences. The latest state-of-the-art developments in stochastic discrete-event simulation and agent-based simulation are presented annually in December at the Winter Simulation Conference, which makes its proceedings freely available online at its Web site.

Simulation Optimization

Michael C. Fu
University of Maryland, College Park, MD, USA

Introduction

Optimization in operations research and management science is generally identified with mathematical programming, where analytical expressions for quantities of interest (comprising the objective function and constraint functions) are assumed to be readily available and relatively easy to evaluate, so that the primary focus is on the *search* for the optimal solution(s). In simulation optimization, the objective function and/or constraints require expensive (in terms of computational effort) simulations to estimate or evaluate. In the stochastic setting considered here, multiple simulation runs (or replications) are used for estimating (through statistical sampling) system performance measures. The usual generic form of the optimization problem takes a form similar to that found in mathematical programming:

$$\min_{\theta \in \Theta} l(\theta), \tag{1}$$

where θ denotes the (vector of) controllable parameters or decision variables and Θ defines the constraint set on θ. Thus, each point $\theta \in \Theta$ represents one possible solution in the feasible solution space Θ. Assume throughout that the objective function is an expectation, i.e.,

$$l(\theta) = E[L(\theta, \omega)],$$

with ω representing a sample path (or simulation replication) and $L(\theta, \omega)$ the corresponding sample performance estimate. Objective functions of other forms (e.g., quantiles) can also be handled in a similar manner, and of course probabilities are simply expectations of indicator functions. In contrast to mathematical programming objective functions, the quantity $l(\theta)$ is not only expensive to evaluate, but it is generally quite nonlinear. Moreover, the constraint set Θ may itself also involve quantities that must be estimated from simulation, although the majority of existing techniques assume that they are available analytically.

As in mathematical programming, the set of solution techniques can be subdivided according to the state space of the controllable parameter θ: discrete or continuous. In addition, for the discrete case, there is a distinction between relatively small state spaces and larger (including infinite) state spaces; furthermore, the discrete state space may not possess a natural ordering/metric, e.g., the integers vs. purely categorical variables. As an example, consider a queueing network, where decision parameters might include the service rate at a station, which is generally continuously valued; the number of servers at a station, which is discrete valued and could be relatively small if considering stations individually or combinatorially large if considering the allocation of a fixed (large) number of servers among all stations in a

large network; and the queue discipline — first-come, first-served vs. various possible (static or dynamic) priority schemes, which involves a discrete categorical choice.

Small State Space

In this situation, the approach is analogous to enumeration in the deterministic setting, but it takes on a statistical flavor since there is randomness involved. Two (related) categories of statistical procedures are most applicable: ranking and selection, and multiple comparisons (Bechhofer et al. 1995). An applicable ranking-and-selection method will provide a sequential procedure that will select the minimizing θ among a finite set according to some statistical criterion such as a pre-specified confidence level. A number of these procedures pertinent to the simulation setting can be found in Law and Kelton (2000). Multiple-comparisons procedures, on the other hand, specify the use of certain pairwise comparisons to make inferences in the form of confidence intervals; they are not inherently sequential procedures. In terms of optimization, the most useful of these procedures are multiple comparisons with the best, which leads to $|\Theta|$ (size of state space) simultaneous confidence intervals. A review of these procedures in the context of simulation can be found in Kim and Nelson (2006). Other related approaches include optimal computing budget allocation (OCBA) and optimal learning, described in Powell and Ryzhov (2012) and Chen and Lee (2010), respectively; see also Branke et al. (2007) for a comparison of many of these procedures.

Large Discrete State Space

The main class of algorithms for this setting are random search methods, which iteratively update a single point by selecting the next point θ_{n+1} from a neighborhood of the present point θ_n. The resulting algorithms differ in specification of (i) neighborhood structure $N(\theta)$, and (ii) updating from θ_n to θ_{n+1}. Variants include the stochastic ruler, as well as those implementing simulated annealing. One recent algorithm using an interesting neighborhood structure is Convergent Optimization via Most-Promising-Area Stochastic Search (COMPASS) proposed in Hong and Nelson (2006). For a more detailed discussion on random search methods with references, see Andradóttir (2006) and Nelson (2010).

Other algorithms that can treat large discrete state spaces include genetic algorithms, estimation of distribution algorithms (Larrañaga and Lozano 2001), the cross-entropy method (Rubinstein and Kroese 2004), the nested partitions method (Shi and Ólafsson 2008), and model reference adaptive search (Hu et al. 2007). Another general approach is ordinal optimization (Ho et al. 1992), which is based on the idea that order converges (exponentially) faster than (statistical) estimation, a notion that can be made mathematically rigorous through large deviations theory. Massive parallel computation (e.g., simultaneously simulating a huge number of different alternatives) is especially suited for implementing this framework.

Continuous State Space

Most of the OR/MS research has focused on this case. Pattern search methods based on deterministic analogs directly adapted to the stochastic setting constitute one set of techniques. Examples include the Nelder-Mead method and its variants [2] where a simplex family of points is updated at each iteration according to some prescribed rules that control movements and possible expansion or contraction; and the Hookes-and-Jeeves method. Random search methods can also sometimes be adapted to the continuous parameter case.

Aside from the aforementioned methods, there are three major approaches to the continuous parameter problem. The first approach, stochastic approximation (SA), uses a stochastic version of gradient-based local improvement to iteratively update a single point. The second approach, sample average approximation (SAA) — also known as sample path optimization, the stochastic counterpart method, or retrospective optimization — uses multiple simulation replications to obtain a sufficiently precise estimate of the objective function (and constraints, if also noisy) in order to apply a deterministic optimization algorithm. The third approach, response surface methodology (RSM), uses simulation replications to fit a surface (e.g., the objective function) in either a global or local manner, on which optimization is performed

globally or sequentially. These approaches are now briefly discussed further in the context of simulation optimization; more details and further references on all three approaches can be found in the corresponding entries in this volume.

Stochastic Approximation

Stochastic approximation methods are the stochastic versions of gradient-based deterministic search algorithms. The basic underlying assumption of stochastic approximation when used in simulation optimization is that the original problem given by (1) can be solved by finding the zero of the gradient, i.e., by solving $\nabla l(\theta) = 0$, where ∇ denotes the gradient operator, which may only give a local optimum. The SA algorithm is of the following form:

$$\theta_{n+1} = \Pi_\Theta\left(\theta_n - a_n \widehat{\nabla} l(\theta_n)\right), \tag{2}$$

where θ_n is the parameter value at the beginning of iteration n, $\widehat{\nabla} l(\theta_n)$ is an estimate of $\nabla l(\theta_n)$ from iteration n, a_n is a (positive) sequence of step size multipliers, which shall henceforth be called the gain sequence, and Π_Θ is a projection onto Θ. When an unbiased estimator is used for $\widehat{\nabla} l(\theta_n)$, (2) is called a Robbins-Monro algorithm and when a finite difference estimate is used, it is called a Kiefer-Wolfowitz algorithm. Sometimes, the term Robbins-Monro-like algorithm is used for those procedures that estimate the gradient with some bias but without resorting to finite differences.

The main considerations in using an SA algorithm for simulation optimization are the following:

- obtaining a gradient estimate $\widehat{\nabla} l(\theta_n)$;
- selecting the gain sequence $\{a_n\}$;
- choosing a stopping rule.

Stopping rules are based on the progression of the iterates, the gradient estimates, or some combination. When considering long-run (steady-state) performance measures, there is an additional consideration of choosing the observation length for each iteration. Each of the first two items are now discussed in more detail.

Gradient estimation in stochastic simulation has been a very active research field, starting in the 1980's. Approaches that provide an unbiased estimate of the gradient (leading to Robbins-Monro SA algorithms) rely on some knowledge of the underlying system, and include perturbation analysis, the likelihood ratio/score function method, and weak derivatives; see Fu (2006, 2008) for recent surveys/tutorials with references. These techniques are sometimes referred to as "white box" approaches to simulation optimization (Pflug 1996).

When the simulator is treated as a black box of inputs and outputs, the usual approach is to use finite differences, either one-sided or symmetrical, given respectively by

$$\frac{L(\theta_n + c_n e_i, \omega_n^{i+}) - L(\theta_n, \omega_n)}{c_n}, \tag{3}$$

$$\frac{L(\theta_n + c_n e_i, \omega_n^{i+}) - L(\theta_n - c_n e_i, \omega_n^{i-})}{2c_n}, \tag{4}$$

where e_i denotes the unit vector in the ith direction, $\{c_n\}$ is a positive sequence converging to 0, ω_n^{i+} and ω_n^{i-} denote the pair of sample paths (simulation replications) used for the ith component of the n th iterate of the algorithm, and ω_n denotes the original sample path (replication) used to estimate the performance measure itself. The method of common random numbers employs $\omega_n^{i-} = \omega_n^{i+} = \omega_n$. Other approaches that also treat the simulator as a black box include harmonic differences based on frequency domain experimentation and simultaneous perturbations (Spall 2003). The latter approach has the advantage that it only requires two simulation replications per gradient estimate, regardless of the dimension of the parameter vector.

Convergence of SA algorithms can be guaranteed by establishing conditions on the objective function $l(\theta)$, the gain sequence $\{a_n\}$, and the bias and variance of the gradient estimator $\widehat{\nabla} l(\theta)$. Generally, the objective function should be differentiable and either convex or unimodal; in the unconstrained version (without the projection operator), additional conditions are needed. The gain sequence should be diminishing at an appropriate rate: too fast will lead to premature convergence to a suboptimal solution, and too slow will not guarantee (almost sure or with probability 1) convergence to the optimum. The bias of the gradient estimate must go to zero, and the variance must generally be uniformly bounded. As opposed to conditions placed on the gain sequence,

conditions on the objective function and gradient estimator may not be directly verifiable in simulation optimization.

One set of common assumptions satisfying the gain sequence conditions for convergence w.p. 1 is $\sum_n a_n = \infty, \sum_n a_n^2 < \infty$, which for example the harmonic series $a_n = a/n$ (for some constant a) satisfies. In the harmonic series sequence of step sizes, a decrease is taken at every iteration, but this may lead to rather slow convergence, so in practice, sequences that decrease more gradually, or even constant step sizes, are often employed. The gain sequences are generally of the form $a_n = a/n^{\alpha}$ and $c_n = c/n^{\beta}$, where α, β, a, and c are constants to be selected, subject to $\alpha \leq 1$ and $\alpha - \beta > 0.5$. Under these conditions, the optimal asymptotic convergence rates can be achieved: $n^{-1/2}$ for the Robbins-Monro algorithm, and $n^{-1/3}$ ($n^{-1/4}$) for the Kiefer-Wolfowitz symmetric (one-sided) differences.

One empirical observation to note is that iterate averaging often demonstrates superior performance over simply using the iterate itself, i.e., using $\overline{\theta}_n = \sum_{i=1}^{n} \theta_i/n$ as the estimate of the optimum; see Pflug (1996) for further discussion and references.

Sample Average Approximation

The basic idea of the sample average approximation approach is to replace expectations in the objective function and/or constraints with their sample averages, where the samples are obtained through simulation replications, and then solving the resulting problem formulation using deterministic optimization techniques, e.g., from mathematical programming. For example, in the formulation given by (1), where $l(\theta) = E[L(\theta, \omega)]$, if a sample of N independent and identically distributed versions ω_i, $i = 1, \ldots, N$, are obtained through simulation, then one would simply solve the sample average problem (sometimes called the stochastic counterpart)

$$\min_{\theta \in \Theta} \frac{1}{N} \sum_{i=1}^{N} L(\theta, \omega_i),$$

where the formulation written in this manner implicitly assumes the constraint set Θ does not involve quantities estimated from simulation. In many (if not most) SAA applications, much more is known about the form of L than in the settings assumed by other procedures described in this entry, e.g., linearity or convexity, because the types of problems that are solved by this method generally arise in mathematical programming settings where there is structural knowledge about the problem. For example, SAA is used for stochastic programming when the scenario structure makes it impractical to calculate the expectation analytically, so that sampling becomes the preferred computational method. More details on convergence and statistical properties can be found in the accompanying SAA entry.

Response Surface Methodology

Response surface methodology is based on statistical design of experiments methodology. The approach falls into the black box category and attempts to fit a polynomial of appropriate degree (possibly after some initial transformation on the input parameters, called factors) to the performance measure of interest (called the response). The application of RSM to simulation optimization takes one of two forms:

- metamodels,
- sequential procedures.

Using a metamodel for optimization means simply dividing the problem into two separate problems of estimation and optimization, similar in philosophy to the sample average approximation approach, the big difference being that in metamodeling an estimate of the output L is obtained for specific values of θ to be determined through appropriate statistical design of experiments. After choosing the design points of θ at which to simulate, the outputs are used to fit a global response curve called the metamodel – a complete functional relationship between the performance measure and the parameters of interest – which is then treated as a deterministic function and optimized using applicable deterministic procedures. An extensive discussion of the statistical issues involved can be found in Kleijnen (2008), which also discusses alternatives to polynomial regression such as kriging.

The more common use of RSM for simulation optimization is a sequential procedure. Instead of exploring the entire feasible region, which may be

inefficient or impractical, small subregions are explored in succession according to their potential improvement. A point – usually the center of the subregion currently being explored – would represent the current best value of the parameter. The basic algorithm can be described as follows:

Phase I (iterated a number of times)

- First-order experimental designs are used to obtain a least-squares fit linear model. Then, a steepest descent direction is estimated from the model, and a new subregion chosen to explore via

$$\theta_{n+1} = \theta_n - a_n \widehat{\nabla} l(\theta_n),$$

where θ_n is the representative point of the n th explored subregion, $\widehat{\nabla} l(\theta_n)$ is the estimated (from the fitted linear response) gradient direction, and a_n represents the step size multiplier determined by a line search or some other means. This is repeated until the linear response surface becomes inadequate, which is indicated when the slope is approximately zero, by which the interaction effects become larger than the main effects.

Phase II (performed once)

- A higher order (e.g., quadratic) response surface is fitted using more detailed second-order experimental designs, and then the optimum determined analytically from this fit.

Since Phase I is iterative, it is desirable to carry out fewer simulation replications if possible, whereas in Phase II, the region should be explored quite thoroughly by using a large number of replications. The iterative algorithm in Phase I is identical in form to SA as given by (2), although in RSM, θ is simply a representative point of the current subregion being explored, and $\{a_n\}$ is not generally a decreasing sequence nor is it held constant.

Concluding Remarks

Due to the rapid advances in computational power, the possibilities for simulation optimization have made this topic a very active area of research of OR/MS; more technical details on the areas touched upon here can be found in Fu (2013). Much of the most current work is reported in the annual *Proceedings of the Winter Simulation Conference*. Discussion of issues separating theory and practice can be found in Fu (2002, 2007).

A closely related field that has shown great promise in large-scale problems is the use of simulation in conjunction with stochastic dynamic programming problems, as opposed to the static optimization setting described here. In particular, simulation is used to estimate the optimal cost-to-go or value function. More details on this approach called approximate dynamic programming, which grew out of ideas in the artificial intelligence community in a field called reinforcement learning, can be found in Gosavi (2003) and Powell (2011); see also Chang et al. (2007) for the Markov decision process setting.

Simulator

An artificial means used to model a real-world system, generally falling into two categories: physical simulator or computer simulator. The former category typically consists of machines – e.g., flight or other vehicle simulators, or military weapons systems – which mimic the real world by generating cues for the operator(s), accepting inputs by the operator(s), and simulating realistic responses by the machine. The cues may include visual, auditory, and tactile sensations. The operator inputs consist of manipulation of control systems similar to those of the equipment being simulated. A computer simulator refers to the underlying computer code or software of a mathematical simulation model, e.g., Monte Carlo or discrete-event simulation. Obviously, machine simulators incorporate computer simulation, as well. Simulators are also commonly used for gaming.

Single-server Network

A queueing network with one or more nodes and one server servicing all of them. Examples are a token-ring system with (rotating) possession of the token giving a particular node the right to access the server, and polling systems whereby a rule governs the movement of the server around a sequence or loop of queueing stations. Practical applications include local area computer networks, robots working on a production line, and sequential physical service operations.

See

- ▶ Networks of Queues
- ▶ Queueing Theory

Singular Matrix

A square matrix whose determinant is equal to 0, which means that the columns (and rows) of the matrix are linearly dependent.

See

- ▶ Matrices and Matrix Algebra

Sink Node

A node in a network through which all (or some) of the flow in the network leaves the network.

See

- ▶ Network

SIRO

Service in random order; a queueing service discipline in which customers are served in random order unrelated to their arrival times.

See

- ▶ Queueing Theory

Six Sigma

- ▶ Quality Control

Skew-symmetric Matrix

A square matrix $\boldsymbol{A} = (a_{ij})$ is skew-symmetric if $a_{ij} = -a_{ji}$. Thus, all diagonal elements are zero.

See

- ▶ Matrices and Matrix Algebra
- ▶ Symmetric Zero-Sum Two-Person Game

Slack Variable

A nonnegative variable that is added to a linear inequality of the form $\sum_j a_{ij} x_j \leq b_i$ to transform the inequality into an equation. The slack variable measures the difference between the right-and left-hand-sides of the inequality.

See

- ▶ Logical Variables
- ▶ Slack Vector
- ▶ Surplus Variable

Slack Vector

The column representation of a slack variable in a linear-programming problem.

See

- ▶ Slack Variable

SLP

Successive linear programming.

Smooth Patterns of Production

In a production-planning problem with many production cycles, one usually attempts to have the

amounts produced in the sequence of cycles to be the same or as similar as possible. Such a smooth production pattern (one with small fluctuations) tends to be more cost efficient than one that has large fluctuations. Many such production problems can be formulated as linear-programming problems.

Societal Complexity

Dorien J. DeTombe
International Research Society on Methodology of Societal Complexity, Amsterdam, The Netherlands

Introduction

The methodology of societal complexity is in essence a field of Operational Research in the way the founders of Operational Research wanted to look at the world and wanted to help the problems in the world (Ackoff 1974, 1978). The field of methodology of societal complexity concentrates on handling real life problems, everyday problems that are described on the front page of newspapers.

Complex societal problems are worldwide natural problems caused by viruses like flu pandemics, fowl plagues and HIV/AIDS, local natural disasters such as earthquakes, hurricanes, avalanches and floods, technical dangers caused by industry like pollution (CO2), traffic, nuclear power plants, climate change and agricultural business, manmade threats like (world) wars, terrorism, Internet vulnerability and stock exchange manipulation, credit crisis and identity theft. These problems cause much trouble to the people, the economy and the stability of states. Handling these kinds of problems belongs to the field of methodology for societal complexity. The claim of this field is that complex societal problems should be handled in according to the approaches, methods and tools of this field.

The Field of Methodology of Societal Complexity

The field of methodology of societal complexity focuses on handling complex societal problems. A complex societal problem can be defined as

> a complex interdisciplinary societal problem is a real life problem, which concerns a real life situation. The problem can be in the present or in the (near) future, latent or manifest, structural or incidental. The problem is often undefined. The problem concerns many domains. The problem is dynamic and imbedded in a dynamic world. There are many phenomena and parties involved. The problem has a large impact on each level of aggregation of the society and provokes much emotion. Due to the many aspects of the problem the problem is complex. The problem can be urgent or less urgent. A solution is not easy at hand and the desired situation is not always clear and difficult to find.

and problem handling as

> Handling a problem is the process of analyzing, defining or changing a problem in order to gain more insight into the problem, whether or not this leads to influencing the problem in order to reach the desired situation. This process can be performed actively or passively, consciously or unconsciously, routinely or once-only, whether it is by circumventing or by forgetting the problem, by shifting the problem to another party or by (partly) changing the problem, by imagination or in real life, whether through thinking, applying tools and/or methods.

Not every complex societal problem will be handled. It depends whether it will be put on the political agenda. If the problem-handling process is examined it can be distinguished between several phases of the problem-handling process (Fig. 1).

After becoming aware of a complex societal problems and reflecting on the problem to be able to do some real-life interventions, the problem should be placed and accepted on the political agenda of a recognized problem owner who has credibility to handle this type of problem. For instance, reflection on the CO2 emission problem in relation to climate change, a recognized problem owner could be the Kyoto convention of 1997 or the decision of the G20.

When one decides to handle the complex societal problem, one should look at the field of societal complexity for a methodology the guide the problem-handling process.

Complex Societal Problems

Complex societal problems are commonly handled as mono-disciplinary problems by considering just

Societal Complexity, Fig. 1 The sub-cycles of the problem handling process

Sub-cycle I: defining the problem

phase 1.1	becoming aware of the problem and forming a (vague) mental idea of the problem
phase 1.2	extending the mental idea by hearing, thinking, reading, talking and asking questions about the problem
phase 1.3	putting the problem on the political agenda and deciding to handle the problem
phase 1.4	forming a problem-handling team and starting to analyze the problem
phase 1.5	gathering data, exchanging knowledge and formulating hypotheses about the problem
phase 1.6	formulating the conceptual model of the problem

Sub-cycle II: changing the problem

phase 2.1	constructing the empirical model and establishing the desired goal
phase 2.2	defining the handling space
phase 2.3	constructing and evaluating scenarios
phase 2.4	formulating hypotheses and suggesting interventions
phase 2.5	implementing interventions
phase 2.6	evaluating interventions and the problem handling process

a single disciplinary department and by asking single disciplinary experts for advice in handling the problem. However more and more politicians are aware of the limitations of the boundaries of their department and of disciplines to handle complex societal problems. Complex societal problems often extend the boundaries of their primary field.

For example, handling a natural disaster like a hurricane, a tsunami or an earthquake takes preparation to mitigate the damage beforehand and needs much coordination at the moment of the disaster and support afterwards. Not only are scenarios and plans required, but also training, communications and coordination are vital. There is a distinction between prevention and disaster, in case of a tsunami, building flood free safe houses in protected areas, preparation for the moment of a disaster, handling on the moment of the disaster and shortly after the disaster and reflecting on the effects in the years afterwards the disaster. To be prepared for disasters, multidisciplinary groups of experts should discuss how science, updated technology and communication tools can support the prevention, the moment of and the support afterwards in a disaster. The support of methods and tools of the field of societal complexity can help prevent unnecessary damages when disaster threatens, coordinate support, and protect people and goods.

The healthcare system is also a complex societal system. Therefore some of the interventions in the healthcare system should be done along the lines of the field of societal complexity. The healthcare system includes many aspects like prevention, healthcare of the patient, and patient follow-up afterwards. The doctor-patient relation is not a one-to-one relationship; it is part of a network of relationships. The patient is imbedded in a societal relation as daughter, mother, grandmother, employee, and citizen. A doctor is imbedded in a network of professional assistance, such as social work, pharmacy, medical specialism, hospital, medical research medical industry, assurance company.

Prevention is preferred to curing. The chain of patient safety starts with prenatal baby care and is closely related to social policy to prevent pollution, connected with sustainable food production, preventing smoking, traffic safety, preventing child and elderly abuse, education on drinking, etc. In this chain the medical world should give feedback to the society of the diseases they encounter. Improving patient safety is improving people safety. Specialization and division in tasks is fruitful. However, a patient is not just a hip, or a leg, the patient is a human being and a member of the society.

The medical world is a part of the horizontal and a vertical chain. The horizontal chain is, for instance, on the level of family doctor: the social worker, employer, dentist family members. The vertical chain is the family doctor, specialist, hospital and insurance companies. Medical professionals and non medical professionals on micro, meso and macro level.

The medical world is imbedded in the social world, and has aspects of law, psychology, sociology, policy on local, state and international level. Therefore some of the healthcare problem should not be handled mono-disciplinary but should be approached as a complex societal problem using methods and tools of the field of societal complexity.

Compram Methodology

One of the methodologies for handling societal complexity is the Compram methodology, developed by DeTombe (1994–2010) (DeTombe 1994, 1999, 2001, 2008a, b, 2010).

The Compram is the next step after Soft Systems Methodology (Checkland 1982) and System Dynamics. It combines aspects of different approaches into a structured interactive approach for policy making in collaboration with experts and stakeholders in order to find possible transitions of the situation that can be mutually accepted and implemented into real life.

The Compram methodology is based on the idea that societal problems must be handled multidisciplinary and cooperatively with experts, policy makers and stakeholders together. These difficult and complicated group processes are guided and structured by a facilitator in a six step approach. Multidisciplinary experts, stakeholders and policymakers discuss the content and possible solutions based on a cooperative (simulation) model of the problem. The method emphasizes facilitating the exchange of knowledge, and understanding and communication among the experts, stakeholders and politicians.

Knowledge, power and emotions are the basic elements in handing complex societal problems. The Compram methodology is a prescriptive framework method to which all kind of sub-methods can be applied. The Compram methodology has been used as a theoretical basis for handling over sixty real life cases in the field of societal policy making and in real life complex societal problems in several countries of all continents. The Compram methodology is advised by the OECD (July 2006) to handle complex societal issues. The 'Final consensus report' from the OECD Global Science Forum Workshop held in Tokyo, Japan, on December 5–6, 2005 organized by the JST-RISTEX (Research Institute for Science and Technology for Society, Japan Science and Technology Agency).

Many complex societal problems are a threat to people, the economy and the stability of the state, but most of all the quality of life. In order to create a safer society one needs to know where the danger comes from and what causes the threat. Each threat has different causes and different effects on different elements in society. Therefore, one has to carefully analyze the situation, make a distinction between causes and effects, see the elements and how they are related, see which power groups are involved, and to find out which package of sustainable changes can have the desired effects.

To find out what is known about the problem one has to analyze who is effected by it, which parties are involved, who benefits and who suffers, and what emotions and political vulnerability are going on. This needs an interdisciplinary approach. An interdisciplinary group of knowledge experts should analyze the situation and discuss possible changes. Then stakeholders should discuss the issue and give their opinion on the situation. Together the experts and stakeholders should find some fruitful changes. The interventions should be carefully implemented and evaluated on their desired effect on the problem. Each complex societal problem has knowledge, power and an emotional element.

The Compram methodology starts when the problem owner invites a facilitator to guide the problem by handling the process according to the Compram methodology.

Handling complex societal problems needs a special approach. Handling societal problems in an interdisciplinary way has become a must for society and a challenge for the human sciences. The problems society is confronted with are difficult to handle. There is a growing gap between the complexity of these problems and the human capacity to deal with them. There is a need for better methods and tools, more knowledge and imagination. Scientific knowledge is needed to survive amidst these problems.

Some of the scientific reasons for this special approach are that the problems are seldom defined, change during their development, many stakeholders are involved often with a different view on the problem, with different interest and with different 'solutions' in mind. Societal reasons for this special approach are the importance of these problems for society, the impact they have on many people, and the large amount of money involved. Combining the

effort of scientists who are working in this field is an inspiring serious challenge from the perspective of a number of disciplines. Combining existing knowledge and creating new insights with methods and tools for supporting complex societal problems is a challenge for scientists from different fields.

Most political problems are handled directly in relation with powerful groups involved in the problem, who by way of lobbyists influence the decisions of the political interventions. However, this directs the definition of the problem and therefore the solution of the problem directly to the definition of the most powerful groups in the problem handling process neglecting the more powerless groups. In order to give the powerless group also a chance and in order to be able to really see how the problem looks like a team of so-called neutral experts should first define the problem before the problem is handled. These neutral experts are selected based on their knowledge of a part of the field of which the problem is.

The facilitator therefore selects a group of neutral experts, neutral toward a certain definition and a certain solution to the problem and invited them to make a definition of the problem. In several meeting the experts each coming from a different discipline defines the problem. They do this guided by the facilitator with the help of a seven layer communication model (see Fig. 2), in which they first describe the problem in words, then define the concepts , then identify the knowledge. Is what the experts say based on theory, assumption or experience? Then base on the description of the problem they make together a simulation model. The relations of the phenomena and their effect on each other can then be carefully described and simulated. In the conceptual model next to the phenomena the power groups and their emotions are identified and described. This conceptual model can then after agreeing on the content be altered in an empirical model.

After the empirical model the handling space will be discussed. How much space is there for the problem owner to change the problem? Should this be here and now concerning a country, a continent or the world? Then, based on several scenarios the group of experts can suggest several intervention and intervention strategies.

The Compram methodology consists of 6 steps of interventions of a complex societal problem (see Fig. 3).

The second step is inviting the power groups. Power groups with much influence and less influential power groups.

Groups of stakeholders who benefit from the problem and groups of stakeholders who suffer from the problem. The facilitator invite each group separate and stimulated them to undergo the same process of problem handling described above to define their own view of the problem, their own definition and to describe the interventions they want to do and their intervention strategies.

Based on these outcome mutual meetings of neutral experts and stakeholders groups are then invited to look at the problem and find mutual accepted interventions. Then groups are formed to formulate implementations strategies for changing the problem and to guide and later on evaluate implementations for changing the problem (Fig. 3).

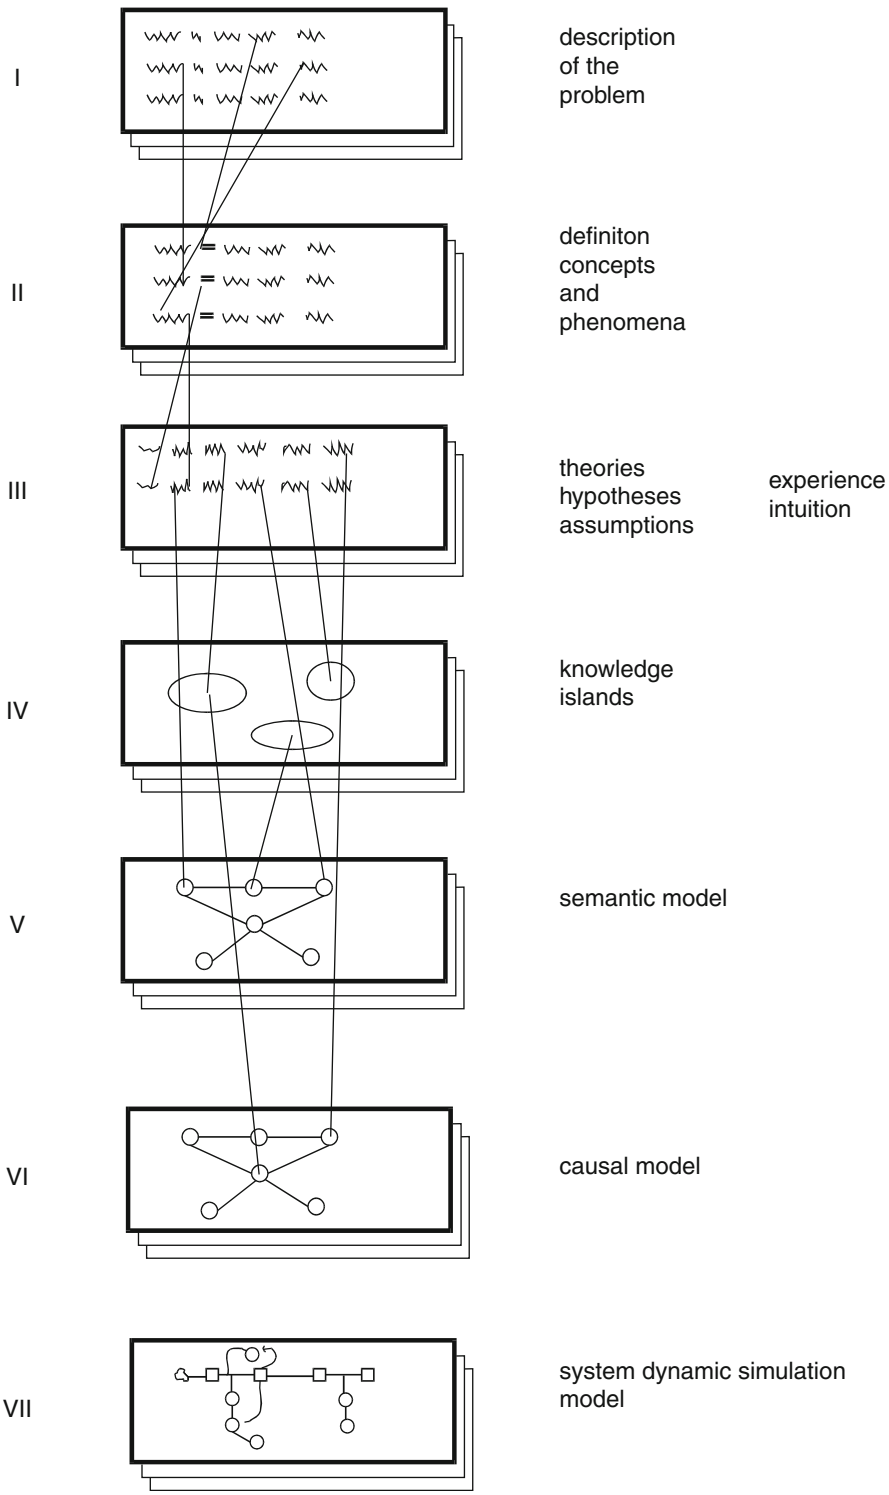
The Use of the Methodologies of the Field of Societal Complexity in Real Life

The Compram methodology is recognized by the OECD for handling global safety. That means that in order to develop and combine the knowledge, the methods and tools for handling societal complexity problems, special multidisciplinary knowledge institutes should be created that can become aware of future and now-a-days dangers and threats. These institutes perform multidisciplinary research and advice policy makers how to handle global safety issues in an integrated multidisciplinary, multi actor approach. In order to accomplice this, each country should establish multidisciplinary centers for research on societal complexity. These institutes should focus on their own specific local complex societal problems in cooperation with the already existing local institutes on safety. International they should cooperate with same kind of institutes on global threats.

These centers should be closely connected to the university. Inside the university a department for societal complexity may be established. In order to give some ideas this department can start with a team of scientists mainly interested or educated in methodology, coming from alpha, beta and gamma sciences.

Although researchers in this field are convinced that complex societal problems should be handled according to the direction of the field of methodology of societal complexity, relatively few complex societal problems are handled in this way. There are

Societal Complexity,
Fig. 2 The seven-layer model



step 1 analysis and description of the problem by a team of neutral content experts
step 2 analysis and description of the problem by different teams of stakeholders
step 3 identification of interventions by experts and stakeholders
step 4 anticipation of the societal reactions
step 5 implementation of the interventions
step 6 evaluation of the changes

Societal Complexity, Fig. 3 The six steps of the Compram methodology

several reasons for the reluctance of the politicians to handle complex societal problems.

First of all, most of the politicians are not aware of or unfamiliar with the methodology. This could be met by a more structured approach to teach managers, future politician and university students in their basic study in the field of for instance agriculture, healthcare, economy and transport. The main concepts and ideas of the field of societal complexity could be included in their basic university education. So that they are later on in their professional life at least aware of a more fruitful and sustainable approach towards complex societal problems.

A second point is that politicians want to jump to conclusions and do not want to spend too much time in defining the problem. They want directly to deal with the powerful stakeholders to find mutual accepted solutions. They like to start directly with problem handling phase 2.3 and 2.4 (see Fig. 1).

Another point is the transparency of, for instance, Compram. This methodology is based on a democratic decision-making process and is made transparent by prescribing that all the activities in each step should be open reported afterwards including the result, who were involved in the decision process, and what has be discussed in this process. Not all politicians want this openness.

Yet another point is the structure of most of the government departments. These departments are separated from each other and it is very hard due to competition and power fights and budgets to work together on a mutual problem.

Soft Systems Methodology

Peter Checkland
Lancaster University, Lancaster, UK

Introduction

Soft Systems Methodology (SSM) is an approach to tackling the kind of problematical situations with

which managers of all kinds and at all levels have to deal in their professional lives. As its name implies, SSM is based upon systems ideas, and a systems approach, but not in the conventional sense in which those phrases are usually used. Normally those words imply taking parts of the real world to be systems, and improving the performance of those systems in meeting their declared objectives. This is the approach found, for example, in systems engineering, systems analysis, classical operations research (OR), and in most management science textbooks. SSM was developed in the 1970s and 1980s in management situations in which objectives were themselves problematic and the engineering/optimizing approaches developed in the 1950s and 1960 could not be used unchanged. It is thus complementary to the earlier methods.

SSM was developed in a program of action research in the kinds of real-world situations that are often referred to as wicked problems (Rittel and Webber 1973) or messes (Ackoff 1974), and it is SSM which is the main source of the distinction now commonly made between hard and soft methods (discussed below); and it is a main component of what is thought of (especially in Europe) as soft OR.

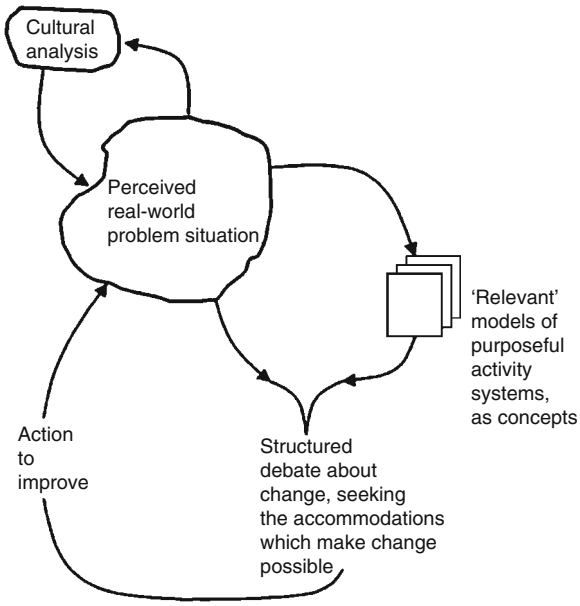
Origins and Development

At Lancaster University in the UK in the mid-1960s, a postgraduate department of systems engineering was established. The first external project carried out examined the possibility of controlling a paper-making line by computer, a classic systems engineering study. However, the late Gwlym Jenkins, who established the department, always interpreted the word engineering in its broad sense, the sense in which you can engineer a meeting with someone, or the release of hostages. A program of action research was therefore established by Checkland in order to investigate the possibility of using systems engineering methods not in technically defined problems but in the kind of general problem situations faced by managers. It was discovered that in such situations the straightforward definition of the relevant system and its defined objectives was not possible. Individuals and groups of people having different interests were always involved in such situations; what was problematical, and how, was always a matter of judgment; and the idea of finding solutions that eliminated problems was too simplistic a concept. For example, an early study examined the then-current Anglo-French Concorde project, already beginning to overrun its cost and time estimates, and a matter for much public debate in the U.K. It was not enough to think of such a development only as "a system to develop the world's first supersonic passenger-carrying aircraft." The problem situation as a whole included political, cultural, economic, environmental and employment issues, having been set up when President de Gaulle of France was vetoing British entry into the European Common Market.

Progress was made in such situations by realizing that all real-world problem situations, large or small, public-sector or private-sector, have at least one characteristic in common: they contain people seeking to take purposeful action. Methods were developed of making systems models of human-activity systems. However, it was soon also realized that any purposeful action is always open to many different interpretations, one observer's terrorism being another's freedom-fighting. Therefore the approach emerged of first making a number of models thought relevant to the different interests at work in a problem situation, each model being based upon an explicit declared world view. Such a clutch of models could then be used to structure a debate with people in the problem situation, the debate focusing on a search for action likely to bring about improvement in the situation. The structuring of the debate was done by using the models as a source of questions to ask of the real situation, or a source of possible scenarios that could be compared with recent happenings in the situation in question.

SSM thus developed as a learning, or inquiring system having the form shown in Fig. 1, one based on models of human activity systems as an explicit structuring device which could bring rigor to a debate about change. The change itself might be procedural, structural, attitudinal or, as is common, some mix of all three. It is important to note that the models are never taken to be descriptions of the real world; they are only devices to help structure debate.

The first paper on SSM was published in the early 1970s (Checkland 1972), and there is now a large literature, both primary and secondary. The development of SSM over more than 40 years has



Soft Systems Methodology, Fig. 1 The learning system which is Soft Systems Methodology (reprinted with permission of John Wiley and Sons from Checkland and Holwell's *Information, Systems and Information Systems*, 1997)

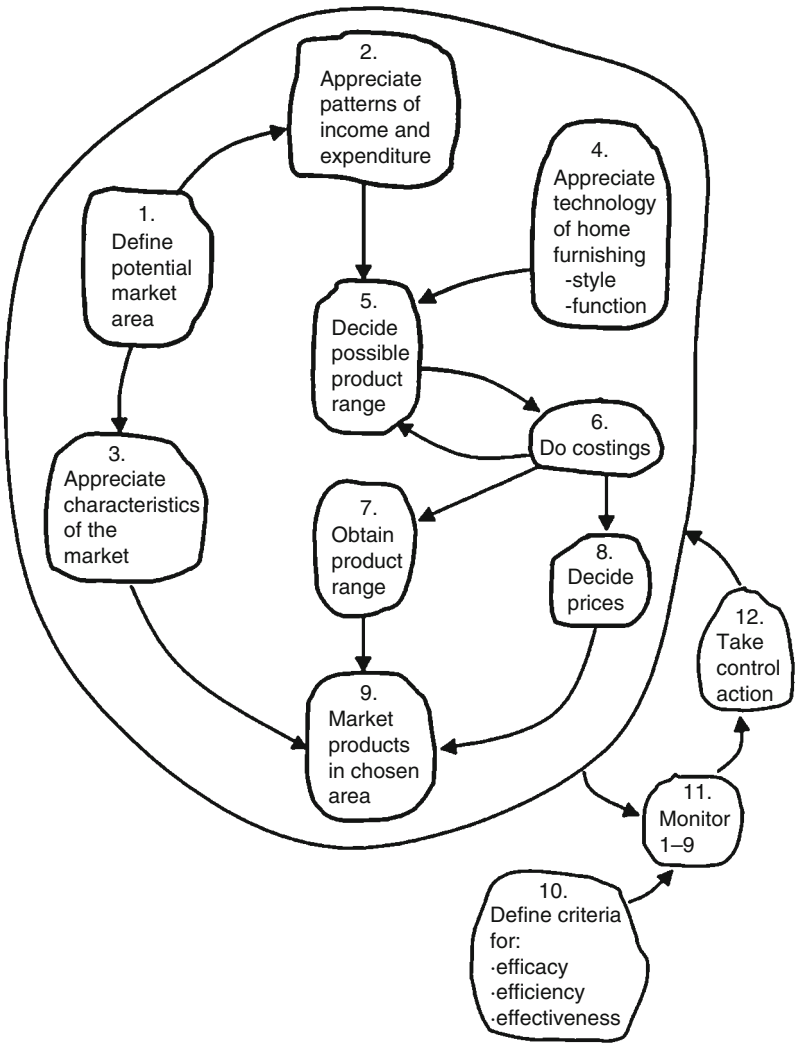
entailed the refinement, in practice, of the different aspects of the inquiring system: ways of finding out about a problem situation; choosing relevant models; model building; conducting the debate; defining useful change. These aspects will be briefly described. See Checkland and Poulter (2006) for a detailed account.

The Process of SSM

Overall, a use of SSM can be thought of as an intervention in a human situation that has arisen among a group of people in a particular setting, in order to find accommodations which will enable action to improve the situation to be taken. It therefore consists of analysis to understand the story of the situation and how it has arisen, and analysis to find out (and help to create) the accommodations between different interests and world views which enable action to be taken. Explicit use of the approach leaves a recoverable trail that can be traced by anyone interested. It has to be accepted that action in human situations cannot match the repeatability criterion of natural science carried out in laboratories. But SSM allows the full recoverability of the intellectual process that enables action-to-improve to be taken (Checkland and Holwell 1998).

Three analyses serve the finding out about the problem situation, something which will inevitably continue throughout a study. Discovering the history of the situation is reinforced, in Analysis One, by an analysis of the intervention itself. Who caused it to take place?; Who is doing something about it?; and most important – Who could the issue owners be taken to be? A list of plausible issue owner's is a useful source of choices of models of human-activity systems likely to be relevant to exploring the situation. (Discovering which models are truly relevant will emerge in moving round the learning cycle of Fig. 1, something which will be done many times during a serious study.) Analyses Two and Three feed an understanding of the context of the problem situation. The former explores the social reality: the roles, norms, and values taken seriously by people in the situation; the latter finds out the ways in which power is manifest in the situation. Both will enrich understanding of what action might be taken to bring about improvement.

SSM's stream of logical (task-oriented) analysis starts by building the devices that are human-activity system models. They consist of a structured set of activities that as a whole would constitute purposeful activity, together with monitoring and control activities which would in principle enable the purposeful whole to adapt and survive in a changing environment. Such models are normally built from a statement of a purposeful activity, known as a root definition, which embodies a declared Weltanschauung or world-view. A full root definition will usefully use the formula: a system to do P by means of Q in order to help achieve R. This answers What? How? and Why? questions about the activity and leads to the monitoring and control of the system being in terms of criteria for efficacy (is the output achieved?) efficiency (are minimum resources used?) and effectiveness (is this contributing to a longer term aim?). Figure 2 (Checkland and Holwell 1997) shows a model built by taking the existing mission statement of the Scandinavian home furnishing company IKEA as a root definition. IKEA's worldview is that a successful home furnishings business can be operated which combines elegant design with good functionality, and, what is more, can do this for a mass market. The model assembles the activities necessary to do this and links them by arrows that



Soft Systems Methodology, Fig. 2 An SSM-style model from the IKEA mission statement, concerned with marketing home furnishing items of good design and function at prices low enough to enable a majority of people to afford them (after Checkland and Holwell 1997)

show how the activities are contingent upon each other. Each activity could now be expanded into a model of higher resolution.

A final aid to formulating root definitions and building models is a set of elements that are relevant to all purposeful activity. They make up the mnemonic CATWOE, the central T of which indicates that any purposeful activity can be expressed as a transformation of an input into an output, not infrequently a need into that need met. The other elements are: customers (those directly affected by the activity, whether as victims or beneficiaries); actors (who would carry out the activities); the world-view which makes sense of this purpose; the owner who could stop the activity; and the constraints from the environment which this activity takes as given.

Once models have been built they can be used as intellectual devices to structure a questioning of the real situation. The models are of course much simpler than any description of actual real-world purposeful action (which will always embody more than one world view) but they serve to tease out often unquestioned assumptions and to initiate, as well as structure, a learning process within the situation studied.

The purpose of the comparing of models with perceptions of the real situation is, by structuring debate, to get assent to changes that are both desirable and culturally feasible, and would improve the problem situation. Obtaining that assent of course changes the original situation, so the cyclic learning process is in principle never-ending.

SSM in Use

SSM is normally taught as a stepwise process, and users at first normally approach it in this way, but that is not how experienced practitioners use it. SSM is, as its name indicates, a methodology, that is, a logos of method: a set of principles of method. This means that although uses of it will bear a family resemblance, it has to be adapted by a particular practitioner to a specific situation (Atkinson 1984). For experienced practitioners the methodological principles become tacit knowledge, and they will react to an evolving situation as its fluctuations demand. They will use Fig. 1 and will draw on the specific features of SSM in whatever ways are appropriate in their particular situation.

SSM can be seen as building upon work done in the systems and management science area by Churchman (1971), Ackoff (1974) and, especially, Vickers (1965). Its primary and secondary literatures contain many descriptions of its use, usually in organizational settings, the primary literature, in book form, being that which describes the action research program in which it has been developed: Checkland (1981), Checkland and Scholes (1990) and Checkland and Holwell (1997), Checkland and Poulter (2006).

Hard and Soft Systems Thinking

It is frequently stated that such hard problem-solving approaches as systems engineering and classical OR are most appropriate in well-defined situations in which objectives are known, and it is ways of achieving them which are problematical. On the other hand, a soft approach such as SSM is said to be appropriate in confused, unstructured situations in which both what to do and how to do it are problematical. This is not untrue, but it fails to make a sharp distinction between the two kinds of approach.

The core difference between hard and soft approaches lies in the different ways in which they use systems ideas (Checkland 1985). A very influential early textbook of OR, written in the 1950s (Churchman et al. 1957) argues that "the comprehensiveness of OR's aim is an example of a systems approach" and that "OR is concerned with as much of the whole system as it can encompass." This latter statement sees OR as intervening in systems assumed to exist in the real world. This is a familiar thought, deeply embedded in all of us by the way in which the word is used system in everyday language. One casually speaks of the legal system, health care systems, or the education system, assuming that these systems truly exist in the world. This is the hard assumption: that the world contains systems. In reality these areas of human activity only very rarely approach the concept of system as a fully-integrated adaptive whole. The soft approaches, on the other hand, do not assume that systemicity lies in the world. There the assumption is that whatever the perceived real world consists of (on which they are neutral), the process of inquiry into the world can be organized as a learning system. Thus, in SSM, the system is the process of inquiry itself – though SSM happens also to make use of systems models of purposeful activity, though these are not would-be descriptions of anything in the world, only devices used to structure debate.

It is this different answer to the question, "where are systems to be found?" which marks the difference between hard and soft approaches. This makes the two complementary to each other and powerful in combination.

Extensions and Advances

SSM was developed in the action research program at Lancaster University, which ran for 30 years and included more than 300 projects carried out in real situations. So it can fairly be described as a mature and well-tested process. But such a process, formed through real-world experience, can never be regarded as having reached a final state. So it is appropriate to indicate some developments that have extended the process.

As project experience accumulated it was realized that a user of SSM always faces two problematic situations. Obviously one of these is the real-world situation in which the methodology is to be used; but also there is the situation in which the user has to decide how to do the study, how to craft the principles of the methodology into an approach to this particular situation, involving the requisite people, with their particular history and world-views, now. It was realized that SSM could be used in both situations. Thus, every use of SSM could, if it seemed appropriate, entail both SSM using models to explore

the content of the situation, SSM(c), and SSM using models to explore the process of tackling the issues giving rise to the study, SSM(p). Discussion of this is found in Checkland and Winter (2006), and Checkland and Poulter (2006). It is frequently the case that as ideas for models relevant to the situation content emerge, the first model to be built is of a system to do the study, i.e. part of a use of SSM(p).

Also, the use of SSM(p) as an overall approach to project management has been taken further by Winter and collaborators. See their papers in a special issue of the International Journal of Project Management edited by Maylor (2006): Rethinking Project Management; see also Winter and Checkland (2003) and Winter and Szczepanek (2009).

Related to the recognition of SSM(c) and SSM(p) is another example of learning from experience which arose during SSM's development. Retrospective examination of a large number of root definitions from which models had been built in earlier studies revealed that most of them were of purposeful activity which was present in the real world in organizational form, as departments or divisions, or sections within organizations. (This limitation was probably due to the initial legacy of the kind of thinking embodied in hard systems engineering, namely that the real world contains systems which can be engineered, the stance which had to be replaced as SSM emerged and the fundamentals of the hard/soft distinction were recognized.) It became important to note that although organizations could create purposeful functions (such as Production, Marketing or Distribution) and embody them as structures, every organization has to carry out many more important actions beyond those that could be embodied in functional structures. For example, a major UK charity, Oxfam, grew from its origins in relief work (beginning as the Oxford Committee for Famine Relief) into a major source of development projects in the Third World. A permanent issue in the charity is the balance of resources between these two very different activities. Thus, in an SSM study of Oxfam, a highly relevant purposeful activity worth modeling is a notional system to balance resource allocation between relief and development, though this is not the function of any one structure within the organization. Such a root definition is called an Issue-based definition, whereas root definitions that relate to organization structures are known as primary task definitions (Checkland and Poulter 2006). Much experience has shown that it is best always to work with both kinds of model, not least because the boundary of an issue-based model will cut across organizational boundaries. Since internal organizational boundaries always relate to issues of politics and power within organizations, issue-based models always raise awareness and attract attention and energy.

A third area of SSM which remains to be cautiously mined concerns the nature of the very subtle process which is initiated when purposeful activity models, built according to different world-views, are used as a source of questions to explore a real-world situation. The caution stems from the fact that no two projects using SSM ever have more than a broad family resemblance to each other, simply because no two situations involving human beings are ever exactly the same. Neither are human situations ever static. In addition, the discussion and debate initiated by consideration of models based on different world-views provokes and stimulates a level of discussion beyond that which is normal in most Western organizations. Mental furniture tends to get shifted in such a debate. Unsurprisingly, attention to this aspect of SSM has arisen from Eastern interest in the approach, especially in the work of Kenichi Uchiyama, which interprets SSM from the Japanese point of view in his book, *The Theory and Practice of Actuality* (Uchiyama 2003). He came to SSM as an experienced manager. Working in both Casio and in IBM Japan, he observed two very different ways of thinking about a market. IBM conceptualized a market as an external thing outside themselves that they would enter and try to capture. In Casio, the chief executive, addressing managers in the company, would say "We must find ourselves in our market", a very different concept to that of IBM.

Uchiyama's work is centred on making the distinction between reality and actuality, a distinction that he takes from the work of Bin Kimura, an eminent Japanese psychiatrist. Uchiyama uses the example of listening to music to illustrate the reality/actuality relationship. The reality of a musical performance is that a succession of external notes (vibrations in the air) are produced and delivered. What is heard, however, is not that, but a melody, as a whole entity, and hearing it stems from a two-way link between this particular performance and one's whole already-existing experience of listening to music. It is heard in actuality, not reality. Uchiyama argues that,

via the modelling and debate stages, SSM is best seen as a methodology to bridge reality (where most Western thinking is focused) and the actuality of the people in the problem situation addressed, of which Eastern thought is more aware. This is the most insightful contribution that has so far been made to the error-strewn secondary literature on SSM, and it opens up new developmental possibilities. Uchiyama sees SSM as closer to Japanese models of thought than it is to Western thinking, and this may explain the extraordinary difficulty many people in Europe and America have in grasping, for example, the difference between hard and soft systems thinking. In the West, it is evidently extremely difficult for many people to give up the idea that systems are things out there in the world, rather than being world-view-based epistemological devices for trying to understand the world.

Expositions of SSM come in books from the Open University in the U.K., where thinking and systems methodologies have been taught since the early 1970s. The book edited by Reynolds and Holwell (2010) describes SSM and other systems approaches; Ramage and Shipp (2009) in their book, *Systems Thinkers*, describe the work of thirty selected people in the field, including Checkland, in short chapters which introduce the work and include an extract from the writings of the chosen thirty. For a discussion of the difference in treatment of SSM between the U.S. and the U.K., see Paucar-Caceres (2011).

Probably the best attempt to express the essence of SSM in a single phrase comes from J.M. Gvishiani, who was head of the Moscow Research Institute for Systems Analysis when Checkland was invited to spend a week there giving lectures and seminars. "I see your approach," he said, "as a rigorous approach to the subjective."

Sojourn Time

The total time spent in a queueing system, including both the delay and service times; sometimes called the total waiting time or just waiting time. Often used as the time spent in a visit to a state of a stochastic process such as a Markov chain.

See

- ▶ Markov Chains
- ▶ Markov Processes
- ▶ Queueing Theory

Solution

A set of values for the variables of a problem that satisfy all the constraints of the problem.

See

- ▶ Feasible Solution

Solution Space

For a constrained mathematical programming problem, the solution space is a portion of Euclidean space defined by all the constraints of the problem. For a linear-programming problem, the solution space is defined by the intersection of the nonnegative portion of Euclidean space and the constraints of the problem.

Introduction

Man's venture into outer space began on October 4, 1957, with the successful launch by the U.S.S.R. of the first artificial Earth satellite, Sputnik I. This was soon followed on November 3 by the dog (Laika)-manned Sputnik II. The first American satellite, Explorer I, was launched on January 31, 1958. From this period on, both the U.S. and the U.S.S.R. have mounted extensive research and development activities for putting manned space vehicles into Earth orbit. In particular, the U.S. established the National Aeronautics and

Space Administration (NASA) on October 1, 1958 with the mission "... to achieve at the earliest practicable date orbital flight and successful recovery of a manned satellite, and to investigate the capabilities of man in this environment," (Swenson et al. 1966, p. 111). From this beginning, the U.S. man-in-space program can be traced from Project Mercury (Glenn in Earth orbit on February 20, 1962), to Project Gemini (two-manned space capsule in Earth orbit), to Project Apollo (the moon-landing on July 20, 1969), and to the Space Shuttle. However, the Soviet effort succeeded in sending the first manned satellite into Earth orbit with the launch of Gagarin on April 12, 1961.

During the 1970s, countries in addition to the United States and the Soviet Union/Russia became involved in the exploration of outer space. For example, the European Space Agency (ESA), established in 1975, has 18 member states and a staff of approximately 2000. The ESA has engaged in both manned exploration, mainly through its participation in the International Space Station Progam, and unmanned exploration of the moon and other planets. In addition, the People's Republic of China was the third country to independently send humans into space in 2003 (Clark 2004). For information about U.S. activities with respect to space exploration prior to the formation of NASA, see Roland (1985). For historical perspectives on space flight, see Emme (1977) and Siddiqi (2010).

Missions to outer space might be classified as involving: (1) space shuttle/other manned space flights involving travel to and from the International Space Station, maintenance of the Hubble Telescope, or independent earth orbit, (2) satellites launched into earth orbit for communication, scientific experimentation, and/or defense, or (3) unmanned spacecraft with a destination of the moon of earth/moons of other planets and/or the other planets of the solar system. In the last category, the missions can involve the actual landing on and exploration of planetary surfaces and/or atmospheres (e.g., see the discussion of the Cassini mission to Saturn by Savory and Saghi 1997).

Throughout this time, OR/MS techniques have been used by NASA and the space industry in general in the management and analysis of their space activities. It is especially interesting to compare the level of technological sophistication of space-project planning in 1962 with what accompanied Senator Glenn when he went back into space in October 1998. Applications over the years have included project management, forecasting, scheduling, cost estimating, optimization, simulation, and multi-objective decision analysis.

Applications

Motivation

Many of the activities, projects and programs associated with space exploration are characterized by (1) high degrees of risk, with respect to both human life and cost, (2) the use of advanced technology, some facets of which may not have even been developed at the onset of a mission, (3) the long time frame associated with many missions (e.g., a manned mission to Mars would require a time frame of 20–40 years), (4) organizational challenges resulting from required inputs of diverse public and private organizations, and (5) the multiple objectives in the areas of safety, cost, scheduling and performance which must be considered. These characteristics would imply that the modeling techniques associated with OR/MS are even more important for space exploration, than they are for earth-based endeavors. For example, the high cost of the Cassini-Huygens Mission to Saturn, descibed below, motivated the use of sophisticated models to test various scheduling policies for its hardware data control system in order to minimize risk of failure.

Applications Involving the Space Shuttle and Potential Future Systems

NASA's Space Transportation System consists of an orbiter and its three engines (i.e., the Space Shuttle), two solid rocket boosters, and an external fuel tank. The shuttle began operational flights in 1982 and was retired from service in 2011, after 135 launches, all from the Kennedy Space Center in Florida. Each flight of a Space Shuttle requires the scheduling of thousands of activities that have certain precedence relationships and require the use of various types of scarce resources. Scheduling these activities to meet criteria relating to time, cost, and quality is a complex process. Developing feasible schedules requires the use of sophisticated project management techniques, including project networks, heuristic scheduling rules, and. Paté-Cornell and Fischbeck (1994) used

a probabilistic risk analysis procedure to set priorities for the maintenance of the heat shield tiles of the space shuttle orbiter. They showed that implementation of the policy suggested by their procedure would result in a 70% reduction in the probability of a shuttle accident attributable to tile failure. Morris and White (1987) employed a SLAM II simulation model (Pritsker 1986) to analyze the operational support requirements of the space shuttle under a delivery payload scenario from the earth to the proposed space station. The model consists of three major modules: one each for ground-base operations, space station operations, and orbital operations. The main inputs to the model include the delivery requirements at the space station. The model can be used to help determine the delivery rate capability of the system, the support resources required, and the utilization of various system resources. Bell (1994) developed a heuristic approach for scheduling the training sessions in shuttle cockpit simulators.

Numerous new launch systems have been proposed. Kaylani et al. (2008) have developed GEM-FLO (A Generic Environment for Modeling Future Launch Operations), a generic simulation-based modeling approach for accurately predicting processing turnaround times and other performance measures in order to support key program decisions in the selection of a new launch system. The system assumes that any new launch vehicle would be composed of several major components; e.g., the major components of the STS are noted above. Each major component follows a generic conceptual flow process, which is integrated into a generic flow process for the launch vehicle as a whole. The model was validated with historical data from space shuttle operations.

Padula et al. (2006) address the problem of optimization of aerospace design under conditions of uncertainty. The specific applications addressed involved three that were undertaken at the NASA Langley Research Center: (1) impact dynamics for airframes, (2) transonic airfoil design for low drag, and (3) coupled aerodynamic and structures optimization for a 3-D wing.

Applications Involving the International Space Station

The International Space Station (ISS), the largest artificial satellite that has ever orbited earth, is a joint project involving participation of five different space agencies: NASA, the ESA, the Russian Federal Space Agency, the Japanese Aerospace Exploration Agency, and the Canadian Space Agency. Its on-orbit construction began in 1998, and it is scheduled for completion in 2011. The cosmonauts and astronauts who man the station conduct a variety of scientific experiments. The initial design process of ISS was obviously a complex one. For example, Quirk et al. (1989) addressed the problem of selecting one of two energy module alternatives (photovoltaic or solar dynamic) for the space station. A chance-constrained programming model was developed to select the system that minimized the expected cost, subject to the constraint that the probability that the net output would be less than or equal to some given net output would be no more than a prespecified value. The structure underlying the model is a stochastic Leontief system. Inputs to the model include subjective probability distributions of energy requirements associated with various activities, as given by Johnson Space Center engineers. Hence, the model accounted for the inherent uncertainties associated with each alternative. Groen et al. (2006) describe a probabilistic risk assessment for the ISS using a PC-based software package, the Quantitative Risk Assessment System (QRAS). The algorithms embodied in the package employ event sequence diagrams (ESDs) as opposed to event trees to model various scenarios; the authors note that the use of ESDs allow for better communication between mangers and engineers.

Applications Involving a Proposed Manned Mission to Mars

An important long range program for NASA is a manned mission to Mars. In this regard, Tavana (2004) examined three alternative mission architectures for such a mission: (1) split mission scenario (pre-deployment of mission assets to Mars, followed by the mission crew), (2) combo lander scenario (mission assets travel with the crew), and (3) dual scenario (a combination of the previous two scenarios). The approach employs the analytic hierarchy process (AHP), subjective probability assessments (attained from personnel at the Johnson Space Center), and the entropy method in order to consider the risks and benefits of the seven phases of such a mission: earth vicinity/departure, Mars transfer, Mars arrival, planetary surface, Mars vicinity/departure, Earth transfer, and Earth arrival.

In another study related to a manned mission to Mars, Chamitoff et al. (2005) discuss a software package, Planetary Resource Optimization and Mapping Tool (PROMT), which provides as output a global map indicating the relative value of various Martian landing sites. The software is illustrated through the use of data provided by the Mars global surveyor and the Odyssey Spacecraft. The paper notes that one important aspect in the evaluation of landing sites is the location of indigeneous resources that can be used by the mission.

Miscellaneous Applications Involving Scheduling

There are a myriad of applications of scheduling in space exploration activities, one of which has already been described above (Bell 1994). The papers discussed in the following paragraphs will describe applications involving the scheduling of activities for the Hubble Space Telescope, the scheduling of data transmissions from satellites to earth receiving stations, and the scheduling of a software simulator for the Cassini spacecraft.

Muscettola et al. (1992) described the Heuristic Scheduling Testbed System (HSTS) used for generating observation schedules for the Hubble Space Telescope (HST). The HST is a $1.4 billion observatory, with an expected operational lifetime of 15 years. It was placed into earth orbit in 1990. In any period of time, there are many different observational requests for the telescope's resources. Scheduling these requests is a difficult process for several reasons. A particular observation may require that several different operations be performed with six different scientific instruments that make up the HST. Several observations may be grouped together within a particular window of opportunity, depending on the locations of the telescope and the space objects to be observed. Parallel observations may be made with different viewing instruments; yet, not all six instruments may be turned on simultaneously because of energy constraints. The HSTS employs artificial intelligence procedures that provide a flexible approach to scheduling HST operations. This approach allows the "effective balancing of conflicting scheduling constraints and objectives."

Bell (1996) illustrated the practical use of a new approach to finding the dual prices in a Lagrangian relaxation problem. The practical application involves the transmission of data from satellites to receiving stations on earth. Such transmissions require a "line of sight" from the satellite to the station, and hence can only be accomplished at certain times of the day. Given the increasing number of satellites as compared to the number of receiving stations, this problem is becoming increasingly complex. The approach was illustrated with a case study involving 12 satellites and three receiving stations over a 1 week period.

Savory and Saghi (1997) developed a model to simulate various queue scheduling policies to improve the performance of a software simulator. The simulator was used to emulate the hardware data control system of the Cassini spacecraft, which was launched towards Saturn in 1997. The mission itself consists of an orbiter, which entered orbit around Saturn in 2004 and continues currently, and a probe which was the first man-made device to accomplish a landing in the outer solar system, on one of Saturn's moons, Titan. At the time of its launch, the Cassini was thought to be "the best instrumented planetary probe ever developed." Its cost (estimated at more than $3 billion) and importance mandated the use of extensive testing of its various systems, including its data control system. In order to perform these tests, scientists at NASA's Jet Propulsion Laboratory developed a computer program to represent the spacecraft's data control system. Implementation of the simulation results combined with a software code redesign resulted in greatly improved performance of the data control system.

Applications Involving Organizational Design, Project/Program Selection, or Project/Program Management

The organizational challenges associated with the planning, execution, and control of long range missions for space exploration are daunting. These challenges include coordinating the activities of numerous, geographically dispersed technical experts over an extended period of time. In this regard, Carroll et al. (2006) describe a study for developing a new organizational design tool for the NASA Systems Analysis Integrated Discipline Team (SAIDT). The study considered the various interfaces between the organization, activities, and the environment, and involved the use of various simulation tools.

Strategic (long range) planning for any organization which plans and conducts missions to outer space is

especially important (and difficult) for the reasons noted above. Decisions include which missions to undertake, which programs to fund, the amount of funding to give to each program, what designs to use for new spacecraft, etc. For example, a long-range planning problem encountered by NASA is discussed in Evans and Fairbairn (1989). This research addressed the problem of determining which missions, out of many possibilities, NASA should undertake during the next decades. A 0-1 integer linear programming model was formulated in which the decision variables determine whether or not to include a particular mission in NASA's long-range plan. The model allows for the consideration of several criteria relating to benefits derived in various areas (e.g., intellectual, humanistic, and utilitarian), as well as cost. In addition, the model implicitly considers the dependence among the various missions in the plan by specifying appropriate constraints. An example of dependence would be the fact that a manned mission to Mars would require the undertaking of several precursor missions. See the NASA Office of External Relations (1986) report and Paine (1991) for a discussion of potential missions to space during the twenty first century.

As implied in the previous paragraph, the concept of group decision making is important at NASA. Tavana (2003) developed a group decision-making tool called CROSS (consensus-ranking organizational support system) for evaluating and ranking advanced technology projects using the Analytic Hierarchy Process, subjective probabilities, and the entropy concept. The process includes decision makers and stakeholders and has three phases: an interaction phase, an integration phase, and an interpretation phase. The interaction phase involves identifying the stakeholders and gathering information from them on their criteria well as the probabilities of occurrence of each criterion for each project. Also in this phase, the decision makers use AHP to weight each of the stakeholder's respective departments. The integration phase calibration of results and the use of the maximum agreement heuristic in order to achieve a consensus ranking. Finally, in the interpretation phase, the decision makers make a final recommendation to management who makes the final decision. A case study involving ten projects, six stakeholder departments, and 38 criteria is used to illustrate the methodology.

Because of the high cost and wide variety of tasks associated with space flight, cost estimation, budget allocation, cost accounting and control are obviously important, and difficult, aspects in this area. Dillon et al. (2003) described the Advanced Programmatic Risk Analysis and Management (APRAM) model, a framework for allocating the budget for a program among its various dependent engineering projects. The process allows for the consideration of tradeoffs between technical failure risk and managerial failure risk. The process is illustrated with an application to the Mars Explorer Program.

Castillo et al. (1992) discussed GOST, a modeling system for cost estimation and mission planning. Berente and Youngjin (2010) discussed various issues associated with the implementation in 2004 of NASA's Full Cost, an activity-based accounting program. They noted that "some elements (termed dressage by control) of Full Cost . . .were geared towards satisfying disciplinary requirements without necessarily contributing towards productive activity." Their main conclusion was that the ultimate goal of full enterprise control is not attainable.

Bearden (2003) studied the relationships among risk, cost, and schedule for 45 low-cost small satellite, planetary missions over the period of 1990–1999, such as the Mars Polar Lander, the Mars Climate Orbiter, and the Mars Global Surveyor. One motivation for Bearden's efforts was the debate concerning NASA's Faster, Better, Cheaper (FBC) approach to satellite missions and the thought that, while the approach may have resulted in improvements to criteria related to cost and schedule, this was at the expense of a lower probability of mission success. As part of his efforts, Bearden developed a complexity index that could be derived for a specific mission as a function of its performance, mass, power, and technology choices. This complexity index was used to normalize development time and spacecraft cost across missions. The two main conclusions derived by Bearden through his study were (1) there is a clear dependence of success rate on system complexity, and (2) "that low-cost, planetary missions cost more, are developed faster, and fail more often than do Earth-orbiting missions".

Applications Involving Risk Analysis

Risk analysis is another important aspect of space exploration. Saunders et al. (2003), described

a process for estimating the likelihood of success of the missions associated with NASA's Explorer and Discovery Programs. Four evaluation criteria are considered by the process: scientific merit, feasibility of achieving the mission's scientific objectives, feasibility of the mission implementation approach, and social benefits associated with the mission.

Newman (2001) used a systems engineering approach to examine the causes of the failures associated with 50 space systems occurring from 1960 to 2000. About 70% of the cases examined were from 1990 to 2000. Newman noted that these failures can be classified according to whether or not the proximate (i.e., immediate) cause(s) are known. For example the proximate cause for the space shuttle Challenger failure was an o-ring failure, but that the proximate cause of the 1999 loss of the Mars Polar Lander is not known for certain. However, Newman notes that whether or not the proximate failure cause is known for certain, the basic purpose of any mission failure analysis is to emerge with something on which to act, and this requires an analysis which moves backwards from proximate cause(s) through multiple, possibly intersecting, paths to a variety of root causes.

Spanning Tree

A subnetwork (graph) of a given network that connects all the nodes of the network and which has the property that once a path travels through a node, it cannot return to that node (the path has no cycles). A spanning tree is a tree of the network. If a network has n nodes, then the spanning tree has $n - 1$ arcs.

Special-Ordered Sets (SOS)

Types of constraints in optimization models. SOS of type 1 require that only one variable in the set may be nonzero; SOS of type 2 require that only two variables in the set may be nonzero and they must be adjacent. SOS of type 1 are used in problems in which the variables in the set are binary and only one of them can be equal to one (e.g., assignment of personnel). SOS of type 2 occur when transforming a separable-programming problem into an equivalent linear structure. Special computational approaches are used to simplify the handling of both types of SOS problems.

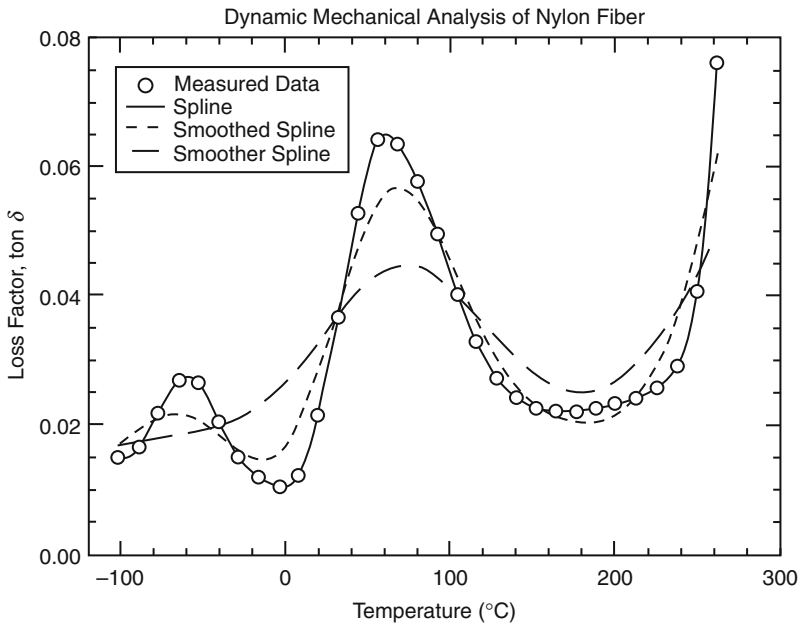
Splines

Sharon A. Johnson
Worcester Polytechnic Institute, Worcester, MA, USA

Introduction

Splines are an important class of mathematical functions used for approximation. A spline is a piecewise polynomial function that is commonly described as being "as smooth as it can be without reducing to a polynomial" (de Boor 2001). For example, the cubic spline shown as the solid line



Splines, Fig. 1 Spline approximations to data collected from a dynamic mechanical analysis of nylon fiber (courtesy of Monsanto Chemical Company)

in Fig. 1 is composed of individual cubic polynomials, each defined between two adjacent data points, such that the function values and first and second derivatives of adjoining polynomial pieces are the same. In general, a function defined on an interval $[a, b]$ is defined as a polynomial spline of degree k, having knots $t_1, \ldots, t_r$, if the following three conditions hold: (i) $a < t_1 < \ldots < t_r < b$, so the knots $t_1, \ldots, t_r$ partition the interval $[a, b]$ into $r + 1$ smaller subintervals, (ii) on each subinterval $[t_i, t_{i+1}]$, the spline is given by a polynomial function of at most degree k, and (iii) the spline and its derivatives up to order $k - 1$ are all continuous on $[a, b]$. The definition of splines is sometimes extended to allow the knots to be coincident (e.g., so that $t_i = t_{i+1}$), in which case the spline has less continuity at that knot (de Boor 2001). Recognition in the early 1960s that splines could mathematically model the physical process of drawing a smooth curve with a mechanical spline resulted in further investigation of their approximation and methods for computing them efficiently (Schumaker 2007).

The benefits of splines as approximating functions are discussed below, followed by an application to illustrate when spline approximation can be effective. The B-spline representation of a spline is then introduced. Finally, multivariate approximation is briefly addressed.

Splines as Approximating Functions

Scientists create mathematical models to describe a physical system or problem, then experiment with the model to draw conclusions about that system. Functions that relate decisions or independent variables to output or dependent variables form the basis of these models. While these underlying functions are sometimes known explicitly, they are often created by collecting discrete data about the system, then constructing an approximation to the unknown underlying response function. Suppose that the value of a function is measured at points $x_1, \ldots, x_n$, yielding values $f(x_1), \ldots, f(x_n)$. In interpolation problems, the goal is to find an approximating function $s(x)$ that passes through the points $f(x_1), \ldots, f(x_n)$, so that $s(x_i) = f(x_i)$. When the measured values $f(x_1), \ldots, f(x_n)$ contain errors, an approximating function $s(x)$ is created to balance the desire to obtain an approximation with smooth behavior and the desire to fit the data closely enough (Dierckx 1993). For example, the smoothing splines shown with dashed lines in Fig. 1 are constructed with a smoothing factor that allows deviations from the data (de Boor 2001); permitting larger deviations results in a cubic spline with a smaller second derivative. Broken curve regression can also be used (Seber and Wild 1989) to fit data with errors.

The data fitting problems described above are one major category of valuable approximation (Schumaker 2007). Other common approximation problems involve replacing a known function with one that is easy to compute, or estimating solutions to models involving differential equations, which can only be solved explicitly for simple cases.

Spline functions are effective approximations because they are relatively smooth, and splines of low degree usually provide an adequate fit with reasonable computational effort (Dierckx 1993). Every continuous function on an interval can be approximated arbitrarily well by a polynomial spline of a particular order, provided a sufficient number of knots are allowed. For example, adding more segments to a linear spline (a piecewise linear function) will better fit a curve. Low order splines are flexible and do not exhibit the oscillations usually associated with polynomials. The ease with which splines can be stored and evaluated on a computer makes them powerful for a variety of applications. Spline fitting routines are included in most general software libraries (e.g., the NAG subroutine libraries developed by the Numerical Algorithms Group, Inc., or the Spline Toolbox for MATLAB developed by Mathworks, Inc.).

An Application

The cost-to-go function $f_t(x_t)$ and optimal solution for a finite horizon dynamic programming problem can be found by solving the functional (optimality) equation:

$$f_t(x_t) = \max_{R_t} \{B_t(x_t, R_t) + E_{q_t}[f_{t+1}(x_{t+1})]\} \quad (1)$$

which in period t represents the expected benefit from operating the system from period t to the end of the horizon, given the system begins period t in state x_t. Such problems arise in managing inventory or planning water reservoir operations, where the state x_t would represent the amount in inventory or the volume of water in a reservoir. In stochastic problems, the system is subject to random influences q_t, such as uncertain demand or the inflow to a reservoir. In each period t, the decision r_t is made to maximize both the benefit B_t occurring from operation in the current period as well as expected future benefits $E_q[f_{t+1}]$. For example, the decision r_t might correspond to how much to produce or how much to release. The status of the system x_{t+1} at the end of each period t is determined by a transition function $g(x_t, q_t, r_t)$; for example, in inventory planning, g is $x_t + r_t - q_t$.

When the state vector x_t is continuous, the cost-to-go function f_t and policy r_t are often found by discretizing x_t and recursively solving (1) backward, for $t = T$ (the last time period) to $t = 1$. Because the function $f_{t+1}(x_{t+1})$ is only known at a finite number of points, interpolation can be used to generate a value when it is needed at other points. Using cubic splines to approximate the cost-to-go function can significantly reduce the effort required to solve such dynamic programming problems, particularly when the state vector is of high dimension, because of their accuracy relative to piecewise linear approximations (so fewer knots are needed) and because their smoothness allows efficient optimization methods to be used to find the decisions r_t (Johnson et al. 1993). Splines can also be applied to more general dynamic programming algorithms (Schweitzer and Seidmann 1985). They are also used extensively in computer-aided design and visualization, as well as in regression and statistical applications.

The B-Spline Representation

Any spline $s(x)$ of degree k can be written as a linear combination of B-splines $B_i(x)$:

$$s(x) = \sum_i a_i B_i(x),$$

where each B-spline $B_i(x)$ is a spline of degree k (de Boor 2001; Dierckx 1993). B-splines permit the efficient evaluation of a spline and its derivatives because they have local support, i.e., outside of a small range, they take the value of zero.

A particular spline is selected as an approximating function by choosing the degree k of the spline, the number and position of the knots t_i, and the coefficients a_i. Choosing the number and/or the position of the knots is often a matter of trial and error. Theory may suggest points in the data where the underlying model changes (Smith 1979). More knots should generally be placed in those regions where the underlying data change rapidly. Algorithms have been developed for some spline problems where the knot locations are

treated as parameters and optimized. Because the problem is nonlinear, the computational effort in these algorithms increases significantly as the number of knots increases (Dierckx 1993).

The conditions that determine the coefficients a_i of the spline depend on how closely the spline is expected to fit the data, the desired smoothness, and specified boundary conditions. In problems where the function underlying the data are known to have certain properties, such as convexity or monotonicity, it may be desirable to develop an approximation with the same properties constraining the coefficients a_i. Such shape-preserving approximations may also be beneficial because they prevent undesirable oscillations.

Multivariate Approximation

Tensor products are an efficient way to construct and evaluate multivariate approximations because they allow a multivariate problem to be solved as a series of one-dimensional problems (de Boor 2001). A bicubic spline constructed using tensor product methods would be a cubic spline in each coordinate direction. The major drawback of such splines is that they require the approximation domain to be a rectangle, or easily transformed to a rectangle (Dierckx 1993). In addition, constructing tensor product approximations is appropriate only when it makes sense to have preferred directions in the approximant. For example, a bicubic spline could efficiently approximate a peak that occurred along one axis. However, many knots would be required in each dimension if the peak occurred along a diagonal.

When tensor product methods are not appropriate, constructing multivariate spline approximations is much more complex and thus computationally less attractive. First, an appropriate partition of the data must be chosen. Next an appropriate set of basis functions (similar to B-splines) must be defined that permit efficient evaluation of the approximating function. Dierckx (1993) described two spline generalizations based on triangularizations of a surface. Chen et al. (1999) used multivariate adaptive regression splines to approximate functions in dynamic programming applications; computational effort is reduced by constructing the spline using discrete points determined by orthogonal array experimental designs.

Sports

Shaul P. Ladany
Ben-Gurion University of the Negev, Beer Sheva, Israel

Introduction

The history of the applications of quantitative methods and systems analysis to sports events is very much the history of systems analysis and its applications to many fields of human endeavor. For a thorough review of all the sports applications up to 1976, see Ladany and Machol (1977), while for the second half of the same two-pronged effort which culminated in invited research articles of the mid 1970s,

see Machol et al. (1976). A further review, incorporating most of the later applications, can be found in Gerchak (1994). In 2005 the *Journal of Quantitative Analysis in Sports* was established, publishing a wide range of relevant O.R. articles. A Special Issue of *Sports Management*, containing a variety of new O.R. sports papers, was edited by Ladany (2006). Many of the summaries incorporated here are based on the overview by Cochran (2008).

The first studies of sports were purely descriptive; the earliest such technical articles, on cricket, by Elderton (1909, 1927, 1945) and Wood (1945), are described in Pollard (1977). The application of sophisticated statistical analysis started with Mosteller (1952), who estimated the probability that the better team wins in the baseball World Series competition. The next stage was Mottley's (1954) suggestion that operations research could be profitably applied to sports, specifying football and basketball examples. Bona fide optimization applications followed when Howard (1960) and Bellman (1964) applied dynamic programming to baseball.

In line with the beginning, most of the studies were applied to team sports, initially dealing with issues of individual teams, later moving to organizational matters preoccupying leagues and associations. The applications to individual sports have been much fewer.

Team Sports

Baseball – Most of the studies were applied to baseball, a sport particularly suitable for OR approaches because the action occurs in discrete events, and because the state of the game is simple to specify. The benefit of the strategy of intentional walk and base-stealing was thoroughly investigated by Lindsey (1959, 1961, 1963, 1977). The best batting order was analyzed by Cook and Garner (1964); Cook and Fink (1972); Freeze (1975) and Peterson (1977), by Bukiet et al. (1997) using a Markov chain method, and finally by Sokol (2003) using a robust heuristic. A team's elimination from playoff consideration was explored by Robinson (1991). Persistence of racial discrimination was discussed by Kolpin and Singell (1993) using a game-theoretic model, and Anderson and Sharp (1997) used Data Envelopment Analysis to create an alternative to the traditional batting statistics. Brimberg and Hurley (2004) dealt with a decision problem, final offer arbitration applied to Major League Baseball players salary negotiation was addressed by Greenstein et al. (2004) and by Hannany et al. (2007); investigated whether the pitcher or the batter control home plate. The popular book that was made into a movie, *Moneyball* (Lewis 2003), highlighted the use of quantitative statistical methods in baseball in evaluating the total value of players.

Basketball – Based on analysis of playing statistics, players are classified by Ghosh and Steckel (1993) as filling distinct roles, providing guidelines for selecting draft choices and executing trades. Sinuany-Stern et al. (2006) applied the analytic hierarchy process for the evaluation of basketball teams, while Kvam and Sokol (2006) and Brown and Sokol (2010) used a logistic Regression/Markov chain model for NCAA basketball prediction.

Cricket – The decision whether to run when the batsman is next to strike, was analyzed by Clarke and Norman (1998a, b) using dynamic programming. A method for setting revised target scores at a match, which has been forcibly shortened, is described by Duckworth and Lewis (1998; Carter and Guthrie (2004) analyzed fairness and incentive in limited overs cricket matches, Barr and Kantor (2004) suggested a criterion for comparing and selecting batsmen, while Scarf and Shi (2005) modeled match outcomes and the setting of final innings target.

Football – The value of field position was investigated by Carter (a former National Football League quarterback) and Machol (1971, 1978). The value of a tie and extra-point strategy was analyzed by Porter (1967) and Bierman (1968). For the Australian rules football Clarke and Norman (1998a, b) suggested a new strategy for defending teams, using a dynamic programming model, while Tomecko and Filar (1998) analyzed player assignments using an analytic hierarchy process. Morrison and Kalwani (1993) analyzed the ability of field goal kickers, Bilder and Loughin (1998) investigated the probability of success for placekicks, Brimberg et al. (1999) discussed the punt returner location problem, Hurley (1998) derived optimal sequential decisions, Brimberg and Hurley (2006) have shown that championships are won based on the ability of a team to run and to defend the run, while Rosen and Wilson (2007) analyzed the defense first strategy in overtime games.

Hockey – The problem when to pull the goalie was considered by Morrison (1976); Morrison and Wheat (1986); Erkut (1987); Nydic and Weiss (1989), and Washburn (1991). League playoff strategies were analyzed by Monahan and Berger (1977); Thomas (2007) analyzed the time between goals, Cochran and Blackstock (2009) applied the Pythagoras model of the win/loss percentage and goals scored to the National Hockey League (NHL), Brimberg and Hurley (2009a, b) investigated whether NHL referees represent Markovian behavior and questioned the importance of the first goal in an NHL game.

Soccer – Rivett (1975) modeled the attendance at soccer matches and suggested changes in the organization of clubs. Shikata (1977) tried to analyze the motions of ball and players in a four-dimensional space. Mehrez et al. (1987) evaluated a new point system for the soccer leagues, while Mehrez and Hu (1995) constructed predictors for outcomes in the league, and Mosheiov (1998) used an integer program to the generalized knapsack problem to find the optimal "Dream Team." Hirotsu and Wright (2002) used a Markov model for optimal timing of substitution of players, and (2003) determined the best strategy for changing the configuration of a team. Hope (2003) investigated the conditions for firing a team manager, Wright and Hirotsu (2003) discussed the tactics and deterrents of fouls, McHale and Scarf (2007) modeled soccer matches, while Scarf and Shi (2008) measured the importance of a match in a tournament. In a sequence of articles, with psychological orientations, Bar-Eli et al. (2007) and Azar and Bar-Eli (2008) analyze the game between the goal keeper and the penalty kicker, from the view point of the goal keeper, while Bar-Eli and Azar (2009) treat it from the point of view of the kicker, the irrationality of the performances of the kickers and the goal keepers is investigated by Bar-Eli et al. (2009), and in Azar and Bar-Eli (2011) mixed-strategy Nash equilibrium model is used to predict the results of penalty kicks.

General League Issues – The problem of planning the schedule of the games for the entire season with the objective to minimize traveling distance and/or number of tours, under various constraints, was attacked – for various leagues – by Campbell and Chen (1976); Ball and Webster (1977); Bean and Birge (1980); Schreuder (1980, 1992); Ferland and Fleurent (1991); Russell and Leung (1994); Wright (1994); Kostuk (1997) developed a decision support system for elimination tournament scheduling. Andreu and Corominas (1989) scheduled the Olympic Games, Armstrong and Willis (1993) scheduled the Cricket World Cup, Costa (1995) used a tabu search algorithm to schedule the National Hockey League, Nemhauser and Trick (1998), Heinz (2001), and Voorhis (2002) dealt with college basketball scheduling, and Kendall (2007) scheduled an English soccer league over holiday periods. The related counterpart problem of scheduling umpires was considered by Evans (1988); Wright (1991), and Farmer et al. (2007) scheduled umpire crews for tennis tournaments. The optimal realignment of the teams in the National Football League to minimize total intradivisional travel is discussed by Saltzman and Bradford (1996) and Smith et al. (2006) optimized team travel in a basketball tournament. Horen and Riezman (1985) dealt with drawing methods for single elimination tournaments, Clarke and Allsiopp (2001) attempted scheduling cricket tournaments fairly, Fleurent and Ferland (1993) dealt with allocating games in the National Hockey League, analyzed the effects of home-away sequencing on the length of best-of-seven game playoff series, Smith et al. (2006) used bracket assignments for basketball and baseball tournaments, while Briskoin (2008) summarized the sports leagues scheduling models in a book.

Draft issues prevailing in North American professional sports were the subject of investigations by Price and Rao (1976); Brams and Straffin (1979).

The presence of streaks in baseball was analyzed and rejected by Tversky and Gilovich (1989), as well as by Albright (1992). The advantage of splitting a league into smaller leagues to lead to more pennant races was studied by Winston and Soni (1982). Finding the optimal location of a new arena using an analytic hierarchy process is discussed by Carlsson and Walden (1995).

The problem of ranking teams (and applicable also to individuals) has drawn considerable attention by researchers. Leake (1976) used electrical network theory, to rank football teams, while Wilson (1995) used a neural network approach. Ushakov (1976) presented a methodology for ranking participants playing in a round robin tournament like in chess. Applying the analytic hierarchy approach to predict the true strength of sport teams was discussed by Sinuany-Stern (1988) and by Takahashi (1990).

The effect of choosing different point values in ranked voting systems with scoring was analyzed, using a stochastic dominance analysis, by Stein et al. (1994). A system for selecting the best among a set of competing players or teams, that minimizes the number of rounds, was developed by Adler et al. (1994). Finally, Stefani (1999) provided a general taxonomy of sports rating systems.

The playing order to avoid dead finals and the calculation of premiership odds for the Australian Football League's final eight playoff was discussed by Clarke (1996), while the problem of fair assignment of season tickets was solved with mixed integer programming by Grandine (1998).

Evaluation of individual player performances were discussed by Fry et al. (2009); Terpstra and Schauer (2007), and by Alamar and Weinstein-Gould (2008), while entire teams were evaluated by Rosner (1976); Coleman and Lynch (2001); Martinich (2002); Horowitz (2004); Cassady et al. (2005); Coleman (2005); Baker and Scarf (2006), and by Rump (2008).

Individual Sports

Track and Field – The derivation of optimal training plans for pentathlon (applicable also to decathlon, triathlon, biathlon, etc.) was pioneered by Ladany (1975b) using linear programming with physiological constraints. Whether Bob Beamon's miracle jump in Mexico City was affected by the altitude was first analyzed by Brearley (1972). Related jump decision problems, such as aiming at take off, were studied by Ladany et al. (1975); Sphicas and Ladany (1976); Ladany and Singh (1978), and Mehrez and Ladany (1987). The tactical issues in pole-vaulting (which are similar to those prevailing in high-jump) for the selection of the optimal starting height were investigated by Ladany (1975a), and after change in the rules reinvestigated by Hersh and Ladany (1989) using dynamic programming. The sequential and competitive nature of several athletic events led to the coinage of the term games of boldness and to their analysis by Gerchak and Henig (1986); Henig and O'Neill (1992), and Gerchak and Kilgour (1992). Optimal assignments of runners (or swimmers) to relay teams, were put forward by Machol (1970) and Heffley (1977), advancing from the use of the simple deterministic assignment model to conditional and stochastic treatments. Strategy in fell running was analyzed by Hayes and Norman (1994); Friedman et al. (2006) and Mizrahi et al. (2006) developed a set of models for determining and analyzing the optimal threshold in athletic games.

Brimberg et al. (2006) analyzed the optimal allocation of effort among the stages in the triple jump, while Gerchack (2000) proposed a method applicable to decathlon and pentathlon scoring tables – for athletes rewards based on difficulty of achievements.

Optimization of the biomechanical aspects were investigated in various fields. The optimal angle to release a shot put or a hammer were discussed by Townend (1984). The influence of slope gradient on running uphill and the change of the optimal strategy with the slope were discussed by Davey et al. (1995).

Golf – The evaluation of the handicap system and its fairness occupied all researchers in the field, starting with Scheid (1972), and followed by Pollock (1974, 1977). Handicapping was applied also to other sports events; Camni and Grogan (1988) applied it to road-running races using frontier analysis.

Levy (1976) estimated a golfer's tournament score, while Hurley (2002) investigated the impact of the order of the golfers on the final day of the Ryder Cup matches.

Tennis – Analysis of the most important points was performed by Morris (1977); Gale (1971) investigated the optimal serving strategies, and justified the greater risk taken on the first serve. Norman (1985) applied dynamic programming to determine when to use a fast serve. Blackman and Casey (1980) suggested a player rating system.

Other Sports – Selection of teams for gymnastic competition was dealt with bivalent integer programming by Ellis and by Corn (1984) and by Eilon (1986). Optimal weight-lifting policies were derived by Lilien (1976). Oar arrangements in rowing eights to prevent fish-tail behavior were analyzed using the mechanical theory of moments by Brearley (1977). The unfairness of the existing scoring systems for jai-alai was evaluated using simulation by Hannan and by Smith (1981) and by Skiena (1988); Henig and O'Neill (1992) considered games where the player performing the hardest task wins, Larkey et al. (1997) investigated the importance of skill in games, Beis et al. (2006) described the use of O.R. to manage the 2006 Athens Olympic Games, Percy (2007)

analyzed the badminton scoring system, Scarf (2007) discussed the choice of the route in mountaineering, Scarf and Grehan (2005) evaluated the route choice in cycling.

Spreadsheets

Donald R. Plane[1] and Cliff T. Ragsdale[2]
[1]Rollins College, Winter Park, FL, USA
[2]Virginia Polytechnic Institute and State University, Blacksburg, VA, USA

Introduction

The electronic spreadsheet is a computer application that displays on a computer screen one or more worksheets. A worksheet is a rectangular grid of numeric and text information. The row and column organization of worksheets mimics many situations, such as an accountant's worksheet, a teacher's grade book, an invoice, or a scientist's data journal. Through the use of the computer keyboard and pointing device (mouse), the user is able to manipulate the information using mathematical, logical, and text operations. The worksheet is the foundation for graphs and reports designed to communicate information in a user-friendly manner.

The computer spreadsheet, operating primarily on personal computers, is a serious and powerful business tool. It is used for many applications including from printing address labels and developing simple budgets to conducting cash flow analysis, financial planning, optimizing investments, tracking production, forecasting, and facilities analysis.

VisiCalc, the first personal computer spreadsheet, was introduced in October, 1979 (Saffo 1989). Until then, the personal computer had been viewed more as a hobbyist's interest than as a serious office machine. Users soon began to realize that the electronic spreadsheet enabled them to change one or more numbers and immediately see the results of the changes in other parts of the worksheet. This capability was instrumental in causing the personal computer, with spreadsheet software, to become an important management tool. The 1982 introduction of Lotus Development Corporation's spreadsheet software called Lotus 1-2-3 marked the availability of a computer application that combined three functions (worksheet, graphics, and database) into software designed for the then new IBM personal computer. The electronic spreadsheet was a very important driving force in the development of the personal computer industry, with the dominant spreadsheet soon being Microsoft's Excel, surpassing Corel's Quattro Pro and IBM's Lotus 1-2-3. Apache OpenOffice (formerly under Sun, then Oracle) and Google Docs are alternatives offering free or inexpensive packages that provide basic spreadsheet functionality while lacking some more advanced features offered by more mature commercial products.

Example

A monthly budget demonstrates the organization of a worksheet and its basic capabilities. The columns of the worksheet show expenditures by monthly, while

Spreadsheets, Table 1 A simple budget spreadsheet

B7	= B2 + B3 + B4 + B5				
	A	B	C	D	E
1		Jan	Feb	Mar	Total
2	Food	220	230	300	750
3	Housing	400	400	400	1,200
4	Clothing	200	50	75	325
5	Entertainment	150	300	75	525
6					
7	Total	970	980	850	

the rows display expenditures by budget category. Totals are shown for each expenditure category and for each month. On a computer screen a very simple worksheet might appear as shown in Table 1. The worksheet columns are identified by letters; the rows are identified by numbers. Cells are identified by the column letter(s) followed by the row number. In Table 1, cell B7 (column B, row 7) contains the total expenditures for January.

The user can change any monthly expenditure item, and the spreadsheet will automatically recalculate the row and column totals. As the size and complexity of a worksheet grow, this ability to recalculate the entire spreadsheet rapidly and automatically replaces many hours of manual labor. Often, a worksheet contains many more columns and rows and the screen can display at one time. The mouse or keystrokes can be used to show any part of the worksheet on the screen.

Prior to the development of spreadsheets, a user wishing to solve a problem using a computer had to write a program using a very precise programming language, with each command, or statement, fed into the computer in a definite order. Such programs often had to be run several times to discover programming and logical errors before they could be used to solve a problem or prepare an analysis. Spreadsheets, on the other hand, allow users to enter spreadsheet cell information in any order and location on the worksheet, even if that organization does not mimic familiar manual computation procedures.

Basic Operations

Formulas, data, and text labels are entered from the keyboard. The formulas define the relationships and logic for each value calculated by the spreadsheet. Data values in various cells are used by the formulas. Text labels are important to users of the spreadsheet and users of reports generated by the spreadsheet. The formulas in a worksheet are the driving force behind a spreadsheet. In Table 1, cell B7 is selected to show its contents, which is the formula defining this cell:

$$= B2 + B3 + B4 + B5$$

where the cells B2, B3, B4, and B5 contain values for food, housing, clothing, and entertainment expenditures for January. Similar formulas are used for other calculated cells in the worksheet.

There are many aspects of modern electronic spreadsheets that enhance their usefulness to people not trained in computer programming. Among the more important:

(a) Formulas can be copied from one cell to another, without disturbing the logic of the formula. In the budget example, the formula for January total can be copied to corresponding cells for February and March.

(b) The worksheet can be organized in a way meaningful to the user, rather than in a way required by computational procedures. A user may elect to put monthly totals at the top, and category totals in another part of the worksheet, without regard to the fact that these values depend upon cells below and to the right. This may be contrary to the way one would manually calculate the budget, which might be column by column or row by row. This natural order of recalculation is intelligence within the program that frees the user from the procedural steps followed in computer programming.

(c) Reports can be printed by the spreadsheet. The spreadsheets available today provide substantial flexibility in formatting the report to meet the needs of the users. Most spreadsheets include spelling checkers to assist in report preparation. Spreadsheets also contain sophisticated formatting capabilities, allowing the user to change the appearance of the screen and report. The spreadsheet may permit the user to change many appearance items, including color, typeface, and character size. Reports can also include graphical images, lines, arrows, boxes, shading, and other visual enhancements often associated with desktop publishing.

(d) Graphs can be created from the numbers in or calculated by the spreadsheet. Graphs are an

integral and dynamic part of the spreadsheet, so that changes in the numbers on the worksheet also appear as changes in the graph. The graphs can be displayed on the screen as separate images, on paper, or as part of the spreadsheet. Modern spreadsheets allow small graphs (called sparklines) to be displayed in individual cells. By including a graphical image as a part of the spreadsheet screen display, the graph may become a part of a report. Some spreadsheets include tools to assist in a slide-show presentation of a sequence of screen images displaying tables, graphs, and text.

Capabilities

Spreadsheets can be used in many different ways, by users with a wide variety of skills. A beginning spreadsheet user may view a worksheet as a way of saving time that would otherwise be spent using a calculator. This capability of spreadsheets is likely the initial reason for their popularity. As spreadsheets have progressed, their capabilities have grown immensely. Some of the more important of these enhanced capabilities are:

(a) Spreadsheets may be linked to external database or websites so that data-intensive applications can be addressed in a spreadsheet environment. Needed information can be selectively retrieved from these data sources and used as inputs for spreadsheet models or summarized using graphs or cross tabulations using pivot tables.

(b) Extensive tools for statistical analysis are included in spreadsheets. Techniques such as regression analysis, correlation analysis, tests of significance, and analysis of variance are typically a part of a spreadsheet's capabilities.

(c) Mathematical capabilities required for engineering and scientific calculations are included in spreadsheets.

(d) Matrix operations (multiply, transpose, invert) can be performed using the commands of a spreadsheet.

(e) Extensive tools for financial analysis are included in spreadsheets.

(f) Optimization algorithms are a part of most spreadsheets. These optimizers, sometimes called Solvers, are capable of addressing linear and nonlinear constrained optimization problems with continuous or discrete decision variables. The method of communicating an optimization problem to a spreadsheet solver may be very different from the traditional methods used by OR/MS practitioners. Instead of formulating a problem as a set of equations and inequalities to be satisfied, the spreadsheet view of an optimization problem might be described by these steps:

1. Construct a model to evaluate or calculate the value of the objective, such as profit, for an arbitrary set of values for the decision variables. Include in the model the values that need to be checked to see if constraints have been exceeded. This includes limiting factors such as raw materials, production capacity, and human resources
2. Identify to the spreadsheet solver the components of the optimization problem:
   - Which cell computes the objective to be maximized or minimized;
   - Which cells are to be adjusted by the optimizer (the decision variables), and
   - Which cells are constraints, and what are the limiting values.
3. Issue the appropriate 'solve' command to the spreadsheet.

In this spreadsheet optimization environment, the spreadsheet is serving as a powerful problem generator, as an optimizing algorithm, and as a report generator to communicate the results of the optimization.

(g) Spreadsheet add-in software is available to expand spreadsheet capabilities in areas such as Monte Carlo risk analysis, optimization (including optimization with genetic algorithms), forecasting, data mining and analysis, and other applications involving neural networks.

(h) Spreadsheets may serve as the environment for developing sophisticated software. The capability to include macros or a set of procedures or steps to follow, gives the spreadsheet many of the structures of traditional programming languages, such as sequence, decision, loop, and case. The application programming interface (API) of spreadsheets can also be used by other programs to access spreadsheet functionality from outside the visible spreadsheet environment.

Concluding Remarks

Spreadsheets have become the primary computer application software for many business managers and other professionals. Many introductory OR/MS textbooks center on a spreadsheet-based approach to presenting the topics (e.g., Ragsdale 2010; Winston and Albright 2012). While this approach may (or may not) ignore the algorithmic and mathematical aspects of OR/MS, it presents the basic tools of the discipline in a user-friendly manner, using spreadsheets as a language that is more comfortable than mathematics to many potential users of OR/MS. This provides both opportunities and pitfalls. As more end-users are aware of the spreadsheet OR/MS tools, these tools will be applied more widely. But as the use expands, those using the tools will be less familiar with mathematics and assumptions behind the tools, leading to a new set of challenges.

Square Root Law

When a model result is proportional to the square root of input variables and/or parameters. One example is the formula that indicates that the average distance that an emergency unit must travel to a call scene is proportional to the square root of the area it services. Another example is the economic order quantity (EOQ) result from inventory modeling.

st or s.t.

Abbreviation: (i) "subject to" as in the linear-programming problem: Minimize $\boldsymbol{cX}$ st $\boldsymbol{Ax} = \boldsymbol{b}$, $\boldsymbol{x} \geq \boldsymbol{0}$. (ii) "such that" as in a mathematical statement: There exists a constant N s.t. for all $n > N \ldots$

St. Petersburg Paradox

Paradox that arises in a simple gambling game in which a fair coin is tossed repeatedly until a heads appears, at which point the payoff is \$2 doubled for each toss. Since the expected value of such a game is given by $(0.5)(2) + (0.5)^2(2)^2 + (0.5)^3(2)^3 + \ldots$, which is infinite, a decision maker who uses expectation to value the game would assign an infinite value. The concepts of utility and risk can be used to resolve this apparent paradox.

Stages

The set of sequential steps in a model for either (i) probability distributions, or (ii) dynamic programming. In applied probability models, especially queueing, such modeling allows

non-exponentially distributed random variables such as interarrival and service times to be represented as a sequence of exponentially distributed random variables, each of which is referred to as a stage, thus enabling the system to be modeled by a Markov chain. If there are k stages that are independent and identically distributed, the resulting distribution is called a k-Erlang distribution, represented as E_k in Kendall's queueing notation; if the stages are only independent, the distribution is called a generalized Erlang; further extensions lead to Coxian and phase-type distributions. In dynamic programming, stages are the time subdivisions of a dynamic programming model where decisions are made upon which the state then evolves to the next state; also called periods.

Staircase Structure

A linear-programming problem in which the constraint set can be arranged into connecting blocks such that the first block is connected to the second block by a few variables, the second block is connected to the third block by a few variables, and so on. Staircase structures arise in production problems over time in which the connecting variables are inventories that carry over from one time period to the next. The matrix of coefficients defined by such structures is very sparse.

Stationary Distribution

In a discrete-time Markov chain, the state probability distribution (vector) $\boldsymbol{\pi}$ that satisfies $\boldsymbol{\pi} = \boldsymbol{\pi}\boldsymbol{P}$, where $\boldsymbol{P}$ is the single-step transition matrix. Mathematically, this is equivalent to finding the eigenvector associated with the eigenvalue 1 of the stochastic matrix $\boldsymbol{P}$. Similarly, for a continuous-time Markov chain, the stationary distribution satisfies $\boldsymbol{\pi}\boldsymbol{Q} = \boldsymbol{0}$, where $\boldsymbol{Q}$ is the transition rate matrix. Also known as the invariant distribution. If the Markov chain is ergodic, it has a limiting (or steady-state) distribution that equals the stationary distribution.

Stationary Stochastic Process

A stochastic process in which the state probability distributions are invariant over time.

Stationary Transition Probabilities

When the transition probabilities of a Markov chain or Markov process are time-invariant, i.e., for times $s < t$ in the time domain T, and any state x and any set A in the state space, $\Pr\{X(t) \in A | X(s) = x\} = \Pr\{X(t-s) \in A | X(0) = x\}$.

See

- ▶ Markov Chains
- ▶ Markov Processes

Statistical Equilibrium

Let $p_{ij}(t)$ be the probability that a stochastic process takes on value j at time t (discrete or continuous), given that it began at time 0 from state i. If for each j, $p_{ij}(t)$ approaches a limit p_j independent of i by taking $t \to \infty$, then the process is said to reach statistical equilibrium. For an ergodic Markov chain in statistical equilibrium, the corresponding limiting distribution is identical to the stationary distribution.

Statistical Ranking and Selection

Seong-Hee Kim
Georgia Institute of Technology, Atlanta, GA, USA

Introduction

Ranking and selection (R&S) procedures are statistical tools for selecting the best system among a finite number of simulated systems. Depending on the definition of the best, there exist at least four classes of R&S problems in simulation studies: selecting the system with the largest or smallest expected performance measure (selection of the best); finding systems whose performance measures are significantly better than a standard and, if there is any, selecting the one with the largest or smallest performance (comparison with a standard); selecting the system with the largest probability of actually being the best performer (multinomial selection); and selecting the system with the largest probability of success (Bernoulli selection).

Approaches to solve R&S problems include subset selection methods, indifference-zone methods, Bayesian methods, and optimal computing budget allocation (OCBA). Subset selection and indifference-zone (IZ) methods find the best system with a guarantee on the probability of correct selection (PCS), whereas the other two methods maximize the PCS under a limited computational budget. The focus here will be on procedures for the selection-of-the-best problem with a guarantee on the PCS. Other classes of R&S problems are briefly discussed in the concluding section; see Chick (2006) for a review of Bayesian and OCBA methods.

Development of efficient R&S procedures has led to combining these procedures with optimization via simulation (OvS) algorithms, so some R&S procedures related to OvS are discussed. R&S procedures can be applied to "clean up" at the end of an OvS search, finding the best among all the solutions actually simulated so far by the search with a statistical guarantee, or they can be embedded within these OvS algorithms to help them move to the improving direction correctly and efficiently.

Also discussed in more detail is a more complicated form of R&S, namely constrained R&S, where the goal is to find the best system under a primary performance measure while also satisfying stochastic constraints on secondary performance measures. For example, the decision maker may want to select a production schedule for a manufacturing system that yields the largest expected throughput among a number of different schedules, while keeping the expected lead time in the system bounded (smaller than or equal to some constant) at the same time.

Problem Setting

Let X_{im} denote the mth observation from system $i (i = 1, 2, \ldots, k)$. The set of all possible systems is defined as $S = \{1 \ldots, k\}$. Let $x_i = E[X_{im}]$ and $\sigma_i^2 = Var[X_{im}]$ be the mean and variance of the outputs from system i, respectively.

The problem is to determine which system has the best performance measure:

$$\arg\max_{i \in S} x_i.$$

Without loss of generality, assume that $x_k \geq x_{k-1} \geq \cdots \geq x_1$, so that (unknown to the decision maker) system k is the best system. Moreover, the $\{X_{im}\}$ are assumed to satisfy the following assumptions.

Assumption 1. *For each* $i = 1,2,\ldots,k$,

$$X_{im} \overset{iid}{\sim} \mathcal{N}\left(x_i, \sigma_i^2\right) \; m = 1, 2, \ldots$$

Where $\overset{iid}{\sim}$ *denotes independent and identically distributed (iid) and* $\mathcal{N}(\mu, \sigma^2)$ *denotes the normal distribution with mean* μ *and variance* σ^2.

Assumption 1 is a common assumption in many R&S procedures. When the outputs from system i (X_{i1}, X_{i2},...) are either within-replication averages or batch means from a single sufficiently long replication after accounting for the elimination of the initialization bias, the iid normality assumption is reasonable (Law and Kelton 2000).

Assumption 2. *For* $(i,m) \neq (j,m')$, X_{im} *and* $X_{jm'}$ *are independent*.

Assumption 2 implies that all systems are simulated independently. Assigning different streams of pseudo-random numbers to the simulation of each system ensures independence of systems. Procedures that require this assumption for statistical validity are reviewed in the next section, while the subsection on common random numbers reviews procedures that do not need the independence assumption.

For the selection of the best, two approaches are considered: subset selection and IZ approaches. Gupta (1965) presented the subset selection formulation of the problem, and Bechhofer (1954) established the IZ formulation.

The subset selection procedures use outputs available for each system to obtain a subset $I \subseteq \{1, 2, \ldots, k\}$ such that

$$\Pr\{k \in I\} \geq 1 - \alpha \tag{1}$$

where $1/k<1-\alpha<1$.

On the other hand, the IZ approach suggested by Bechhofer (1954) attempts to find the single best system k whose mean is at least a user-specified amount better than the means of the other systems with a guarantee on PCS. The IZ parameter is denoted as δ, a practically significant difference worth detecting. Specifically, the IZ procedure should guarantee

$$\Pr\{\text{select } k | x_k - x_{k-1} \geq \delta\} \geq 1 - \alpha \tag{2}$$

where $1/k<1-\alpha<1$. If there are systems whose means are within δ of the best, then the decision maker is indifferent to which of these is selected.

Other notation is defined as follows:

n_0 = first-stage sample size

n_i = sample size available for system i

$\bar{X}_i(n)$ = sample average of n observations of system i, i.e., $\frac{1}{n}\sum_{m=1}^{n} X_{im}$

$S^2_{x_i}(n)$ = sample variance of $\{X_{i1}, \ldots, X_{in}\}$

$S^2_{x_{ij}}(n)$ = sample variance of $\{X_{i1} - X_{j1}, \ldots, X_{in} - X_{jn}\}$

$R(r;v,w,z) = \max\left\{0, \frac{wz}{v} - \frac{v}{2}r\right\}$, for $v,w,z \in \mathbb{R}^+, v \neq 0$

Finding the Best

A few illustrative procedures for the selection-of-the-best problem are provided in this section: one from the subset selection approach and two from the IZ approach.

Subset Selection

Suppose that a number of samples are already available for each system. A subset selection procedure returns a subset that contains the best system with probability at least $1 - \alpha$. A single-stage subset selection procedure that allows for unequal and unknown variances across systems was developed by Nelson et al. (2001), with a generalization that also permits unequal sample sizes presented below.

Extended Screen-to-the-Best Procedure (Boesel et al. 2003)

1. Select the overall desired confidence level $1 - \alpha$ and sample size n_i for system i, $i = 1,2,\ldots,k$. Set $t_i = t_{\frac{1}{(1-\alpha)^{\frac{1}{k-1}}}, n_i - 1}$, where $t_{\beta,\nu}$ is the β quantile of the t distribution with ν degrees of freedom.
2. Obtain n_i outputs $X_{im}(m = 1, 2, \ldots, n_i)$ from each system $i(i = 1, 2, \ldots, k)$.

3. Compute the sample means and variances $\bar{X}_i(N_i)$ and $S^2_{x_i}(n_i)$ for $i = 1,2,\ldots,k$. Let

$$W_{ij} = \left(\frac{t_i^2 S^2_{x_i}(n_i)}{n_i} + \frac{t_j^2 S^2_{x_j}(n_j)}{n_j}\right)^{\frac{1}{2}}, \forall i \neq j.$$

4. Set $I = \{i : 1 \leq i \leq k \text{ and } \bar{X}_i(n_i) \geq \bar{X}_j(n_j) - W_{ij}, \forall j \neq i\}$.
5. Return I as the subset of retained systems.

The above procedure satisfies (1) under Assumptions 1 and 2, and is incorporated into the output analysis package of the simulation software Arena (Rockwell Software). A disadvantage of this procedure is that the size of I is unknown and can be as large as k, but no procedure can guarantee a subset of size one and simultaneously satisfy (1) for arbitrary n_i. The next subsection discusses procedures that return one single system which is likely to be the best or near-best.

Indifference-Zone Procedures

In stochastic simulation, it is impossible to find the true best with certainty when the sample size is finite. Instead many procedures employ the IZ approach as a compromise. The IZ approach guarantees (2), finding the best with high probability whenever the best is at least δ amount better than the means of the other systems. Many IZ procedures are sequential with multiple stages. For example, Rinott's procedure (1978) has two stages. In the first stage, the procedure obtains initial samples for each system and pauses sampling to calculate some statistics (usually sample means and variances). Then it resumes sampling to obtain additional samples for each system in the second stage.

Classical IZ procedures become inefficient when the number of alternatives is large, because they are developed under the Least Favorable Configuration (LFC) condition. If a procedure guarantees at least $1 - \alpha$ PCS under the LFC, it will do so for all other configurations. The Slippage Configuration (SC) is the configuration $\mu_i = \mu_k - \delta$ for all $i \neq k$, which is known to be the LFC in most IZ procedures. When the number of systems is large, it is unlikely that systems face the SC, as means of the systems tend to be spread out rather than all clustered near the best. Thus, a procedure developed under the SC takes more samples than needed when actual differences are greater than δ.

To overcome the inefficiency of IZ procedures, screening is used. The idea is to identify clearly inferior systems after some initial samples and eliminate them from further consideration early. Combining subset selection algorithms with two-stage IZ procedures, the NSGS procedure due to Nelson et al. (2001) ensures the overall PCS $1 - \alpha$ by decomposing the overall error α into α_0 and α_1, and use the decomposed errors for setting up procedure parameters for an initial screening stage and a second ranking stage, respectively.

Procedure NSGS (Nelson et al. 2001)

1. *Setup*. Select the overall desired confidence level $1 - \alpha$, IZ parameter δ, and common first-stage size $n_0 \geq 2$. Set

$$t = t_{1-(1-\alpha/2)^{\frac{1}{k-1}}, n_0-1}$$

and obtain Rinott's constant $h = h(n_0, k, 1 - \alpha/2)$ from Table 8.3 in Goldsman and Nelson (1998).
2. *Initialization*. Obtain n_0 outputs $X_{im}(m = 1, 2, \ldots, n_0)$ from each system $i(i = 1, 2, \ldots, k)$. Calculate $S^2_{x_i}(n_0)$ for $i = 1, 2, \ldots, k$.
3. *Subset Selection*. Calculate the quantity

$$W_{ij} = t\left(\frac{S^2_{x_i}(n_0) + S^2_{x_j}(n_0)}{n_0}\right)^{1/2}, \forall i \neq j.$$

Form the screening subset I, containing every alternative i such that $1 \leq i \leq k$ and

$$\bar{X}_i(n_0) \geq \bar{X}_j(n_0) - \max\{0, W_{ij} - \delta\}$$
for all $j \neq i$.

4. *Ranking*. If $|I| = 1$, then stop and return the system in I as the best. Otherwise, for all $i \in I$, calculate the second-stage sample sizes

$$N_i = \max\left\{n_0, \left\lceil\frac{hS_{x_i}(n_0)}{\delta}\right\rceil^2\right\},$$

where $\lceil\cdot\rceil$ is the ceiling function.

5. Take $N_i - n_0$ additional outputs from all systems $i \in I$.
6. Calculate the overall sample means $\bar{X}_i(N_i)$ for all $i \in I$. Select the system with the largest $\bar{X}_i(N_i)$ as best.

Note that NSGS has two stages and screens out systems only once after the first stage. There are fully sequential procedures that take a single basic observation from each alternative still in play at each stage and eliminate systems from further consideration when it is statistically clear that they are inferior. The KN procedure (Kim and Nelson 2001) is a fully sequential procedure that allows for unequal and unknown variances across systems, useful in simulation environments.

Both NSGS and KN are statistically valid guaranteeing (2) under Assumptions 1 and 2. Also, they have been shown to be efficient when hundreds of systems (up to 500) are compared. Note that $R(r; \cdot)$ in KN defines a triangular continuation region for the partial sum process, $\sum_{m=1}^{r}(X_{im} - X_{jm})$. As long as the partial sum process stays within the triangular continuation region, sampling for systems i and j continues. Otherwise, an elimination decision is made. A different shape of continuation regions can be used. For example, Batur and Kim (2006) present fully sequential procedures with a parabolic continuation region, which show a meaningful improvement over the triangular continuation region.

Procedure KN (Kim and Nelson 2001)

1. *Setup*. Select the overall desired confidence level $1 - \alpha$, IZ parameter δ and common first-stage sample size $n_0 \geq 2$. Set

$$\eta = \frac{1}{2}\left[\left(\frac{2\alpha}{k-1}\right)^{-2/(n_0-1)} - 1\right].$$

2. *Initialization*. Let $I = \{1, 2, \ldots, k\}$ be the set of systems still in contention, and let $h^2 = \eta(n_0 - 1)$.
   Obtain n_0 outputs $X_{im}(m = 1, 2, \ldots, n_0)$ from each system $i(i = 1, 2, \ldots, k)$.
   For all $i \neq j$ calculate $S^2_{x_{ij}}(n_0)$, the sample variance of the difference between systems i and j. Set $r = n_0$.
3. *Screening*. Set $I^{\text{old}} = I$. Let

$$I = \left\{ i : i \in I^{\text{old}} \text{ and } \sum_{m=1}^{r}(X_{im} - X_{jm}) \geq -R\left(r; \delta, h^2, S^2_{x_{ij}}(n_0)\right), \forall j \in I^{\text{old}}, j \neq i \right\}.$$

4. *Stopping Rule*. If $|I| = 1$, then stop and select the system whose index is in I as the best. Otherwise, take one additional output $X_{i,r+1}$ from each system $i \in I$, set $r = r + 1$ and go to *Screening*.

Typically, KN reaches a decision faster than NSGS with fewer number of observations. However, KN tends to require a large number of switches from simulating one system to simulating another, whereas NSGS needs at most $2k - 1$ switches. The cost of stopping and restarting complex simulations can be quite high both in time and storage. In modern computing environments that utilize parallel computing, the switching cost is less of an issue, making KN attractive. The KN procedure is incorporated into the output analysis package of Simio® (Simio LLC).

Some subset selection and IZ procedures are closely related to multiple comparison procedures. For detailed discussion for the connection to the multiple comparison procedures, see Kim and Nelson (2006b).

Efficiency

There are a number of ways to further enhance efficiency of procedures discussed in the previous section.

Common Random Numbers

Many procedures require Assumption 2 that systems are simulated independently. If the same random number streams are assigned to each simulation known as common random numbers (CRN), then under fairly general conditions, positive correlation is induced among the systems, and the variance of the

difference is decreased in observed average performances between two systems. Although CRN makes statistical procedures more complicated when there are more than two systems, CRN makes comparison sharper, meaning spending fewer number of observations until a decision is made.

For subset selection procedures, a special case of the Extended Screen-to-the-Best procedure where $n_i = n$ for all i remains valid under CRN (Nelson et al. 2001) provided $S^2_{x_i}(n)/n + S^2_{x_j}(n)/n$ is replaced by $S^2_{x_{ij}}(n)/n$ and $t = t_{1-\alpha/(k-1),n-1}$. For unequal sample sizes n_i, the statistical validity of the Extended Screen-to-the-Best procedure does not hold under CRN.

For IZ procedures, the procedure of Nelson and Matejcik (1995) extended Rinott's two-stage procedure. Their procedure works in conjunction with CRN under a special structure of the variance-covariance matrix, called sphericity. As the sphericity assumption is often violated for large k, the use of CRN is not recommended in Nelson and Metejcik's procedure when k is large. NSGS requires systems to be simulated independently, whereas KN is statistically valid with or without CRN.

Steady-State Simulations

The R&S procedures discussed so far require Assumption 1, which is appropriate for terminating simulations. In steady-state simulation, the goal is to estimate long-run performance, after the impact of the initial conditions have vanished. The iid normality assumption applies to steady-state simulation experiments if the experimenter is willing to make multiple replications of each system with a good warm up and use the within-replication averages as the basic observations. Or the experimenter can generate a single long replication of each system to avoid estimation bias due to residual effects of the initial conditions. The difficulty in a single-replication design is that the raw outputs within a replication (such as waiting times of individual customers in a queueing system) are typically neither normally distributed nor independent. In order to achieve the iid normality, one can take batch means of many individual raw outputs as the basic observations when only a single replication is made. Then, batch means are approximately iid normal for a large enough batch size. See Law and Kelton (2000) for a more detailed discussion of replication versus batching in steady-state simulation.

Both of these remedies for dependent data are inefficient. Multiple replications require warm up from each replication and may result in deletion of a large number of outputs; and batching within a replication forces selection procedures to make elimination and selection decisions at long intervals. This is especially undesirable for fully sequential procedures where elimination occurs every basic observation. Thus, procedures that take the raw outputs within a single replication as basic observations are desirable for steady-state simulation.

A few procedures have been presented specifically for steady-state simulation that make a single replication from each system and take raw outputs rather than batch means as basic observations (e.g., Damerdji and Nakayama 1999; Goldsman et al. 2002; Kim and Nelson 2006a). One of the asymptotically valid procedures, called KN++ (Kim and Nelson 2006a), updates variance estimates as more observations are available. Variance update is shown to improve efficiency of the procedures greatly, although it may cause some technical and computational difficulties such as data storage and recalculation of estimates.

Slippage Configuration

Screening, the use of CRN when applicable, the use of raw outputs rather than within-replication averages or batch means in steady-state simulation, and variance update greatly improve the efficiency of IZ procedures. Unfortunately, the actual PCS of many IZ procedures tends to be close to 100%, i.e., overly conservative, for large k even with all these amendments, which implies that there is room for further improvement.

As discussed earlier, because IZ procedures are derived under the LFC (i.e., the SC), they are generally very conservative. The SC is essential in deriving statistically valid IZ procedures, because it frees the procedures from dependence on the unknown true differences among the means. A remedy to the SC is to replace the IZ parameter with estimated mean differences based on the first-stage samples, e.g., by adjusting the IZ parameter for system i to $\delta_i \equiv \max(\delta, \bar{X}_i(n_0) - \bar{X}_b(n_0))$, where b is the identity of a system with the largest first-stage sample

mean (Chen and Kelton 2005). Then use the adjusted IZ parameter to calculate the total number of observations N_i for each system i in a two-stage procedure such as Rinott's procedure. A similar technique can be used for fully sequential procedures by adjusting the IZ parameter between system i and j to $\delta_{ij} \equiv \max\left(\delta, |\bar{X}_i(n_0) - \bar{X}_j(n_0)|\right)$ (Healey 2010; Wang and Kim 2013). The adjusted IZ parameter δ_{ij} is used to calculate $R(r;\cdot)$ when comparing systems i and j. These modifications allow the procedures to make decisions quicker but at the cost of statistical validity and observed PCS.

R&S in Optimization

The procedures discussed in previous sections require keeping or running simulation models of all systems. When the number of alternative systems is extremely large, it may not be possible to keep simulation models of all systems, and thus those R&S procedures become inappropriate. Instead, a different class of methods, called optimization via simulation (OvS), is needed; for overviews, see Andradóttir (2006) and Fu (2006).

R&S procedures can assist OvS in two ways: clean-up at the end of the search or efficient and correct selection of the best neighbor.

Clean up: Commercial add-on products for simulation software packages employ a combination of heuristic optimization methods (genetic algorithms, tabu search, etc.) originally developed for a deterministic optimization problem. Each alternative is evaluated by a simulation model through a number of replications and sampling error is ignored. As results, heuristic algorithms give no statistical meaningful estimates and provide no information about how close the chosen system is to the true best. To add statistical confidence, a R&S procedure can be employed to ensure that the selected system is the best or near-best of all systems that the search actually did encounter. The number of systems to compare (all those encountered by the search) is large, and they may not have been simulated equally, so a procedure should be able to handle unequal sample sizes. Nelson et al. (2001) provide a revised version of the NGSG procedure, the Group-Screening procedure, in which one can avoid simulating all the systems simultaneously. Boesel et al. (2003) extend the Group-Screening procedure to account for unequal sample sizes to "clean up" after the search is done. Sequential Selection with Memory (SSM), an extension of the KN procedure that uses partial or complete information on systems previously visited, was developed by Pichitlamken et al. (2006), and is used in the commercial product OptQuest (OptTek Systems, Inc.).

Selection of the promising neighbor: Some OvS algorithms require the selection of the best neighbor from a finite number of alternatives. For example, the nested partitions (NP) method (Shi and Ólafsson 2000) and the convergent optimization via most-promising-area stochastic search (COMPASS) (Hong and Nelson 2006) repeat search iterations where a number of candidate solutions are sampled, their performances are evaluated through a number of replications, and the best neighbor is selected. In stochastic simulation, sampling error dramatically complicates selecting the best neighbor. To select the best neighbor confidently, a large number of replications for performance evaluation is needed. But then too much computational effort on the selection hinders the search to make much progress in the time available. Thus, the efficient and correct selection of the best neighbor is critical to the overall performance of an optimization algorithm in stochastic simulation. Pichitlamken and Nelson (2003) use SSM for selection of the best neighbor within their OvS algorithm and show that the use of SSM indeed enhances the overall performance of the algorithm.

Constrained R&S

Due to physical or managerial limits placed on a system, performance measures other than the primary performance measure often need to be considered. To handle multiple performance measures, one can formulate the problem as a multi-objective problem (e.g., Butler et al. 2001) or place constraints on secondary performance measures. The latter approach forms constrained R&S, for which a fully sequential IZ approach developed by Andradóttir and Kim (2010) is presented in this section, including both the feasibility check of multiple secondary performance measures and the comparison of primary performance measures.

Let $x_i = \mathrm{E}[X_{im}]$ and $y_{i\ell} = \mathrm{E}[Y_{i\ell m}]$ be the expected values of the primary and secondary constrained

performance measures for each system $i \in S$ and constraints $\ell = 1, \ldots, s$. The objective is to select a system with the best primary performance measure while satisfying all of the constraints:

$$\arg\max_{i \in S} x_i$$
$$\text{s.t. } y_{i\ell} \le q_\ell \text{ for all } \ell = 1, \ldots, s.$$

Similar to Assumption 1, the following assumption is needed.

Assumption 3. For each $i = 1,2,\ldots,k$,

$$\begin{bmatrix} X_{im} \\ Y_{i1m} \\ \vdots \\ Y_{ism} \end{bmatrix} \overset{iid}{\sim} \mathcal{MN}\left(\begin{bmatrix} x_i \\ y_{i1} \\ \vdots \\ y_{is} \end{bmatrix}, \Sigma_i \right), \; m = 1, 2, \ldots$$

where $\mathcal{MN}$ denotes the multivariate normal distribution and Σ_i is the $(s+1) \times (s+1)$ covariance matrix of the vector $(X_{im}, Y_{i1m}, \ldots, Y_{ism})$.

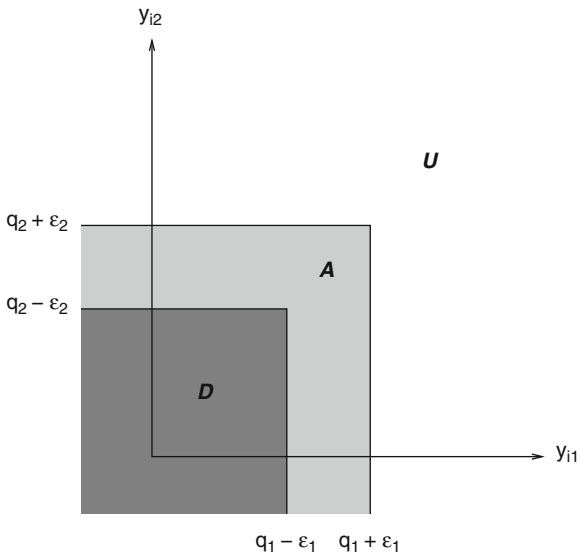
For the primary performance measure, δ still denotes the IZ parameter. The decision maker is essentially indifferent among the feasible systems whose primary performance measures are within δ of each other.

For the secondary performance measures, the smallest significant distance is ε_ℓ, called the tolerance level associated with the constraint ℓ. Systems fall into one of the following three categories for the constraints:

- Any system with $y_{i\ell} \le q_\ell - \varepsilon_\ell$ for all $\ell = 1, \ldots, s$ is considered desirable. The set of all desirable systems is denoted S_D.
- Systems that have at least one mean secondary performance measure greater than $q_\ell + \varepsilon_\ell$ (i.e., $y_{i\ell} \ge q_\ell + \varepsilon_\ell$ for some ℓ) are unacceptable and infeasible, placing them in the set S_U.
- Systems that fall within the tolerance level of q_ℓ for some ℓ, so that $q_\ell - \varepsilon_\ell < y_{i\ell} < q_\ell + \varepsilon_\ell$, and below the tolerance level for the remaining constraints are acceptable and they are placed in the set S_A.

Figure 1 shows the desirable (D), acceptable (A), and unacceptable (U) regions in terms of q_ℓ and ε_ℓ for $\ell = 1,2$ when there are two stochastic constraints.

Let $[b]$ be the index of the best desirable system. In constrained R&S, a CS event is defined as the event



Statistical Ranking and Selection, Fig. 1 D Desirable, A acceptable, and U unacceptable regions when there are two stochastic constraints

that a desirable or acceptable system is selected whose mean is greater than $x_{[b]} - \delta$. The procedures seek to guarantee

$$\Pr\left\{\text{select } i \in S_D \cup S_A \text{ with } x_i > x_{[b]} - \delta\right\} \ge 1 - \alpha. \tag{3}$$

Constrained R&S requires feasibility check of multiple secondary performance measures and selection of the best feasible system. First, some further notation must be introduced (where superscripted "T" denotes the vector transpose):

$$\mathbf{Y}_{im} = (Y_{i1m}, Y_{i2m}, \ldots, Y_{ism})^T;$$
$$\boldsymbol{\varepsilon} = (\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_s)^T, \varepsilon_\ell \in \mathbb{R}^+ \text{for } \ell = 1, \ldots, s;$$
$$\mathbf{q} = (q_1, q_2, \ldots, q_s)^T, q_\ell \in \mathbb{R} \text{ for } \ell = 1, \ldots, s;$$
$$\boldsymbol{a} = (a_1, a_2, \ldots, a_s)^T, a_\ell \in \mathbb{R}^+ \text{for } \ell = 1, \ldots, s;$$
$$Y^a_{im} = \boldsymbol{a}^T \mathbf{Y}_{im};$$
$$\varepsilon^a = \boldsymbol{a}^T \boldsymbol{\varepsilon};$$
$$q^a = \boldsymbol{a}^T \mathbf{q};$$
$$S^2_{y_{i\ell}}(n) = \text{sample variance of} \{Y_{i\ell 1}, \ldots, Y_{i\ell n}\}$$
for the ℓth constraint of system i;
$$S^2_{y^a_i}(n) = \text{sample variance of} \left\{Y^a_{i1}, \ldots, Y^a_{in}\right\}.$$

Feasibility Check

To solve constrained R&S, feasibility check procedures are necessary that find a set F such that $S_D \subseteq F \subseteq (S_D \cup S_A)$ with a pre-specified probability, say $1 - \alpha_0$. Andradóttir and Kim (2010) developed an IZ procedure for feasibility check in the presence of one stochastic constraint, which was extended to multiple stochastic constraints by Batur and Kim (2010) using the Bonferroni inequality, which makes the procedure conservative for large k and s. To lessen the conservativeness, they introduce an accelerated feasibility check which features an artificial constraint in addition to original s constraints. The artificial constraint is obtained by aggregation (or linear combination) of all secondary performance measures $\mathbf{Y}_{im}^a$, the aggregated tolerance level ε^a, and the aggregated target value q^a.

This aggregate constraint adds some complexity, but can quickly eliminate systems that violate multiple constraints. The aggregate constraint should be used only for making infeasibility decisions and not for making a feasibility determination. The accelerated feasibility check procedure with aggregation (F_A) keeps M, the set of systems whose feasibility is yet to be determined, F, the set of systems found feasible, K_i, the set of constraints found feasible for system i, and A, the set of systems whose feasibility needs to be checked by the aggregate constraint. The F_A procedure continues samplings for any system in M and declares system i to be feasible if all constraints are found feasible (i.e., $|K_i| = s$).

Procedure F_A (Batur and Kim 2010)

1. *Setup*. Choose the overall desired confidence level $1 - \alpha_0$, vector of tolerance levels $\boldsymbol{\varepsilon}$, and first stage sample size $n_0 \geq 2$. Compute ε^a and q^a where $\boldsymbol{a} = [a_\ell]_{\ell=1,2,\ldots,s}$ such that $a_\ell = \prod_{v=1,v\neq\ell}^{s} \varepsilon_v$. Set $\eta = \frac{1}{2}\left[(2\beta)^{-2/(n_0-1)} - 1\right]$.
2. *Initialization*. Let $M = \{1, 2, \ldots, k\}$, $F = \emptyset$, $A = S$, and $K_i = \emptyset$, $i = 1,2,\ldots,k$. Set $h^2 = \eta(n_0 - 1)$. Obtain observations $\mathbf{Y}_{im}$ and compute Y_{im}^a, $m = 1,2,\ldots,n_0$, from each system i. For each system i and constraint $\ell = 1,2,\ldots,s$, compute the sample variance $S_{y_{i\ell}}^2(n_0)$ and $S_{y_i^a}^2(n_0)$. Set the number of observations $r = n_0$ and go to *Feasibility Check*.
3. *Feasibility Check*. For each $i \in M$ and any $\ell \notin K_i$, $\ell = 1,2,\ldots,s$, if

$$\sum_{m=1}^{r} (Y_{i\ell m} - q_\ell) \geq +R\left(r; \varepsilon_\ell, h^2, S_{y_{i\ell}}^2(n_0)\right),$$

then eliminate i from M; else if

$$\sum_{m=1}^{r} (Y_{i\ell m} - q_\ell) \leq -R\left(r; \varepsilon_\ell, h^2, S_{y_{i\ell}}^2(n_0)\right),$$

then add ℓ to K_i. For each $i \in M$, if $|K_i| = s$, then move i from M to F.
For each system $i \in M \cap A$, if

$$\sum_{m=1}^{r} \left(Y_{im}^a - q^a\right) \geq +R\left(r; \varepsilon^a, h^2, S_{y_i^a}^2(n_0)\right),$$

then eliminate i from M and A. For $i \in M \cap A$ with

$$\sum_{m=1}^{r} \left(Y_{im}^a - q^a\right) \leq -R\left(r; \varepsilon^a, h^2, S_{y_i^a}^2(n_0)\right),$$

remove i from A.
4. *Stopping Rule*. If $|M| = 0$, then return F as a set of feasible systems. Otherwise, take one additional observation $Y_{i,r+1}$ from each system $i \in M$ and compute $Y_{i,r+1}^a$. Set $r = r + 1$ and go to *Feasibility Check*.

F_A identifies all desirable and some acceptable systems with at least $1 - \alpha_0$ probability when $\beta = \alpha_0/(k(s+1))$ under Assumption 3. For practical use, the choice of $\beta = \alpha_0/ks$ is recommended. The values $a_\ell = \prod_{v=1,v\neq\ell}^{s} \varepsilon_v$, for $\ell = 1,2,\ldots,s$, are chosen to minimize the area where systems may be unacceptable for the original s constraints, but become acceptable for the aggregate constraint.

Finding the Best Feasible

A fully sequential, IZ framework for constrained R&S consisting of two phases, i.e., feasibility check and comparison of alternative systems, was introduced by Andradóttir and Kim (2010) for one stochastic constraint and extended to multiple stochastic

constraints by Healey (2010). These two phases can be performed either sequentially (the feasibility of each system is determined before comparison begins) or simultaneously (the feasibility check and comparison screening occur simultaneously after each additional sample). In either case, the overall error α needs to be split into α_0 for feasibility check and α_1 for comparison, to ensure the overall PCS $1 - \alpha$.

Sequentially running procedures apply a feasibility check procedure such as F_A first to all systems. Then a comparison procedure is applied to only those systems that are survived in the completed feasibility check phase. As feasibility check ends at a different number of observations for each system, the comparison phase needs a procedure that allows for unequal sample sizes across systems such as SSM. Sequentially running procedures are simple to implement but their statistical validity is hard to prove.

Simultaneously running procedures perform the following two steps after each stage of sampling. First, feasibility screening is performed for undetermined systems in M and eliminates systems that are found infeasible. Second, the procedure compares systems in contention. If a system i is found inferior to a feasible system, the inferior system i is eliminated. If a system is found inferior to a system in M, the procedure cannot eliminate the inferior system i until feasibility of the superior system is determined. Sampling from the inferior system continues until the inferior system is declared infeasible, its superior system is declared feasible, or the inferior system is either eliminated by another feasible system or selected as the best. Basically, simultaneously running procedures allow the elimination of a system only when it is declared infeasible or when it is found inferior to a system declared feasible.

Simultaneously running procedures are more complicated than sequentially running procedures but they are statistically valid, guaranteeing (3) whenever $x_{[b]} \geq x_i + \delta$ for all $i \in S_D \cup S_A \setminus \{[b]\}$. There is no uniform superiority between sequentially and simultaneously running procedures. However, under a difficult mean configuration such as the SC, the simultaneously running procedures usually perform slightly better.

Simultaneously running procedures can be further improved using the concept of dormancy (Healey et al. 2013), whereby a system may become dormant – halting sampling for that system – when it is found inferior to another system whose feasibility has not been determined yet, returning to contention only if its superior system is eliminated. If the superior system is found to be feasible, then the dormant system will be eliminated. The dormancy framework prevents procedures from collecting unnecessary observations from inferior systems. Other enhancements consider correlation across systems (allowing for the use of CRN) and procedures that minimize the number of switches (setup cost of starting and stopping simulations) between the simulated alternatives.

Other R&S Problems

Other classes of R&S problems include comparison with a standard, multinomial selection, and Bernoulli selection.

The goal of comparison with a standard is to find systems whose expected performance measures are larger (or smaller) than a standard and, if there are any, to find the one with the largest (or smallest) expected performance. In comparison with a standard, the standard is placed in a special status such as a guarantee that no alternative will be selected unless it beats the standard significantly, i.e., the standard is protected as long as an alternative system is not substantially better than the standard. However, if an alternative system does show a significant improvement, then it needs to be selected. For example, a decision maker will be reluctant to implement an alternative due to time and costs associated with replacement of the existing system (the standard) unless performance of an alternative in terms of some measures other than time and costs is significantly better than the standard. The standard is usually denoted as system 0 and there are k alternative systems. Then procedures for comparison with a standard should satisfy the following:

$$\Pr\{\text{select } 0 \mid x_0 \geq x_k\} \geq 1 - \alpha \text{ and}$$
$$\Pr\{\text{select } k \mid x_k - x_0 \geq \delta, x_k - x_{k-l} \geq \delta\} \geq 1 - \alpha.$$

In multinomial selection, the definition of best is the system that is most likely to be the best in a single trial, i.e., the system with the largest probability,

$p_i = \Pr\{X_{im} > X_{\ell m}, \forall \ell \neq i\}$. On the other hand, Bernoulli selection has basic output X_{im} taking either the value 1 (success) or 0 (failure), and the best system is the one with the largest probability of success, $p_i = \Pr\{X_{im} = 1\}$. When the performance measure is a probability, other types of IZ parameters can be considered. Some multinomial selection procedures guarantee the PCS whenever $p_k/p_{k-1} \geq \theta$, where $\theta > 1$ is the smallest p_k/p_{k-1} ratio (relative risk ratio) worth detecting. Bernoulli selection procedures consider at least three types of IZ parameters: the difference δ between probabilities, relative risk ratio, and odds ratio defined as $\frac{p_k/(1-p_k)}{p_{k-1}/(1-p_{k-1})}$; see Kim and Nelson (2006b).

Steady State

A stochastic process is said to be in its steady state if its state probabilities have (essentially) become independent of initial conditions.

See

► Statistical Equilibrium

Steady-state Distribution

Another name for the limiting distribution of a stochastic process.

Steepest Descent Method

A fundamental procedure for minimizing a differentiable function of several variables. Central to the method is that the direction of steeptest descent, in moving from one intermediate solution point to another, is along the gradient of the function at the current intermediate solution point.

► Nonlinear Programming

Steiner Tree Problem

For a given subset of nodes S from a network with N nodes, the problem is to determine a minimum length (cost) tree that contains all the nodes of S and, optionally, some other nodes from the set N. The Steiner tree problem is often defined on the Euclidean plane where the problem is to find the minimum length (distance) tree that spans a given set of S nodes, where the tree can contain nodes (points) other than those in S.

► Minimum Spanning Tree Problem

Stepping-Stone Method

A procedure for solving a transportation problem based on a simplification of the simplex method as applied to the constraint structure that defines a transportation problem. It starts with an initial basic feasible solution and then evaluates, for every nonbasic variable, whether an improved solution can be obtained by introducing one of the nonbasic variables into the basis. The problem is structured into an m-origin by n-destination rectangular matrix of cells in which the cell location (i, j) corresponds to the variable x_{ij} that represents the amount to be shipped from origin i to destination j. The evaluation process for a nonbasic variable x_{ij} starts in cell (i, j) and finds a path (steps) to current basic variable cells so that if x_{ij} does come into the basis, a new feasible solution is generated. Such a path always exists, although degeneracy procedures may be needed to define the path if the current basic solution is degenerate. Associated with the path is a cost that indicates whether or not the new feasible solution would improve (decrease) the value of the objective function. Although useful for pedagogical purposes, the stepping-stone method is not efficient for computer solution. Most computer-based procedures for solving the transportation problem use the transportation (primal-dual) simplex method or special network algorithms.

Stigler's Diet Problem

A problem formulated by the economist George Stigler in the early 1940s which had as its goal the determination of a minimum cost diet for an adult that met, for a full year, the recommended daily allowances of nutrients and calories, using 77 foods and 1939 prices. It was one of the first problems solved by the simplex method. Stigler's nonoptimal solution cost $39.93, with a diet consisting of wheat flour, evaporated milk, cabbage, spinach, and dried navy beans. The optimal, linear-programming solution cost $39.69 and included wheat flour, cabbage, spinach, beef liver, and dried navy beans.

Stochastic Approximation

David W. Hutchison[1] and James C. Spall[2]
[1]RAND Corporation, Santa Monica, CA, USA
[2]The Johns Hopkins University, Applied Physics Laboratory, Laurel, MD, USA

Introduction

Stochastic approximation is an iterative procedure which, under general conditions, employs noisy observations to estimate the root of a function. If this function is the gradient or an estimator for the gradient of a function of interest, the procedure enables the identification of optima.

The prototype application for stochastic approximation is root-finding. Consider a general function $g : \mathbb{R}^p \to \mathbb{R}^p$ defined for $\theta \in \Theta \subseteq \mathbb{R}^p, p > 0$. Then the root-finding problem is to find at least one $\theta = \theta^*$ such that

$$g(\theta) = 0. \tag{1}$$

The exact form of $g(\theta)$ is not known, and whatever observations exist of the function are obscured by noise.

An important special case of (1) is optimization. Consider a differentiable function $L : \mathbb{R}^p \to \mathbb{R}$ defined for $\theta \in \Theta \subseteq \mathbb{R}^p, p > 0$, and suppose g defined above is the gradient of L. Assume $L(\theta)$ is bounded from below and has a unique minimizer denoted by θ^*. The minimization problem is

$$\underset{\theta \in \Theta}{\operatorname{argmin}}\, L(\theta). \tag{2}$$

The exact form of $L(\theta)$ is not known and observations of L (and g, if it can be observed) are obscured by noise.

Let $\hat{\theta}_k$ be an estimate for θ^* at iteration k, a_k a step size at time k, and $G_k\left(\hat{\theta}_k\right) \in \mathbb{R}^p$ some information related to the gradient of the process, also at time k. Choose an initial estimate $\hat{\theta}_0$ and update the estimates following the iterative scheme

$$\hat{\theta}_{k+1} = \hat{\theta}_k - a_k G_k(\hat{\theta}_k), \;\; k = 0, 1, 2, \cdots. \tag{3}$$

The process in (3), along with a set of conditions for convergence, is the general mathematical model of stochastic approximation.

There are two general methods in stochastic approximation, which differ in their use of gradient information embodied by $G_k\left(\hat{\theta}_k\right)$. Stochastic gradient methods, discussed first, use noisy observations of the gradient, whereas gradient estimation methods use observations of the loss function to estimate the gradient.

Convergence Results

It is of interest to know whether $\hat{\theta}_k$ converges (in a probabilistic sense) to θ^* as k gets large. The convergence of a stochastic approximation algorithm requires that conditions be placed on the objective function, the step size sequence, and the bias and variance of the observed or estimated gradient.

There is not a single "standard" set of conditions; rather, different references offer different sets of conditions that result in almost sure convergence. For the most part, the differences among these sets of conditions lie in weakening one or another condition, usually at the expense of adding elsewhere. These sets of conditions can be broadly categorized as having a statistical perspective (Spall 2003) or an engineering (ODE) perspective (Kushner and Yin 2003; Spall 2003).

The overwhelming majority of what is known about stochastic approximation comes from limit theorems. The robust convergence theory of stochastic approximation is a powerful result. In many cases, it is possible to establish formal convergence of an algorithm or procedure by demonstrating that the problem is equivalent to a form of stochastic approximation.

The conditions for convergence are, in general, global requirements, and thus very broad and difficult to satisfy (and to verify) except in simple cases. However, even if the conditions do not hold globally, there may be a smaller region (still of full dimension p) in which the conditions do hold. In practice, controllable parameters are selected carefully and convergence is assumed.

Practical applications frequently choose other than optimal parameters for algorithms based on (3)—even in violation of the regularity conditions—in order to move the estimate more quickly to the vicinity of θ^* at the sacrifice of more slowly reducing the variability in the estimate. It is often more important to "tweak" the stochastic approximation procedure appropriately for the application being considered in order to obtain satisfactory finite-sample performance. For any particular sequence of estimates, an individual observation of $\hat{\theta}_k$ for some (small) finite value of k could be a poor estimator for θ^*, even when $E\left[\hat{\theta}_k\right]$ is close to θ^*. This is because the variability of the estimate has not yet had a chance to die down.

Also of importance is the probability distribution of the iterate. Having knowledge of the distribution provides key insight into two main aspects of the algorithm: (1) error bounds and stopping procedures and (2) guidance in the choice of algorithm parameters to minimize the deviation of $\hat{\theta}_k$ from θ^*.

Stochastic Gradient Methods

Though analogous to the steepest descent algorithm, stochastic gradient methods are fundamentally different since the deterministic term $\partial L/\partial\theta$ does not equal the stochastic gradient $Y(\theta)$. However, there is an intuitive connection, since $E[Y(\theta)] = \partial L/\partial\theta$ under conventional conditions for convergence.

Robbins-Monro Stochastic Approximation (RMSA)

Denote observations of the gradient by $Y(\theta)$ and model these observations by $Y(\theta) = g(\theta) +$ noise. If the errors have mean zero, then $E[Y(\theta)] = g(\theta)$. Robbins and Monro (1951) studied the problem of finding the roots of an unknown function $g(\theta)$ based on noisy observations of $g(\hat{\theta}_k)$. If g is the gradient of L, the loss function in (2), then this procedure can be used to solve the corresponding minimization problem. After setting $G_k(\hat{\theta}_k) = Y_k(\hat{\theta}_k)$ in (3), the iteration formula for stochastic root-finding is

$$\hat{\theta}_{k+1} = \hat{\theta}_k - a_k Y_k(\hat{\theta}_k). \tag{4}$$

Asymptotic Properties of RMSA. The earliest analytical results were by Robbins and Monro, who proved mean-square convergence of $\hat{\theta}_k$ to θ^* for their algorithm under mild conditions (thereby implying convergence in probability). A slight tightening of these conditions enabled Blum (1954) to prove almost sure convergence (see also Kushner and Yin 2003). Subsequent results have proved asymptotic normality of the estimate $\hat{\theta}_k$ (Fabian 1968), an asymptotic rate of convergence of $O(k^{-1/2})$ (Chen 1998), convergence probability bounds (Davisson 1970), and conditions that are necessary and sufficient for convergence (Kushner and Yin 2003).

With the conditions for convergence established, and with $\hat{\theta}_k$ generated according to (4), one can prove that $\hat{\theta}_k \xrightarrow{\text{a.s.}} \theta^*$ as $k \to \infty$ (see Kushner and Yin 2003).

Probably the best-known conditions for the convergence of RMSA are those on the gain sequence $\{a_k\}$. The conditions provide a balance between wanting to damp out the noise effects as $\hat{\theta}_k$ nears the solution θ^* $(a_k \to 0)$ and avoiding premature convergence of the algorithm $\left(\sum_{k=0}^{\infty} a_k = \infty\right)$. The scaled harmonic sequence $a/(k+1), a > 0$, is an example of a gain sequence that satisfies the gain conditions. Usually some numerical experimentation is required to choose the best value of the scale factor that appears in the decaying gain sequence. Other conditions important for convergence relate to the smoothness of $g(\theta)$, the relative magnitude of the noise, and the position of the initial condition (Spall 2003).

To obtain a non-degenerate limiting distribution, scale the error $\hat{\theta}_k - \theta^*$. If the step size function takes the form $a_k = a/(k+1)^{\beta}$ for $\frac{1}{2} < \beta \leq 1$ (and satisfies certain regularity conditions), one can show that the distribution of the scaled error is asymptotically normal:

$$k^{\beta/2}(\hat{\theta}_k - \theta^*) \xrightarrow{\text{dist}} N_p(0, \Sigma^*) \quad \text{as } k \to \infty,$$

where Σ^* is a covariance matrix determined by the coefficients of the sequence $\{a_k\}$ and by the Hessian of $L(\theta)$ at $\theta = \theta^*$ (Spall 2003, p. 112). One informal but natural interpretation of this fact is that $\hat{\theta}_k$ is approximately multivariate normal with mean θ^* and covariance Σ^*/k^{β}. Various special cases of this result dealing with the situation $\beta = 1$ can be found (Ljung et al. 1992).

Gradient Estimation Methods

Gradient estimation algorithms were first addressed by Kiefer and Wolfowitz (1952) by using finite differences to estimate the gradient of the function $L(\theta)$. These algorithms demonstrate the convergence properties of stochastic gradient algorithms using only measurements of the loss function.

Viewed asymptotically, when speed is measured by the number of iterations, gradient-based algorithms converge faster than those using gradient estimates (convergence being measured in terms of the deviation of the estimate from the true optimal parameter vector). The optimal rate of convergence for gradient-based algorithms is $O(k^{-1/2})$, while for algorithms based on gradient estimates the rate is $O(k^{-1/3})$, where k represents the number of iterations (Spall 2003).

One cannot say in general that a stochastic gradient algorithm is superior to a gradient estimation algorithm even though the stochastic gradient algorithm has a faster asymptotic rate of convergence. However, if direct gradient information is readily available, it is generally advantageous to use this information in the optimization process.

Denote the estimate of the gradient $\partial L/\partial\theta$ at $\hat{\theta}_k$ by $\hat{g}_k(\hat{\theta}_k)$. Then the general recursive procedure (3) with $G_k(\hat{\theta}_k) = \hat{g}_k(\hat{\theta}_k)$ is

$$\hat{\theta}_{k+1} = \hat{\theta}_k - a_k \hat{g}_k(\hat{\theta}_k). \tag{5}$$

Let $y(\theta)$ denote a measurement of $L(\theta)$ (i.e., $y(\theta) = L(\theta) +$ noise) and Δ a perturbation. One-sided gradient estimates involve the measurements $y(\hat{\theta}_k)$ and $y(\hat{\theta}_k + \Delta)$, while two-sided gradient estimates involve the measurements $y(\hat{\theta}_k \pm \Delta)$.

Under appropriate conditions, the iteration in (5) will converge to θ^* in some stochastic sense, usually a.s. (Kushner and Clark 1978). Typical convergence conditions are similar to those mentioned above for the RMSA algorithm.

Finite-Difference Stochastic Approximation (FDSA)

Each component of $\hat{\theta}_k$ is perturbed one at a time, and corresponding measurements y are obtained; each component of the gradient estimate is the difference in the y values divided by the difference interval. This is a standard approach to estimating gradient vectors and is motivated by the definition of the gradient as a vector of p partial derivatives. The ith component of $\hat{g}_k(\hat{\theta}_k), i = 1, 2, \ldots, p$, for a two-sided finite difference estimate is typically given by

$$\hat{g}_{ki}(\hat{\theta}_k) = \frac{y(\hat{\theta}_k + c_k e_i) - y(\hat{\theta}_k - c_k e_i)}{2c_k},$$

where e_i denotes the ith unit basis vector (Kiefer and Wolfowitz 1952).

Simultaneous Perturbation Stochastic Approximation (SPSA)

All components of $\hat{\theta}_k$ are randomly perturbed together (i.e., "simultaneously") to obtain two

measurements y, and each component of $\hat{g}_k(\hat{\theta}_k)$ is the difference in the y values divided by the difference interval. The ith component of $\hat{g}_k(\hat{\theta}_k), i = 1, 2, \ldots, p$, for a two-sided simultaneous perturbation is

$$\hat{g}_{ki}(\hat{\theta}_k) = \frac{y(\hat{\theta}_k + c_k\Delta_k) - y(\hat{\theta}_k - c_k\Delta_k)}{2c_k\Delta_{ki}},$$

where the random perturbations, $\Delta_k = [\Delta_{k1}, \Delta_{k2}, \ldots, \Delta_{kp}]^T$, satisfy the distributional conditions below.

Note that the number of loss function measurements y needed in each iteration of FDSA grows with p, while SPSA requires only two loss function measurements per iteration. Thus there is the potential for SPSA to achieve a savings over FDSA in the total number of measurements required to estimate θ when p is large (Spall 2003).

Asymptotic Properties of SPSA. The conditions for convergence of the SPSA algorithm are somewhat different from those of RMSA. Conditions must be imposed on the gain sequences $\{a_k\}$ and $\{c_k\}$, the distribution of Δ_k, and the statistical relationship of Δ_k to the measurements y (Spall 2003). The gain sequences $\{a_k\}$ and $\{c_k\}$ both must go to zero at rates neither too fast nor too slow, $L(\theta)$ should be sufficiently smooth near θ^* (several times differentiable), and the Δ_{ki} should be independent and symmetrically distributed about zero with finite inverse moments $E[|\Delta_{ki}|^{-1}]$ for all k and i. One distribution that satisfies these conditions is the symmetric Bernoulli distribution on $\{-1, 1\}$.

Under the conditions outlined in Spall, (2003, p. 204) one can show

$$k^{\beta/2}(\hat{\theta}_k - \theta^*) \xrightarrow{dist} N_p(\mu, \Sigma^*) \quad \text{as } k \to \infty.$$

In general, $\mu \neq 0$, in contrast to the asymptotic normality results for RMSA. The optimal rate of convergence for SPSA is $O(k^{-1/3})$, compared to $O(k^{-1/2})$ for the RMSA algorithm. There are exceptions to this result; see Kleinman, Spall, and Naiman (1999).

The efficiency of SPSA (relative to FDSA) depends on the shape of $L(\theta)$, the sequences $\{a_k\}$ and $\{c_k\}$, and the distributions of the Δ_{ki} and measurement noise terms. For most practical problems, SPSA is asymptotically more efficient than FDSA (Spall 2003). In particular, the total number of loss measurements y to achieve convergence in SPSA is proportional to $1/p$ the number needed in FDSA (Spall 2003, Chap. 7).

Extensions to Standard Approaches

Constrained Problems

A simple variation on the form in (3) includes a projection operator Π_Θ that maps solutions outside the constraint set Θ back to its nearest point in Θ. This approach for the Robbins-Monro algorithm is discussed in Kushner and Yin, (2003). In this case, (4) becomes

$$\hat{\theta}_{k+1} = \Pi_\Theta[\hat{\theta}_k - a_k Y(\hat{\theta}_k)].$$

There are implementations of SPSA for constrained optimization as well. See Sadegh (1997) for a projection approach, Wang and Spall (2008) for a penalty approach, and Bhatnagar, Hemachandra, and Mishra (2011) for a Lagrange multiplier approach.

Iterate Averaging

Averaging is an important development in stochastic approximation. The approach—sometimes referred to as Ruppert-Polyak stochastic approximation—was originally introduced as a means to improve the efficiency of the usual stochastic approximation process. Theory supporting the validity of this approach is found in Polyak and Juditsky (1992).

There are several variations, but the basic idea is to replace $\hat{\theta}_k$ as the current "best" estimate of θ^* after k iterations with the average

$$\bar{\theta}_k = \frac{1}{k+1}\sum_{j=0}^{k}\hat{\theta}_j.$$

A variation on this method is to compute a "sliding window" average based on the last m estimates:

$$\bar{\theta}_k = \frac{1}{m}\sum_{j=k-m+1}^{k}\hat{\theta}_j.$$

The advantage of a sliding window approach is that the averaging is focused on the later estimates which are presumably in a neighborhood of θ^*. Further variations on these ideas can be devised.

Recent work has shown some limitations and cautions regarding the method (see, for example, Maryak (1997) and Spall (2003, pp. 117–119)), and the method seems best suited for the class of problems where the estimates loiter approximately randomly in a neighborhood of θ^*.

A further modification to the averaging approach is to use $\bar{\theta}_k$ (together with $\hat{\theta}_k$) in a modified form of the RMSA iteration. This is referred to as the feedback approach (Kushner and Yang 1995), and occasionally yields improvements.

Adaptive Estimation

Kesten (1958) developed an adaptive algorithm for scalar θ that looks at the signs of the difference $\hat{\theta}_{k+1} - \hat{\theta}_k$. Frequent sign changes are seen as an indication that $\hat{\theta}_k$ is near θ^*, while if signs are not changing, it is an indication that $\hat{\theta}_k$ is far from θ^*. A larger step size a_k is used if there are no sign changes and a smaller a_k is used if the signs change frequently. A multivariate extension of Kesten's idea is described in Delyon and Juditsky (1993).

Second-Order Algorithms

There are stochastic analogs of the second-order Newton-Raphson search. The scalar gain a_k is replaced by a matrix H_k that approximates the unknown true inverse Hessian matrix corresponding to the current data point's contribution to the loss function. An accelerated form of SPSA extends the algorithm to include second-order (Hessian) effects. Recent results in adaptive SPSA are discussed in Spall (2003).

Ruppert (1985) describes an approach where the Hessian is estimated by taking finite differences of a gradient measurement. Spall (2000, 2009) gives a more efficient approach to general Hessian estimation based on simultaneous perturbations.

Joint Parameter and State Evolution

A generalization of the stochastic approximation process replaces $G_k(\hat{\theta}_k)$ by $G_k(\hat{\theta}_k, x_k)$, where x_k represents a state vector related to the system being optimized. It is typical to assume that x_k evolves according to Markov transition probabilities.

Time-Varying Loss Functions

The loss function $L(\theta)$ may itself be a function of k. It is assumed that, while $L_k(\theta)$ may change shape with k, the underlying minimum θ^* is either constant for all k or fixed in the limit as $k \to \infty$.

Stopping Rules

The need for a stopping rule for stochastic approximation was recognized by Kiefer and Wolfowitz (1952). Three broad categories of stopping methodologies include sequential methods, Monte Carlo methods, and relaxation methods. Sequential and Monte Carlo methods are discussed below. A review of relaxation methods can be found in Hutchison (2009).

Sequential Methods

Chow and Robbins (1965) developed a method to sequentially determine a bound on the mean of a continuous scalar random variable with unknown variance. They suggested the following rule: stop when the length of the confidence interval based on asymptotic normality of the sample means is smaller than 2δ for some $\delta > 0$. Since this initial work, much of the effort in stopping stochastic approximation has been on estimating the distribution of $\hat{\theta}_k$ in order to apply the Chow-Robbins criterion.

The idea is to fix a level of significance α, estimate the distribution of $\hat{\theta}_k$, and form a confidence region based on the estimated distribution and α. This is done successively as the algorithm steps through the iterations. As the sequence converges, the dispersion of the estimated distribution gets smaller, and the confidence region follows suit. The algorithm is stopped when the size of the $1 - \alpha$ confidence region is small enough.

Theory for the multi-dimensional case can be found in Pflug (1996). The general validity of the approach is demonstrated in Glynn and Whitt (1992).

The method requires knowledge of Σ^*, the covariance matrix of the limiting normal distribution of the scaled error. Using the step size sequence $a_k = a/(k+1)^\beta, \frac{1}{2} < \beta \leq 1$, the covariance matrix Σ^* is computed from one of the following matrix equations:

$$\begin{aligned} \left(aH(\theta^*) - \tfrac{1}{2}I\right)\Sigma^* + \Sigma^*\left(aH(\theta^*) - \tfrac{1}{2}I\right)^{\mathrm{T}} &= a^2 C(\theta^*), \\ &\text{for } \beta = 1; \\ H(\theta^*)\Sigma^* + \Sigma^* H(\theta^*) &= aC(\theta^*), \text{ for } \frac{1}{2} < \beta < 1. \end{aligned} \tag{6}$$

See, for example, Pflug (1996).

Approaches that use the asymptotic distribution as a proxy for the true distribution of $\hat{\theta}_k$ to stop a stochastic approximation may be unsatisfactory for small (finite) samples. Alternatively, one can attempt to directly estimate the true distribution of $\hat{\theta}_k$ or a simpler (but similar) surrogate distribution. Under certain conditions, surrogate-based probability calculations are close to the actual probabilities (Hutchison and Spall 2009).

Sequential procedures tend to perform well when the run lengths are relatively long (Glynn and Whitt 1992). The procedure is less reliable with small samples.

Monte Carlo Methods

A simple idea for stopping is to conduct multiple trials to generate the information necessary for stopping. There are two subcategories of this method: iterate sampling and sample path sampling.

Iterate sampling methods. Iterate sampling obtains repeated observations of $\hat{\theta}_k$ based on having arrived at $\hat{\theta}_{k-1}$. Iterate sampling is not directly useful for determining the distribution of $\hat{\theta}_k$, though it may be used to determine bounds on the next step of the current iteration, on an estimator of the loss, $\hat{L}(\hat{\theta}_k)$, or of the gradient, $\hat{g}(\hat{\theta}_k)$. The most direct approach is to sample at each iteration to obtain information that can be used as the basis for stopping.

Sample path methods. Sample path methods obtain repeated observations of $\hat{\theta}_k$ by running m independent applications of the stochastic approximation process.

Independent copies of the stochastic approximation process may become concentrated in a small region (nominally a ball). As each process converges to θ^*, the tails of the sequences of estimates get "close together." The iteration is stopped when the tails are "close enough."

More direct is to use sample path sampling to estimate the asymptotic distribution of $\hat{\theta}_k$, a hypothesized distribution, or the true distribution. For example, an improvement over using the asymptotic covariance structure in (6) is to use an estimator for the true covariance of $\hat{\theta}_k$, Σ_k. Hsieh and Glynn (2002) apply this approach by taking m sample paths of length k to estimate the covariance matrix Σ_k.

Concluding Remarks

Although stochastic approximation methods have the potential to treat a broader class of problems than many traditional deterministic techniques, their application can be a challenge. A problem common to all stochastic approximation techniques is that values must be specified for the algorithm's tunable coefficients. All stochastic approximation techniques have such coefficients. These coefficient values are typically problem dependent and can have a significant effect on the performance of an algorithm.

Stochastic approximation allows for the treatment of problems such as global optimization and noisy loss-function evaluations that arise frequently in areas such as network analysis, neural network training, image processing, nonlinear control, and simulation optimization. Stochastic approximation addresses a broader range of problems than possible with only standard deterministic methods.

Stochastic Input Model Selection

Bahar Biller and Alp Akcay
Carnegie Mellon University, Pittsburgh, PA, USA

Introduction

Input modeling is the selection of a probability distribution to capture the uncertainty in the input

environment of a stochastic system. Example applications of input modeling include the representation of the randomness in the time to failure for a machining process, the time between arrivals of calls to a call center, and the demand received for a product of an inventory system. Building simulations of stochastic systems requires the development of input models that adequately represent the uncertainty in such random variables. Since there are an abundance of probability distributions that can be used for this purpose, a natural question to ask is how to identify the probability distribution that best represents the particular situation under study. For example, is the exponential distribution a reasonable choice to represent the time to failure for a machining process, or is it better to use an empirical distribution function obtained from the historical time-to-failure data? Recognizing the fact that there is no true input model waiting to be found, the goal of stochastic input modeling is to obtain an approximation that captures the key characteristics of the system inputs.

The development of a good input model requires the collection of as much information as possible about the relevant randomness in the system as well as the historical data consisting of the past realizations of the random variables of interest. In the presence of a data set, the input model can be identified by fitting a probability distribution to the historical data. However, it may be difficult and/or costly to collect data for the stochastic system under study; it can also be impossible to properly collect any data at all such as when the proposed system does not exist. In the absence of historical data, any relevant information (e.g., expert opinion and the conventional bounds suggested by the underlying physical situation) can be used for input modeling. This article addresses the key issues that arise in stochastic input modeling both in the presence and in the absence of historical data.

The first step in input modeling is to identify the sources of randomness in the input environment of the system under study. Many stochastic systems contain multiple sources of uncertainty, e.g., the completion time of an item on a particular machine, the potential breakdown of the machine, and the percentage of defective items produced by the machine might be among the sources of uncertainty in a manufacturing setting. Throughout, the random vector $\mathbf{X} = (X_1, X_2, \ldots, X_K)'$ is used to represent the collection of K different inputs of a stochastic system, where X_k is the random variable denoting the kth system input. The K components of this random vector might also be correlated with each other. Therefore, the stochastic properties of the random inputs X_k, $k = 1, 2, \ldots, K$, are captured in the joint probability distribution function of $\mathbf{X}$. Selecting a joint distribution function to capture the randomness in $\mathbf{X}$ is called multivariate input modeling. It might be the case that the machine breakdown probability is positively correlated with the job completion time on the machine. In this case, stochastic input modeling refers to the specification of a bivariate probability distribution function for the joint representation of the machine breakdown probability and the job completion time. It might also be the case that there is a single source of randomness ($K = 1$), or the random component X_k is independent of the remainder of the components, X_l, $l = 1, 2, \ldots, k-1, k+1, \ldots, K$. In both of these cases, the input-modeling problem reduces to univariate input modeling which selects a univariate distribution for the random component of interest. For example, if the percentage of the defective items is known to be independent of both the job completion time and the potential breakdown of the machine, then the defective-item percentage is represented with a univariate distribution. Furthermore, univariate input modeling, despite failing to capture the dependencies among different random components, is often a good start towards solving the multivariate input-modeling problem. Although the main focus here will be on univariate modeling, the key issues that arise in multivariate modeling will also be addressed.

Univariate Input Modeling

Assuming an independent and identically distributed (i.i.d.) input process, this section treats univariate input modeling both in the presence and in the absence of historical data. Additionally, an autocorrelated input process is considered, with focus on captuning the temporal dependence.

Input Modeling with Historical Data

The input-modeling problem of this section assumes the availability of i.i.d. historical data points x_i, $i = 1, 2, \ldots, n$ of length n, and describes how to use this data set for estimating $F(\cdot;\mathbf{\Psi})$, the underlying cumulative distribution function (c.d.f.) of the random variable X and the unknown parameter vector $\mathbf{\Psi}$.

Preliminary Analysis of the Historical Data

It is possible that the available historical data points are recorded imprecisely or grouped with the observations of the other random variables in the input environment of the stochastic system under study. It might also be the case that the data set is available in an order other than when the values were observed. Such data characteristics do not allow the simulation practitioner to check whether being i.i.d. is a reasonable assumption for the underlying input process; see Vincent (1998) for further examples that turn input modeling into a challenging problem. The input-modeling techniques of this section, on the other hand, assume that the historical data on hand are statistically i.i.d.; therefore, it is critical to perform a preliminary analysis of the historical data and verify the i.i.d. assumption before the implementation of the input-modeling techniques to be discussed shortly.

A graphical method that can be used for assessing the independence of the historical input data is the correlation plot. It shows the sample correlations for various lags; note that a lag ℓ correlation is the correlation between data points that are ℓ values apart. Vincent (1998) reports that lags of size one through ten are the most informative about a sample, whereas lags over 20 are non informational. For an i.i.d. historical data set, the sample correlations are expected to be small in magnitude and clustered around zero, with both negative and positive estimated values.

Another graphical method that can be used for the same purpose is the scatter diagram plotting the data pairs x_i and x_{i+1} for $i = 1, 2, \ldots, n-1$ on each of its axes. If the historical data points are independently distributed, then they are randomly scattered. If the data points lie along a diagonal line with a positive (negative) slope, then the scatter diagram suggests a positively (negatively) autocorrelated input process.

In addition to the assessment of the independence assumption, it should also be checked whether each data point comes from the same probability distribution; i.e., the (unconditional) probability distribution of the input process does not change with time. A way of doing this is to analyze the data for any discernible increasing or decreasing patterns over time; see Vincent (1998) for further discussion on assessing the stationarity of the underlying input process.

The next step in the preliminary analysis of the historical data is the calculation of the summary statistics such as the sample minimum $x_{(1)}$ and the sample maximum $x_{(n)}$ for the range estimation, the sample mean $\bar{x} = \sum_{i=1}^{n} x_i/n$ as the measure of the central tendency, the sample variance $s^2 = \sum_{i=1}^{n} (x_i - \bar{x})/(n-1)$ and the sample coefficient of variation $s/\bar{x}$ as the measures of variability, the sample coefficient of skewness $\sum_{i=1}^{n} (x_i - \bar{x})^3/s^3$ as the measure of asymmetry, and the sample coefficient of kurtosis $\sum_{i=1}^{n} (x_i - \bar{x})^4/s^4$ as the measure of peakedness and tail weight. In addition, the quantile summary and the histogram of the historical data show the level of asymmetry in the empirical density function. However, the use of the histogram for input modeling might lead to different conclusions based on the number of the bins used; therefore, the histograms should always be constructed for various bin sizes.

The summary statistics obtained from the preliminary analysis of the historical data can be used for identifying the form of the underlying probability density function. For example, a sample coefficient of variation close to 1, along with a histogram with an exponential decay, suggests exponential distribution as an input model. A sample coefficient of variation greater than 1 with a right-skewed histogram indicates that a lognormal distribution can be a potential input model, while a symmetric histogram or a sample coefficient of skewness close to zero indicates normal or Student's t distribution as an appropriate candidate for input modeling. Such a preliminary analysis allows the simulation practitioner to gain insights about the key characteristics of the historical input data. A good resource for further discussion on the initial analysis of the historical data for input modeling is Law (2007).

Model Fitting and Parameter Estimation

Standard families of distributions (e.g., beta, binomial, Erlang, exponential, gamma, lognormal, normal,

Poisson, triangular, uniform, or Weibull) are often the immediate choices in the selection of a distribution for the input data. These standard distributions can be classified as discrete and continuous, or with bounded and unbounded ranges. Detailed treatments of standard discrete and continuous distributions are available, respectively, in Johnson, Kemp and Kotz (2005) and Johnson, Kotz and Balakrishnan (1995).

The identification of the best fit (i.e., the probability distribution that provides the best representation for the underlying input process) often requires not only the use of historical data for model fitting but also a good understanding of the source of randomness in the system. Most probability distributions are invented to present a particular physical situation. If the physical basis for a distribution is well understood, that knowledge can be used to match it to the situation being modeled. For example, if the number of patient visits to an emergency room satisfies the assumptions of the Poisson process (i.e., the patients arrive one at a time, the number of arrivals in a time interval is independent of the number of arrivals in an earlier time interval and the times at which these arrivals occur, and the arrival rate of patients does not depend on the time of day), then the exponential distribution can be selected for modeling the interarrival times between patient arrivals. The lognormal distribution would be a potential input model to represent the rate of return on an investment when interest is compounded, because the rate of return in this particular case can be thought of as the product of a number of component processes. The use of the physical basis for distribution selection in this manner is especially important for input modeling in the absence of historical data.

In many practical situations, however, it is not easy to choose and justify an input distribution based on the source of randomness in the system. Moreover, the standard families of distributions might not adequately represent the probabilistic behavior of the input processes. In such cases, the use of flexible families of distributions for input modeling might allow the simulation practitioner to capture the key characteristics of the available data by fine-tuning the shape of the fitted input distribution. Some well-known flexible distribution systems include the curves proposed by Pearson (1895), the generalized lambda distribution (Ramberg and Schmeiser 1974), and the Schmeiser-Deutsch class of distributions (Schmeiser and Deutsch 1977). Other widely-used distribution systems for input modeling are the generalized beta family of distributions and the Bézier distribution family, along with the Johnson translation system; see Kuhl et al. (2010) for a review of these distribution systems with a focus on stochastic simulation.

Independent of whether a standard distribution or a flexible distribution is chosen, the next step in input modeling is to obtain $\hat{\boldsymbol{\Psi}}$, an estimate of the unknown parameter vector $\boldsymbol{\Psi}$, which minimizes the distance between the hypothesized distribution function $F_h(\cdot;\hat{\boldsymbol{\Psi}})$ and the empirical distribution function of the historical data. Assuming that the functional form of $F_h(\cdot;\hat{\boldsymbol{\Psi}})$ is known, the methods of maximum likelihood, least squares, and moment matching are the three widely-used estimation techniques for predicting a value for $\hat{\boldsymbol{\Psi}}$. Specifically, the maximum likelihood method estimates $\hat{\boldsymbol{\Psi}}$ by maximizing the likelihood function of the historical data, while the least-squares method minimizes the sum of squared residuals, each of which is a difference between an observed value and a fitted quantile. The method of moment matching, on the other hand, predicts $\hat{\boldsymbol{\Psi}}$ by matching the moments of the hypothesized distribution $F_h(\cdot;\hat{\boldsymbol{\Psi}})$ to the sample moments of the historical data set; a good resource for details on these estimation techniques is Rohatgi and Saleh (2001).

In situations where no parametric distribution provides a good fit for the historical data, the empirical distribution function can be chosen as the input model. Specifically, the empirical distribution function $\hat{F}$ is the c.d.f. constructed by assigning probability $1/n$ to each of the n data points. It is an unbiased, consistent, and asymptotically normal estimator of the c.d.f. F (Rohatgi and Saleh 2001). A limitation of the empirical distribution is that it ignores the possibility of a realization that does not appear in the historical data set. The common practice is to fill such gaps by linearly interpolating between the sorted values of the historical data. Also, the range of the empirical distribution is limited to that of the historical data set. However, this limitation can be overcome by extending one or both of the empirical-distribution tails with known distribution functions. A distribution that is often used for this purpose is the exponential distribution. A more detailed presentation of the empirical distribution function with a focus on simulation input modeling can be found in Vincent (1998).

Assessing the Goodness of the Fit

After the estimation of the distribution parameters, the next step is to assess how well the resulting fit captures the key distributional characteristics of the historical data. This can be accomplished by using the statistical goodness-of-fit tests and the graphical (heuristic) techniques.

Chi-square, Kolmogorov-Smirnov, and Anderson-Darling tests are the three of the statistical goodness-of-fit tests available in simulation software packages for input modeling. Specifically, the chi-square test provides a formal comparison between the histogram (or the line graph) of the historical data and the fitted density (or mass) function. The major drawback of this test is its sensitivity to the number of intervals (data groups) used for the construction of the histogram. The Kolmogorov-Smirnov and Anderson-Darling tests compare the empirical distribution function to the fitted distribution function. Neither of these tests require the grouping of the data, while the Anderson-Darling test with the higher power detects, in particular, the discrepancies in the distribution tails. It is important to note that each of these tests is unlikely to reject any distribution when there is little data, and is likely to reject every distribution when there is a lot of data. Keeping this caveat in mind, the goodness-of-fit test statistics should be interpreted as a recommendation to accept or reject an input model, but not as a definite rule to be strictly followed.

In addition to the use of goodness-of-fit tests for input modeling, graphical methods are recommended as advisory devices to examine the fits. The graphical tools that can be used for this purpose include the frequency comparison plot, the density-function-differences plot, the probability-probability (P-P) plot, and the quantile-quantile (Q-Q) plot. Specifically, the frequency comparison plot is a graphical comparison of the histogram of the historical data with the estimated density function, while the density-function-differences plot compares the empirical distribution function to the fitted distributed function by plotting their differences over the available data range. The P-P plot, on the other hand, plots the hypothesized (estimated) distribution function $F_h(x_{(i)}; \hat{\boldsymbol{\Psi}})$ against $(i - 0.5)/n$ with $x_{(i)}$ denoting the ith smallest historical data point, while $F_h^{-1}((i-0.5)/n; \hat{\boldsymbol{\Psi}})$ is plotted against $x_{(i)}$ in the Q-Q plot for $i = 1,2,\ldots,n$. Thus, the Q-Q plot (P-P plot) amplifies the differences between the tails (middles) of the hypothesized and sample distribution functions. Both the P-P plot and the Q-Q plot are expected to be approximately linear when the hypothesized distribution function $F_h(\cdot; \hat{\boldsymbol{\Psi}})$ is a good fit. Since it is important that the input model adequately captures the tail behavior of the historical input data, the use of the Q-Q plot is highly recommended for input-model building.

To summarize, identification of a good input model starts with the preliminary analysis of the historical input data, continues with the use of an estimation method for determining the distribution function and its parameters, and ends with the evaluation of the goodness of the resulting fit. The proprietary simulation software packages often include built-in modules that follow these steps to identify the input distribution that best fits the historical data; see Swain (2011) for a survey on such simulation software and their input-modeling capabilities; this survey is usually updated biennially in *OR/MS Today*. Nevertheless, the simulation practitioner should not just rely on the best fit identified by the software; if there is a strong physical basis for a particular distribution choice, then its selection as the input model should be seriously considered even if it is not the best fit.

Input Modeling in the Absence of Historical Data

The setting where no data are available to select a distribution or assess the fit is now considered. This might occur due to time and budget restrictions and/or the challenges in data collection. It might also be the case that the goal of the simulation study is to investigate the impact of design changes on the system performance, so that the (proposed) system does not exist yet. Therefore, the input model has to be developed by using any available information about the underlying input process. For example, if a distributor receives orders from a large number of independent retailers, then the Central Limit Theorem suggests the selection of the normal distribution as the input model for representing the total demand. Similarly, the number of defective items in a shipment of fixed size can be modeled by a binomial distribution when the probability of being defective is the same for each item. In the absence of historical data, the physical limitations of the

underlying process can also be useful for input modeling. For example, if the repair of a machine requires at least 6 hours to run a diagnostic check and the machine is replaced by a new one if it cannot be repaired in 3 days, then the input model for the machine repair time should assume values between 6 hours and 3 days.

The knowledge and experience of the experts (i.e., the people familiar with the system being studied) are called expert opinion. It is an important source of subjective information necessary for developing an input model in the absence of historical data. A way of extracting expert opinion is to use breakpoints; i.e., the numerical values that the input random variable can take and the chances of the random variable being higher or lower than the breakpoints. In this case, the input model is built using as many breakpoints as can be confidently obtained, especially near the extreme values of X. The breakpoints method is useful for modeling inputs with many possible outcomes. However, it is possible that the expert can only provide limited information about the properties of the input random variables such as the lower/upper bound, the most likely value, and the mean value. A way of building an input model in such a case is to consider the use of uniform, triangular, PERT, and beta distributions for incorporating expert opinion into the input-model development. Specifically, the uniform distribution can be used when the expert provides both a lower bound and an upper bound to the values the random variable can take. However, the expert can also provide a most likely value which can be incorporated into the input model as the mode of the triangular or PERT distribution. If the expert additionally provides an average value for the input, then all of the available expert opinion can be used for constructing a beta distribution. A drawback of using the beta distribution for input modeling is that it might be difficult for the expert to differentiate between the most likely and average values, but this difficulty can be overcome by modeling the input with a lognormal or Weibull distribution. The construction of these two distributions requires expert opinion about the location parameter, the most likely value, and the q-quantile of the input distribution. While the location parameter can be interpreted as the lower bound to the values the input random variable can take, the scale and shape parameters are functions of the mean and the q-quantile.

Autocorrelated Input Process

The focus switches now to an autocorrelated input process that exhibits temporal dependence, specifically to input modeling for the stationary univariate time series denoted by $\{X_t;\ t = 1, 2, \ldots\}$. An example of such an input process is the sequence of week-to-week quantities ordered by a distributor, when modeling the weekly orders as independent random variables misses the week-to-week dependence (autocorrelation) in the demand process. Autocorrelation in an input process can have a substantial effect on system performance and hence should not be ignored; see Livny, Melamed and Tsiolis (1993) for a well-known simulation study demonstrating the significant impact of interarrival and service-time autocorrelations on queueing system performance.

Input modeling for a univariate time series of order p refers to the selection of a probability distribution for the random variable X_t and the specification of the autocorrelation structure up to lag p; i.e., $\mathrm{Corr}[X_t, X_{t+l}] = (\mathrm{E}[X_t X_{t+l}] - \mu^2)/\sigma^2$ for $\ell = 1, 2, \ldots, p$, where μ and σ^2 are the mean and variance of X_t. An input model that is widely used for representing such an autocorrelated time series is the AutoRegressive Moving Average (ARMA) process. Specifically, the ARMA(p,q) process is represented by $X_t = \sum_{h=1}^{p} \alpha_h X_{t-h} + Y_t + \sum_{i=1}^{q} \beta_i Y_{t-i}$ for $t = p + 1, p + 2, \ldots$, where the α_h, $h = 1, 2, \ldots, p$ are fixed autoregressive coefficients and the β_i, $i = 1, 2, \ldots, q$ are fixed moving average coefficients that jointly determine the autocorrelation structure of the time series X_t, $t = 1, 2, \ldots$, while Y_t, $t = p + 1, p + 2, \ldots$ are independent and normally distributed random variables each of which has a mean of zero. A good resource for input modeling with ARMA is Box, Jenkins and Reinsel (1994). The major limitation of the linear ARMA model is the restriction of the marginal distribution of X_t to normal, limiting the use of the model for time series with arbitrary marginal distributions. Motivated by this drawback, there has been considerable research on modeling time series with marginals from non-normal families, such as exponential, gamma, geometric, or general discrete marginal distributions. For example, Lewis, McKenzie and Hugus (1989) relax the normal-distribution assumption of the ARMA model by constructing a time series with a gamma marginal distribution.

However, this model allows only limited control of the dependence structure, and a different model is required for each type of marginal distribution.

The Transform-Expand-Sample (TES) process introduced by Melamed (1991) differs from the previous time-series models by its ability to match an arbitrary marginal distribution and a lag-one correlation by applying the inverse-transformation method to a series of autocorrelated uniform random variables. However, the TES process does not guarantee the representation of the autocorrelation structure beyond the first lag, and extreme jumps may appear in its sample paths. In addition, the TES process is limited to the modeling of univariate time series; it cannot be extended to capture the joint distribution of correlated input random variables. The AutoRegressive-To-Anything (ARTA) process developed by Cario and Nelson (1996), on the other hand, allows the modeling of a time series with any marginal distribution and an autocorrelation structure specified up to lag p (≥ 1). Unlike TES, ARTA can represent autocorrelation structures beyond lag one with no extreme jumps in the sample paths. Furthermore, ARTA can be easily extended to model multivariate time series.

Specifically, the ARTA model builds on the autoregressive process of order p; i.e., the ARMA(p,q) process with $q = 0$, which serves as the base process with the following representation:

$$Z_t = \sum_{h=1}^{p} \alpha_p Z_{t-h} + Y_t, t = p+1, p+2, \ldots$$

The autocorrelation structure of the base process Z_t, $t = 1, 2, \ldots$ is uniquely determined by the autoregressive coefficients α_h, $h = 1, 2, \ldots, p$ and the variance of the random variables Y_t, $t = p+1, p+2, \ldots$ that ensure the standard normality of the base process. This allows one to obtain the input random variable X_t from the transformation $X_t = F^{-1}(\Phi(Z_t); \boldsymbol{\Psi})$, where $F^{-1}(\cdot;\boldsymbol{\Psi})$ is the inverse c.d.f. of the marginal distribution function $F(\cdot;\boldsymbol{\Psi})$, and Φ is the c.d.f. of the standard normal random variable. Cario and Nelson (1998) develop the ARTAFACTS software that specifies the autocorrelation structure of the base process Z_t, $t = 1, 2, \ldots$ to obtain the autocorrelation structure of the input process X_t, $t = 1, 2, \ldots$. Building on the input-modeling techniques described earlier, Biller and Nelson (2005) introduce an automated and statistically valid algorithm called ARTAFIT to fit an ARTA process with a marginal distribution from the Johnson translation system to historical data of limited length. It is reported that the ARTAFIT algorithm, which jointly estimates the marginal distribution and the autocorrelation structure of a time series, provides better fits than those obtained under the assumption of an independent input process; it also performs better than the separate estimation of the marginal distribution and the autocorrelation structure. The extension of this univariate time-series input model to multivariate time series is discussed later.

Multivariate Input Modeling

The objective of this section is to describe how to select a multivariate input model for a random vector composed of K correlated random variables. Examples of such a random vector include the demands of K different items in a retailer's product line, the processing times of a product at K different machines, and the financial defaults of K different suppliers in a supply-chain network. First, it is assumed that the K − dimensional random vectors $\mathbf{X}_t = (X_{1,t}, X_{2,t}, \ldots, X_{K,t})'$, $t \geq 1$ are independent over time to focus on capturing the dependence among the K component random variables $X_{k,t}$, $k = 1, 2, \ldots, K$. Then the temporal independence assumption is relaxed to consider multivariate time-series models that additionally account for the autocorrelations within the time series $\mathbf{X}_t$, $t \geq 1$.

Capturing the Joint Distribution of Correlated Inputs

Due to the analytical tractability in parameter estimation and the ease in random-vector generation, multivariate normal distribution has been a widely-used input model for correlated random variables. This model, however, assumes a normal marginal distribution for each input random variable, limiting its use for multivariate input modeling. This has motivated the multivariate extension of various standard distributions for input modeling; see Johnson, Kotz and Balakrishnan (1997) and Kotz, Balakrishnan and Johnson (2000) for a presentation of the resulting multivariate distributions.

The focus of recent multivariate input-modeling research has been on developing flexible input

models with arbitrary marginal distributions and positive definite correlation matrices. More specifically, the goal has been to construct a K-dimensional random vector $\mathbf{X} = (X_1, X_2, \ldots, X_K)'$ with marginal distribution functions $F_k(\cdot;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$ and input correlation matrix $\sum_{\mathbf{X}} \equiv [\rho(i, j); i, j = 1, 2, \ldots, K]$, where $\rho(i,j) = \mathrm{Corr}\left[X_i, X_j\right]$ for $i = 1, 2, \ldots, K$ and $j = 1, 2, \ldots, K$. The joint distribution function of the random vector $\mathbf{X}$ is given by

$$H(x_1, x_2, \ldots, x_k) = \Pr(X_1 \le x_1, X_2 \le x_2, \ldots, X_K \le x_K).$$

The application of the probability-integral transformation $F_k(\cdot;\boldsymbol{\Psi}_k)$ to the random variable X_k results in the uniform random variable U_k in (0, 1); i.e., $F_k(X_k;\boldsymbol{\Psi}_k) \equiv U_k$, and the standard normal random variable Z_k is obtained by applying the inverse c.d.f. Φ^{-1} of the standard normal random variable to U_k, i.e., $Z_k = \Phi^{-1}(F_k(X_k;\boldsymbol{\Psi}_k))$. Therefore, the joint distribution function H of the random vector $\mathbf{X}$ can be alternatively written as follows:

$$\begin{aligned}
&H(x_1, x_2, \ldots, x_K)\\
&= \Pr(F_k(X_k;\boldsymbol{\Psi}_k) \le F_k(x_k;\boldsymbol{\Psi}_k); k = 1, 2, \ldots, K)\\
&= \Pr(U_k \le u_k; k = 1, 2, \ldots, K)\\
&= \Pr\left(\Phi^{-1}(U_k) \le \Phi^{-1}(u_k); k = 1, 2, \ldots, K\right)\\
&= \Pr\left(Z_k \le \Phi^{-1}(F_k(x_k;\boldsymbol{\Psi}_k)); k = 1, 2, \ldots, K\right)\\
&= \Phi_{\Sigma_{\mathbf{Z}}}\left(\Phi^{-1}(F_1(x_1;\boldsymbol{\Psi}_1)), \Phi^{-1}(F_2(x_2;\boldsymbol{\Psi}_2)), \ldots, \Phi^{-1}(F_K(x_K;\boldsymbol{\Psi}_K))\right)
\end{aligned}$$

In this representation, $\Phi_{\Sigma_{\mathbf{Z}}}$ is the joint c.d.f. of the base random vector $\mathbf{Z} = (Z_1, Z_2, \ldots, Z_K)'$ with the correlation matrix $\Sigma_{\mathbf{Z}} \equiv [\rho_{\mathbf{Z}}(i,j); i, j = 1, 2, \ldots, K]$, where $\rho_Z(i,j) = \mathrm{Corr}\left[Z_i, Z_j\right]$ for $i = 1, 2, \ldots, K$ and $j = 1, 2, \ldots, K$. $\Phi_{\Sigma_{\mathbf{Z}}}$ allows the joint distribution function of $\mathbf{X} = (X_1, X_2, \ldots, X_K)$ to be written as a function of the marginal c.d.f.'s $F_k(X_k;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$. This function is known as the K-dimensional normal copula, which can be considered as a multivariate function that couples the arbitrary marginal c.d.f.'s $F_k(X_k;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$ with the correlation matrix Σ_Z to obtain the joint distribution function H. This joint distribution is also known as the Normal-To-Anything (NORTA) distribution in the stochastic input-modeling literature (Cario and Nelson 1997). Therefore, the dependence structure of the K – dimensional NORTA distribution is captured in a K − dimensional normal copula. Since the transformation $F_k^{-1}\left(\Phi^{-1}(Z_k);\boldsymbol{\Psi}_k\right)$ ensures that the input random variable X_k has the marginal distribution $F_k(\cdot;\boldsymbol{\Psi}_k)$, the main challenge in the construction of the NORTA distribution with the input correlation matrix $\Sigma_{\mathbf{X}}$ is to determine the base correlation matrix $\Sigma_{\mathbf{Z}}$ that matches the input correlation matrix $\Sigma_{\mathbf{X}}$. The identification of the base correlation matrix requires the solution of $K(K-1)/2$ individual correlation-matching problems of the form

$$\begin{aligned}
\rho_X(i,j) &= \mathrm{Corr}\left(F_i^{-1}(\Phi(Z_i);\boldsymbol{\Psi}_i), F_j^{-1}\left(\Phi(Z_j);\boldsymbol{\Psi}_j\right)\right)\\
&= \left(\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} F_i^{-1}(\Phi(Z_i);\boldsymbol{\Psi}_i) F_j^{-1}\left(\Phi(Z_j);\boldsymbol{\Psi}_j\right)\right.\\
&\qquad \left.\vartheta_{\rho_Z(i,j)}(z_i, z_j)\,dz_i\,dz_j - \mu_i\mu_j\right) \Big/ (\sigma_i\sigma_j)\\
&= c_{ij}(\rho_Z(i,j))
\end{aligned}$$

for $\rho_{\mathbf{Z}}(i, j)$, where $\vartheta_{\rho_{\mathbf{Z}}(i,j)}$ is the standard bivariate normal probability density function with correlation $\rho_{\mathbf{Z}}(i, j)$, and μ_i and σ_i^2 are the mean and variance of X_i. The function $c_{ij}(\rho_{\mathbf{Z}}(i, j))$ is nondecreasing, lies on the origin for $\rho_{\mathbf{Z}}(i, j) = 0$, and satisfies $|c_{ij}(\rho_{\mathbf{Z}}(i, j))| \le |\rho_{\mathbf{Z}}(i, j)|$ for $\rho_{\mathbf{Z}}(i, j) \in [-1, 1]$. Furthermore, the function $c_{ij}(\rho_{\mathbf{Z}}(i, j))$ is continuous under mild conditions on the marginal distribution functions $F_i(\cdot;\boldsymbol{\Psi}_i)$ and $F_j(\cdot;\boldsymbol{\Psi}_j)$. These properties of the function $c_{ij}(\rho_{\mathbf{Z}}(i, j))$ allow the simulation practitioner to perform a numerical search to find the base correlation $\rho_{\mathbf{Z}}(i, j)$ within a predetermined precision; see Cario and Nelson (1997) for further details on the function $c_{ij}(\rho_{\mathbf{Z}}(i, j))$ and the solution of the correlation-matching problem. However, the solution of the correlation-matching problems might lead to a base correlation matrix that is not positive definite. Therefore, there exist sets of marginal distributions with a feasible input correlation matrix that are not representable by the NORTA transformation. If, after solving the correlation-matching problems, the base correlation matrix is not positive definite, then the procedures introduced by Lurie and Goldberg (1998) and Ghosh and Henderson (2002) can be used for obtaining a symmetric, positive definite approximation of the base correlation matrix. Nevertheless, the failure of the transformation-based method is relatively rare in moderate dimensions of random vectors, and the method fails when the correlations are on the

boundary or within close proximity to the correlation values achievable for the specified marginals of the input process.

Next, consider the problem of estimating the unknown marginal distribution parameters $\boldsymbol{\Psi}_k$, $k = 1, 2, \ldots, K$ and the base correlation matrix Σ_Z from the historical data set $\{x_{k,t}; k = 1, 2, \ldots, K, t = 1, 2, \ldots, n\}$ of length n. The marginal-copula representation of the distribution function $H(x_1, x_2, \ldots, x_K)$ allows the joint density function to be written in terms of the normal copula density function ϕ_{Σ_Z} (i.e., the Kth-order derivative of the normal copula Φ_{Σ_Z} with respect to $F_k(X_k;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$) and the marginal density functions $f_k(x_k;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$:

$$\phi_{\Sigma_Z}(F_1(x_1;\boldsymbol{\Psi}_1), F_2(x_2;\boldsymbol{\Psi}_2), \ldots, F_K(x_K;\boldsymbol{\Psi}_K)) \times \prod_{k=1}^{K} f_k(x_k;\boldsymbol{\Psi}_k).$$

Therefore, the log-likelihood function of the historical data can be written as the sum of the K log-likelihood functions for the marginal distribution functions $F_k(\cdot;\boldsymbol{\Psi}_k)$, $k = 1, 2, \ldots, K$, i.e.,

$$L_k(\boldsymbol{\Psi}_k) = \sum_{t=1}^{n} \log f_k\left(x_{k,t};\boldsymbol{\Psi}_k\right), k = 1, 2, \ldots, K,$$

and the log-likelihood function for the copula density function; i.e.,

$$L_c(\Sigma_{\mathbf{Z}}) = \sum_{t=1}^{n} \log \phi_{\Sigma_{\mathbf{Z}}}\left(F_1\left(x_{1,t};\boldsymbol{\Psi}_1\right), F_2\left(x_{2,t};\boldsymbol{\Psi}_2\right) \ldots, F_K\left(x_{K,t};\boldsymbol{\Psi}_K\right)\right).$$

The structure of the log-likelihood function allows the use of a multi-stage estimation method known as the Inference For Margins (IFM). Specifically, the IFM method obtains the parameter estimate $\hat{\boldsymbol{\Psi}}_k$ by maximizing the log-likelihood function $L_k(\boldsymbol{\Psi}_k)$ for $k = 1, 2, \ldots, K$, followed by the maximization of the log-likelihood function $L_c(\Sigma_{\mathbf{Z}})$ to estimate the correlation matrix $\hat{\Sigma}_{\mathbf{Z}}$ using $\hat{\boldsymbol{\Psi}}_k$, $k = 1, 2, \ldots, K$ obtained in the first K stages. This procedure is computationally simpler than the maximum likelihood estimation which estimates all parameters $\boldsymbol{\Psi}_k$, $k = 1, 2, \ldots, K$, and $\Sigma_{\mathbf{Z}}$ from the full log-likelihood function $L_c(\Sigma_{\mathbf{Z}}) + \sum_{k=1}^{K} L_k(\boldsymbol{\Psi}_k)$. The IFM estimators are different from the maximum likelihood estimators unless the marginal distributions are normal. The IFM estimators are also less efficient than the maximum likelihood estimators, but they are strongly consistent and asymptotically normal under certain regularity conditions (Joe 1997).

The common feature of the multivariate input models presented in this section is the use of correlation as the measure of dependence. Correlation is also the most widely used dependence measure in multivariate input modeling. However, it is not the only dependence measure available for input modeling. A measure of dependence, which has been of particular interest in recent years, is tail dependence; i.e., the amount of dependence in the lower-quadrant tail or upper-quadrant tail of a bivariate distribution. The multivariate input models of this section can be easily extended to work for dependence structures with positive tail dependencies by simply replacing the normal copula with the appropriate multivariate copula; see Biller (2009) for the use of copula theory to extend the transformation-based methods to represent positive tail dependencies. An excellent review of the alternative dependence measures together with the copula theory is available in Joe (1997).

Autocorrelation

In settings with multiple sources of randomness, a correlation might exist not only between the input random variables of the system but also over time. An input model that can be used for representing a stationary multivariate time-series process is the Vector-AutoRegressive-To-Anything (VARTA) model (Biller and Nelson 2003). The measure of dependence assumed in this model is also correlation whose limitations are further inherited by VARTA. Biller (2009) shows that this multivariate time-series model fails to capture the dependencies in the tails of the joint distributions of its K component series, and generalizes VARTA to work for dependence structures with positive tail dependencies by using appropriate families of multivariate copulas.

Specifically, VARTA pulls together the theory behind the ARTA and NORTA input models and extends it to the K – dimensional time series

$$\left\{\mathbf{X}_t = \left(X_{1,t}, X_{2,t}, \ldots, X_{K,t}\right)'; t = 1, 2, \ldots\right\}$$

by taking the inverse transformation of the following vector autoregressive process of order p:

$$\mathbf{Z}_t = \sum_{h=1}^{p} \alpha_h \mathbf{Z}_{t-h} + \mathbf{Y}_t, t = p+1, p+2, \ldots.$$

In this representation, the α_h, $h = 1, 2, \ldots, p$ are fixed K-dimensional autoregressive coefficient matrices and $\{\mathbf{Y}_t; t = p + 1, p + 2, \ldots\}$ is a sequence of K-dimensional normal random vectors with zero mean and the covariance matrix that ensures that each component of $\mathbf{Z}_t = (Z_{1,t}, Z_{2,t}, \ldots, Z_{K,t})'$ is marginally standard normal. Notice that if $K = 1$, then the VARTA process reduces to an ARTA process; and if $K > 1$ and $p = 0$, the VARTA process corresponds to a NORTA vector. The major challenge in the construction of a VARTA process (and hence, for the ARTA and NORTA processes) is to specify the autocorrelation structure of the autoregressive base process $\{\mathbf{Z}_t; t = 1, 2, \ldots\}$ so that the input process $\{\mathbf{X}_t; t = 1, 2, \ldots\}$ exhibits a prespecified autocorrelation structure. Specifically, the base correlation $\rho_{\mathbf{Z}}(i,j,h) = \mathrm{Corr}\left(Z_{i,t}, Z_{j,t+h}\right)$ depends only on the input correlation $\rho_{\mathbf{X}}(i,j,h) = \mathrm{Corr}\left(X_{i,t}, X_{j,t+h}\right)$ for $i, j = 1, 2, \ldots, K$ and $h = 0, 1, 2, \ldots, p$, and the determination of the autocorrelation structure for the base process is equivalent to solving $pK^2 + K(K-1)/2$ individual correlation-matching problems; see Biller and Nelson (2003) for a discussion of solving correlation-matching problems in a multivariate time-series setting.

Concluding Remarks

Practical and theoretical issues for developing input models in both univariate and multivariate settings have been presented. Also considered was the situation where univariate input models fall short of capturing the correlations among different sources of randomness in the input environment of the stochastic system under study. Much research in the last decade has focused on multivariate input modeling to develop flexible input models in correlated settings. Most of the recent developments in input modeling is reported in the annual *Proceedings of the Winter Simulation Conference*, which are publicly available on the World Wide Web.

Stochastic Model

A mathematical model in which some data and parameters are random variables.

See

- ▶ Deterministic Model
- ▶ Mathematical Model

Stochastic Optimization

Optimization in which the objective function and/or constraint functions are "noisy," i.e., involve random variables (e.g., expected values) that cannot be evaluated analytically and thus require estimation, such as through simulation of a stochastic system. Sometimes the term is also used to refer to deterministic optimization problems that introduce randomness in the search process, i.e., the resulting procedures are randomized algorithms for optimization.

Introduction

Stochastic programming (SP) deals with a class of optimization models and algorithms in which some of the data may be subject to significant uncertainty. Such models are appropriate when data evolve over time, and decisions need to be made prior to observing the entire data stream. For instance, investment decisions in portfolio planning must be implemented before stock performance can be observed. Similarly, utilities must plan power generation before the demand for electricity is realized. Such inherent uncertainty is amplified by technological innovation and market forces.

As an example, consider electric power supply. Most states in the U.S. have adopted Renewable Portfolio Standards, which mandate far greater use of renewable resources in the future. However, renewable sources of energy (e.g., wind and solar) are intermittent

resources, because they are governed by highly variable forces of nature. Including such generators into a deterministic generation planning model would require accurate predictions of natural phenomena (i.e., wind and sunshine). Of course, requiring accurate predictions is tantamount to having a crystal ball into the future – an untenable assumption. SP provides a formal approach in which events of the future can be modeled using random variables (or stochastic processes) modeling the future. Because of the wide variety of applications where data uncertainty plays a critical role, this paradigm has also attracted researchers from a variety of academic domains, as well as government and industry. For instance, the area of supply chain management (e.g., Fisher et al. 1997) was an early adopter of SP. More recently, the 2011 report of the Defense Science Board has strongly recommended the use of SP for long-term trade studies carried out for military planning. Indeed, the volume by Wallace and Ziemba (2005) provides an entire collection of papers that are based on applications ranging from airline revenue management, homeland security, network planning and many more. Nevertheless, SP models remain some of the more challenging optimization problems.

While SP grew out of the need to incorporate uncertainty in linear and other optimization models (see Birge and Louveaux 1997), it also has close connections with other paradigms for decision-making under uncertainty. For instance, decision theory, dynamic programming and simulation-optimization, all share some common themes with SP. To explore these connections recall that one of the main strengths of decision theory is its emphasis on decision-maker's preferences, and ideas such as stochastic dominance emerged from the decision-theoretic segment of the OR/MS literature. It turns out that ideas such as stochastic dominance have made significant in-roads into the SP literature (Dentcheva and Ruszczyński 2003). Similarly, there are growing connections between dynamic programming (DP) and SP through new thrusts such as Approximate DP (Powell 2010). SP has a long tradition of creating approximations that provide asymptotic results and many SP methods provide bounds on deviations from optimality when terminated in finite time. The section on Computational Issues provides some examples. Finally, consider the connections between SP and simulation-optimization. The latter category supports models that are reasonably realistic in their description of the system, because they inherit the expressiveness of computer programming within the modeling framework. However, simulation-optimization models are relatively difficult to optimize because of the generality associated with non-convex noisy "Black Box" functions. Accordingly, simulation-optimization often attempts to combine statistical tools with global optimization. The connections between SP and simulation-optimization however are clearest in the context of sampling-based algorithms for SP. The latter draw upon several concepts from simulation-optimization (e.g., importance sampling, Latin hypercube sampling). The interplay between the different paradigms presents fascinating possibilities.

SP provides a general framework for modeling stochastic processes within constrained optimization models. Furthermore, it permits uncountably many states and actions, together with constraints, time lags, etc. One of the important distinctions that should be highlighted is that SP separates the model formulation activity from the solution algorithm. One advantage of this separation is that users need not be intimately familiar with SP algorithms in order to use them. This separation also promotes algorithmic developments that are based on specialized structures (e.g., linear, integer etc.), which may help algorithms to scale up by using special structures. On the downside of the ledger, SP formulations can lead to very large-scale problems, and methods based on approximation and decomposition become paramount. This article provides a road map for these methods and points to fruitful research directions along the way.

Mathematical Models and Properties

General Purpose SP Models

Consider a model in which the design/decision associated with a system is specified via vector x_1. Under uncertainty, the system operates in an environment in which there are uncontrollable parameters that are modeled using random variables. Consequently, the performance of such a system can also be viewed as a random variable. Accordingly, SP models provide a framework in which designs (x_1) can be chosen to optimize some measure of

performance (random variable). It is therefore natural to consider measures such as the worst-case performance, expectation and other moments of performance, or even the probability of attaining a predetermined performance goal. Furthermore, measures of performance must reflect the decision maker's attitudes towards risk. For example in the finance literature, it is common to model risk aversion through maximizing expected utility. However, alternative risk models have also become common in the SP literature. These include measures like conditional value at risk (Rockafellar and Uryasev 2000), semi-deviation (Ogryczak and Ruszczyński 2001), and others. The mathematical structure presented below begins with a traditional SP formulation, and a discussion of risk is revisited subsequently.

The following mathematical model represents a general SP formulation in which the design/decision variable x_1 is restricted to the set X_1 and $\tilde{\omega}_1$ denotes a multi-dimensional random variable:

$$\min_{x_1 \in X_1} \quad f_1(x_1) + E[h_2(x_1, \tilde{\omega}_1)] \tag{1a}$$

$$\text{s.t. } \Pr\{g_1(x_2, \tilde{\omega}_1) \geq 0\} \geq p_1 \tag{1b}$$

Here $E[]$ denotes the expectation with respect to $\tilde{\omega}_1$ and Pr[] is the probability of the event $g_1(x_1, \tilde{\omega}_1) \geq 0$.. The function g_1 is often modeled as a linear form and h_2 is the value function of another optimization problem stated as follows:

$$h_2(x_1, \omega_1) = \min_{x_2 \in X_2(x_1, \omega_1)} f_2(x_2; x_1, \omega_1)$$

In this notation, the subscripts are intended to designate the stage in which the relevant calculations are carried out. Thus f_1 reflects the initial cost in stage 1, whereas, h_2 reflects the cost-to-go in stage 2. In the SP literature, the function h_2 is used to reflect costs associated with adapting to information revealed through an outcome ω_1. For instance, in financial applications, this function may reflect the utility associated with costs of rebalancing the portfolio. Because the function $E[h_2]$ is associated with a recourse action x_2, it is referred to as the recourse function, although the use of the term value function is not uncommon either. Constraint (1b) is called a probabilistic (or chance) constraint. Such a constraint may be used to model system reliability. Note that formulation (1) is somewhat more general than one usually finds in the SP literature. Historically, the probabilistic constraint (1b) is treated separately from models using the recourse functions (1a). However, including both types of functions within one model allows a more cohesive statement of SP problems.

Multi-stage Stochastic Programming — While model (1) appears somewhat static, it is not difficult to glean a dynamic element in the formulation: note that the function h_2 is realized only after the design x_1 is in place. This sequential nature is an essential element of decision making under uncertainty. Indeed, if h_2 is defined recursively, problem (1) may be looked upon as the first-stage problem of a more extensive multi-stage formulation. To present this generalization of (1), consider an N-stage problem. Let the boundary conditions be given by $h_{N+1} \equiv 0$, and let ω_0 denote a degenerate random variable reflecting the deterministic information available prior to decisions of stage 1. For $t = 1,\ldots, N$, let ξ^t denote the history prior to stage t [i.e., $\xi^t = (\omega_0, \ldots, \omega_{(t-1)})$]. Note that the decision variables in stage t depend on the history of the data process. Hence these variables are functions of random variables, and will be denoted $x_t(\xi^t)$. The entire history of decisions until stage t will then be represented as a superscripted vector $x^t(\xi^t) = (x_1(\xi^1), x_2(\xi^2), \ldots, x_t(\xi^t))$, or simply x^t. For $t = 2,\ldots, N$, define the value functions

$$\begin{aligned} h_t(x^{t-1}, \xi^t) = \min_{x_t \in X_t(x^{t-1}, \xi^t)} & f_t(x_t; x^{t-1}, \xi^t) \\ & + E\left[h_{t+1}\left(x^t, \tilde{\xi}^{t+1} | \xi^t\right)\right] \\ \text{s.t } \Pr\{g_t(x_t, \xi^{t+1} | \xi^t) \geq 0\} & \geq p_1 \end{aligned} \tag{2}$$

where $h_{N+1} \equiv 0$, and E and Pr[] denote the conditional expectation and the conditional probability (respectively) associated with the appropriate evolutionary state of the random variables. Using these recursively defined functions in (1) yields a multi-stage SP formulation.

While (1) and (2) present a DP-type recursion to state the SP problem, it is important to note that all random variables are path dependent, and furthermore,

the statement of the model does not constitute the algorithm. In fact, alternative statements of the multi-stage problem are also possible. Consider a formulation in which the decisions are allowed to depend on the entire realization ξ^N. Let $\mathrm{x}^N\left(\tilde{\xi}^N\right)$ denote a sequence of random vectors $\left(x_1\left(\tilde{\xi}^N\right), x_2\left(\tilde{\xi}^N\right), \ldots, x_N\left(\tilde{\xi}^N\right)\right)$. It is important to note that such a policy cannot be implemented since decisions in stage t require the knowledge of the entire realization! Hence, the plans $x^N\left(\tilde{\xi}^N\right)$ cannot be feasible, unless the decisions are such that x_t depends only on data available until stage $t-1$. As shown below, such information constraints can be incorporated explicitly.

Let $\omega^t = (\omega_t, \ldots, \omega_N)$. Since any outcome $\xi^N = (\xi^t, \omega^t)$ for any t, the decisions in stage t can be represented as a random vector denoted $x_t(\tilde{\omega}^t|\xi^t)$. Then the information constraints (also called the nonanticipativity constraints) may be stated as $x_t(\tilde{\omega}^t|\xi^t) - E[x_t(\tilde{\omega}^t|\xi^t)] = 0$, almost surely.

Since an objective function that is non-separable by stage can be written as $\mathrm{E}\left[\mathrm{f}\left(\mathrm{x}^{\mathrm{N}}\left(\tilde{\xi}^{\mathrm{N}}\right), \tilde{\xi}^{\mathrm{N}}\right)\right]$, the inclusion of information (nonanticipativity) constraints provides a legitimate multi-stage model which does not appeal to either separability or recursion. However, multi-stage stochastic programming algorithms are far less advanced than two-stage models.

The formulations presented above impose very few restrictions. Perhaps the most important restriction imposed in an SP formulation arises from the assumption that randomness is exogenous and cannot be affected by decisions. In certain design problems, such an assumption may not be valid, and in these cases, the models outlined above may not be adequate. However, in cases where the impact of decisions on the probability distribution can be reflected via a binary switching variable, then one may be able to introduce binary variables to represent the evolution of the distribution based on prior decisions. Naturally, such a model will lead to a Stochastic Mixed-Integer Program (SMIP) for which there has been considerable interest since 2000. Nevertheless, note that there is a large class of applications where randomness is exogenous (e.g., weather, loads, prices of financial instruments, market demands, etc.), and SP models provide an attractive approach, especially when faced with a continuum of choices in the presence of constraints.

The main challenge in designing algorithms for SP problems arises from the need to calculate conditional expectation and/or conditional probability associated with multi-dimensional random variables. For all but the smallest of problems, one resorts to approximations. The study of SP algorithms has therefore led to alternative ways of approximating problems, some of which satisfy certain asymptotic properties. This reliance on approximations has prompted researchers to study conditions for the convergence of approximations, and/or the convergence of solutions of approximate problems (to a solution of the original). Of course, conditions ensuring the former imply the latter, but the converse does not hold. Issues related to convergence of approximations can be addressed through the theory of epi-convergence, whereas issues pertaining to convergence of solutions of approximations (to a solution of the original) can be addressed through the notion of epigraphical nesting (see Rockafellar and Wets 1998).

Properties of Specific SP Models

Computational challenges associated with SP problems vary a great deal with the class of problems being addressed. As with any large-scale optimization problem, exploiting properties and the structure of problems provides the key to effective algorithms. This subsection presents properties associated with some important classes of SP problems, and related computational issues will be presented in the following section.

Some Properties of Stochastic Linear Programs with Recourse — For this class of problems, all functions and constraints are defined by linear/affine functions, and the probabilistic constraints are absent. This remains one of the more widely studied models, and most of the applications reported in the literature belong to this category (including the applications mentioned earlier). Problems of this type can be shown to be convex optimization problems, and the full power of convex analysis can be brought to bear on such problems. Notwithstanding such mathematical attractiveness, SLP problems lack one of the more desirable numerical properties, namely, smoothness.

Only under very special circumstances (absolute continuity of random variables) can one expect (1a) to be differentiable. Accordingly, many of the more successful algorithms for these problems draw upon non-differentiable optimization methods such as Regularized Decomposition (Ruszczyński 1986), as well as Regularized SD (Higle and Sen 1994), both of which are closely tied to bundle-trust algorithms.

Some Properties of Stochastic Mixed Integer Programs — As in the previous paragraph, suppose that probabilistic constraints are set aside. In a stochastic mixed integer linear program (SMIP), if only the first-stage decisions include integer restrictions, then the remaining problem inherits the properties of a SLP. This class of problems (with first-stage integer variables) is similar to the problems originally envisioned by Benders (1962). In general, though (i.e., when integer variables appear in future stages), SMIP is much more challenging. For such problems, convexity of the objective function is far too much structure to expect. Indeed, the objective function (1a) can be discontinuous. However, by assuming that any setting of decision variables yields a finite objective value (i.e., complete recourse), and assuming a weak covariance condition (Schultz 1993), the objective function can be shown to be lower semicontinuous. As with continuous SP algorithms, scalability is a key requirement, and decomposition-coordination methods remain the basis for effective algorithms.

Some Properties of Probabilistically-Constrained Problems — These models are widely used to reflect grade of service constraints (e.g., Medova 1998). One of the simpler probabilistically-constrained problems arises in cases where the function g_1 used in (1b) assumes values in $\Re$ and is separable (i.e., $g_1(x_1, \omega_1) = \theta_1(x_1) + \omega_1$). In this case a deterministic constraint requiring $\theta_1(x_1)$ to exceed the quantile (level p_1) is equivalent to the chance constraint. There are a few other cases that are easily handled. Prékopa (1971) showed that a much larger class of random variables yield the convexity property; he showed that if the function g (see (1b)) is linear/affine in x and randomness only appears additively, and the random variable has a log-concave probability density function, then the resulting feasible region is convex. However, for discrete random variables this is no longer true, and in this case, the set of feasible solutions can be represented as a disjunctive set. Algorithmic work on probabilistically constrained models also allows MIP models to be extended with probabilistic constraints (see following section).

Risk Modeling in Stochastic Programming — Since 2000, the SP approach has grown enormously in its ability to incorporate risk. One approach, namely the notion of Conditional Value at Risk (CVaR), is discussed next. Recall from (1) that both the objective function and constraints are defined in terms of the first-stage decision x_1, as well as random variables $\tilde{\omega}_1$. For the sake of brevity, the sub/super scripts are dropped and consider any one of the functions, $g(x, \tilde{\omega})$, say. In order to model risk, one typically wishes mitigate the negative impacts of variability (referred to as risk). The real-valued function g may be looked upon as a loss (random variable), and let $\psi(x, \zeta) = \Pr[g(x, \tilde{\omega}) \leq \zeta]$. Given $p \in (0,1)$, define $\zeta_p(x) := \min\{\zeta | \psi(x, \zeta) \geq p\}$. This quantity is known as Value at Risk (VaR_p), a term that is popular in the financial world. Thus, for a given $p \in (0,1)$, VaR_p ensures that a decision x satisfies (1b). However, this constraint does not measure the consequences of outcomes beyond $\zeta_p(x)$. Thus when tail losses are very high, VaR_p is unable to distinguish between decisions that are more risky at the same confidence level p. In addition, as indicated in the subsection on Probabilistic Constraints, these models can be mathematically difficult due to non-convex feasible sets. Due to these difficulties, Rockafellar and Uryasev (2000) suggested an alternative to VaR_p, known as CVaR_p, or Conditional Value at Risk. CVaR_p is defined as the conditional mean of the loss random variable in the tail to the right of $\zeta_p(x)$ in case of continuous random variables. In other words, if $\psi_p(x,\zeta)$ denotes the distribution of the random variable $\mathrm{Max}\{g(x, \tilde{\omega}) - \zeta_p(x), 0\}$, then the expectation of this random variable gives the mean *excess* loss. For cases in which $g(x, \tilde{\omega})$ is a discrete random variable, the definition of CVaR_p can be shown to be a convex combination of VaR_p and CVaR_p^+, which is the conditional mean (of the loss random variable) strictly to the right of $\zeta_p(x)$. One important feature of CVaR_p is its convexity, and is therefore computationally tractability too. For further attractive properties of CVaR_p and other coherent measures of risk, see Rockafellar (2007).

Robust Optimization — The term robust optimization has been used for several different

classes of models, all of which share the goal of providing decisions that are feasible and reasonably good for an entire set of model parameters, rather than one specific instance of parameters. This approach to decision-making is different from other stochastic optimization approaches in at least two substantive ways: (a) the goal of robust optimization is to immunize decisions in case of imperfect information (or data), and (b) the decisions themselves do not evolve as better information becomes available. Such models are useful in applications such as engineering design. For example, in designing a truss, an engineer assumes nominal values for properties of each member of the truss. However, due to manufacturing and material variability, some of the properties may vary from those nominal values. Of course, the design should be such that the truss is able to perform so long as all members satisfy the required properties within some acceptable tolerance. Moreover, in such applications, the design (i.e., the decision) cannot change with the specific realization of parameters, although the objective as well as constraint values (i.e., performance) will vary. This is reflected in items (a) and (b) above.

Robust optimization models, first proposed by Soyster (1973), are distribution-free formulations in which an uncertainty set replaces the notion of a probability space. For the sake of definiteness, consider the approach of Bertsimas and Sim (2004). In their paper the authors start with a nominal deterministic LP, and augment it by incorporating certain protection functions that represent extreme values of constraint coefficients which are allowed to belong to given intervals of uncertainty. The cross product of these intervals forms the uncertainty set. By using LP duality, these protection functions can be shown to have a very simple structure, and the resulting Robust LP is simply another larger LP whose size is only modestly larger than the nominal LP. Similar results have also been obtained for IP formulations (Bertsimas and Sim 2003), and they show that when uncertainty only affects cost coefficients, and the nominal problem is polynomially solvable (e.g., shortest path), then the Robust IP also inherits polynomially solvability. Other approaches to robust optimization, (e.g., using ellipsoidal uncertainty sets leading to conic quadratic programs) have been proposed by Ben-Tal and Nemirovski (1998).

Computational Issues

The main computational challenges for stochastic programming may be attributed to the fact that uncertainty must be quantified every step of the way: input data and model development, algorithmic methods for optimization, and finally, output analysis. It has been suggested that such effort (especially knowledge of distributions), may be far too demanding, thus leading to slower adoption of SP methodology within the modeling and optimization community. Advances in statistical computing, machine learning etc. are making such activities (e.g., estimating/approximating distributions) much less onerous than in the past. Since many tools in OR/MS, e.g., stochastic discrete-event simulation and decision analysis, are deeply steeped in the use of probabilistic knowledge, the need to provide probabilistic description should not be a bottleneck for SP. The challenge is to provide an end-to-end software environment in which decisions under uncertainty can be modeled, processed and analyzed in a manner that distills uncertainty down to statistically quantified reports to support decision-making. In the remainder of this section current approaches towards statistical quantification for SP are summarized, but not before the more traditional deterministic decomposition algorithms.

Deterministic Decomposition Algorithms for SP

Deterministic Algorithms for Stochastic Linear Programs (SLP) — The design of algorithms for SLP is intimately tied to the universe of outcomes reflected in the model. For instances in which the future is encapsulated using only a few outcomes/scenarios, the deterministic equivalent formulation (DEF) can be solved using deterministic decomposition methods that are extensions of Benders' decomposition (e.g., Regularized Decomposition of Ruszczyński 1986). Others (e.g., Linderoth and Wright 2003) are more direct extensions of bundle-trust methods of non-smooth optimization (e.g., Kiwiel 1990). Another class of deterministic decomposition algorithms is based on relaxing the information/nonanticipativity constraints (Rockafellar and Wets 1991). This approach is particularly promising for parallelizing algorithms for multi-stage problems. An overview of all of these methods can be found in the text by Birge and Louveaux (1997). In any event, since

the entire collection of DEF formulations use deterministic methods, the need for statistical quantification of outputs does not apply to them. However, in cases where an instance is created by sampling the original problem, statistical analysis of output is essential.

Algorithms for Stochastic MIPs — One of the major thrusts in the SMIP literature calls for algorithms that go beyond Benders' decomposition so that one can address models in which the second-stage (recourse) decision variables are also restricted to be integer. In cases where the first stage has binary variables, and the second-stage has general mixed-integer variables, Laporte and Louveaux (1993) have proposed an extension of the L-shaped method. Unfortunately, it requires that the second stage problem (possibly a mixed-integer linear program (MIP)) is solved to optimality for all scenarios. It is not difficult to see that solving many MIPs in each iteration can become a major bottleneck. To overcome this, several algorithms have been proposed so that each iteration only requires the solution of an LP relaxation of the scenario problems. In order to achieve asymptotic convergence of such schemes, it becomes necessary to generate cutting planes in a sequential manner so that the approximations become stronger as the algorithm proceeds, and obtains an optimal solution (or a near-optimal solution) in the limit. Since 2000, several algorithms of this genre have been proposed. Some of these are based on parametric Disjunctive Programming where cuts depend parametrically on binary first-stage decisions (e.g., Sen and Higle 2005; Sen and Sherali 2006; Sherali and Fraticelli 2003). A similar approach based on parametric Gomory cuts is presented in Gade et al. (2012) Computational results for parametric disjunctive cuts are given in Yuan and Sen (2009). For a more complete exposition of these algorithms and computations, see Sen (2010).

Successive Approximation Algorithms for SP

Unlike the deterministic decomposition methods mentioned above, there are many realistic instances for which the sample space is so large that enumerating every outcome may be impossible. In such cases, one resorts to successive approximation methods. In the following the focus is on alternative ways to construct approximations.

Bound-based Approximations for SLP Problems — For two-stage models, there are essentially two major approaches to generating approximations. One is based on aggregating data points, and another based on selecting data points. Algorithms in the former class of lead to successive approximation methods in which finer discretizations of the sample space are created based on the solution of an aggregated stochastic program. These successive approximation schemes (e.g., Frauendorfer 1992; Edirisinghe and Ziemba 1996) are able to provide bounds on the optimality gap, thus providing the decision-maker some guarantees. Similar bounds on the gap are also possible for multi-stage models as suggested in Casey and Sen (2005). Unfortunately the scalability of these methods has remained unresolved, and the literature has moved steadily towards sample-based methods, which are presented next.

Sampling-based Approximations for SLP Problems — Sampling in SP includes both Monte-Carlo as well as quasi-Monte Carlo methods. The latter draws upon the numerical integration literature, and its application to SP appears in Pennanen and Koivu (2005). However, one of the main distinctions to bear in mind for SP is that the expectation (integrand) depends on the decisions. For the most part, SP algorithms tend to generate a sample prior to optimization, so that the approximation does not typically adapt to the decision. This is also true for most Monte-Carlo approaches such as Sample Average Approximation (Shapiro and Homem-de-Mello 1998). The separation between generation of the sample, and the application of an optimization algorithm tends to preclude inexact optimization, which has been a very powerful concept in many areas of optimization (e.g., inexact Newton's method). The concept of inexact optimization between samples is highlighted in the Stochastic Decomposition (SD) algorithm for two-stage SLP (Higle and Sen 1996). Such inexact optimization is also adopted in a robust stochastic approximation (RSA) algorithm (Nemirovski et al. 2009), where the adaptation of stochastic approximation generates excellent solutions with a fraction of the computational effort required by SAA. In defense of SAA, however, one is able to obtain relatively low variance lower bound estimates at the end of an experiment with a few runs using a relatively large sample approximation (Linderoth et al. 2006).

Such lower bound estimates are difficult to obtain for RSA, and further post-processing becomes necessary. Moreover, RSA computations presented in Nemirovski et al. (2009) do not include computational times for post-processing. It is interesting to note that SD is, in some ways, a compromise between RSA and SAA: as with RSA, SD works with inexact subgradients that are observed dynamically as the algorithm proceeds, and as with SAA, it provides a capability for estimating sampled lower bound as well as its variability. In addition, both SAA and SD are also capable of providing reasonable estimates of the first-stage dual multipliers, which may be useful in certain pricing applications of SP (Higle 2007).

Sampling-based Approximations in SMIP Problems — For cases where the integer variables only appear in the first stage, algorithms based on Benders' decomposition are generally sufficient, although for cases in which a large number of scenarios arise, one may have to combine ideas from Benders' decomposition with those from sampling as discussed above. Such a method has been presented in Norkin et al. (1996). Sampling has also been part of the motivation for MIP with chance constraints, where Leudtke and Ahmed (2008) provide performance guarantees by setting up a convex approximation by sampling. In related work on jointly chance constrained MIPs, Kucukyavuz (2012) presents strong valid inequalities by using mixing sets with cardinality constraints (for the sampled case), as well as a knapsack constraint for the more general case. Compact extended formulations are also suggested for obtaining strong relaxations for solving chance constrained MIPs.

Multi-stage SP: Scenario Generation and Sampling — Two early approaches to scenario tree generation were Hoyland and Wallace (2001) and Pflug (2001). The former is designed to match certain known moments of a stochastic process using optimization, where as the latter generates a scenario tree using a simulation model, coupled with a stochastic approximation algorithm. Other approaches combining Monte Carlo sampling and clustering have also been proposed in Gulpinar et al. (2004). These methods are independent of the solution algorithm used to solve the multi-stage SP, and it is likely that the scenario tree generated by any one exceeds the capability of most solution algorithms. In order to allow users to formulate a smaller SP model, Dupacova et al. (2003) (see also Heitsch and Romisch 2007) present a scenario reduction scheme based on the nearest discretization for a prescribed number of scenarios. This approach, which also incorporates some heuristics to enhance scalability, is now available through GAMS.

As for combining both sampling in solution algorithms for multi-stage SLP, the idea of stochastic dual decomposition, originating with Pereira and Pinto (1991), has continued to attract attention. Asymptotic results are provided by Philpott and Guan (2008). In Shapiro (2011), the author suggests that in many previously reported papers, the quality of solutions reported for multi-stage models were unclear. In order to give the reader a sense of what the future of multi-stage SP may hold, the special case of statistical quantification for two-stage SLP is discussed below.

Statistical Quantification of SP Output: Two-Stage Models

Sampling methods for two-stage SLPs (i.e., SAA as well as SD) have been tested on several test instances of varying sizes. Unlike deterministic optimization where the size of an optimization model is unambiguous (because the size of the input is well defined), this is not necessarily the case for SP. To appreciate this, note that instances that are defined by continuous random variables should be looked upon as infinite-dimensional problems, although the first-stage (here-and-now) decisions may be finite dimensional. As a result, an exact representation of an SP instance may be difficult, and in fact, an exact solution as well as the exact optimal value may also be elusive. For these reasons, it is important to report the degree of accuracy of both the objective function estimate, as well as any lower bound estimate that may provide a sense of the quality of one or more feasible solutions. Simply reporting the objective function value of an approximation (using a few scenarios) without providing an estimate of errors can be misleading!

Bayraksan and Morton (2009) discuss a framework which highlights the need for reporting variability of objective value estimates by replicating the optimization process using independent samples. The estimated sample mean obtained after multiple runs then provides an estimated lower bound on the optimal value of the original (unsampled) model (Mak et al. 1999). It is not difficult to see that the

Stochastic Programming, Table 1 SP test instances

Problem name	No. of first stage variables	No. of second stage variables	No. of random variables	Universe of scenarios
LandS	4	12	3	$O(10^6)$
20TERM	63	764	40	$O(10^{12})$
SSN	89	706	86	$O(10^{70})$
STORM	121	1,259	117	$O(10^{81})$

estimated sample mean increases with sample size and asymptotically approaches the optimal value of the SP problem. As for estimated upper bounds, the obvious strategy is to fix a first-stage decision, and use i.i.d. sampling to estimate an upper bound. However, the reader should bear in mind that a low variance upper bound estimate is often computationally as demanding as solving an approximation that yields a lower bound. Striking a reasonable balance between these is important for overall efficiency.

Table 1 presents some characteristics of a few test instances that have been used for computational experiments in the literature. These instances are listed in increasing order of random variables, and are useful in illustrating statistically quantifiable bounds for SP problems whose sample space may contain so many outcomes that they are best described as being infinite dimensional. Again, if one uses sampling to provide approximate solutions for any of these instances, it is important to report errors with respect to the original SP instance.

The SAA estimates of Table 2 appear in Linderoth et al. (2006), and these are compared with computational results from Regularized SD (Higle and Sen 1994). In addition to the four instances above, Linderoth et al. (2006) also include a test instance named "gbd". This instance has not been included here because it is a simple-recourse model with independent random variables; for such instances, bounds-based approximation (see the previous subsection) provides a more accurate and scalable approach.

For the SAA experiment of Table 2, Linderoth et al. (2006) report solving SAA experiments with several different sample sizes. In the interest of brevity, as well as best accuracy in estimates, their results are summarized for a sample size of 5,000 using Latin hypercube sampling. In the SAA-(Average Values) column of Table 2, the entries in rows OBJ-LB for each instance correspond to the average value from solving 7-10 SAA replications in which each replication contained 5,000 sampled scenarios. The authors used a grid-enabled bundle-trust algorithm presented in Linderoth and Wright (2003) to solve each replication. The computational grid was managed by Condor, and consisted of hundreds of Linux PCs at several locations around the U.S. However, the runs apparently used only 100 PCs at any given time. One might recall that Pentium IV processors, with average clock speeds of 2.0–2.4 Ghz were average PC processors in 2005. In any event, the wall clock time for an instance like SSN was reported to be about 30-45 min per SAA instance, suggesting a total wall clock time of about 3.5 h for seven replications (@30 min/replication) and 7.5 h for ten replications (@ 45 min/replication). Once the solutions to these 7–10 instances were obtained, they were each evaluated to some degree of accuracy using a sample size of 20,000 for each SAA solution. From this preliminary estimate, the authors chose the solution with the lowest (preliminary) estimate of the objective value, and sampled further 50 batches, with each batch consisting of 20,000 outcomes. The OBJ-UB estimates reported in the SAA-(Average Values) column is the estimate obtained from this upper bounding exercise. It is important to note that with each upper bounding entry, one associates exactly one primal solution – a solution that is recommended for decision-making.

In Table 2, the set of columns adjacent to the SAA columns is data from the SD experiment. For the SD-(Average Values) column, the OBJ-LB entries correspond to the average value from solving 20 SD replications of the Regularized SD algorithm (Higle and Sen 1994). The reader might observe that there is no sample size reported for SD, because it samples until a non-parametric stopping rule (based on bootstrapping) terminates a replication of the algorithm. In any event, these calculations were carried out on a laptop-grade platform: MacBook Air with 1.8 GHz Intel Core i5 processor, 4 GB of 1,600 MHz DDR3 Memory.

The last column of Table 2 summarizes the differences in average values obtained from these two experiments. For the most part, the differences in average bounds are less than a small fraction of 1%. The only bound whose difference (with SAA) is close to 1% is the lower bound for SSN. Considering that the

Stochastic Programming, Table 2 Statistical quantification with SAA and SD

Instance name	Upper (UB) and lower bounds (LB)	SAA estimates using a computational grid		SD estimates using a laptop		Percentage difference in Average values
		Average values	95% CI's	Average values	95% CI's

upper bound for SSN is only 0.03% different from the average reported in Linderoth et al. (2006), it is fair to suggest that the average bounds produced by SAA with 5,000 samples and SD are comparable. However it is difficult to make precise comparisons of computational effort between algorithms implemented and tested using software and hardware from different eras. To give the reader a sense of the computational time for SD, note that all 20 SD replications for SSN were completed within 50 min. Suffice to say that using SD on computing platforms of today provides a widely accessible approach for realistic stochastic programming models (e.g., SSN – see Sen et al. 1994).

Software for SP

Since 2000, there have been significant advances in the development of modeling environments for SP. Watson, Woodruff, and Hart (2010) have developed a Python-based modeling environment for Stochastic Programming (PySP). In addition to its modeling capabilities, PySP also provides an implementation of the scenario aggregation (progressive hedging) algorithm for SP. Other notable developments include the implementation of the scenario reduction framework within GAMS. This has the potential to move multi-stage SP into a higher level of usage, and perhaps, there will be reports of accuracy of multi-stage models in the same manner that Table 2 presents confidence intervals for both upper as well as lower bounds. In 2012, Frontline Systems released their platform (Risk Solver Platform) for Robust Optimization as well as two-stage Stochastic Decomposition. Similarly, a product named Portfolio Safeguard (by AORDA) uses SP for portfolio optimization. Two-stage SLP is at the cusp of breaking into a new segment of the modeling world that brings together risk analysis and optimization. In other words, the time for two-stage SLP as a practical modeling tool has arrived.

Concluding Remarks

Several prevailing trends in SP are expected to continue. For instance, it is expected that there will be continued growth in modeling risk; greater emphasis on multi-stage models and methods; greater focus on scalable (e.g., decomposition) methods for SMIP models; greater visibility for strategic models under uncertainty (e.g., stochastic games and stochastic variational inequalities). Nevertheless, it is also important to recognize some important challenges: (a) As pointed out in the introduction, there are several areas of OR/MS that address decision-making under uncertainty. In this sense, there is a relatively large community of researchers from DP, Decision Theory, and Simulation-Optimization with significant overlaps with SP. It is a challenge to put these areas on a common unified footing. Such a development would allow greater cross-fertilization between the areas. (b) Most approaches to multi-stage SP (see (2)) are unable to address models driven by continuous stochastic processes. A statistically quantifiable approach to such models would be very satisfying; however, such a capability is not available yet. By emphasizing statistical quantification for similar two-stage models, it is hoped that this article provided a sense of the types of outputs that are necessary for multi-stage models. Finally, SP computations are not difficult to perform on today's hardware environment. What is holding SP

back is the lack of end-to-end software support. Given the new breed of SP software that is becoming popular, it is expected that there will be a full-fledged SP environment before too long.

Strategic Assumption Surfacing and Testing (SAST)

A problem structuring method for use in situations where decisive action is obstructed by internal disagreements. Coherent sub-groups are formed with the purpose of advocating differing strategies, and each identifies the significant assumption on which its preferred strategy depends. The sub-groups are then reunited to debate the differences in assumptions, with the aim of achieving a compromise on assumptions so that a consensus strategy can be derived.

Strategic Choice Approach (SCA)

Strategic Choice Approach (SCA) is a problem structuring method centered on the management of uncertainty and commitment in strategic situations, where strategic refers to the advisability of considering particular decisions in the context of others. Strategic occasions can occur at any level. For fuller descriptions see Friend (2001), Friend and Hickling (2004).

The structure of the planning situation is elicited from stakeholders in a workshop format. This structure is built up in a participatory manner, with the aid of facilitators. SCA is a member of the Problem Structuring Methods family; within that

group it is notable for the variety of tools and techniques available to make progress with the problem. It has been widely used in diverse areas of public planning.

There are four modes of analysis within SCA. Switching between modes, which may be recursive, is guided by the facilitator. The modes are:

- Shaping – in which the stakeholder group identifies relevant areas for choice, and the linkages between them. They select a subset of these as a problem focus by reference to their urgency, importance and inter-connectedness
- Designing – here the options for action within each of the selected decision areas are identified, plus any incompatibilities between options in different decision areas. The feasible decision schemes (consisting of one option choice within each decision area) are derived using the AIDA algorithm
- Comparing – criteria for choice, often non-quantitative, are agreed by the group. A small number of the decision schemes are short-listed, and pairwise comparisons are made between short-listed schemes. The group agrees the relative advantage on each criterion between the two schemes, commonly revealing significant uncertainties.
- Choosing – bearing in mind the surfaced uncertainties, a 'progress package' is agreed consisting of partial commitments, explorations to reduce key uncertainties areas, contingency plans, and a timetable for later choices.

The progress package summarizes the outcomes of a SCA application. Other outputs include improved understanding of the problem area and better working relations among group members.

Strictly Quasi-Concave Function

A function $f(x)$ is strictly quasi-concave over a convex set S if for any two points $x_1 \neq x_2$ in S and for any $0 < \alpha < 1$, $f(x_2) \geq f(x_1)$ implies that $f(\alpha x_1 + (1 - \alpha)\, x_2) > f(x_1)$.

Strong Duality Theorem

Consider the following primal linear-programming problem and its dual problem:

$$\begin{aligned} &\textit{Dual} \\ &\text{Maximize} \quad \boldsymbol{b}^{\mathrm{T}}\boldsymbol{y} \\ &\text{subject } \textit{to} \quad \boldsymbol{A}^{\mathrm{T}}\boldsymbol{y} \leq \boldsymbol{c} \\ &\qquad\qquad \boldsymbol{y} \geq \boldsymbol{0} \\ &\textit{Primal} \\ &\text{Minimize} \quad \boldsymbol{c}^{\mathrm{T}}\boldsymbol{x} \\ &\text{subject } \textit{to} \quad \boldsymbol{A}\boldsymbol{x} \geq \boldsymbol{b} \\ &\qquad\qquad \boldsymbol{x} \geq \boldsymbol{0} \end{aligned}$$

The strong duality theorem is usually stated as follows: If either the primal or the dual has a finite optimal solution, then the other problem has a finite optimal solution, and the optimal values of their objective functions are equal, i.e.,

$$\text{minimum } \boldsymbol{c}^{\mathrm{T}}\boldsymbol{x} = \text{maximum } \boldsymbol{b}^{\mathrm{T}}\boldsymbol{y}$$

The weak duality theorem basically relaxes the equality result to a bound by removing the optimizing operator as in the following statement: If $\boldsymbol{x}$ is a feasible solution to the primal problem and $\boldsymbol{y}$ is a feasible solution to the dual problem, then $\boldsymbol{b}^{\mathrm{T}}\boldsymbol{y} \leq \boldsymbol{c}^{\mathrm{T}}\boldsymbol{x}$.

Strongly NP-Complete (NP-Hard)

- ▶ Computational Complexity

Strongly Polynomial-time Algorithm

An algorithm whose running time is bounded polynomially by a function only of the inherent dimensions of the problem and is independent of the sizes of the numerical data of the instance.

See

- ▶ Computational Complexity

Structural Variables

The original variables of a linear-programming problem as differentiated from slack, surplus and artificial variables. Structural variables are usually the variables of interest and have a physical interpretation such as production or shipments. They appear in the original defining inequalities or equations prior to the conversion of the problem to all equations.

Structured Modeling

Arthur M. Geoffrion
University of California, Los Angeles, CA, USA

Introduction

Structured modeling was developed as a comprehensive response to perceived shortcomings of modeling systems available in the 1980s. It is

a systematic way of thinking about models and their implementations, based on the idea that every model can be viewed as a collection of distinct elements, each of which has a definition that is either primitive or based on the definition of other elements in the model. Elements are categorized into five types (so-called primitive entity, compound entity, attribute, function, and test), grouped by similarity into any number of classes called genera, and organized hierarchically as a rooted tree of modules so as to reflect the model's high-level structure. It is natural to diagram the definitional dependencies among elements as arcs in a directed acyclic graph. Moreover, this dependency graph can be computationally active because every function and test element has an associated mathematical expression for computing its value.

Using a model for any specific purpose involves subjective intentions. Structured modeling makes a sharp distinction between the resulting user-defined problems or tasks associated with a model, and the relatively objective model per se. A typical problem or task has to do with ad hoc query, drawing inferences, evaluating model behavior with specified inputs, determining a constrained solution, or optimization, and requires applying a computerized model manipulation tool (solver). For certain recurring kinds of problems and tasks, these tools are highly developed and readily available for incorporation into a structured modeling software system.

The theoretical foundation of structured modeling is formalized in Geoffrion (1989), which presents a rigorous semantic framework that deliberately avoids committing to a representational formalism. The framework is semantic, because it casts every model as a system of definitions styled to capture semantic content. Ordinary mathematics, in contrast, typically leaves more of the meaning implicit. Twenty-eight definitions and eight propositions establish the notion of model structure at three levels of detail (so-called elemental, generic, and modular structure), the essential distinction between model class and model instance, certain related concepts and constructs, and basic theoretical properties. This framework has points in common with certain ideas found in the computer science literature on knowledge representation, programming language design, and semantic data modeling, but is designed specifically for modeling as practiced in OR/MS and related fields (Geoffrion 1987; Section 4).

Structured Modeling Languages

An executable model description language called SML (Structured Modeling Language) fully supports structured modeling's semantic framework (Geoffrion 1992). Other languages for (at least parts of) structured modeling also exist, including ones that are graph-based, logic-based, SQL-oriented, subscript- free, or object-oriented. SML can be viewed in terms of four upwardly compatible levels of increasing expressive power. The first level encompasses simple definitional systems and directed graph models such as those found in Harary et al. (1965) The second level covers more complex extensions of these, spreadsheet models, numeric formulas, and propositional calculus models. The third level encompasses mathematical programming and predicate calculus models with simple indexing over sets and Cartesian products. Finally, the fourth level covers sparse versions of the above plus relational and semantic database models.

Exhibits A and B, taken from Geoffrion (1987), show an SML schema (third level) specifying the general structure of the classical feedmix model, and sample SML elemental detail tables specifying model elements. The latter, together with the schema, yield a specific feedmix model instance.

Space does not permit a proper description of SML's syntax, but a few hints are as follows. Schemas are organized as a tree of paragraphs whose leaves are the genera and whose interior nodes are the modules. The boldfaced part of each paragraph is the formal definition of the genus or module, as the case may be, and the rest consists of documentary comments about the formal part that are informal except for conventions about the use of underlining and upper case. The formal definition of a genus paragraph begins with the name of the genus, a parenthetical statement of definitional dependencies (if any), a slash-delimited statement of genus type, a colon-announced statement of data type if an attribute genus, and a semicolon-announced mathematical expression called a generic rule if a function or test genus. The formal definition of a module paragraph consists only of its name. Note that a schema is always specified independently

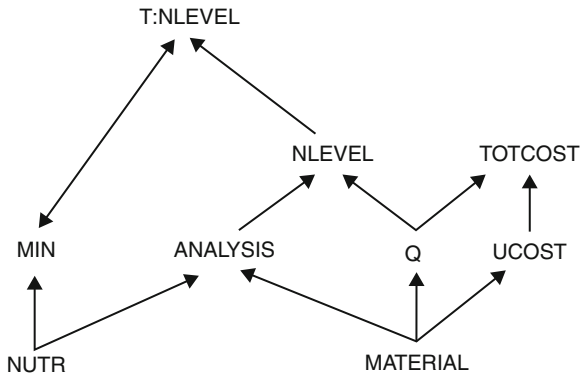
C	4.50	TRUE	

of any problem or task that might be posed on it. A common problem associated with the above schema is to find values for all Q elements such that all T:NLEVEL elements evaluate to true and the value of the TOTCOST element is minimal.

The structure and sequence of the following elemental detail tables are determined procedurally from the schema. Each table is named, has column names that usually coincide with genus names, and has a row for each element of the corresponding genus.

Figure 1 shows the so-called genus graph associated with the above schema. It represents definitional dependencies at the level of genera.



Structured Modeling, Fig. 1 Genus graph for the feedmix schema

Structured Modeling Systems

Owing to the design of the underlying semantic framework and of SML itself, SML-based modeling systems can have certain features often lacking in modeling systems of more conventional design, including:

- Error checking, of the formal specification of general model structure, that is exhaustive with respect to the underlying semantic framework
- Detailed semantic connections among model parts, a feature that facilitates maintaining, enhancing, and integrating models, and that enables automatic generation of several kinds of model reference documents useful for communication, debugging, model maintenance and evolution, and other essential activities;
- The ability, owing to the generality of structured modeling's view of models as definitional systems, for a single modeling system to accommodate a wide variety of modeling paradigms, which leads to easier model integration and many of the benefits of standardization;
- Browsable definitional dependency graphs at three levels of abstraction, constructs useful for visualizing and communicating the general structure of any model;
- The use of hierarchical organization as an approach to managing model complexity, and also as a visual device for model navigation;
- Automatic generation of relational data table designs for model instance data, a feature that facilitates exploiting relational database tools for data management;
- Partial consistency checking of SML's informal sublanguage for documenting the formal model specification, and also partial consistency and completeness checking of formal specifications by reference to this documentation;
- Complete independence between the general structure of a class of models and instantiating data, a feature that promotes the reuse of each of these, conciseness, efficient communication, and dimensional flexibility;
- Complete independence between models and solvers, a feature that promotes using multiple solvers with a single model, multiple models with a single solver, and conceptual clarity.

A research prototype implementation exhibiting the above features is described in Geoffrion (1991) and Neustadter et al. (1992). The first paper references several other research prototypes for structured modeling with different emphases, including: graph- based modeling, hybrid information/mathematical modeling systems, model management with a SQL database server in a networked environment, optimization-based applications, statistical analysis, and syntax-directed model editing. Other implementations include those of Chari and Sen (1998), Hamacher (1995), Iyer et al. (2005), Makowski (2005), Maturana et al. (2004), and Wright et al. (1997).

Concluding Remarks

An ample foundation has been laid for the development of software intended for commercial application. Experimental studies and a few real applications have taken place in the consumer appliance, food, industrial gases, oil, steel, and tire industries, and there are ongoing applications to environmental policy-making at IIASA.

Promising topics for future work include discrete-event simulation (Lenard 1993), graph-based modeling (Jones 1992), language-directed editors (Vicuña 1990), object-oriented systems (Muhanna 1993), model integration (Dolk and Kottemann 1993; Gagliardi and Spera 1995), distributed and semantic-web-based service-oriented architectures for model management (El-Gayar and Deokar 2008; Deokar et al. 2010), improved languages for model

definition and manipulation, applications to early and late modeling life-cycle phases not supported by conventional modeling systems, and structured modeling-based enhancements and usage disciplines for other modeling approaches and systems. See Geoffrion (1999) for an extensive annotated bibliography on structured modeling, Krishnan and Chari (2000) for a broad survey of the literature and research opportunities of model management that is explicitly in accord with structured modeling's modeling-lifecycle worldview, and Dolk (2010) for a thoughtful retrospective on structured modeling.

SUB Problem

- ▶ Simple Upper-bounded Problem (SUB)

Subderivative

For a real-valued convex function f defined on an open interval of the real line, a subderivative at a point x^0 is any real number y that satisfies

$$f(x) - f(x^0) \geq y(x - x^0) \text{ for all } x$$

See

- ▶ Subdifferential
- ▶ Subgradient

Subdifferential

Set of all subderivatives or subgradients at a point.

See

- ▶ Convex Optimization
- ▶ Lagrangian Relaxation
- ▶ Subderivative
- ▶ Subgradient

Subgradient

For a real-valued convex function f defined on a convex open set in R^n, a vector y is a subgradient at a point $\boldsymbol{x^0} \in R^n$ if for all $\boldsymbol{x} \in R^n$

$$f(\boldsymbol{x}) - f(\boldsymbol{x^0}) \geq \boldsymbol{y} \cdot (\boldsymbol{x} - \boldsymbol{x^0}),$$

where the '$\cdot$' operator denotes inner product.

Super-Sparsity

In most large-scale mathematical-programming problems, especially linear-programming problems, the number of nonzero elements in the problem matrix is quite small. Such problems are said to have a low density. Further, it has been noted that the number of distinct numerical values in the problem matrix is usually much smaller than the number of nonzero coefficients. This characteristic is known as super-sparsity. Computational savings in storage and processing time can be achieved by taking advantage of super-sparsity, as follows. Each distinct numerical value is recorded once in a value table stored in main memory. Each nonzero coefficient is recorded in an index array by means of a number triple: row index, column index, and a pointer. The pointer locates the coefficient's numerical value in the value table.

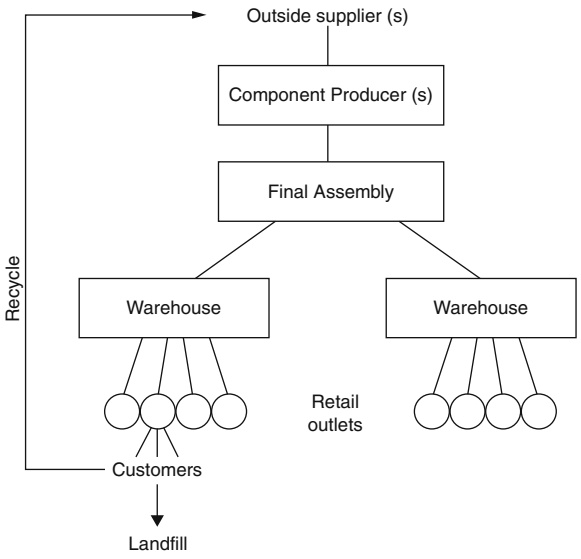
Supply Chain Management

M. Eric Johnson[1] and David F. Pyke[2]
[1]Dartmouth College, Hanover, NH, USA
[2]University of San Diego, San Diego, CA, USA

Introduction

Supply chain management (SCM) is the term used to describe the operational management of the flow of materials, information, and funds across the entire supply chain, from suppliers to component producers to final assemblers to distribution (warehouses and retailers), and ultimately to the consumer. In fact, it often includes after-sales service and returns or recycling. Figure 1 is a schematic of a supply chain. In contrast to multiechelon inventory management, that coordinates inventories at multiple locations, SCM typically involves coordination of information and materials among multiple firms. Much of the material in this article is based on Chapter 12 of Silver et al. (1998) and Johnson and Pyke (2000a).

Supply chain management has generated much interest in the OR/MS community in recent years for a number of reasons. Many managers now realize that actions taken by one member of the chain can influence the profitability of all others in the chain. Certain industries use other terms in place of SCM. For example, many grocery industry executives are pursuing efficient consumer response (ECR), the equivalent of just-in-time distribution or "continuous replenishment." Initiatives such as ECR are within the purview of supply chain management.



Supply Chain Management, Fig. 1 A schematic of a supply chain

Many firms now think of competition as pitting their supply chain against other supply chains, rather than their firm against other individual firms. Also, as firms successfully streamline their own operations, the next opportunity for improvement is through better coordination with their suppliers and customers. The costs of poor coordination can be extremely high. In the Italian pasta industry, consumer demand is quite steady throughout the year. However, because of trade promotions, volume discounts, long lead times, full-truckload discounts, and end-of-quarter sales incentives, the orders seen at the manufacturers are highly variable (Hammond 1994). In fact, the variability increases in moving up the supply chain from consumer to grocery store to distribution center to central warehouse to factory, a phenomenon that is often called the bullwhip effect (Fig. 2). The bullwhip effect has been experienced by many students playing the "Beer Distribution Game" (Sterman 1989; Sterman 1992; Chen and Samroengraja 2000; Jacobs 2000). The costs of this variability are high — inefficient use of production and warehouse resources, high transportation costs, and high inventory costs, to name a few. Acer America, Inc. sacrificed $20 million in profits by paying $10 million for air freight to keep up with surging demand, and then paying $10 million more later when that inventory became obsolete (Business Week 1996, p. 72; Towill and Vecchio 1994; Berry et al. 1995; Buzzell and Ortmeyer 1995).

Supply Chain Management, Fig. 2 An illustration of the bullwhip effect

It seems that integration, long the dream of management gurus, has finally been sinking into the minds of managers. Some would argue that managers have long been interested in integration, but the lack of information technology made it impossible to implement a more "systems-oriented" approach. Clearly industrial dynamics researchers dating back to the 1950s (Forrester 1958; Forrester 1961) have maintained that supply chains should be viewed as an integrated system. With the recent explosion of inexpensive information technology, it seems only natural that business would become more supply chain focused. However, while technology is clearly an enabler of integration, it alone can not explain the radical organizational changes in both individual firms and whole industries. Changes in both technology and management theory set the stage for integrated supply chain management. One reason for the change in management theory is the power shift from manufacturers to retailers. Wal-Mart, for instance, has forced many manufacturers to improve their management of inventories, and even to manage inventories of their products at Wal-Mart.

While integration, information technology and retail power may be key catalysts in the surge of interest surrounding supply chains, electronic-based business — eBusiness — is fueling even stronger excitement. eBusiness facilitates the virtual supply chain, and as companies manage these virtual networks, the importance of integration is magnified. Firms like Amazon are superb at managing the flow of information and funds, via the Internet and electronic funds transfer. Now, the challenge is to efficiently manage the flow of products.

Some would argue that the language and metaphors are wrong. "Chains" evoke images of linear, unchanging, and powerless. "Supply" feels pushy and reeks of mass production rather than mass customization. Better names, like "demand networks" or "customer driven webs" have been proposed. Yet, for now, the name "supply chain" seems to have stuck. And under any name, the future of supply chain management appears bright.

Key Components of Supply Chain Management

Supply chain management is an enormous topic covering multiple disciplines and employing many quantitative and qualitative tools. Within the last few years, several textbooks on supply chain have arrived on the market providing both managerial overviews and detailed technical treatments. For examples of managerial introductions to supply chain, seeby Copacino (1997), by Fine (1998), and Handfield and Nichols (1998), and for logistics texts, see Lambert et al. (1997) and by Ballou (1998). For more technical, model-based treatments, see Silver et al. (1998) and Simchi-Levi et al. (1998). Tayur et al. (1999) is an extensive collection of research papers, while Johnson and Pyke (2000b) is a collection papers on teaching supply chain management. Also, there are several casebooks that give emphasis to global management issues, includingby Taylor (1997),

by Flaherty (1996), and Dornier et al. (1998). Introductory articles include Cooper et al. (1997b), by Davis (1993), Johnson (1998a), and Lee and Billington (1992).

To help order the discussion, the supply chain management is divided into twelve areas [see Johnson and Pyke (2000a) for a list of teaching cases and popular press articles that fit within each area].

Each area represents a supply chain issue facing the firm. For any particular problem or issue, managers may apply analysis or decision-support tools. For each of the twelve areas, a brief description of the basic content is provided, along with a few relevant research papers OR/MS-based tools that may aid analysis and decision support are also mentioned. For a more detailed review of recent research and teaching in supply chain management, see Ganeshan et al. (1999) and Johnson and Pyke (2000a).

The twelve categories defined are:

- location
- transportation and logistics
- inventory and forecasting
- marketing and channel restructuring
- sourcing and supplier management
- information and electronic mediated environments
- product design and new product introduction
- service and after sales support
- reverse logistics and green issues
- outsourcing and strategic alliances
- metrics and incentives
- global issues.

Location pertains to both qualitative and quantitative aspects of facility location decisions. This includes models of facility location, geographic information systems (GIS), country differences, taxes and duties, transportation costs associated with certain locations, and government incentives (Hammond and Kelly 1990). Exchange rate issues fall in this category, as do economies and diseconomies of scale and scope. Decisions at this level set the physical structure of the supply chain and therefore establish constraints for more tactical decisions. Binary integer programming models play a role here, as do simple spreadsheet models and qualitative analyses. There are many advanced texts specially dedicated to the modeling aspects of location (Drezner 1996) and most books on logistics also cover the subject. Simchi-Levi et al. (1998) presented a substantial treatment of GIS, while Dornier et al. (1998) dedicated a chapter to issues of taxes, duties, exchange rates, and other global location issues (Brush et al. 1999). Ballou and Masters (1999) examined several software products that provide optimization tools for solving industrial location problems.

The transportation and logistics category encompasses all issues related to the flow of goods through the supply chain, including transportation, warehousing, and material handling. This category includes many of the current trends in transportation management including vehicle routing (Bodin 1990; Gendreau et al. 1996; Anily and Bramel 1999), dynamic fleet management with global positioning systems, and merge-in-transit. Also included are topics in warehousing and distribution such as cross docking (Kopczak et al. 1995) and materials handling technologies for sorting, storing, and retrieving products (Johnson and Brandeau 1999; Johnson 1998b).

Because of globalization and the spread of out-sourced logistics, this category has received much attention in recent years. However, a separate category will examine issues specifically related to outsourcing and logistics alliances. Both deterministic (such as linear programming and the traveling salesman problem) and stochastic optimization models (stochastic routing and transportation models with queueing) often are used here, as are spreadsheet models and qualitative analysis. Recent management literature has examined the changes within the logistics functions of many firms as the result of functional integration (Greis and Kasarda 1997) and the role of logistics in gaining competitive advantage (Fuller et al. 1993).

Inventory and forecasting includes traditional inventory and forecasting models. Inventory costs are some of the easiest to identify and reduce when at-tacking supply chain problems. Simple stochastic inventory models can identify the potential cost savings from, for example, sharing information with supply chain partners (Lee and Nahmias 1993), but more complex models are required to coordinate multiple locations. A few years ago, multiechelon inventory theory captured most of the research in this area that would apply to supply chains. However, in nearly every case, multiechelon inventory models assume a single decision-maker. Supply chains, unfortunately, confront the problem of multiple firms, each with its own decision-maker and objectives.

Of course, there are many full texts on the subject, such as Silver et al. (1998) and Graves et al. (1993). Useful managerial articles focusing on inventory and forecasting includeby Davis (1993) and Fisher et al. (1994).

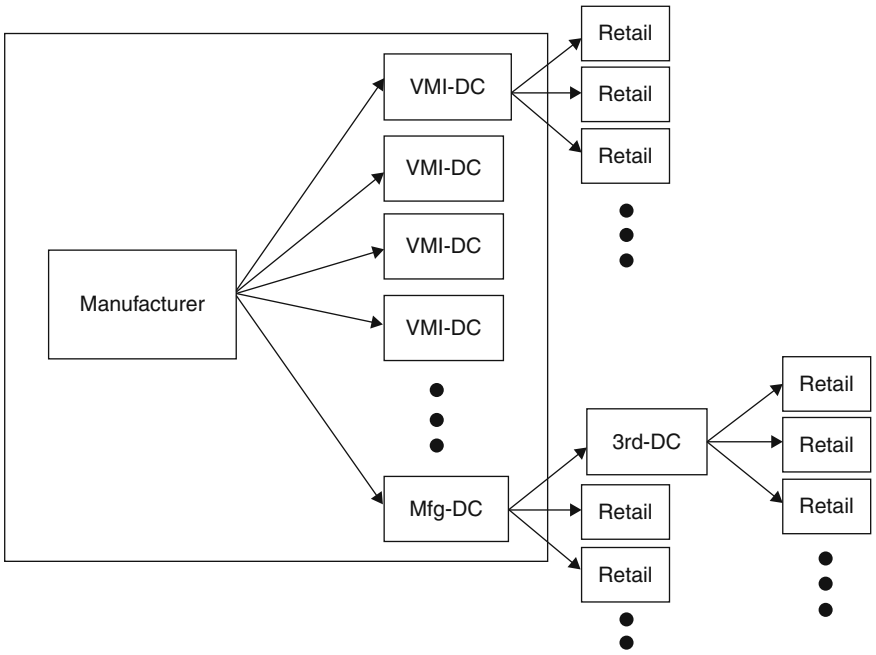
Clark and Scarf (1960) performed one of the earliest studies in serial systems with probabilistic demand. They introduced the concept of an imputed penalty cost, wherein a shortage at a higher echelon generates an additional cost. This cost decomposes the multiechelon system into a series of stages so that, assuming centralized control and the availability of global information, the ordering policies can be optimized. Lee and Whang (1999a) and Chen (1996) both proposed performance measurement schemes for individual managers that allow for decentralized control (so that each manager makes decisions independently), and in certain instances, local information only. The result is a solution that achieves the same optimal solution as if centralized control and global information were assumed.

Marketing and channel restructuring includes fundamental thinking on supply chain structure (Fisher 1997) and covers the interface with marketing that emerges from having to deal with down-stream customers (Narus and Anderson 1996). While the inventory category addresses the quantitative side of these relationships, this category covers relationship management, negotiations and even the legal dimension. Most importantly, it examines the role of channel management (Anderson et al. 1997) and supply chain structure in light of the well-studied phenomena of the bullwhip effect that was noted in the introduction.

The bullwhip effect has received enormous attention in the research literature. Many authors have noted that central warehouses are designed to buffer the factory from variability in retail orders. The inventory held in these warehouses should allow factories to smooth production while meeting variable customer demand. However, empirical data suggest that exactly the opposite happens (e.g., see Blinder 1981, and Baganha and Cohen 1998). Orders seen at the higher levels of the supply chain exhibit more variability than those at levels closer to the customer. In other words, the bullwhip effect is real. Typically, causes include those noted in the introduction, as well as the fact that retailers and distributors often over-react to shortages by ordering more than they need. Lee et al. (1997) showed how four rational factors help to create the bullwhip effect: demand signal processing (if demand increases, firms order more in anticipation of further increases, thereby communicating an artificially high level of demand); the rationing game (there is, or might be, a shortage so a firm orders more than the actual forecast in the hope of receiving a larger share of the items in short supply); order batching (fixed costs at one location lead to batching of orders); and manufacturer price variations (which encourage bulk orders). The latter two factors generate large orders that are followed by small orders, which implies increased variability at upstream locations.

Some recent innovations, such as increased communication about consumer demand, via electronic data interchange (EDI) and the Internet, and everyday low pricing (EDLP) (to eliminate forward buying of bulk orders), can mitigate the bullwhip effect. See Bell et al. (1998a, 1998b) for a discussion of EDLP versus High-Low pricing. They showed with a simple model that High-Low pricers can charge a higher average price without risking the loss of rational customers. In addition, Baganha and Cohen (1998) noted that, if locations that are designed to buffer the factory from variability in retail orders follow the optimal policy, the variance can in fact be reduced. In particular, these locations should account for autocorrelation in the demand process; that is, if a retailer orders today, it is unlikely that it will order in the next few days (Bourland et al. 1996; Srinivasan et al. 1994; Lee et al. 1999).

In fact, the number of firms ordering, and receiving orders, via EDI and the Internet is exploding. The information available to supply chain partners, and the speed with which it is available, has the potential to radically reduce inventories and increase customer service. For example, see Moinzadeh and Aggarwal (1997) and Lee and Whang (1999b). Milgrom and Roberts (1988) noted that inventory and information are substitutes. Other initiatives can also mitigate the bullwhip effect. For example, changes in pricing and trade promotions (Buzzell et al. 1990) and channel initiatives, such as vendor-managed inventory (VMI), coordinated forecasting and replenishment (CFAR), and continuous replenishment (Fites 1996; Verity 1996; Waller et al. 1999), can significantly reduce demand variance. VMI is one of the most widely discussed partnering initiatives for improving multi-firm supply chain efficiency. Popularized in the late 1980s by Wal-Mart and Procter and Gamble,



Supply Chain Management, Fig. 3 Typical VMI implementation (adapted from Waller et al. 1999)

VMI became one of the key programs in the grocery industry's pursuit of efficient consumer response and the garment industry's quick response. Successful VMI initiatives have been trumpeted by other companies in the United States, including Campbell Soup and Johnson and Johnson, and by European firms like the pasta manufacturer Barilla.

In a VMI partnership, the supplier — usually the manufacturer but sometimes a reseller or distributor — makes the main inventory replenishment decisions for the consuming organization. This means the supplier monitors the buyer's inventory levels (physically or via electronic messaging) and makes periodic resupply decisions regarding order quantities, shipping, and timing. Transactions customarily initiated by the buyer (like purchase orders) are initiated by the supplier instead. Indeed, the purchase order acknowledgment from the supplier may be the first indication that a transaction is taking place; an advance shipping notice informs the buyer of materials in transit. Thus the manufacturer is responsible for both its own inventory and the inventory stored at is customers' distribution centers (Fig. 3).

Because many of these initiatives involve channel partnerships and distribution agreements, this category also contains important information on pricing, along with anti-trust and other legal issues (Train 1998). These innovations require interfirm, and often intrafirm, cooperation and coordination that can be difficult to achieve.

While marketing focuses downstream in the supply chain, sourcing and supplier management looks upstream to suppliers. Make/buy decisions (Venkatesan 1992; Carroll 1993; Christensen 1994; Quinn and Hilmer 1994; Kelley 1995; Robertson and Langlois 1995) fall into this category, as does global sourcing (Little 1995; Pyke 1994). The location category addresses the location of a firm's own facilities, while this category pertains to the location of the firm's suppliers. Supplier relationship management falls into this category as well (McMillan 1990; Womack et al. 1991). Some firms are putting part specifications on the Web so that dozens of suppliers can bid on jobs. GE, for instance, has developed a trading process network that allows many more suppliers to bid than was possible before. The automotive assemblers have developed a similar capability. Independent Internet firms, such as Digital Market, are providing services focused on certain product categories. Other firms are moving in the opposite direction by reducing the number of suppliers, in some cases to a sole source (Helper and Sako 1995; Cusumano and Takeishi 1991). Determining the number of suppliers and the best

way to structure supplier relationships is becoming an important topic in supply chains (Cohen and Agrawal 1996; Dyer 1996; Magretta 1998; Pyke (1998).

Much of the research in this area makes use of game theory to understand supplier relationships, contracts, and performance metrics. See, for instance, Cachon and Lariviere (1999), by Cachon (1997), and Tsay et al. (1999).

The information and electronic mediated environments category addresses long-standing applications of information technology to reduce inventory (Woolley 1997) and the rapidly expanding area of electronic commerce (Benjamin and Wigand 1997; Schonfeld 1998). Often this subject may take a more systems orientation, examining the role of systems science and information within a supply chain (Senge 1990). Such a discussion naturally focuses attention on integrative ERP software such as SAP (Whang et al. 1995), Baan and Oracle, as well as supply chain offerings such as i2's Rhythm and Peoplesoft's Red Pepper. The many supply chain changes wrought by electronic commerce are particularly interesting to examine, including both the highly publicized retail channel changes (like Amazon.com) and the more substantial business to business innovations (like the GE trading process network). It is here that OR/MS interfaces most directly with information technology and strategy, which again creates opportunities for cross-functional integration (Lee and Whang 1999b).

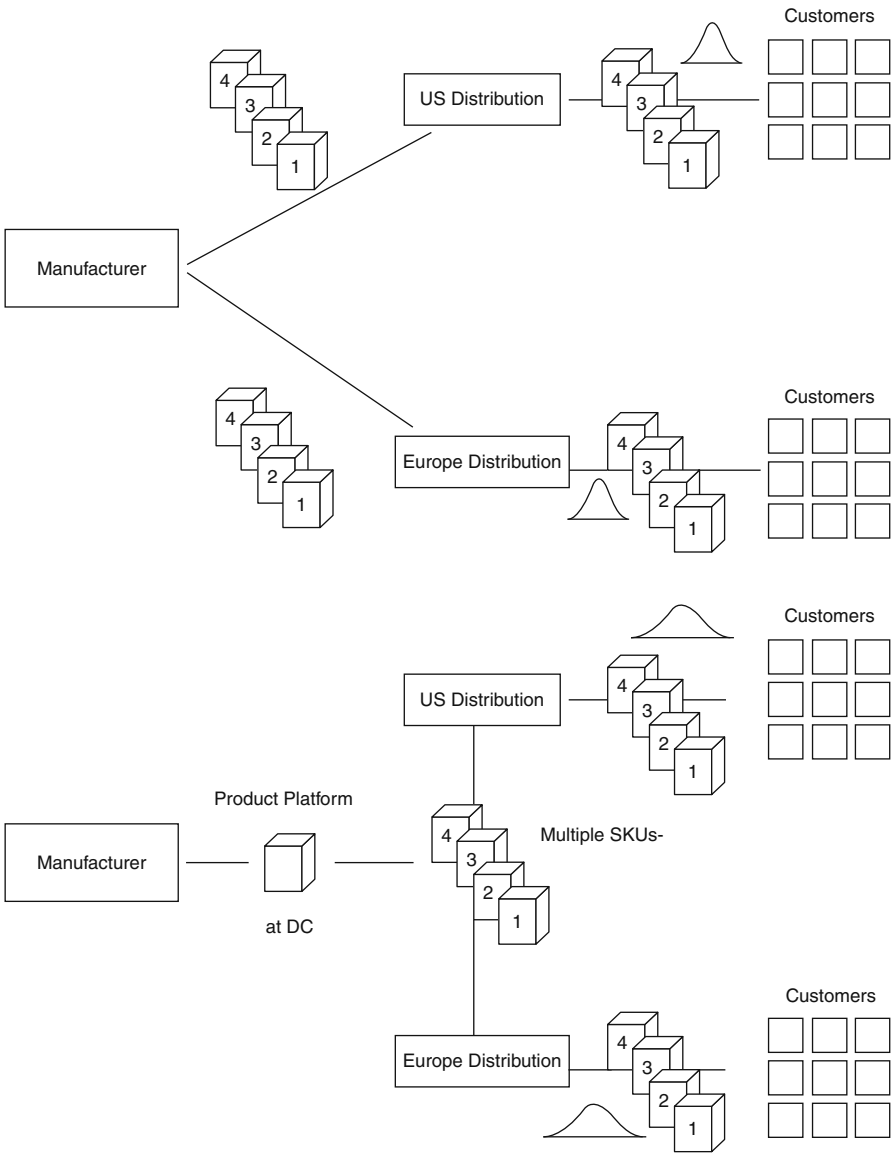
Product design and new product introduction deals with design issues for mass customization, delayed differentiation, modularity and other issues for new product introduction. With the increasing supply chain demands of product variety (Gilmore and Pine 1997) and customization (McCutcheon et al. 1994), there is an increasing body of research available. One of the most exciting applications of supply chain thinking is the increased use of postponed product differentiation (Feitzinger and Lee 1997). Traditionally, products destined for world markets would be customized at the factory to suit local market tastes. While a customized product is desirable, managing worldwide inventory is often a nightmare. Using postponement, the product is redesigned so that it can be customized for local tastes in the distribution channel. The same generic product is produced at the factory and held through-out the world (Fig. 4). Thus, if the French version selling well, but the German version is not, the German product can be quickly shipped to France and customized for the French market.

For these problems, there is an interface with engineering and development, with clear implications for product cost and inventory savings. Stochastic inventory models are often used to identify some of the benefits of these initiatives (Lee et al. 1993). Also important are issues related to product design (Ulrich and Ellison 1999; Robertson and Ulrich 1998), managing product variety (Fisher et al. 1999) and managing new product introduction and product rollover (Billington et al. 1998).

The service and after sales support category addresses the critical, but often overlooked, problem of providing service and service parts (Cohen and Lee 1990). Some leading firms, such as Saturn and Caterpillar, build their reputations on their ability in this area, and this capability generates significant sales (Cohen et al. 1997). Stochastic inventory models for slow-moving items fall into this category, and there are many papers on this topic related to inventory management (Williams 1984; Cohen et al. 1986) and forecasting (Johnston and Boylan 1996). While industry practice still shows much room for improvement (Cohen et al. 1997), several well-known firms have shown how spare parts can be managed more effectively (Cohen et al. 1990; Cohen et al. 1992; Cohen et al. 1999).

Reverse logistics and green issues are emerging dimensions of supply chain management (Marien 1998). This area examines both environmental issues (Herzlinger 1994) and the reverse logistics issues of product returns (Padmanabhan and Png 1995; Clendenin 1997; Rudi and Pyke 1999). Because of legislation and consumer pressure, the growing importance of these issues is evident to most managers. Managers are being compelled to consider the most efficient and environmentally friendly way to deal with product recovery and researchers have begun significant effort in modeling these systems.

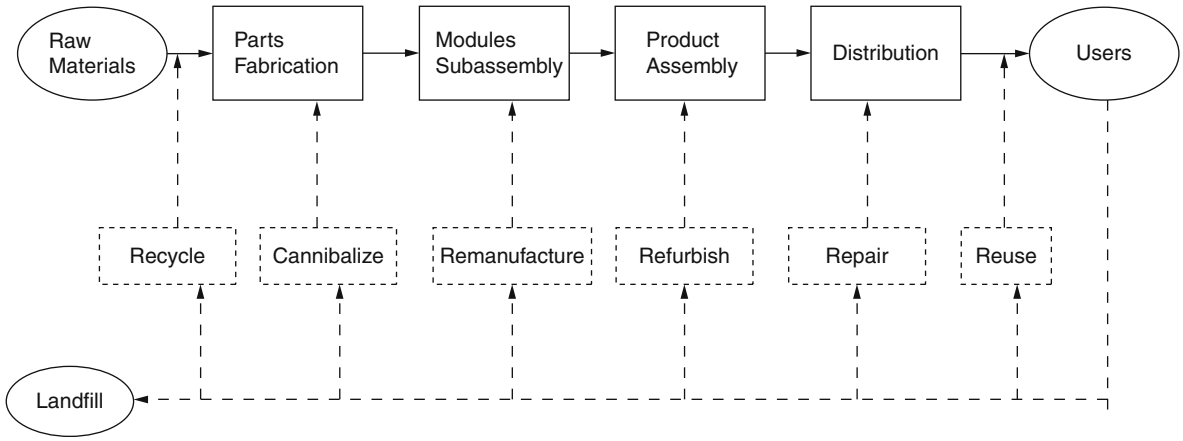
The term product recovery encompasses the handling of all used and discarded products, components and materials. Thierry et al. (1995) noted that product recovery management attempts to recover as much economic value as possible, while reducing the total amount of waste. They also provided a framework and a set of definitions that can help managers think about the issues in an organized way (Fig. 5).



Supply Chain Management, Fig. 4 Using postponement a product destined for both US and Europe markets is redesigned so that local content can be added to a common platform within distribution (adapted from Johnson and Anderson 1999)

These authors examine the differences among various product recovery options including repair, refurbishing, remanufacturing, cannibalization, and recycling. The whole process of manufacturing begins, of course, with product design. Firms are beginning to consider design for the environment (DFE) and design for disassembly (DFD) in their product development processes. Unfortunately, AT&T discovered that designing products for reuse can result in more materials and complexity, thereby violating other environmental goals. (See Frankel 1996, who also reports on product takeback and recycling initiatives in numerous countries).

The analysis of the recovery situation is considerably more complicated than that of consumables. Normally, in a recovery situation some items cannot be recovered, so the number of units demanded is not balanced completely by the return of reusable units. Thus, in addition to recovered units, a firm must also purchase some new units from time to time. Consequently, even at a single location,



Supply Chain Management, Fig. 5 Product recovery options (adapted from Thierry et al. 1995)

there are five decision variables: (1) how often to review the stock status, (2) when to recover returned units, (3) how many to recover at a time, (4) when to order new units, and (5) how many to order. When there are multiple locations, the firm must decide how many good units to deploy to a central warehouse and how many to deploy to each retailer or field stocking location.

With consumable items, the lead time to the retailers is a transportation time from the warehouse plus a random component, depending on whether the warehouse has stock. With recoverable items, the lead time is the transportation time plus the time to recovery, if the warehouse does not have stock. So in some cases, the two systems can be treated in almost the same way. However, if the recovery facility has limited capacity or if the number of items in the system is small, the systems will differ significantly. For example, if many items have failed and are now in recovery, they cannot be in the field generating failures. Therefore, the demand rate at the ware-house will decline. In a consumable system, it is usually assumed that the demand rate does not depend on how many items have been consumed.

Most of the research in this area concerns products and packaging after manufacturing has been completed. For example, a large U. S. chemical company gained significant market share in water treatment chemicals by delivering its products in reusable containers. The customers (hospitals and other large institutions, for example) need never touch the chemicals or deal with the disposal of used containers. This problem has been addressed by Goh and Varaprasad (1986), Kelle and Silver (1989), and Castillo and Cochran (1996).

Some products that are not reused "as is" can be disassembled so that some of the parts can be used in remanufactured products. Muckstadt and Isaac (1981) reported on a model developed in connection with a manufacturer of reprographic equipment. There is a single location with two types of inventory: serviceable and repairable. Demands for serviceable units and returns of repairable units occur probabilistically, specifically, according to independent Poisson processes with rates D and fD, respectively (where f is a fraction). In addition, repairs are done on a continuous, first come-first served basis (e.g., at a local machine shop). Any demands for serviceable units, when none is available, are back-ordered at a cost per unit short per unit time. Purchases of new stock from outside involve a known lead time. With respect to purchase decisions, a continuous review (s,Q) system is used; specifically, when the inventory position drops to s or lower, a quantity Q is purchased.

Inderfurth (1997) extended the Muckstadt and Isaac model to a remanufacturing problem in which there are two decisions each period: how many returned products to remanufacture (the remainder will be disposed of), and how many new parts to procure. In this system, returned products arrive probabilistically and are either remanufactured or thrown away. (In other words, there is no stock of returned products). Newly procured products are stored with

remanufactured products in a finished goods inventory that serves demand that arrives probabilistically. There are per-unit costs to procure, remanufacture, and dispose, and holding costs are charged against ending inventory each period. For the case of equal lead times to remanufacture and to procure, by Inderfurth (1997) showed that the structure of the optimal policy is based on two parameters, L_t and U_t, in each period t. To describe the policy, define the following:

d_t=	the number of units to be disposed of in period t;
p_t =	the number of units to procure in period t; and
IP_t=	the inventory position at the beginning of period t = stock on hand (which includes products returned this period and finished goods inventory) + procurement orders outstanding − remanufacturing orders out-standing − backordered demand

The optimal policy is then:

p_t =	$L_t - IP_t$ and $d_t = 0$ for a $IP_t < L_t$
p_t =	0 and $d_t = 0$ for $L_t > IP_t \leq U_t$
p_t =	0 and $d_t - IP_t - U_t$ for $IP_t > U_t$

In words, if the inventory position is lower than the lower limit, L_t, order-up-to L_t and do not dispose of any units. If the inventory position is higher than the upper limit, U_t, dispose "down to" U_t and do not procure any units. Otherwise, do not buy or dispose. (Again, all returned units, not disposed of, are remanufactured). by Inderfurth (1997) pointed out that when one permits a stock of returned units waiting for disposal or remanufacturing, or when the lead times to procure and remanufacture are different, the policy is similar but more complex.

van der Laan et al. (1996) proposed a policy for a continuous review version of this problem. Thierry et al. (1995) looked at the strategic issues related to product recovery. Also seeby Heyman (1977) and Penev and de Ron (1996), who studied the disassembly process; and van der Laan et al. (1996, 1997, 1999), by Ferrer (1995), by Richter (1996), Guide and Spencer (1997), and Taleb et al. (1997), who studied other aspects of the remanufacturing process. Other reverse logistics issues were also examined by Carter and Ellram (1998), while Fleischmann et al. (1997) provided a review of quantitative models for reverse logistics.

Outsourcing and strategic alliances examines the supply chain impact of outsourcing logistics services. With the rapid growth in third party logistics providers, there is a large and expanding group of technologies and services to be examined. These include initiatives such as supplier hubs managed by third parties. The rush to create strategic relationships with logistics providers and the many well-published failures have raised questions about the future of such relationships (Bowersox 1990). In any case, outsourcing continues to raise many interesting issues (Cooper et al. 1997a).

Metrics and incentives examines measurement and other organizational and economic issues. This category includes both measurement within the supply chain (Meyer 1997) and industry benchmarking (Council of Logistics Management Consortium 1994; Pittiglio, Rabin, Todd, and McGrath 1997). Because metrics are fundamental to business management, there are many reading materials outside of the supply chain literature, accounting texts, for instance. Several articles concentrate on the link between performance measurement and supply chain improvement (O'Laughlin 1997; Johnson and Davis 1998).

Finally, global issues examines how all of the above categories are affected when companies operate in multiple countries. This category goes beyond country specific issues to encompass issues related to crossboarder distribution and sourcing (Kouvelis 1999). For example, currency exchange rates, duties and taxes, freight forwarding, customs issues, government regulation, and country comparisons are all included. Note that the location category, when applied in a global context, also addresses some of these issues (Cohen and Huchzermeier 1999; Huchzermeier and Cohen 1996; Arntzen et al. 1995). There are several texts devoted to global management. Many articles also examine challenges in specific regions of the world (e.g., Asia: Lee and Kopczak 1997; Europe: Sharman 1997).

Concluding Remarks

Supply chain management is an expanding field, both in research and in practice. Major international consulting firms have developed large practices in the supply chain field and the number of research papers in the field is growing rapidly. The discussion covered twelve areas often seen in supply chain research and practice.

These areas appear to be somewhat disparate, but they are all linked by the integrated nature of the problems at hand. Firms operate in global environments, deal with multiple suppliers and customers, are required to manage inventories in new and innovative ways, and are faced with possible channel restructuring. The field promises to continue growing as the research advances and as firms continue to apply new knowledge in their global networks. Finally, as the Internet changes fundamental assumptions about business, firms operating in supply chains will be required to understand this new phenomenon and respond accordingly.

Surplus Variable

A nonnegative variable that is added to a linear inequality of the form $\sum_j a_{ij} x_j \geq b_i$ to transform the inequality into an equation. The surplus variable measures the difference between the left-and right-hand-sides of the inequality.

See

- ▶ Logical Variables
- ▶ Slack Variable
- ▶ Surplus Vector

Surplus Vector

The column representation of a surplus variable in a linear-programming problem.

See

► Surplus Variable

Swarm Intelligence

Population-based metaheuristic search approaches that use groups of decentralized agents inspired by animal behavior from nature; examples include Ant Colony Optimization, Particle Swarm Optimization, and the Bees Algorithm.

See

► Ant Colony Optimization
► Metaheuristics
► Particle Swarm Optimization

Symmetric Matrix

A square matrix $\boldsymbol{A} = (a_{ij})$ is symmetric if $a_{ij} = a_{ji}$. Thus, $\boldsymbol{A} = \boldsymbol{A}^T$.

System Dynamics

George P. Richardson
University at Albany, State University of New York, Albany, NY, USA

Introduction

System dynamics is a computer-aided approach to policy analysis and design. It applies to dynamic problems arising in complex social, managerial, economic, or ecological systems – literally any dynamic systems characterized by interdependence, mutual interaction, information feedback, and circular causality.

The field developed initially from the work of Jay W. Forrester. His seminal book *Industrial Dynamics* (Forrester 1961) is still a significant statement of philosophy and methodology in the field. Within 10 years of its publication, the span of applications grew from corporate and industrial problems to include the management of research and development, urban stagnation and decay, commodity cycles, and the dynamics of growth in a finite world. It is now applied in economics, public policy, environmental studies, defense, theory-building in social science, and other areas, as well as its home field, management. The name industrial dynamics no longer does justice to the breadth of the field, so it has become generalized to system dynamics. The modern name suggests links to other systems methodologies, but the links are weak and misleading. System dynamics emerges out of servomechanisms engineering, not general systems theory or cybernetics (Richardson 1991).

The system dynamics approach involves:

- Defining problems dynamically, in terms of graphs over time.
- Striving for an endogenous, behavioral view of the significant dynamics of a system, a focus inward on the characteristics of a system that themselves generate or exacerbate the perceived problem.
- Thinking of all concepts in the real system as continuous quantities interconnected in loops of information feedback and circular causality.
- Identifying independent stocks or accumulations (levels) in the system and their inflows and outflows (rates).
- Formulating a behavioral model capable of reproducing, by itself, the dynamic problem of concern. The model is usually a computer simulation model expressed in nonlinear equations, but is occasionally left unquantified as a diagram capturing the stock-and-flow/causal feedback structure of the system.
- Deriving understandings and applicable policy insights from the resulting model.
- Implementing changes resulting from model-based understandings and insights.

Mathematically, the basic structure of a formal system dynamics computer simulation model is a system of coupled, nonlinear, first-order differential (or integral) equations,

$$\frac{d}{dt}x(t) = \boldsymbol{f}(\boldsymbol{x}, \boldsymbol{p}),$$

where x is a vector of levels (stocks or state variables), $\boldsymbol{p}$ is a set of parameters, and $\boldsymbol{f}$ is a nonlinear vector-valued function.

Simulation of such systems is easily accomplished by partitioning simulated time into discrete intervals of length dt and stepping the system through time one dt at a time. Each state variable is computed from its previous value and its net rate of change $x'(t) : x(t) = x(t - dt) + dt * x'(t - dt)$. In the earliest

simulation language in the field (DYNAMO) this equation was written with time scripts K (the current moment), J (the previous moment), and JK (the interval between time J and K): X.K = X.J + DT*XRATE.JK (see, e.g., Richardson and Pugh 1981). The computation interval *dt* is selected small enough to have no discernible effect on the patterns of dynamic behavior exhibited by the model. In more recent simulation environments, more sophisticated integration schemes are available (although the equation written by the user may look like this simple Euler integration scheme), and time scripts may not be in evidence. Important current simulation environments include Vensim (Ventana Systems, www.vensim.com/) STELLA and iThink (iSee Systems, www.iseesystems.com/), PowerSim (www.powersim.com/), and AnyLogic (xj technologies, www.xjtek.com/).

Forrester's original work stressed a continuous approach, but increasingly modern applications of system dynamics contain a mix of discrete difference equations and continuous differential or integral equations. Some practitioners associated with the field of system dynamics work on the mathematics of such structures, including the theory and mechanics of computer simulation, analysis and simplification of dynamic systems, policy optimization, dynamical systems theory, and complex nonlinear dynamics and deterministic chaos.

The main applied work in the field, however, focuses on understanding the dynamics of complex systems for the purpose of policy analysis and design. The conceptual tools and concepts of the field – including feedback thinking, stocks and flows, the concept of feedback loop dominance, and an endogenous point of view – are as important to the field as its simulation methods. The material in the next three sections is abstracted from Richardson (1991a, b).

Feedback Thinking

Conceptually, the feedback concept is at the heart of the system dynamics approach. Diagrams of loops of information feedback and circular causality are tools for conceptualizing the structure of a complex system and for communicating model-based insights. Intuitively, a feedback loop exists when information resulting from some action travels through a system and eventually returns in some form to its point of origin, potentially influencing future action. If the tendency in the loop is to reinforce the initial action, the loop is called a positive or reinforcing feedback loop; if the tendency is to oppose the initial action, the loop is called a negative or balancing feedback loop. The sign of the loop is called its polarity. Balancing loops can be variously characterized as goal-seeking, equilibrating, or stabilizing processes. They can sometimes generate oscillations, as when a pendulum seeking its equilibrium goal gathers momentum and overshoots it. Reinforcing loops are sources of growth or accelerating collapse; they are disequilibrating and destabilizing. Combined, reinforcing and balancing circular causal feedback processes can generate all manner of dynamic patterns.

Loop Dominance and Nonlinearity

The loop concept underlying feedback and circular causality by itself is not enough, however. The explanatory power and insightfulness of feedback understandings also rest on the notions of active structure and loop dominance. Complex systems change over time. A crucial requirement for a powerful view of a dynamic system is the ability of a mental or formal model to change the strengths of influences as conditions change, that is to say, the ability to shift active or dominant structure.

In a system of equations, this ability to shift loop dominance comes about endogenously from nonlinearities in the system. For example, the S-shaped dynamic behavior of the classic logistic growth model $\left(dP/dt = aP - bP^2\right)$ can be seen as the consequence of a shift in loop dominance from a positive, self-reinforcing feedback loop (aP) producing exponential-like growth to a negative balancing feedback loop ($-bP^2$) that brings the system to its eventual goal. Only nonlinear models can endogenously alter their active or dominant structure and shift loop dominance. From a feedback perspective, the ability of nonlinearities to generate shifts in loop dominance and capture the shifting nature of reality is the fundamental reason for advocating nonlinear models of social system behavior.

The Endogenous Point of View

The concept of endogenous change is fundamental to the system dynamics approach. It dictates aspects of model formulation: exogenous disturbances are seen at most as triggers of system behavior (like displacing a pendulum); the causes are contained within the structure of the system itself (like the interaction of a pendulum's position and momentum that produces oscillations). Corrective responses are also not modeled as functions of time, but are dependent on conditions within the system. Time by itself is not seen as a cause.

But more importantly, theory building and policy analysis are significantly affected by this endogenous perspective. Taking an endogenous view exposes the natural compensating tendencies in social systems that conspire to defeat many policy initiatives. Feedback and circular causality are delayed, devious, and deceptive. For understanding, system dynamics practitioners strive for an endogenous point of view. The effort is to uncover the sources of system behavior that exist within the structure of the system itself.

System Structure

These ideas are captured in Forrester's (1969) organizing framework for system structure:

Closed boundary

- Feedback loops
  - Levels
  - Rates
    - Goal
    - Observed condition
    - Discrepancy
    - Desired action

The closed boundary signals the endogenous point of view. The word closed here does not refer to open and closed systems in the general system sense, but rather refers to the effort to view a system as causally closed. The modeler's goal is to assemble a formal structure that can, by itself, without exogenous explanations, reproduce the essential characteristics of a dynamic problem.

The causally closed system boundary at the head of this organizing framework identifies the endogenous point of view as the feedback view pressed to an extreme. Feedback thinking can be seen as a consequence of the effort to capture dynamics within a closed causal boundary. Without causal loops, all variables must trace the sources of their variation ultimately outside a system. Assuming instead that the causes of all significant behavior in the system are contained within some closed causal boundary forces causal influences to feed back upon themselves, forming causal loops. Feedback loops enable the endogenous point of view and give it structure.

Levels and Rates

Stocks (levels) and the flows (rates) that affect them are essential components of system structure. A map of causal influences and feedback loops is not enough to determine the dynamic behavior of a system. A constant inflow yields a linearly rising stock; a linearly rising inflow yields a stock rising along a parabolic path, and so on. Stocks (accumulations, state variables) are the memory of a dynamic system and are the sources of its disequilibrium and dynamic behavior.

Forrester (1961) placed the operating policies of a system among its rates (flows), many of which assume the classic structure of a balancing feedback loop striving to take action to reduce the discrepancy between the observed condition of the system and a goal. The simplest such rate structure results in an equation of the form NETFLOW = (GOAL - STOCK)/(ADJTIM), where ADJTIM is the time over which the level adjusts to reach the goal.

Behavior Is a Consequence of System Structure

The importance of levels and rates appears most clearly when one takes a continuous view of structure and dynamics. Although a discrete view, focusing on separate events and decisions, is entirely compatible with an endogenous feedback perspective, the system dynamics approach emphasizes a continuous view. The continuous view strives to look beyond events to see the dynamic patterns underlying them. Moreover,

the continuous view focuses not on discrete decisions but on the policy structure underlying decisions. Events and decisions are seen as surface phenomena that ride on an underlying tide of system structure and behavior. It is that underlying tide of policy structure and continuous behavior that is the system dynamicist's focus.

Therefore, there is a distancing inherent in the system dynamics approach – not so close as to be confused by discrete decisions and myriad operational details, but not so far away as to miss the critical elements of policy structure and behavior. Events are deliberately blurred into dynamic behavior. Decisions are deliberately blurred into perceived policy structures. Insights into the connections between system structure and dynamic behavior, which are the goal of the system dynamics approach, come from this particular distance of perspective.

Concluding Remarks

System Dynamics Review, the journal of the System Dynamics Society, is the best source of current activity in the field, including methodological advances and applications. Other important journal sources include *Management Science*, the *European Journal of Operational Research* (EJOR), the *Journal of the Operational Research Society* (JORS), and *Systems Research and Behavioral Science*. For texts on the modeling process in system dynamics, see Sterman (2000), Maani and Cavana (2007), Ford (2009), Morecroft (2007), Wolstenholme (1990), and Richardson and Pugh (1981).

An early interesting collection of applications is Roberts (1978); Richardson (1996) is a more recent two-volume edited collection in the same spirit, containing prize-winning work in philosophical background, dynamic decision making, applications in the private and public sectors, and techniques for modeling with management.

One direction within the field is the use of model-based insights for organizational learning, represented most forcefully in Senge (1990) and Morecroft and Sterman (1994). The important effort to build models with relatively large groups of experts and stakeholders, known as group model building, is described in Vennix (1996) and Richardson and Anderxsen (2010).

Richardson (1991/1999) puts the endogenous feedback perspective of the system dynamics approach in its historical context and includes an extensive bibliography.

Systems Analysis

Sue A. Conger[1] and Richard O. Mason[2]
[1]University of Dallas, Irving, TX, USA
[2]Southern Methodist University, Dallas, TX, USA

Introduction

Systems analysis is a broad term applied to the study of real-world processes. It involves the careful examination of systems – entities, organisms, organizations, beings and things. Systems analysis breaks problems associated with entities down into their component parts and relationships in order to formulate a conceptual definition of the situation. The purpose is to develop "an overall understanding of optimal solutions to executive type problems" (Churchman et al. 1957, p. 7). The resulting conceptual definition is then often translated into a Web site, a process-support system, or a mathematical model. Systems analysis has been applied to complex, dynamic systems — both physical and social — such as businesses, governments, and computer software, as well as to economic, weapons, mechanical, and manufacturing systems. While it is ultimately a subjective form of innovation, systems analysis is based on a growing set of key theories: systems, cybernetics, mathematical modeling, graphical design, data management for knowledge management, and computational linguistics.

Systems theory describes how related elements can be organized to achieve a purpose. Elements form "an interconnected complex of functionally related components" (Churchman et al. 1957, p. 7), each having inputs, processes, and outputs. At the most detailed and fundamental level of analysis, elements are generally treated as 'black boxes.' At a high level of abstraction, what goes into and out of each black box is described, but the activities within the box are not described. Each black box is analyzed in turn to define the transformation process through which its inputs generate its outputs. The concepts of flow, relationship, message, initiator, terminator, and connection are used to portray the structure of the system being analyzed. These terms describe the interrelationships of its elements. The transformation processes are described in terms including transaction, process, and problem.

Cybernetic theory integrates feedback in systems. Feedback provides communication about the system's outputs, which in turn causes the system to adjust either the inputs or the process, as necessary, to achieve the system's purpose. This is called control. Mathematical system theories define a "collection of mathematical relationships which characterize the feasible programs" for improving a system (Dantzig 1963). Building a mathematical model provides insight into a system and its properties, and the model elements can be manipulated to derive conclusions about the system.

Mathematical models and other operations research/management science (OR/MS) techniques may be applied to the conceptual definition of a system and used to determine the best possible solution — the optimum decision, policy, or design — for the problem the system represents.

Graphs and graph theory are the basis for systems analysis relating to Web site and page design for target business processes. A graph is a collection of points and lines connecting these points used to represent relations between sets of objects. Graph theory is used to study some of the many possible properties of the identified objects (Berge 1962). Graphical theory is applied to business process information to develop abstract presentation forms using everyday metaphors and otherwise meaningful renditions. Then, the abstractions are translated into individual Web components that are compiled into Web pages, which together comprise a Web site.

Theories on data management and knowledge management provide a basis for data warehousing and retrieval systems (Alavi and Leidner 2001; Jarke and Vassiliou 1997). Like graphical theory, the emphasis of these theories is on business practice and use of system artifacts in addition to efficient uses of technology resources and application functionality. As a result, the expanded skills needed to analyze data technology and its use add to the techniques for systems analysis.

Churchman (1968) posed five necessary conditions for completing any systems analysis:

1. The total system objectives or, more specifically, the performance measures for the whole system;
2. The system's environment of fixed constraints, which are outside the system;

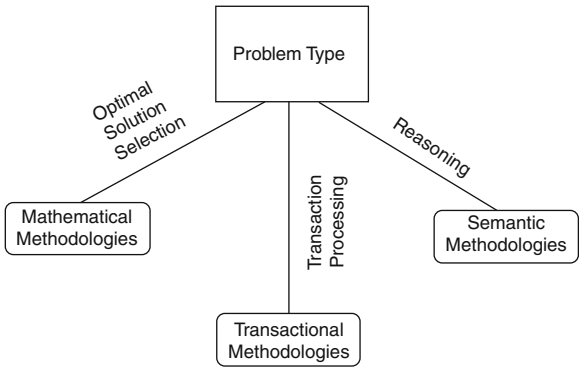
3. System resources that are capabilities found "inside" the system and that, therefore, can be analyzed and possibly designed;
4. System elements, including their activities, functions, goals, and measures of performance;
5. System management processes for allocating resources to system elements.

Most systems contain recognizable sub-systems, sub-sub-systems, and so on, organized in a hierarchy. Their arrangement often involves a "Chinese box" form of nesting that permits them to be defined by recursion. A solution that is best for the system as a whole is called an optimum, whereas a solution that is best relative to the functioning of one or more elements is called a sub-optimum or local optimum. One of the challenges of systems analysis is to improve the performance of a sub-system in terms of its own goals and purposes — sub-optimization — without either harming the total system or, worse, defeating the system's overall purpose.

Systems Analysis and Computer Systems

Systems analysis is the first stage in presenting any large task to a computer (the other principle stages being design and implementation). It is performed by a systems analyst and consists of analyzing the whole task in its setting and deciding how best to arrange it for processing by a computer. It includes estimation of how much work is involved, how powerful a computer is required, and the quality of the operating environment for security, recoverability, and reliable availability of computing resources. A problem is divided into a number of relatively independent parts that are specified, together with their interconnections, in sufficient detail for a programmer to take over. Options for arrangement of problem components can be hardware, firmware, or software; in hierarchies, sequences, or networks; for local, remote, or virtual computing.

Computer applications are developed through a series of translations. The first translation, as noted above, is from a real-world situation to a conceptual definition of the situation. This conceptual model is thentranslated via a design activity to an implementation model that can still be read by human beings and that describes the conceptual model in a language related to the target computer environment.



Systems Analysis, Fig. 1 Methodology classes

The implementation model is then translated into the specific coded language(s) of the target (hardware, software, firmware, and data) environment. These three translations define phases of activity that constitute an application's development life cycle. The translations relate to the thinking processes involved and are called analysis, design, and implementation, respectively. Implementation can be divided into sub-phases for programming, testing, and production.

Software development methodologies are used to guide the development processes through the life cycle. (Technically, methodology is the study of tools, techniques, and guidelines for choosing among them; methods are specific tools and techniques to be chosen and applied to a given situation. The common term for system development methods used as a package of tools and techniques is methodologies, and it is used here.) The different approaches currently used are: mathematical, process, data, object, information, and artificial intelligence. The techniques typically use top-down strategies for problem solving and progressively decompose a target task area into smaller, solvable tasks for independent solution (Laszlo 1972); however, bottom-up and middle-out strategies can also be applied to aspects of problems. The approaches can be further divided into classes: mathematical, transactional, semantic, and informational — depending on the type of problem being solved (Fig. 1). Mathematical methodologies solve selection and alternative analysis problems. Process, data, and object methodologies solve transactional processing problems. Information methodologies solve data storage, retrieval, and presentation problems. Semantic methodologies, in general, deal with understanding complex information

and artificial intelligence problems. Applications often encompass several of these problem types, requiring hybrid approaches to their solution.

Mathematical Methodologies

Mathematical methodologies employ mathematical models of a system and focus on the logical relationships within the system. They are often formulated by interdisciplinary teams who adapt scientific theories and methods to solve practical problems (Ackoff and Rivett 1963). OR/MS and cybernetic methods are applied. Classes of problems to which mathematical methods apply include inventory, allocation, sequencing, queueing, routing, replacement, competition, and search. The problems solved by OR techniques all deal with selection from many alternatives and sensitivity analysis to develop alternative, robust, or contingent courses of action.

Mathematical cybernetic systems seek optimal solutions based on unambiguous but possibly incomplete information. The inputs to mathematical applications define the alternatives and resources available from which an optimal selection must be made. The tools and techniques used to develop mathematical models include linear, network, dynamic, and stochastic programming methods. The results of these applications are usually presented in the form of suggested machine schedules, resource allocations, and so on. These problems, while the original focus of computing in the 1950s, have mostly been reduced to software packages and are rarely developed as custom software. As a result, application of mathematical methodologies has become a scarce skill.

Transactional Methodologies

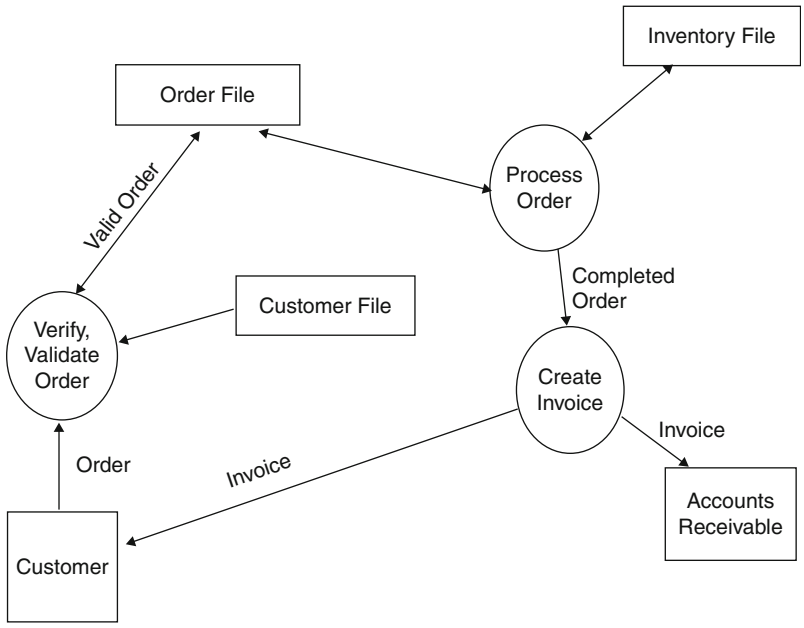
Transactional methods focus on the flows of information between the elements of a system. Three different methodology classes have evolved to develop transactional, information retrieval, and data analysis applications: process, data, and object. No single methodology currently supports all three application types well. Further, as the demand for client/server systems and distributed systems evolves, improved methodologies have evolved to support their development.

Process Methodologies — Process methods were developed during the 1950s and 1960s to mirror von Neumann computer architecture, which separates inputs and outputs from processes. Since computing was the difficult issue at the time, processing was the initial focus of process methods. The types of problems automated included accounting procedures, order entry, inventory, and other back-office applications. These applications all deal with transactions that support the basic white-collar operations of an organization.

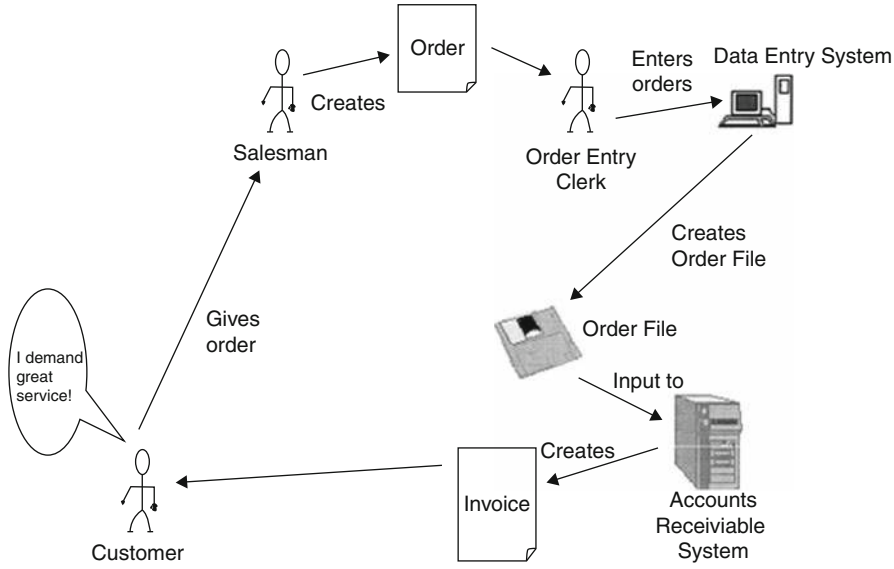
The development techniques focus on data flowing between processes, which transforms the data in some way (DeMarco 1979; Jackson 1983; Yourdon and Constantine 1979), or on data flows between people, each performing different processes (Checkland 1981; Checkland and Holwell 1998). The sample process data flow diagram in Fig. 2 shows the processes as circles connected via directed lines (i.e., data flows) to external entities and data stores. External entities are depicted on the diagram as squares and represent people, organizations, or other computer systems from which and to which information flows. Data stores, depicted in the diagram as open-ended rectangles, indicate files of information that persist over time. The lines connecting the other icons indicate temporary data flowing through the system, hence the term data flow diagram.

Process methodologies and methods have undergone several iterations of refinement to support real-time systems development and increased evaluation of the ethical and human aspects of systems (Ward and Mellor 1985, 1986; Checkland and Holwell 1998; Avison and Wood-Harper 1990). The lack of integration of data throughout analysis and design has led to an abandonment of process methods per se in favor of techniques that provide such integration.

Figure 3 shows the same order problem as that in Fig. 2, but in the more detailed European-school view, which shows people who act as agents involved in the work process. This type of diagram and the related methodologies are explicitly less mechanistic and more humanistic than their American data-flow diagram (DFD) counterpart. As a result, Soft Systems Methods explicitly deal with the nature, type, and impact of human-computer interactions more than other methods of systems development (Checkland and Scholes 1990).



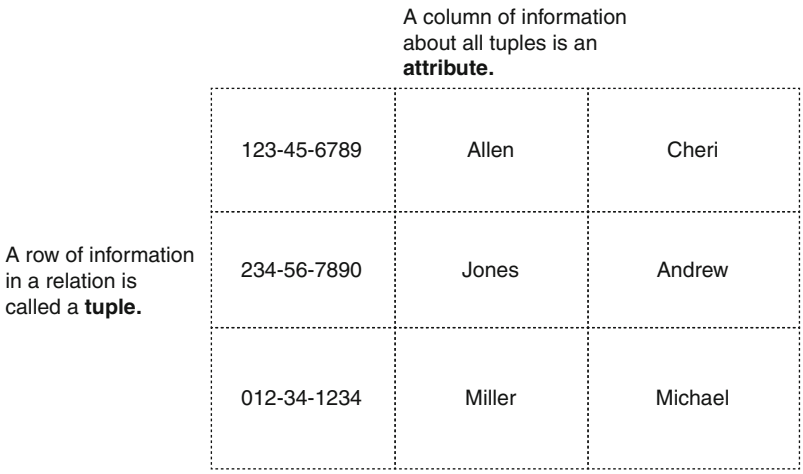
Systems Analysis, Fig. 2 Sample data flow diagram



Systems Analysis, Fig. 3 Human-centric work flow diagram

Data Methodologies — Data methodologies developed as the database technologies that matured in the 1960s and 1970s were found to require specific attention to data design. Data methods are based on theories of semantic modeling (Chen 1981), relational database design (Codd 1972), and data normalization (Kent 1983). These theories are significant in business because they result in mathematically, provably correct processing of data, a key in mission-critical applications. They are also significant because they encouraged the application of mathematical foundations to transaction processing, which had previously relied primarily on analyst and programmer ingenuity and accuracy.

The essence of relational data design is that information should look to the user as if it were composed of rows and columns, similar to a spreadsheet (Fig. 4). The physical implementation



Systems Analysis, Fig. 4 Relational database view

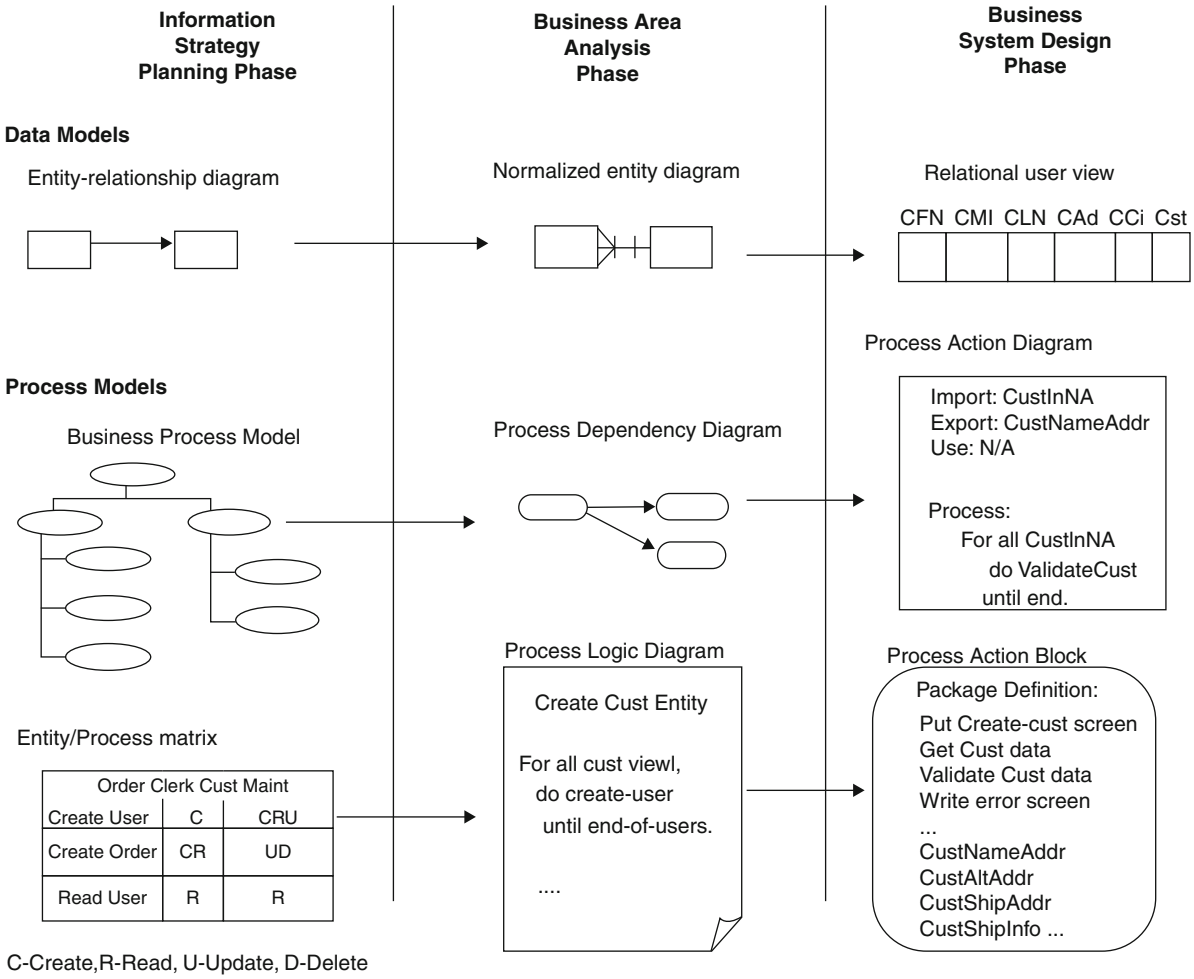
should be transparent, and entity and referential integrity must be maintained. Entity integrity refers to primary keys as unique identifiers of relations and states that no component of a key may accept null values (Date 1990). Referential integrity guarantees that no relation contains unmatched foreign key values. A foreign key is a primary key in one relation that appears as an attribute in another relation (Date 1990).

Early data methods focused only on data, with the assumption that all primitive processing — create, retrieve, update, and delete — followed logically from the correct definition of data (Warnier 1981). Demands to capture the complexities of the world led to significant extensions of process data flow analysis and the development of data modeling with integration of data and process throughout the information engineering (IE) methodology (Martin and Finkelstein 1981). Data models in the form of entity-relationship diagrams, process models similar in form to data flow diagrams, and integration models that link data and process are all found at each stage of information engineering (Fig. 5).

Information-engineered applications are assumed to integrate traditional process-oriented languages with database technologies. Computer-aided software engineering (CASE) tools that support the development of IE applications also generate process program code with imbedded relational database code (e.g., COBOL with embedded SQL). Data methodologies assume on-line applications but can be used for batch processing as well. They are less adapted to real-time applications. Data methodologies are widely used in large, U.S. Fortune 500 organizations that rely on databases containing millions of tuples (e.g., data records that consist of ordered lists of elements).

Object Methodologies — Object techniques were formalized for commercial computing at Xerox PARC in the 1970s with the development of *Smalltalk* and eventual commercialization of the Apple Lisa. As online and real-time technologies migrated from the aerospace and defense industries to commercial development of client–server applications, improved methods were needed to explain the interactions of system elements. Object-oriented analysis (OOA) was the proposed solution. It involves development of three models: (1) an information model describes elements in terms of objects and attributes, (2) a state model describes object behaviors and relationships over time, and (3) a process model specifies object actions in terms of elementary and reusable processes (Schlaer and Mellor 1992).

The goal of object methods is complete integration of data and processes in encapsulated objects (Fig. 6). Objects may be members of classes and exhibit inheritance, a property such that the properties, data, and processes of related objects may be reused without redefinition — that is, inherited. Objects may have multiple inheritances from competing objects throughout a hierarchy (Fig. 7). Objects may also exhibit polymorphism, i.e., the ability to have the same process, using one public name, take different forms when associated with different objects (Booch 1987, 1991). Client/server technology embodies the

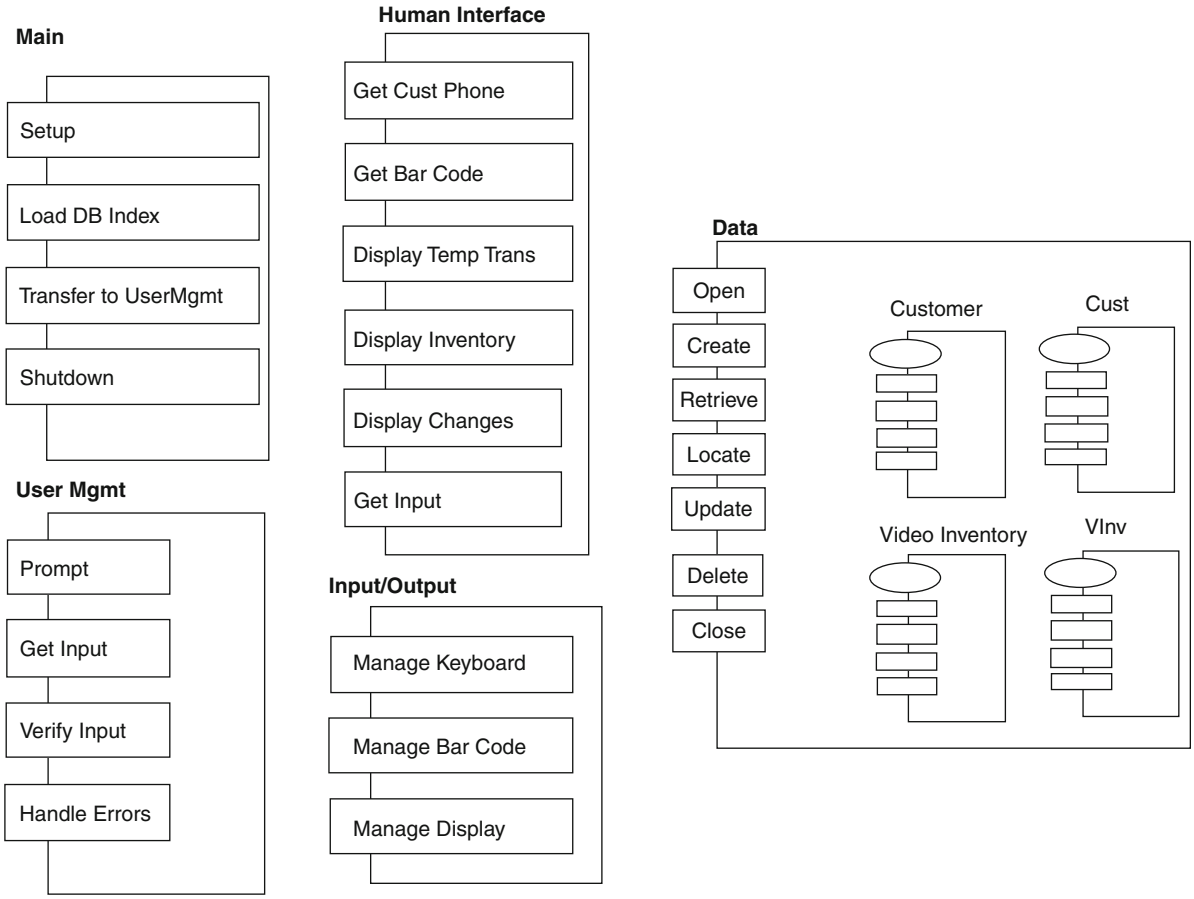


Systems Analysis, Fig. 5 Information engineering data, process, and integration models

concepts of object orientation. Client objects request a process from a supplier or server; server objects perform the requested process.

Object orientation is based on the same theories that data methodologies are based on, carrying normalization to the encapsulated (data + process) object units (Kent 1983). The most visible example of object applications is MS Windows, which uses windows, icons, menus, and pointers in an object-oriented human interface to personal computers. Object-oriented methodologies are currently adopted widely in the embedded systems and software markets (e.g., graphical user interfaces, or GUIs, such as MS Windows).

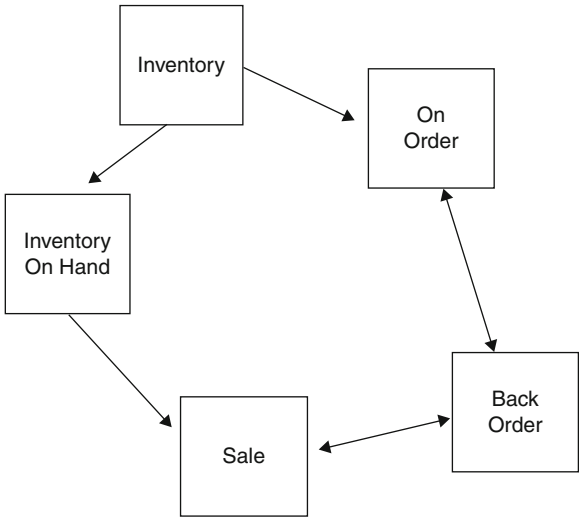
Object methods, which were experimental in the late 1980s, matured considerably during the 1990s, and are applied with great success to problems such as client-server applications. One issue with object methods was the need for an object broker software that interpreted requests, forwarded requests for processing, and coordinated the return of the response. In early object-oriented applications, each application built its own broker. In the late 1990s, broker software was commercialized and popularized through services oriented architectures (SOA). SOA applications are suites of self-contained, loosely coupled preprogrammed services, capable of communicating with others. The services are compiled and made available for applications with reusability a key characteristic. SOA defines how two or more computing entities such as programs are allowed to interact so as to enable each entity to perform a unit of work that can be passed on to another entity.



Systems Analysis, Fig. 6 Encapsulated objects

A mashup (a term from the field of music) is a variation on SOA that combines preprogrammed functionality derived from any number of sources to create a new application or service. A successful mashup removes the burdens of detailed analysis and coding and allows the designer to simply choose and connect to desired functions, thus creating a new application.

The success of object methods notwithstanding, obstacles that appeared intractable in the short run still remain. The two problems that were the biggest obstacles originally still remain the biggest problems — data persistence and standardization of object analysis and design methods. The issue of persistence means that few object-oriented systems are purely object oriented. Rather, they have program code objects that revert



Systems Analysis, Fig. 7 Inheritance lattice of objects

to data methods for database interactions. The issue with standards diminished with the integration of the key methodologies of Booch et al. (1999), coalescing the knowledge base.

Semantic Methodologies

Semantic refers to meaning. Semantic methods focus on the role of knowledge and meaning in a system. They imbed meaning in data and in the reasoning rules used to process it by drawing on theories of cognitive development as it applies to computer reasoning and learning. Two types of semantic methodology have evolved, one dealing with artificial intelligence and the other with presentation of World Wide Web-like business applications.

Artificial Intelligence methodologies — Artificial intelligence (AI) methodologies are used to design computer systems that are able to understand languages, learn, reason, solve problems, and exhibit other characteristics associated with intelligence in human beings. AI methodologies differ from mathematical and transactional methodologies in several ways. AI methods produce a decision, a course of action, or an answer to a question based on the application of qualitative knowledge and information. The more qualitative the systems situation being examined, therefore, the more advanced the techniques required. For instance, whether or not you have toast for breakfast in the morning might depend on numerous factors such as how well you slept the night before, what you had for dinner, and so on. This simple example illustrates two of the many non-trivial problems AI applications must solve: making their reasoning sufficiently generic and identifying all of the relevant quantitative and qualitative relationships in the system.

AI problems deal with incomplete information, probabilistic outcomes, and ambiguities in the reasoning and data to be used in developing a solution. In contrast, traditional methods assume complete information and single outcomes with few or no ambiguities. Similarly, AI methods differ from OR methods. In AI problems, complexes of potentially conflicting rules are expertly reasoned through to a logical conclusion. OR methodologies describe probable situational relationships to develop an optimal solution from an unlimited number of possible outcomes. The difference here is that AI problems have an unknown number of relevant inputs whereas OR problems have an unknown number of outcomes.

A program called DENDRAL was an early result of AI research. DENDRAL is a chemist's assistant that interprets data from a mass spectrograph and infers the chemical structure of an unknown organic compound. The program is based on an algorithm, developed by J. Lederberg in 1964, that generates all possible acyclic graphs given the number of systems elements (the compound's chemical composition) and the number of links (relationships) pertaining to each element (the technical valences). The number of possibilities generated for any given compound is enormous. To avoid an exponential search, DENDRAL automates rules to apply heuristics and knowledge gained from practicing chemists to delimit radically the number of alternatives that must be evaluated to determine the compound's molecular structure. DENDRAL introduced the idea of using *rules* to represent expert knowledge, a concept that has prevailed in AI work since (Feigenbaum et al. 1971). DENDRAL outperforms expert chemists on this task (Buchanan and Feigenbaum 1981; Churchman 1971; Feigenbaum et al. 1971; Smith et al. 1973).

New in the 1990s, neural networks model human intellectual activity on a broad scale by mirroring human brain functioning. A neuron is the smallest possible processing element and is related to other neurons via synapses. Objects called dendrites are message transmitters that flow between neurons over synaptic connections. Single neurons can have thousands of synapses. Inputs via dendrites can either excite (i.e., initiate) or inhibit action of a neuron. The number and frequency of messages sent to a neuron create an activity level that can be triggered when some predefined threshold is reached. Each neuron has axons through which output signals are transmitted to the dendrite network. These terms have parallels in the other AI methodologies but work slightly differently in neural nets. Neural network problems, however, are different in kind from those solved by the other AI methodologies with applications to machine learning, generalization based on past reasoning success, and partial

matching. Familiar applications include pattern recognition of written characters, voices, or faces. Neural net analysis is applied to problems that have subjective outcomes, ambiguous reasoning and components, are vague in definition, or have contradictory results.

The techniques that constitute semantic methodologies are not mature enough to strictly qualify as methodologies. Rather they are individually applied, taught in a master-apprentice relationship, and based on practical experience with a given set of problems.

At this time, different types of reasoning problems require different types of methods and approaches to automating intelligence (Winograd and Flores 1986). The problem types that are addressed by semantic methods include language understanding and translation, sensory understanding (i.e., sight, touch, etc.), memory recall and forgetting, and coordination and control of movement. The most common of these are expert systems, which exhibit intelligence in selecting an action by reasoning through numerous, sometimes contradictory, rules. Expert systems have found acceptance in industry and government for applications such as surveillance of nuclear plant operations, selection of geological drilling sites, and diagnosis of medical problems (Kaufmann and McCorduck 1979). Expert reasoning systems, such as DENDRAL, are ubiquitous and are used in most areas of human activity from basic product design, to agriculture, appliances, medicine, and finance.

AI techniques and methodologies are in an emergent stage, experiencing continuous refinement and evolution. Like object-oriented methods, AI methods are also closely coupled to the target implementation language. For instance, some AI languages require data integration with reasoning rules while others require separation of data from reasoning rules. Most languages offer one reasoning approach that determines the nature of the reasoning process as forward, backward, depth-first, breadth-first, custom-defined, or other. The major commercial promise of AI is to augment existing applications by including reasoning about the processes and data they maintain. Neural nets are promising as generic reasoning systems that may coalesce these diverse methods and techniques some time in the future.

Information Methodologies

Data refers to elementary facts and figures that can be used as a basis for reasoning, calculation or discussion. Information is data that has meaning. High quality information typically is accurate, complete, consistent, unique, and timely. Data, numbers and letters, becomes information (what) which leads to knowledge (how) which, in turn, leads to wisdom (why) (Buckland 1991; Langefors 1966). Wisdom relating to information systems is the desired outcome of information methodologies and technologies. As globalization increases, multi-location and multi-national organizations require historical data storage in a manner that

- Supports large-scale data integration from any number of sources
- Priortizes data source for 'official' data when multiple copies occur
- Stores data for simplicity and speed of retrieval
- Allows multiple views of the data
- Provides easily-used data query and retrieval capabilities.

The first four goals are supported through information methodologies and technologies for information storage and retrieval. The last two goals are supported through methods and technologies for information presentation.

Information Storage and Retrieval – A data warehouse is a collection of data from any number of sources that supports analysis and decision making. Three main areas of concern are imbedded in information methodologies that are de facto conventions rather than formal standards. The term 'data warehouse' first appeared in Inmon (1993) as a tool supporting organizational decision-making. A data warehouse provides for both storage and retrieval of its contents.

The first task of data warehouse analysis is the extract- transform-load (ETL) process through which data is taken from multiple sources, integrated, cleaned, and loaded into a consolidated database. If multiple views of data are provided, this outcome is also known as a 'data mart.' Data warehouses are often referred to as a 'cube,' consisting of data over time and over organizations (hence three dimensions). Design complexity derives from multiple issues relating to logical and physical data design and to tradeoffs between speed, simplicity, and completeness.

Logical design refers to design of the business data and its characteristics, including data type, length, name, source, and so on. Logical design decisions relate to data relationships as hierarchic or networked, how to prioritize data from multiple sources, and data cleansing. Physical design refers to design of the data warehouse within its intended hardware infrastructure. Some key physical design decisions include items such as whether or not to provide in-memory indices, size of data blocks, number and type of storage devices, managing and synchronizing data requests, and number of data request queues.

Data retrieval relates to development of reports through a data warehouse. Three options for reporting include pre-defined queries, structured language queries, and ad hoc queries. As hoc queries often use a capability called 'natural language processing' (NLP). Though data retrieval is typically provided through data warehouse software, the three types of queries are not necessarily guaranteed. These in turn have their own issues with which analysts contend. Pre-defined queries can only be defined for about 80% of processing that is recurring and standardized. An example of this is a monthly report. Structured language and ad hoc queries are useful for the remaining 20% of queries. Both of these raise issues relating to ambiguity, such as 'all sales in New York.' The reference 'New York' could be the city or the state. Thus, the software needs a means to recognize and resolve ambiguities in real-time. Other design issues include how to deal with inaccurate or missing data – reporting it or not, using it in computations or not, and so on. NLP has given rise to one of the emerging problem areas discussed below.

Information Presentation – With Internet commercialization in 1994 and the advent of sophisticated, user-friendly graphical user interface browser software in 1993, businesses flocked to the World Wide Web (Web). By 1996, companies saw the potential to eliminate internal communication bottlenecks via intranets, which also use browser interfaces. By 1997, business-to-business relationships were supported by private extranets and in 1998 by virtual private networks (VPNs) on the Internet. Web innovation was followed shortly by unprecedented acceleration and growth in technologies supported by Web browsers, from text-only in 1994 to full multimedia, audio, video, and telephony support in 1998. The increasing population of Web users has been equally astonishing: from two million (mostly academic users) in the early 1990s to 100 million in 2000 to over 4.5 billion in 2010.

The popularity of the Web as a vehicle for electronic commerce (E-commerce) necessitated development of advanced developer skill sets to support the new technologies of integration and graphical composition. The new analytical skills focus on understanding and presenting business information in ways that add value to users (to keep them coming back to the Web site), and, therefore, increase the profits of the presenting organizations.

Information analysis methodologies, based on systems theory evolved to provide techniques and methods for Web presentation development (Conger and Mason 1998). The first part of information analysis incorporates analysis of user groups' needs and wants and the information the business developing the presentation wants to provide. Then, information analysis organizes data objects into relational structures reflecting how the business and the user groups view information. Information objects are then expressed in unambiguous, concise language for Web presentation. Once information objects are defined, graphical design techniques and methods are applied to identify individual Web pages and to guide the layout of information on each page. Hyperlink analysis is a form of systems analysis used to determine the set of threads between pages that will best accommodate the view of the information objects and their interrelationships that the business wants to present and the user want to see. (Nelson 1981) Finally, multimedia are used to enhance the value of information to users either by augmenting the current presentation or by replacing words with some other, more easily digested representation of the information.

Concluding Remarks

The problems companies seek to solve through automation have shifted to dealing with legacy applications, loosely defined as any application that has been operational in an organization for more than

seven years, to the development of data warehouses to support extended trend analysis. One element that is common to analytical problems is that their solutions will depend on the integration of different theories and methodologies. This is a major shift in emphasis from prior to 2000, during which problem types were addressed by means of separate and distinct problem-solving activities. Three problems persist in systems analysis at present – legacy applications integration, application quality, and universal translation. The first two are persistent problems that have been intractable but appear to have solutions on the horizon. The last is a more recent issue that exemplifies the desire to automate beyond current technical and analytical capabilities.

Legacy Applications — Legacy applications may have been operational anywhere from 7 to 40 years. These applications manage much valuable corporate information and are the cash cows of the information systems world. Legacy applications still contain more than one trillion lines of COBOL code, down by 50% in 10 years. COBOL was developed in 1959 by Grace Hopper well before most current methodologies were adopted by large corporations. Replacement of these applications represents a prohibitively large investment that most companies are reluctant to make unless forced to do so. Legacy applications are often poorly designed, poorly coded, and undocumented. Maintaining this inherently inefficient and bug-ridden code requires increasingly expensive maintenance support staff whose programming skills are essentially obsolete. The challenge to corporations is to replace or up-grade non-strategic legacy applications with superior packaged software or custom-built applications or to outsource operations without making a huge financial reinvestment.

Application Quality — As sophisticated as systems analysis has become, it still often leads to failed applications. Application success and use is best summarized by the DeLone and McLean (1992, 2003) and Petter et al. (2008), who found the following constructs of importance in Table 1.

DeLone and colleagues built on hundreds of other research projects to develop both a parsimonious list of critical factors that generally fits all applications. The details of each characteristic is beyond the scope of this paper, but the key drivers are of interest because they span all applications types with many sub-factors seeming to be universal. Three types of quality are expected of successful applications: System, information, and service (Conger 2011). Systems quality refers to the application in its operational environment and the extent to which it performs at the time needed and in the manner expected. System quality is important because inattention to system quality early in the development cycle can easily result in poor quality upon implementation.

Systems Analysis, Table 1 Key drivers of successful information systems (DeLone and McLean 2003, p. 26)

Key driver	Sub-Characteristics
Systems quality	Adaptability
	Availability
	Reliability
	Response time
	Usability
Information quality	Completeness
	Ease of understanding
	Personalization
	Relevance
	Security
Service quality	Assurance
	Empathy
	Responsiveness
Use	Nature of use
	Navigation patterns
	Number of site visits
	Number of transactions executed
User satisfaction	Repeat purchases
	Repeat visits
	User surveys
Net benefits	Cost savings
	Expanded markets
	Incremental additional sales
	Reduced search costs
	Time savings

Information quality refers to the suitability and usefulness of the data provided to the user. Information quality in any transactional system needs to be complete and accurate. Similarly, relevant, secure data seem to be universal in their appropriateness across application types.

Service quality also may be appropriate for all applications but in a different sense than expressed by the sub-factors provided here. The sub-factors in the De Lone and McLean list are from SERVQUAL,

a well-researched model of service quality in an online environment (Parasuraman et al. 1988). SERQUAL needs additional research to determine characteristics that fit other arenas of IT support. Gap analysis to evaluate expectations versus attributes of objective product, specific characteristics of service quality and how they are developed within IT analysis methodologies. Further, contextualizing service concepts may lead to more accurate service design. For instance, in e-commerce, service and system quality are used interchangeably and no known research has teased out the nuances of their differences.

Thus, completing an application with technical quality is insufficient to develop a contribution to its using organization. Rather, the application in use must comply with all of its needs. Yet, application developers persist in thinking of 'needs' as confined to functional requirements. Rather, functional and non-functional requirements are necessary, as are requirements for more ephemeral aspects of contribution such as simplicity, learnability, usability, and so on (Nielsen 2000). To determine value added to an organization, application development must attend to an application's use in context, particularly as it relates to the using organization's success. Current thinking on these operational activities is that taking a services orientation that mirrors the services orientation the organization seeks to perfect, will lead to value-adding outcomes for IT. IT service management is in its infancy as it relates to systems analysis but promises to become an increasingly important aspect of analysis activities (Conger 2011).

Universal Translation — The ultimate goal in machine translation (also called computational linguistics) is to support machine-only, seamless translation from one language to any other without special equipment or human intervention. Work on universal translation dates to the 1950s and was then conducted using semantic methods. However, as understanding of the uses for this technology became more global, the work focused less on software and more on data. The idea was for language translation technology to be imbedded in any type of application and applied to data into and out of the application while being stored in the original language. With this technology, a purchase via the Web, conducted through, e.g., a smart phone, would identify global goods and prices all displayed in the user's preferred language.

For systems analysis, hybrid techniques, including aspects of mathematical, AI, information, and object methodologies are all required to result in embeddable translation capabilities. In addition, these computer-oriented methodologies must be successfully coupled with linguistics methodologies for morphology, syntax, semantics, and inference understanding and automation. This is a huge task that has had great success in limited domains, such as automated voice response systems and online web sites such as babelfish.com.

For the first 30 years, machine translation technology focused on a process that decoded source language to an intermediate, neutral language then encoded the neutral language to target language. This approach has been marginally successful. More recently, research that removes the intermediate language has shown promise but runs into language accuracy issues. Multiple 'grammars' have been developed to identify intra-lingual relationships including, generative, dependency, unification, and case. Then, hybrid methods arose that combine elements of intermediary language with some direct translation. Probably the most successful translations are performed within a known domain, such as going to a restaurant, however, no complete, unaided translation systems have been successful to date. The issues relating to this capability lie not only in technology but also in linguistics knowledge and capabilities to describe languages.

Technologies for machine translation capabilities exist in definitional tools such as extensible markup (XML), OWL (web ontology language), and other World Wide Web Consortium (W3C) developments for web services. One problem is that vendor support for these languages imbed custom tags and, therefore, require adherence to some vendor's products. In addition, attempts at reaching agreement on a global ontology to categorize domain information, such as health care, have not been successful. As with all systems analyses, global projects take time and at some point participants become impatient, leave, and develop their own ontology, often thinking that it will become a de facto standard. In developing something custom, these ontologies automatically become biased and/or incomplete. In addition, these technologies and lingual grammars are complex. Automating them is even more complex, thus rendering them beyond the reach of the average application analyst.

The state of linguistics knowledge also delays development of universal translation. Much is understood about languages and language structures in terms of their basic syntax (e.g., noun – verb-object structures versus other orders or alternatives). However, issues such as ambiguity, ('the man hit the woman with the baby', 'whatever'), alternative meanings and uses of words (e.g., "hit" as subject, verb, or object), and idioms ('he went to town on that steak') all cause havoc with translators and these are just English examples. Further, until projects such as propbank, verbnet, and semlink are completed in many languages, unaided, accurate machine translation will remain elusive.

Tabu Search

Fred W. Glover
OptTek Systems, Inc., Boulder, CO, USA

Introduction

Tabu Search (TS) is a metaheuristic that guides a local heuristic search procedure to explore the solution space beyond local optimality. Widespread successes in practical applications of optimization include finding better solutions to problems in scheduling, sequencing, resource allocation, investment planning, telecommunications and many other areas. Some of the diversity of tabu search applications is shown in Table 1. (For a more comprehensive list of applications, see the book by Glover and Laguna 1997.)

Tabu search is based on the premise that methods for complex optimization problems, particularly those arising in real world applications, can function more effectively if they incorporate flexible and responsive memory. Accompanying this premise is the corollary that such memory is employed together with strategies expressly designed for exploiting it. More broadly, tabu search embodies the following principle: If a problem has exploitable features, but contains a structure sufficiently complex to prevent these features from being known in advance, then a method can derive advantages by monitoring its behavior in relation to the space in which it operates. The purpose of the monitoring is effectively to generate a map of the regions the method has visited as a foundation for modifying its behavior, where this map can take multiple forms that ultimately become expressed in the decision rules employed to negotiate the solution space. The hallmark of a TS method is therefore a capacity to guide its progress by reference to its own unfolding history. Such a method evidently is implicitly or explicitly structured to employ learning. Based on this perspective, methods that incorporate a significant portion of the tabu search framework are sometimes called Adaptive Memory Programming (AMP) methods.

The emphasis on responsive exploration (and hence purpose) in tabu search, whether in a deterministic or probabilistic implementation, derives from the supposition that a bad strategic choice can yield more information than a good random choice. In a system that uses memory, a bad choice based on strategy can provide useful clues about how the strategy may profitably be changed. Even in a space with significant randomness – which fortunately is not pervasive enough to extinguish all remnants of order in most real-world problems – a purposeful design can be more adept at uncovering the imprint of structure, and thereby at affording a chance to exploit the conditions where randomness is not all-encompassing.

These basic elements of tabu search have several important features that are summarized in Table 2.

Tabu search is concerned with finding new and more effective ways of taking advantage of the concepts embodied in Table 2, and with identifying associated principles that can expand the foundations

Tabu Search, Table 2 Principal tabu search features

Adaptive Memory
Selectivity (including strategic forgetting)
Abstraction and decomposition (through explicit and attributive memory)
Timing:
recency of events
frequency of events
differentiation between short term and long term
Quality and impact:
relative attractiveness of alternative choices
magnitude of changes in structure or constraining relationships
Context:
regional interdependence
structural interdependence
sequential interdependence
Responsive Exploration
Strategically imposed restraints and inducements (tabu conditions and aspiration levels)
Concentrated focus on good regions and good solution features (intensification processes)
Characterizing and exploring promising new regions (diversification processes)
Non-montonic search patterns (strategic oscillation)
Integrating and extending solutions (path relinking)

of intelligent search. As this occurs, new strategic mixes of the basic ideas emerge, leading to improved solutions and better practical implementations.

Tabu Search Foundations

The basis for tabu search may be described as follows. Given a function $f(x)$ to be optimized over a set X, TS begins in the same way as ordinary local search, proceeding iteratively from one point (solution) to another until a chosen termination criterion is satisfied. Each $x \in X$ has an associated neighborhood $N(x) \subset X$, and each solution $x' \in N(x)$ is reached from x by an operation called a move.

TS goes beyond local search by employing a strategy of modifying $N(x)$ as the search progresses, effectively replacing it by another neighborhood $N^*(x)$. As the previous discussion intimates, a key aspect of tabu search is the use of special memory structures which serve to determine $N^*(x)$, and hence to organize the way in which the space is explored.

The solutions admitted to $N^*(x)$ by these memory structures are determined in several ways. One of these, which gives tabu search its name, identifies solutions encountered over a specified horizon (and implicitly, additional related solutions), and forbids them to belong to $N^*(x)$ by classifying them tabu (The tabu terminology is intended to convey a type of restraint that embodies a cultural connotation – i.e., one that is subject to the influence of history and context, and capable of being surmounted under appropriate conditions).

The process by which solutions acquire a tabu status has several facets, designed to promote a judiciously aggressive examination of new points. A useful way of viewing and implementing this process is to conceive of replacing original evaluations of solutions by tabu evaluations, which introduce penalties to significantly discourage the choice of tabu solutions (i.e., those preferably to be excluded from $N^*(x)$, according to their dependence on the elements that compose tabu status). In addition, tabu evaluations also periodically include inducements to encourage the choice of other types of solutions, as a result of aspiration levels and longer term influences. The following subsections describe how tabu search takes advantage of memory (and hence learning processes) to carry out these functions.

Explicit and *Attributive Memory* – The memory used in TS is both explicit and attributive. Explicit memory records complete solutions, typically consisting of elite solutions visited during the search (or highly attractive but unexplored neighbors of such solutions). These special solutions are introduced at strategic intervals to enlarge $N^*(x)$, and thereby provide useful options not in $N(x)$.

TS memory is also designed to exert a more subtle effect on the search through the use of attributive memory, which records information about solution attributes that change in moving from one solution to another. For example, in a graph or network setting, attributes can consist of nodes or arcs that are added, dropped or repositioned by the moves executed. In more abstract problem formulations, attributes may correspond to values of variables or functions. Sometimes attributes are also strategically combined to create other attributes by using vocabulary building methods (Glover and Laguna 1993; Glover 1999; Glover et al. 2000).

Short-Term Memory and its Accompaniments – An important distinction in TS arises by differentiating between short-term memory and longer-term memory. Each type of memory is accompanied by its own special strategies. The most commonly used short-term memory keeps track of solution attributes that have changed during the recent past, and is called recency-based memory. To exploit this memory, selected attributes that occur in solutions recently visited are designated tabu-active, and solutions that contain tabu-active elements, or particular combinations of these attributes, are those that become tabu. This prevents certain solutions from the recent past from belonging to $N^*(x)$ and hence from being revisited. Other solutions that share such tabu-active attributes are also similarly prevented from being revisited. The use of tabu evaluations, with large penalties assigned to appropriate sets of tabu-active attributes, can allow tabu status to vary by degrees.

Managing Recency-Based Memory – The process is managed by creating one or several tabu lists, which record the tabu-active attributes and implicitly or explicitly identify their current status. The duration that an attribute remains tabu-active (measured in numbers of iterations) is called its tabu tenure. Tabu tenure can vary for different types or combinations of attributes, and can also vary over different intervals of time or stages of search. This varying tenure makes it possible to create different kinds of tradeoffs between short-term and longer-term strategies. It also provides a dynamic and robust form of search. (See, e.g., Glover 1990; Taillard 1991, Glover and Laguna 1993, 1997.)

Aspiration Levels – An important element of flexibility in tabu search is introduced by means of aspiration criteria. The tabu status of a solution (or a move) can be overruled if certain conditions are met, expressed in the form of aspiration levels. In effect, these aspiration levels provide thresholds of attractiveness that govern whether the solutions may be considered admissible in spite of being classified tabu. Clearly a solution better than any previously seen deserves to be considered admissible. Similar criteria of solution quality provide aspiration criteria over subsets of solutions that belong to common regions or that share specified features (such as a particular functional value or level of infeasibility). Additional examples of aspiration criteria are provided later.

Candidate List Strategies – The aggressive aspect of TS is reinforced by seeking the best available move

that can be determined with an appropriate amount of effort. It should be kept in mind that the meaning of best is not limited to the objective function evaluation. (As already noted, tabu evaluations are affected by penalties and inducements determined by the search history.) For situations where $N^*(x)$ is large or its elements are expensive to evaluate, candidate list strategies are used to restrict the number of solutions examined on a given iteration.

Because of the importance TS attaches to selecting elements judiciously, efficient rules for generating and evaluating good candidates are critical to the search process. Even where candidate list strategies are not used explicitly, memory structures to give efficient updates of move evaluations from one iteration to another, and to reduce the effort of finding best or near best moves, are often integral to TS implementations. Intelligent updating can appreciably reduce solution times, and the inclusion of explicit candidate list strategies, for problems that are large, can significantly magnify the resulting benefits.

The operation of these short-term elements is illustrated in Fig. 1. The representation of penalties in Fig. 1 either as large or very small expresses a thresholding effect: either the tabu status yields a greatly deteriorated evaluation or else it chiefly serves to break ties among solutions with highest evaluations. Such an effect of course can be modulated to shift evaluations across levels other than these extremes. If all moves currently available lead to solutions that are tabu (with evaluations that normally would exclude them from being selected), the penalties result in choosing a "least tabu" solution.

The TS variant called probabilistic tabu search follows a corresponding design, with a short-term component that can be represented by the same diagram. The approach additionally keeps track of tabu evaluations generated during the process that results in selecting a move. Based on this record, the move is chosen probabilistically from the pool of those evaluated (or from a subset of the best members of this pool), weighting the moves so that those with higher evaluations are especially favored. Fuller discussions of probabilistic tabu search are found in Glover (1989), Glover and Laguna (1997), Soriano and Gendreau (1993) and Crainic et al. (1993).

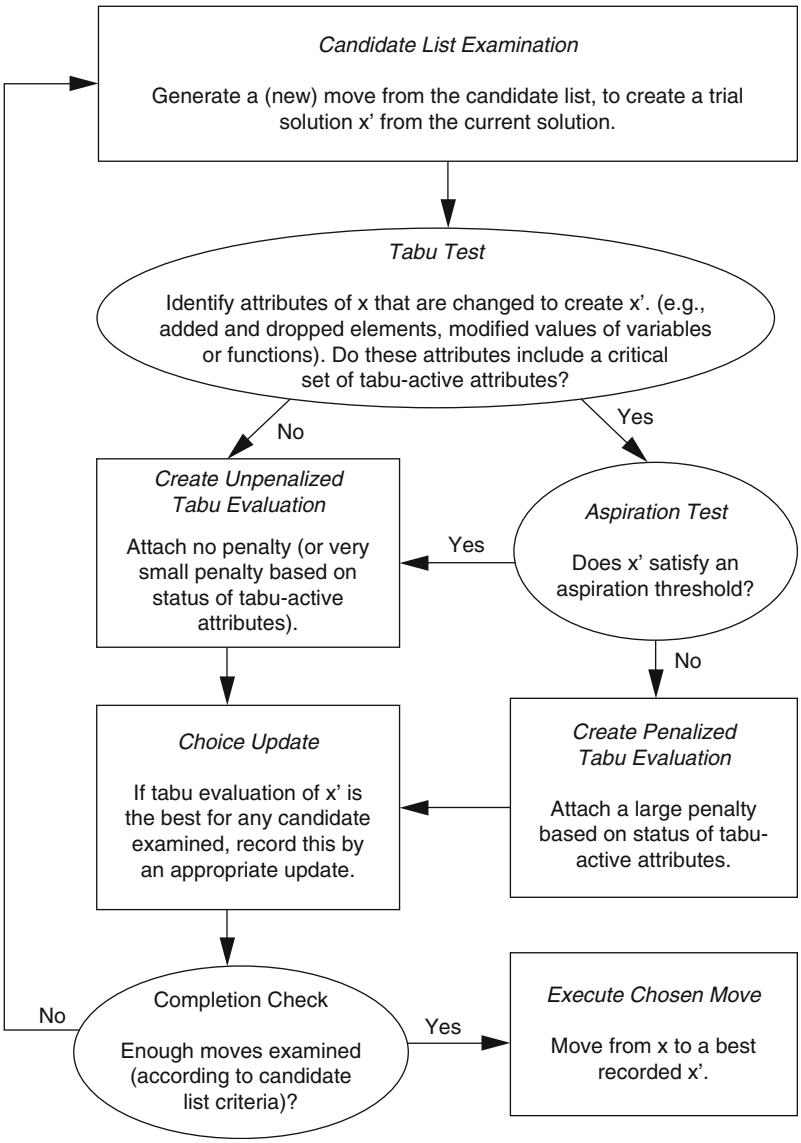
Longer-Term Memory – In some applications, the short-term TS memory components are sufficient to produce very high quality solutions. However, in general, TS becomes significantly stronger by including longer-term memory and its associated strategies.

Special types of frequency-based memory are fundamental to longer-term considerations. These operate by introducing penalties and inducements determined by the relative span of time that attributes have belonged to solutions visited by the search, allowing for regional differentiation.

Perhaps surprisingly, the use of longer-term memory does not require long solution runs before its benefits become visible. Often its improvements begin to be manifest in a relatively modest length of time, and can allow solution efforts to be terminated somewhat earlier than otherwise possible, due to finding very high quality solutions within an economical time span. The fastest methods for job shop and flow shop scheduling problems, for example, are based on including longer-term TS memory. On the other hand, it is also true that the chance of finding still better solutions as time grows – in the case where an optimal solution is not already found – is enhanced by using longer-term TS memory in addition to short-term memory.

Intensification and Diversification – Two highly important longer-term components of tabu search are intensification strategies and diversification strategies. Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. A simple instance of this second type of intensification strategy is shown in Fig. 2.

The strategy for selecting elite solutions is italicized in Fig. 2 due to its importance. Two variants have proved quite successful. One, due to, introduces a diversification measure to assure the solutions recorded differ from each other by a desired degree, and then erases all short-term memory before resuming from the best of the recorded solutions. The other variant, due to Nowicki and Smutnicki (1993), keeps a bounded length sequential list that adds a new solution at the end only if it is better than any previously seen. The current last member of the list is always the one chosen (and removed) as a basis for resuming search. However, TS short-term memory that accompanied this solution also is saved, and the first move also forbids the move previously taken from this solution, so that a new solution path will be launched.

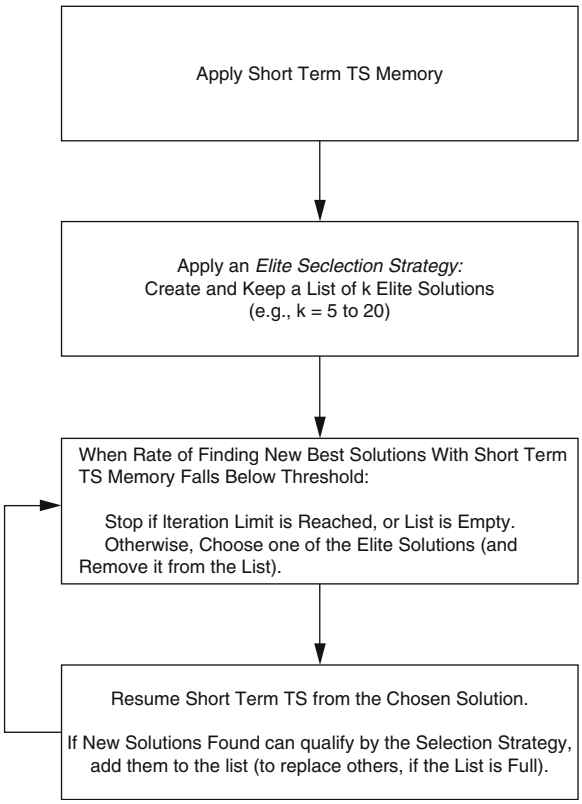


Tabu Search, Fig. 1 Tabu evaluation (short term memory)

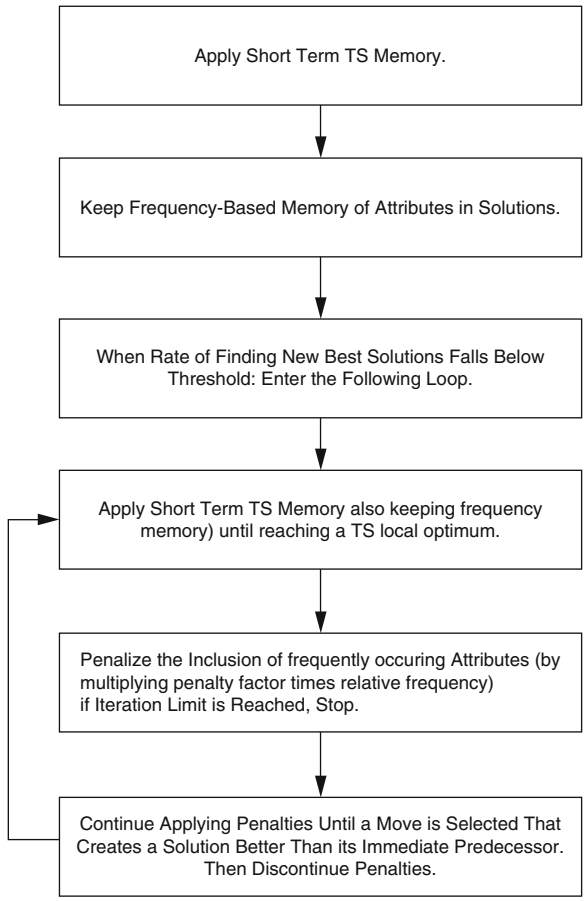
This second variant is related to a strategy that resumes the search from unvisited neighbors of solutions previously generated (Glover 1990). Such a strategy keeps track of the quality of these neighbors to select an elite set, and restricts attention to specific types of solutions, such as neighbors of local optima or neighbors of solutions visited on steps immediately before reaching such local optima. This type of unvisited neighbor strategy has been little examined. It is noteworthy, however, that the two variants previously indicated have provided solutions of remarkably high quality.

Diversification Strategies – TS diversification strategies, as their name suggests, are designed to drive the search into new regions. Often they are based on modifying choice rules to bring attributes into the solution that are infrequently used. Alternatively, they may introduce such attributes by partially or fully re-starting the solution process.

The same types of memories previously described are useful as a foundation for such procedures, although these memories are maintained over different (generally larger) subsets of solutions than those maintained by intensification strategies. A simple diversification



Tabu Search, Fig. 2 Simple TS intensification approach



Tabu Search, Fig. 3 Simple TS diversification approach

approach that keeps a frequency-based memory over all solutions previously generated, and that has proved very successful for machine scheduling problems, is shown in Fig. 3. Significant improvements over the application of short term TS memory have been achieved by this procedure.

Diversification strategies that create partial or full restarts are important for problems and neighborhood structures where a solution trajectory can become isolated from worthwhile new alternatives unless a radical change is introduced. Diversification strategies can also utilize a long-term form of recency-based memory, which results by increasing the tabu tenure of solution attributes.

The two special TS strategies called path relinking and strategic oscillation embody aspects of both intensification and diversification and have proved highly effective in a variety of contexts (Glover and Laguna 1993; Yagiura et al. 2006). The determination of effective ways to balance the concerns of intensification and diversification represents a promising research area. These concerns also lie at the heart of effective parallel processing implementations. The goal from the TS perspective is to design patterns of communication and information sharing across subsets of processors in order to achieve the best tradeoffs between intensification and diversification functions. General analyses and studies of parallel processing with tabu search are given in Taillard (1991, 1993), Battiti and Tecchiolli (1992), Chakrapani and Skorin-Kapov (1993), and Crainic et al. (1993a, 1993b).

Concluding Remarks

Complementarities among the perspectives of tabu search and those favored by the artificial intelligence and neural network communities raise the possibility of creating systems that integrate their fundamental

concerns. Examples are provided by the creation of tabu training and learning models (de Werra and Hertz 1989; Beyer and Ogier 1991; Battiti and Tecchioli 1993; Gee and Prager 1994) and tabu machines (Chakrapani and Skorin-Kapov 1993). The outcomes from this work have shown promising consequences for supplementing customary connectionist models – as by yielding levels of performance notably superior to that of models based on Boltzmann machines, and by yielding processes for modifying network linkages that give more reliable mappings of inputs to outputs.

The practical successes of tabu search have promoted useful research into ways to exploit its underlying ideas more fully. At the same time, many facets of these ideas remain to be explored. The issues of identifying best combinations of short- and long-term memory and best balances of intensification and diversification strategies still contain many unexamined corners (Glover 2007), and some of them undoubtedly harbor important discoveries for developing more powerful solution methods in the future.

Fundamental advances in applications of tabu search have been assembled in a collection of "Tabu Search Vignettes" accessible via the Internet at the author's Web site. These include summaries of key developments in a variety of areas, including:

Constraint Solving and Its Applications (Resource Assignment, Planning and Timetabling, Integer Programming Feasibility, Satisfiability, Mobile Network Frequency Assignment)
Chemical Industry Applications (Computer Aided Molecular Design (CAMD), Heat Exchanger Network (HEN) Synthesis, Phase Equilibrium Calculations, Gibbs Free Energy Minimization, Optimal Component Lumping Problems)
Classification
Feature Selection
Satellite Range Scheduling
Maritime Transportation for International Trade
Conservation Area Network Design
High Level Synthesis
Graph Coloring
Delivery
Routing with Loading and Inventory Constraints
Heterogeneous Routing and Scheduling
Capacitated Facility Location
Multi-period Forest Harvesting
Manpower Scheduling
DNA Sequencing
Airline Disruption Management
Internet Traffic Engineering
Matrix Bandwidth Minimization
Generalized Assignment
Constraint Satisfaction (Work Shift Scheduling, Set-Covering and Nurse Scheduling)
Resource-Constrained Project Scheduling
Dynamic Optimization (Trade Market Prediction, Meteorological Forecast, Robotics Motion Control)

The Institute of Management Sciences (TIMS)

Founded in 1953, The Institute of Management Sciences (TIMS) was an international organization for management science professionals and academics. It was merged with the Operations Research Society of America (ORSA) into the Institute for Operations Research and the Management Sciences (INFORMS) effective January 1, 1995. The objectives of TIMS were

(1) to identify, extend and unify scientific knowledge contributing to the understanding and practice of management, (2) to promote the development of the management sciences and the free interchange of information about the practice of management among managers, scientists, scholars, students, and practitioners of the management sciences within private and public institutions, (3) to promote the dissemination of information on such topics to the general public, and (4) to encourage and develop educational programs in the management sciences. TIMS published the journal *Management Sciences* (in 40 volumes) and other publications (some jointly with ORSA). It held national meetings (jointly with ORSA), sponsored meetings by its technical colleges and geographic sections, and held international meetings in various countries.

Theorem of Alternatives

Many such theorems exist, with a typical one being: either $\boldsymbol{Ax} = \boldsymbol{b}$ has a solution or $\boldsymbol{yA} = \boldsymbol{0}$, $\boldsymbol{yb} \neq \boldsymbol{0}$ has a solution. They can be shown to be equivalent to the strong duality theorem of linear programming.

Theory of Constraints

Graham K. Rand
Lancaster University, Lancaster, UK

In the early 1980s, a novel was published which has subsequently been read all over the world by many executives, production planners and shop floor workers. *The Goal* sets out Eli Goldratt's ideas on how production should be planned (Goldratt and Cox 2004). The ideas were developed in the production planning system OPT (Optimized Production Technology) which was marketed by Creative Technology, Inc. (Rand 1990). These ideas were later broadened to encompass other areas such as marketing, distribution and project management in two further novels, *It's Not Luck* (Goldratt 1994) and *Critical Chain* (Goldratt 1997), and the theory widened to become the Theory of Constraints. In the novel, *Necessary but Not Sufficient* (Goldratt et al. 2000), set in the computer software industry, it is argued that although new technology may be necessary for major improvements, it is not sufficient. The theory has been applied to retailing through two further books, first by means of a conversation between Goldratt and his daughter, *The Choice* (Goldratt 2008), and in the novel, *Isn't it Obvious?* (Goldratt et al. 2009). Among the methods in his approach, Evaporating Clouds and Current Reality Tree have become widely used. Technical details are found in Goldratt (1990a, b).

Time Series Analysis

Christina M. Mastrangelo[1], James R. Simpson[2] and Douglas C. Montgomery[3]
[1]University of Virginia, Charlottesville, VA, USA
[2]Florida State University, Tallahassee, FL, USA
[3]Arizona State University, Tempe, AZ, USA

Introduction

A time series is an ordered sequence of observations. This ordering is usually through time, although other dimensions, such as spatial ordering, are sometimes encountered. A time series can be continuous, as when an electrical signal such as voltage is recorded. Typically, however, most industrial time series are observed and recorded at specific time intervals and are said to be discrete time series. If only one variable is observed, the time series is said to be univariate. However, some time series involve simultaneous observations on several variables. These are called multivariate time series.

There are three general objectives for studying time series: 1) understanding and modeling of the underlying mechanism that generates the time series, 2) prediction of future values, and 3) control of some system for which the time series is a performance measure. Examples of the third application occur frequently in industry. Almost all time series exhibit some structural dependency. That is, the successive observations are correlated over time, or autocorrelated. Special classes of statistical methods that take this autocorrelative structure into account are required.

Figure 1 shows examples of time series with distinctly different features. In Fig. 1a, the time series x_t appears to vary around a constant level. Such a time series is said to be stationary in the mean. In Fig. 1b, non-stationary behavior can be observed, i.e., the time series x_t drifts with no obvious fixed level. Some nonstationary time series may exhibit trends, or the variance of the series may increase as the level of the time series increases. Seasonal variation is illustrated in Fig. 1c.

The autocorrelation function is a very useful tool in characterizing time series behavior. The autocorrelation between x_t and x_{t+k} is defined as

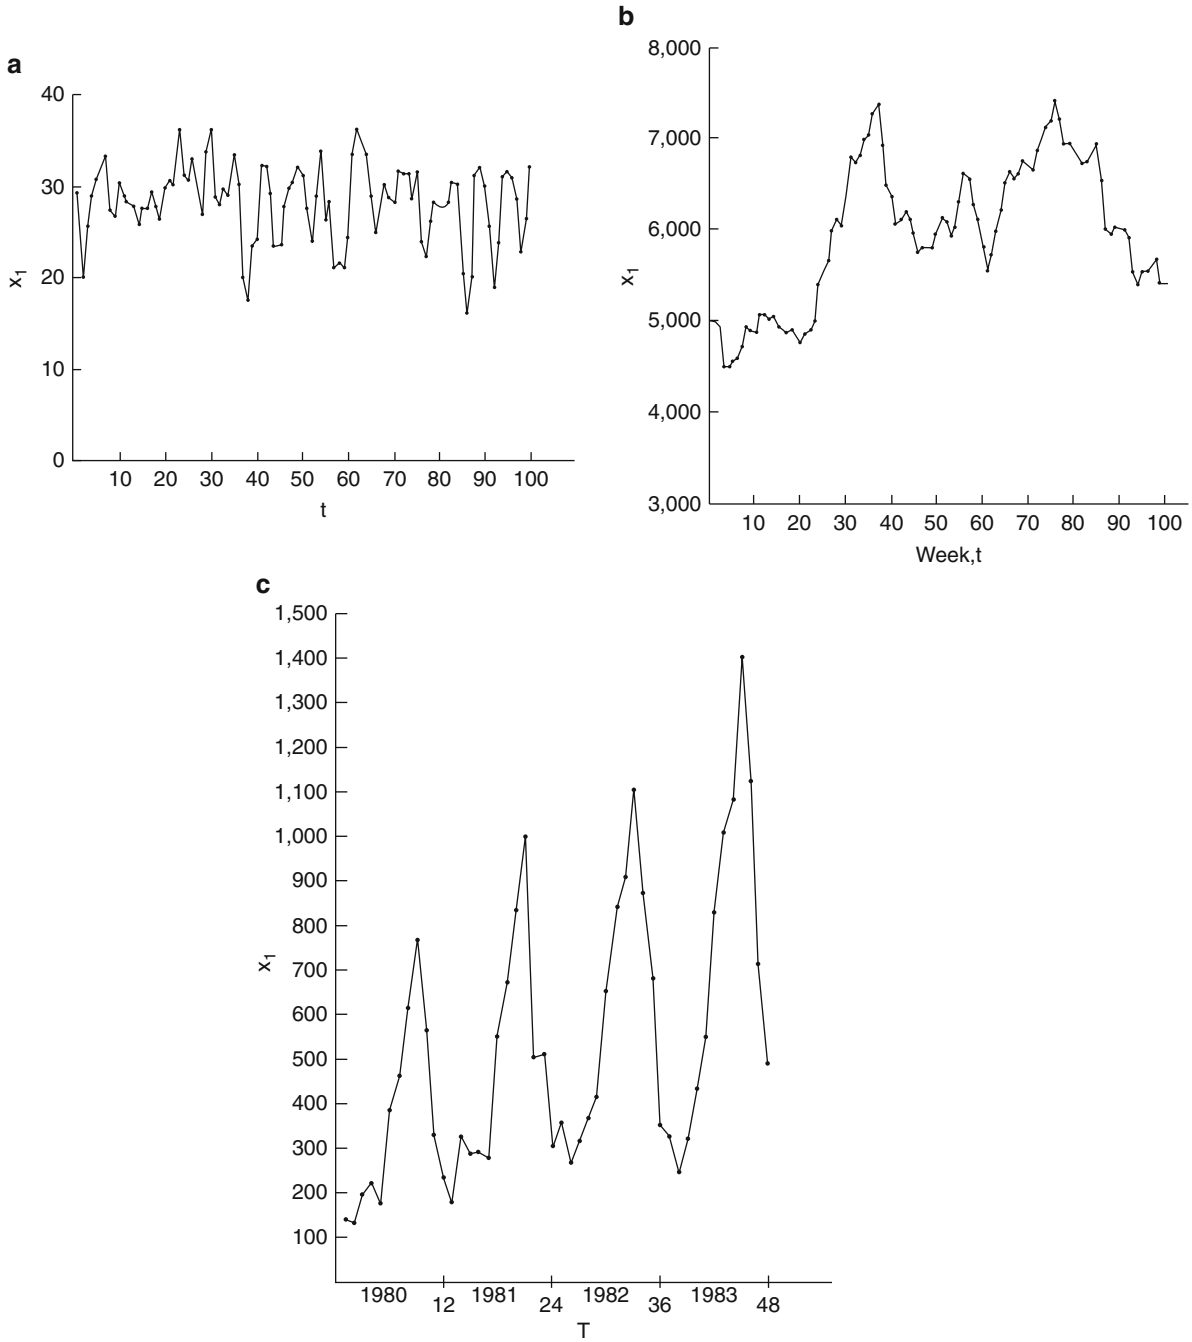
$$\rho_k = \frac{\mathrm{cov}(x_t, x_{t+k})}{\sqrt{V(x_t)V(x_{t+k})}} = \frac{\gamma_k}{\gamma_0}$$

where $\mathrm{cov}(x_t, x_{t+k}) = E[(x_t - m)(x_{t+k} - m)]$. This is called the autocorrelation at lag k. The usual estimate of ρ_k, $k = 1, 2, \ldots, K$, is the sample autocorrelation function

$$r_k = \frac{\hat{\gamma}_k}{\hat{\gamma}_0} = \frac{\sum_{t=1}^{n-k}(x_t - \bar{x})(x_{t+k} - \bar{x})}{\sum_{t=1}^{n}(x_t - \bar{x})^2}$$

Figure 2 shows the sample autocorrelation function for the time series in Fig. 1a. The dotted lines are two standard error limits. Notice that there is a large positive value or spike at lag 1 and the sample autocorrelation function decays as a damped sine wave from lag 1. The sample autocorrelation function is very useful in the identification of an appropriate time series model.

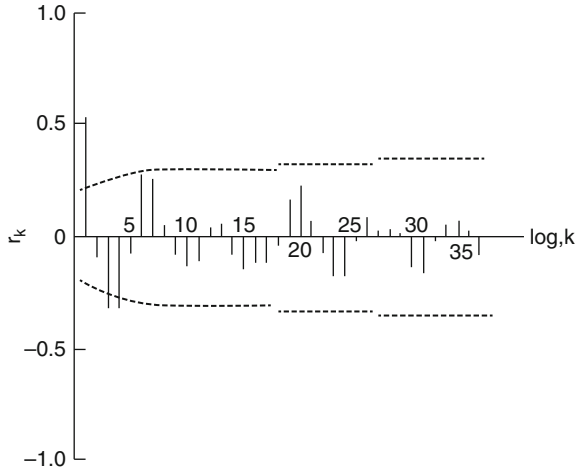
The partial autocorrelation function, denoted by ϕ_{kk}, is also useful in the identification process. It can be interpreted as the simple correlation between two random variables x_t and x_{t-k} after adjusting for the intermediate variables x_{t-1}, $x_{t-2}, \ldots, x_{t-k+1}$. Once the sample autocorrelation and partial autocorrelation functions are estimated, they may be plotted. A tentative model is then identified by comparing the observed patterns with the theoretical function patterns. For an autoregressive process of order p, ϕ is nonzero when k is less than or equal to p and greater than zero for k greater than p. In other words, while



Time Series Analysis, Fig. 1 (**a**) Viscosity of a chemical product. (**b**) Demand for a plastic container. (**c**) Monthly demand for a 48-oz soft drink in hundreds of cases

the autocorrelation function of an autoregressive process decays in an exponential fashion, the partial autocorrelation function cuts off after lag p.

In addition, the inverse autocorrelation function and the extended sample autocorrelation function are useful in time series model identification. See Fuller (1996), Montgomery, Johnson, and Gardiner (1990), Cleveland (1972), and Abraham and Ledolter (1983) for definitions of these functions and more details.



Time Series Analysis, Fig. 2 Sample autocorrelation function

Time Series Modeling Methods

There are several widely-used approaches for modeling and analysis of time series data. Regression methods play a fundamental role. If y_t represents the time series of interest and $x_{jt}, j = 1, 2, \ldots, k$ are a collection of other time series thought to be related to y_t, then it is possible to fit a regression model of the form

$$y_t = \beta_0 + \sum_{t=1}^{n} \beta_j x_{jt} + \varepsilon_t, \qquad t = 1, \ldots, n$$

using least squares or some suitable variation. Usually, however, the errors e_t are autocorrelated and more complex estimation schemes are needed. Several estimation methods are available which result in estimates similar to least squares estimates, but the standard errors may be very different. Yule-Walker estimation uses the Yule-Walker equations to estimate the autoregressive parameters of the errors and generalized least squares to estimate $\boldsymbol{\beta}$. Harvey (1990) gives a full description of this and other methods.

Smoothing methods are frequently used in time series analysis. In particular, exponential smoothing is widely used for producing short-term forecasts of many types of industrial time series. Much of the original work in this area is by Brown (1962), Holt (1957), and Winters (1960). Exponential smoothing is often developed heuristically starting with a simple model such as $x_t = b + e_t$, where e_t are independent random variables and b is an unknown constant. Simple or first-order exponential smoothing is defined as

$$S_t = \alpha x_t + (1 - \alpha) S_{t-1}$$

where $0 \leq \alpha \leq 1$. The smoothed statistic S_t estimates the constant b, so the forecast for any future observation $X_{t+\tau}$ made at the end of period t is

$$\hat{x}_{t+\tau}(t) = S_t$$

Extensions of this methodology to forecasting linear and quadratic trend and incorporating seasonal behavior are described in Montgomery, Johnson and Gardiner (1990). Goodman (1974) and Cogger (1974) showed that exponential smoothing for a kth order polynomial results in forecasts that are optimal in a mean square error sense for certain classes of non-stationary time series. McKenzie (1978) extended these results to models that may include transcendental terms.

The class of autoregressive integrated moving averages (ARIMA) models proposed by Box, Jenkins and Reinsel (2008) and Jenkins (1979) have been very successful for time series modeling and forecasting. The general form for this family of models is

$$(1 - \phi_1 \beta - \phi_2 B^2 - \cdots - \phi_p B^p)(1 - B)^d x_t = \theta_0 + (1 - \theta_1 B - \theta_2 B^2 - \cdots - \theta_q B^q)\varepsilon_t$$

where ϕ_i are the autoregressive parameters, θ_j are the moving average parameters, B is a backshift operator defined such that $B^r x_t = x_{t-r}$,$(1 - B)^d = \Delta^d$ is the backward difference operator, and $\in_t$ is an uncorrelated sequence of random disturbances with mean zero and variance σ^2. This model can also be extended to incorporate seasonal behavior (see Box et al. 2008; Montgomery et al. 1990). One chooses a model by specifying the integers p, d, and q, resulting in an ARIMA(p, d, q) model. This is usually done by examining the sample autocorrelation and partial autocorrelation function. For example, if the sample autocorrelation function decays as a damped sine wave and the partial autocorrelation function has large spikes only at lags 1 and 2, a tentative ARIMA model estimation with $p = 2$ and $q = 0$ might be considered.

Nonlinear regression methods are used to estimate the parameters ϕ_i and θ_j. The approach requires initial point estimates of the parameters and then uses an iterative search technique to minimize the residual sums of squares. Most computer packages implement a modification of the Gauss-Newton method suggested by Marquardt (1963). The Gauss-Newton method first linearizes the nonlinear function with a Taylor series expansion and then iterates to find improved parameter estimates. Unfortunately, the original Gauss-Newton approach will not always converge. So Marquardt proposed a modified search procedure that adds a small bias to the parameter estimates to ensure convergence to the minimum residual sums of squares. Computer packages provide reasonable initial point estimates making the estimation routine transparent to the user.

Finally, the residuals from the fitted model are studied to test model adequacy. Generally, one should examine the autocorrelation function of the residuals, for if the model is adequate, the residuals should be approximately uncorrelated. The tests on residual autocorrelations suggested by Box and Pierce (1970) and Ljung and Box (1978) are useful in this regard. Residual plots, such as a plot of residuals verses the fitted x_t, and a normal probability plot of the residuals, are useful in detecting model inadequacy. Thus model estimation is typically iterative involving cycles of tentative model identification, estimation, and residual analysis.

To illustrate, consider the container demand data from Fig. 1b. It can be shown that an appropriate choice of p, d, and q is $p = 0$, $d = 1$, and $q = 1$, resulting in the ARIMA(0,1,1) = IMA(1,1) model

$$(1 - B)x_t = (1 - \theta B)\varepsilon_t.$$

The least squares estimate of the parameter θ in this model is $\bar{\theta} = -0.70$. Therefore, the final model is

$$x_t = x_{t-1} + \varepsilon_t + 0.7\varepsilon_{t-1}.$$

This model is satisfactory with respect to the adequacy criteria cited above.

Forecasting

An important objective of any time series model is forecasting future values. The term forecasting is used in the time series analysis literature although most results are based on the general theory of linear prediction developed by Kalman (1960), Whittle (1963), Box, Jenkins and Reinsel (2008), and many others. The objective is to produce minimum mean square error forecasts.

Minimum mean square error forecasts for ARIMA models are obtained by taking the conditional expectation $E(X_{t+\tau}|X_t, X_{t-1}, \ldots)$. For example, the minimum mean square error forecast for the ARIMA (0,1,1) = IMA(1,1) model shown earlier for the container data is

$$E(x_{t+\tau}|x_t, x_{t-1}, \ldots) \equiv \hat{x}_{t+\tau}(t) = x_t + 0.7\varepsilon_t \quad (1)$$

where $e_t(1) = x_t - \hat{x}_t(t-1)$ is the one-step ahead forecast error. Figure 3 shows the forecasts obtained from this model. It is usually necessary to provide prediction intervals for forecasts as well as point estimates. Figure 3 shows the 50% and 95% prediction limits for the forecast of future container demand. For details of the construction of these limits, see Box, Jenkins and Reinsel (2008) and Montgomery, Johnson and Gardiner (1990).

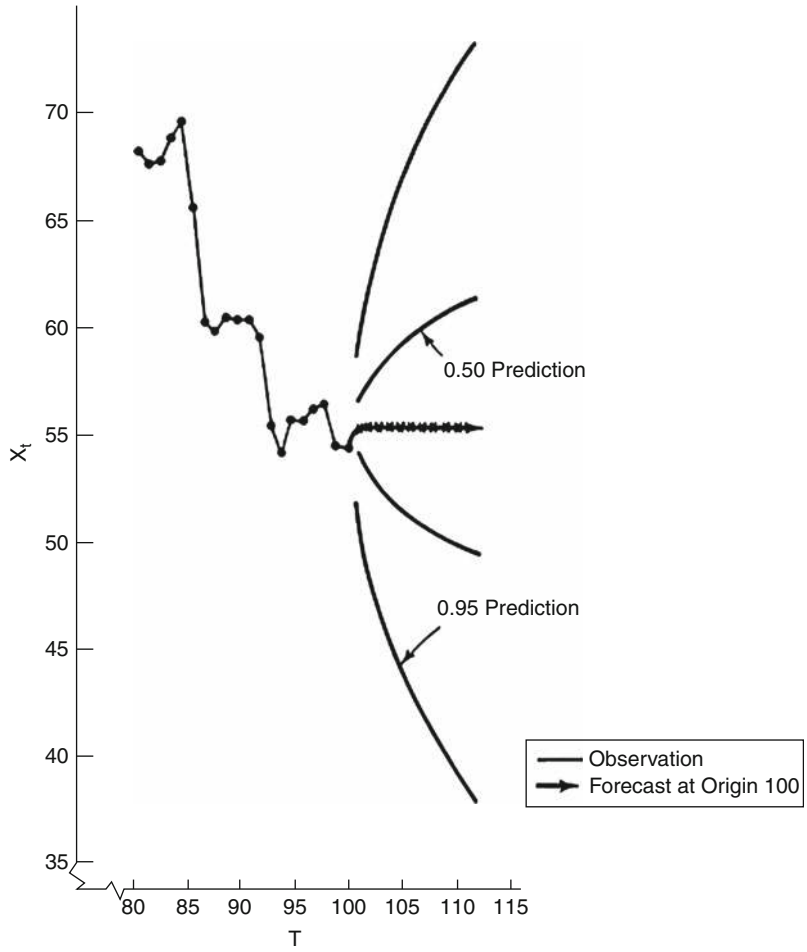
Forecasts from ARIMA models are equivalent to forecasts produced by other methods in certain cases. For example, the forecasts from an IMA(1,1) model, such as that given above for the container demand data, are identical to those produced by simple first-order exponential smoothing. Other relationships between exponential smoothing and ARIMA models are given by Box, Jenkins and Reinsel (2008) and Pandit and Wu (1974).

The form of the eventual forecast function for ARIMA models is also of interest, because it leads in some cases to efficient methods for forecast generation and updating. The form of the forecast function or several common ARIMA models is given in Box, Jenkins and Reinsel (2008).

Transfer Functions and Related Topics

If y_t and x_t are two stationary time series related through the mean filter

$$y_t = V(B)x_t + \varepsilon_t$$



Time Series Analysis, Fig. 3 Forecast of plastic container demand at origin 100, with 0.50 and 0.95 percent prediction limits

then $V(B) = \sum_{j=-\infty}^{\infty} v_j B^j$ is called the transfer function of the filter and e_t is called the noise series of the system. Typically, x_t and e_t are assumed to follow ARMA = ARIMA(p,0,q) models. It is customary to write

$$V(B) = \frac{\omega_S(B)B^b}{\delta_r(B)}$$

where $\omega_S(B) - \omega_0 - \omega_1 B - \omega_2 B^2 - \ldots - \omega_S B^S$, $\delta_r(B) - \delta_0 - \delta_1 B - \delta_2 B^2 - \ldots - \delta_r B^r$ and b is a delay representing the time before the input at time t produced an effect on the output. A transfer function model is identified by choosing appropriate values of s, r, b, and a model for the noise e_t. Usually s, r, and b will be no larger than 2. The cross-correlation function is useful in model identification.

Once a suitable transfer function model is identified, the parameters are estimated by nonlinear regression methods, and diagnostics checks are applied, much like in classical univariate ARIMA modeling. Minimum mean square error forecasts are generated using a similar approach, based on conditional expectation at time t of $y_{t\tau}$. For detailed examples of identification, estimation, diagnostic checking, and forecasting with transfer functions, see Box, Jenkins and Reinsel (2008) and Montgomery, Johnson and Gardiner (1990). The latter authors presented an example showing that for relatively short forecast lead times, the forecasts from a transfer function model will usually be superior to those produced by a univariate ARIMA model.

An important special case of the transfer function occurs when the input series x_t is a sequence of indicator variables that represent the occurrence

of identifiable, unique events that are thought to influence the output y_t. These events are called interventions and the resulting models are called intervention models. An intervention model is often used to provide a statistical basis for concluding that the identifiable event has resulted in a change in the time series.

Box and Tiao (1975) developed the basic intervention analysis methodology and applied it to photo chemical pollution data from the Los Angeles basin. They showed that the opening of the Golden State Freeway and the adoption of a new law, that reduced the proportion of reactive hydrocarbons in local gasoline, reduced ozone levels, and that required changes in automobile engines reduced ozone levels only in warm weather months. Other intervention studies were reported by Montgomery and Weatherby (1980) and Wichern and Jones (1977).

Intervention models are also useful in the study of time series outliers. Fox (1972) proposed two types of outliers, additive and innovational. Other useful references on this topic are Tsay (1986) and Chang, Tiao and Chen (1988).

In some time series problems, one observes m different variables x_{1t}, x_{2t},..., x_{mt} in a multivariate framework. One way to model this structure is with a multivariate ARIMA model of the form

$$\Phi_p(B)X_t = \Theta_q(B)\varepsilon_t$$

where $x_r' = [x_{1t}, x_{2t}, \ldots, x_{mt}]$, Φ_p (B) and Θ_q (B) are matrix polynomials of autoregressive and moving average parameters, respectively, and ε_t is a sequence of independent multivariate random vectors each with mean zero and covariance matrix $\sum$. These are sometimes called vector time series models. Basic references for these models include Jenkins (1979), Granger and Newbold (1977), and Hannan (1970). The state space modeling approach is also useful for representing multiple series. See Hannan (1970) and Akaike (1976) for a complete description of state space modeling.

Computing

A number of software packages perform the time series modeling and forecasting functions previously described, including some spreadsheet statistical analysis add-ins. The two high-end software support tools commonly used by researchers and practitioners are SAS and S-Plus. Both programs provide a wide range of modeling options including various smoothing alternatives and extensive ARIMA modeling features. SAS is also capable of developing transfer function and intervention models. S-Plus provides the capability to model time series in the presence of outliers. More advanced procedures are also available from SAS and S-Plus. Several other PC-based software programs, including MINITAB, STATGRAPHICS, R, JMP, Autobox, and EViews, provide high-quality time series modeling and forecasting support. For ARIMA modeling, the software programs provide the plots, nonlinear estimation, and forecasting tools necessary to develop successful models.

Time-stepped Simulation

A computer model in which time is incremented by a simulated clock. Each appropriate function is recomputed after the clock is incremented in a cyclic manner. A model may be linearly coded and entirely time-stepped or an event-driven simulation may use time-stepping for some critical function with a cycle of sub-functions.

Timetabling

Michael W. Carter
University of Toronto, Toronto, Ontario, Canada

Introduction

Most dictionaries do not include the word timetabling as a single word. It is often listed as either two words (time table) or hyphenated (as time-table). The Oxford English Dictionary defines a timetable as:

> A tabular list or schedule of times at which successive things are to be done or happen, or of the times occupied in the parts of some process. spec. **a.** A printed table or book of tables showing the times of arrival and departure of railway trains at and from the stations; also a similar table of times of arrival and departure of passenger boats or other public conveyances. **b.** A chart used in railway traffic offices, showing by means of cross lines, in one direction representing hours and minutes and in the other miles, the position of the various trains at any given moment. **c.** A time-sheet on which a record is kept of the time worked by each employee. **d.** A table showing how the schedule of a school or other educational institution, for any day, or for a week, is allotted to the various classes and subjects. **e.** Mus. A table of notes showing their relative time value.

The Oxford dictionary also defines the verb time-table as "To schedule, to plan or arrange according to a timetable, to include in a timetable. Hence time-tabled and timetabling."

Professor Anthony Wren, at the first Practice and Theory of Automated Timetabling (PATAT) conference in Edinburgh, 1995, defined timetabling as "the allocation, subject to constraints, of resources to objects being placed in space-time, in such a way as to satisfy as nearly as possible a set of desirable objectives. Examples are class and examination time-tabling and some forms of personnel allocation, for example manning of toll booths subject to a given number of personnel." In the latter case, the process is defined in terms of developing timetables for each individual employee.

In other words: timetabling involves deciding when events/activities will take place in time; but it does not involve assigning resources to those activities. For example, a bus timetable for a particular metropolitan bus route may require "one bus to leave the main terminal every 30 minutes between 6:00 am and 11:00 p.m.; and every 10 minutes during rush hours 7:00 am to 9:00 am and 4:00 p.m. to 6:00 p.m.". The time table does not specify which buses or drivers should be allocated to each trip. In course timetabling, the objective is to decide what day and time each section of each course should be held. It does not specify which students will be assigned to each section.

Normally, when one sees the word timetabling in an operations research context, people are referring to problems relating to timetabling of courses or examinations in a school. Furthermore, it refers to the concept of developing algorithms, usually computer programs, for the automatic construction of time-tables. There are a number of other related problems in timetabling which will be described; but they are often referred to under different titles. As described by McCollum and Burke (2010) in the Preface to the Proceedings for PATAT 2010, "computer-aided timetable generation ... includes personnel rostering, school timetabling, sports scheduling, transportation timetabling and university timetabling."

Timetabling can also be described as a subset of the larger discipline called scheduling. One can define scheduling as the more general problem of determining the times for activities and assigning the necessary resources. In some cases, for example in Sports Time tabling, once it is decided when a match will occur between a pair of teams, (and who the home team is), all major resources have already implicitly been assigned (the two teams and the stadium). Hence Sports Time tabling is commonly referred to as Sports Scheduling. In this case, the terms are justifiably interchangeable.

It will be frequently distinguished between feasibility and optimality. A feasible solution is any solution that satisfies all of the constraints. An optimal solution is the (possibly unique) solution among all feasible answers which maximizes (minimizes) some objective function. In some timetabling problems, it is sufficient to find a feasible solution.

Examination Timetabling

Examination Timetabling is the simplest timetabling problem to describe, although it is not always easy to solve. The basic problem is to assign examinations to a limited number of available periods in such a way that there are no conflicts or clashes. That is, no student is required to write two examinations at the same time. The problem is closely related to the graph coloring problem. Each examination is represented by a node. Two nodes are connected by an edge if there is at least one student who is required to write the two corresponding exams. The graph coloring problem asks the question: Can the nodes of this graph be colored using p colors such that no two nodes with the same color are connected by an edge? If each color represents an examination period, and if p is the number of periods available, then coloring the graph is equivalent to finding a conflict free assignment of exams to the available periods.

In practice, the basic feasibility issue may be the critical problem. In particular, for any given problem instance, there is a minimum number of periods required to allow a feasible solution. In graph theory terminology, this is called the chromatic number of a graph. If the number of periods provided is close to the theoretical minimum, then you need an algorithm that concentrates on finding a feasible solution. There has been considerable research on good coloring algorithms. Given plenty of periods, it is easy to find a conflict free timetable. The coloring problem is trivial, and efforts can be focused on searching for a good answer using some secondary objectives. Without enough periods, it is not possible to find a feasible solution, and the objective must be changed to something like minimize the number of student conflicts.

The most common secondary objective is to try to spread each student's exams as evenly as possible. Each institution will impose a variety of additional constraints on the basic model such as:

- Some exams may have precedence constraints (e.g., "exam A must precede exam B");
- Some exams must be consecutive (e.g., "exam C must immediately precede exam D");
- Some exams are excluded from certain periods;
- Limited available rooms and/or seats; and
- There may be special resource requirements.

For a more comprehensive description of the exam timetabling problem and a survey of practical approaches, refer to Carter (1986), and Qu et al. (2009).

School Timetabling

Class-Teacher timetabling is normally associated with high schools or elementary level schools where the students are grouped into a set of classes and each class has a set of courses that it must take. Professor Dominique de Werra (1985) defines the basic class-teacher model in the following terms. Let $C = \{c_1, c_2, \ldots, c_m\}$ be a set of classes and $T = \{t_1, t_2, \ldots, t_n\}$ be a set of teachers. An $n \times m$ requirements matrix, $R = \{r_{ij}\}$ is given where r_{ij} is the required number of times class c_i must meet with teacher t_j. In the basic model, it is assumed that all lectures are the same length (say one period). Given a set of p periods, the problem is to assign each meeting to some period such that no teacher (and no class) is involved in more than one meeting at a time. The basic problem has no objective function, so the issue is simply to find a feasible solution.

It can be shown that this problem is easy to solve (in the computational complexity sense) in that there exists a polynomial algorithm to find a solution (using a matching algorithm) under the simple and obvious conditions that no teacher (or class) is required to attend more than p periods. The problem remains easy if the basic model is extended to include assigning meetings over a week, where limits are imposed on the number of times each class-teacher pair can meet on any one day.

Unfortunately, most practical problems will have a few extra conditions, and the problem quickly becomes computationally intractable (NP-Complete). For example, if it is assumed that some of the teachers (and/or classes) are not available in every period, then the problem is no longer easy. This is also true if the teachers and classes are available every period, but some of the meetings have been preassigned to specific periods. Another common complication is that some meetings are for more than one period. For example, some meetings may require two or three consecutive periods.

The problem is also often complicated by adding room availability constraints. For example, there may be certain meetings (science, physical education, music, etc.) which require specific rooms. This problem can be expressed using a three dimensional requirements matrix that specifies the number of meetings between class i and teacher j in a room of type k, where there are a limited number of each type of room. This problem is also NP-Complete. Refer to Kingston (2008) for more details.

Course Timetabling

Course timetabling is normally associated with universities, and involves the assignment of sections of courses (lectures, laboratories, tutorials, seminars, etc.) to specific days of the week and times of day. In the course-timetabling problem, unlike the class concept, each student selects a set of courses personally tailored to their own needs. (In practice, many students will have very similar selection patterns.) The primary objective is often to find a timetable that minimizes the expected number of student conflicts.

Strictly speaking, based on the definition given here, course timetabling does not include the assignment of resources (teachers, rooms, special equipment, or even students). In many practical instances, most teachers will be assigned to teach specific course sections before timetabling, while rooms, special equipment and students are assigned after time-tabling. In large schools, many of the courses will be offered in more than one section. Students must be divided up into (roughly equal) groups and assigned to separate sections. This problem is referred to as sectioning or student scheduling. Some packages have been designed to attack all of these problems simultaneously. However, due to the large number of variables involved, most practical methods approach the

problems sequentially. The basic course-timetabling problem will be described here. The interested reader can refer to Lewis (2008) for a more detailed discussion of each of the subproblems, and references to practical applications.

The basic course-timetabling problem usually includes a number of side constraints. Courses and course sections should be spread in a particular way throughout the week. For example, an institution may require that all sections of the same course be timetabled at the same times. A course may be divided into multiple meetings (two or three times per week), and there may be restrictions on the meeting patterns that can be used (e.g., Mon., Wed., Fri. at 9:00 a.m.). Some schedules include an allowance for lunch periods, travel time between classes, and the number of hours per day for students and teachers.

In practice, there are two main variations of the course-timetabling problem: the master timetable approach, and the demand driven system. Practitioners typically feel very strongly about their preference for one or the other. Under a master-time-tabling system, the institution will first create a course timetable, and then students register for courses (after consulting a list that describes when each class is offered). The term master timetable refers to the common practice of starting this year's timetable based on the previous year, and making any required changes based on revisions to course offerings. With a demand driven timetable, the institution posts a list of (proposed) course offerings without any times, and students pre-register for courses before timetabling is performed.

The main advantage of a demand driven system is that the timetable can be constructed using actual student course requests. With a master-timetable system, the timetable must be developed without knowing what the students really want or need. Individual department timetable representatives try to build a timetable that will work for students in their own program in each year. This is very difficult unless the programs are highly structured. In more flexible environments, students often have difficulty selecting the credits that they need without conflicts. A major problem in the U.S. today is that students in many institutions find it impossible to complete their program in the nominal program length due to timetable issues.

There are several disadvantages of a demand-driven system. It requires additional data collection effort, since students must pre-register for courses (typically 4–5 months before term starts) and then, when they get the results of their requests, they start making changes in a second round. In a master-timetabling system, students should be able to construct a conflict free timetable on the first attempt. A demand-driven system also puts fairly tight time constraints on the timetabling process. In a master timetable system, the institution can construct the timetable a year in advance, and some schools publish the times in the course calendar. In a demand-driven system, the students submit course requests a few months before the term starts, and all of the timetabling activity is compressed.

One of the curious issues in the timetabling problem creates a bit of a paradox in the demand-driven system when courses are taught in multiple sections. You cannot assign students to sections (conflict-free) until you have timetabled the sections; but, you cannot timetable the sections until you know which students are in each section. One solution is to assign students to a specific section in advance of timetabling, for the purpose of finding good times. These assignments can be re-evaluated in the student scheduling phase at the end.

Anyone interested in timetabling should refer to the Web site maintained by the University of Nottingham, on automated scheduling, optimisation and planning.

There are a number of other (less common) problems that share the basic timetabling structure. Sports timetabling is the problem of trying to find a rotation for a set of teams such that each team can play every other team twice (once at home and once away). If there are no side constraints, there are some elegant solutions related to tournaments, including a mathematical construction based on permutations (see survey by Kendall et al. 2010). There has also been some research on Employee Timetabling/Rostering, where you want to determine shift work patterns for employees in order to meet a given demand pattern. A particular well-studied variation on this problem is the nurse-rostering problem (see review by Burke et al. 2004).

Tolerance Analysis

A sensitivity analysis procedure applied to a linear-programming problem that allows for simultaneous changes of the objective function cost coefficients and/or right-hand-sides of the constraints.

See

- ▶ Hundred Percent Rule
- ▶ Sensitivity Analysis

Total Float

The amount of time a project work time can be delayed without affecting the duration of the project. Total float can be used in only one activity in a path. If no schedule times are specified for starting and finishing the various activities, then the float is calculated as the difference between the latest start time and the earliest start time, or the difference between the latest finish time and the earliest finish time. Float can be positive, negative or zero.

Total Quality Management

John S. Ramberg
Pagosa Springs, CO, USA

Introduction

During the decade of the 1980s, U.S. corporations recognized the quality achievements of their Japanese counterparts and began to understand the messages being delivered by Deming, Juran and others on the importance of quality (Deming 2000; Defeo and Juran 2010). They devised methods for obtaining, understanding and communicating customer needs and requirements within their organizations, developed strategies for improving their engineering design, development, manufacturing and delivery processes, and created new corporate cultures that included the formation of self-directed working groups and encouragement of employee participation. Through this focus on quality and the development and adaptation of techniques for achieving customer

satisfaction, some of these corporations have demonstrated improvement in achieving high quality, timely deliveries at low costs and ultimately improved their business performance. Many of these firms called this new management and operations philosophy Total Quality Management or TQM.

At the outset, many TQM programs were simply copies of Japanese efforts. As cultural differences between the Japanese and western world were better understood, and as other quality contributions were recognized, many U.S. firms developed their own unique quality programs. See Prybutok and Zhang (2010) and Vol. 4 of *Quality Management Journal* for health care agency examples.

Other firms, frustrated by false starts and questionable implementations, began to question the value of total quality management, and some have given up, regarding it as just another fad (Senge 1993). In many of these latter situations, quality efforts have been misdirected or unfocused. In some cases, quality improvement activities were simply knee-jerk reactions to the customers who complained most vehemently to the highest level of the organization. Ramberg (1994) described some of the scurrilous characters who proclaim TQM, while delivering just another program; he raised the question, "TQM: Thought Revolution or Trojan Horse." Three decades later, many organizations, especially nonprofits and governmental, are still not aware of total quality management.

While TQM connotes much more than simply the three words total, quality and management, nevertheless, definitions of each of the three words seem an appropriate place to begin. A typical dictionary definition of total is: all or whole, that is constituting the whole; complete. The definition of quality is a bit more difficult to comprehend as U.S. firms have come to understand. A formal definition, as given by the American Society for Quality (ASQ). "The totality of features and characteristics of a product or service that bear on its ability to satisfy stated or implied needs." Finally, management is the act, be it a science, an art or manner, of planning, directing, organizing and controlling a firm's decisions and actions. As an aside, it is interesting to note that the phrase "to manage" originated as "to train (a horse) in his paces, or to cause to do the exercises of the manage (Merriam-Webster, 2004)!"

A Profound Understanding of Quality

Quality is the pivotal word in TQM. A fundamental reason for the U.S. losing world leadership in manufacturing during the 1960s and 1970s was its lack of a profound understanding of the Q word. The gurus of quality, in the interest of developing a better understanding of the importance of quality, created shorter, more explicit, operationally oriented definitions such as "fitness for use" (Juran, 1988), "conformance to specifications" (Crosby 1989), "long term loss to society" (Taguchi 1986), and "a predictable degree of uniformity and dependability, at a low cost and suited to the market" (Deming, as paraphrased by Gitlow, Oppenheim, and Oppenheim, 1995).

Some have made light of the differences in these operational definitions of quality. A few have concluded that even the quality gurus cannot agree on the definition of quality. They should be viewed as being complementary, each definition emphasizing its definer's experience base in relation to the customer in question. "Fitness for use" is an appropriate operational definition of quality in the creation and marketing of a product or service on the production floor, where an employee may be far removed from the customer, the translation of quality performance measures into specific dimensions having specified targets and specification limits seems a necessity. Finally, if "loss to society" is thought of as "long-term business loss," then its relation to the other two operational definitions becomes clearer. Deming's definition exhibits his emphasis on variability and its reduction as a fundamental step in improving quality.

A first step in attaining a profound understanding of quality is the realization that it is customer-driven. It not only begins with the customer, in the end, it is judged by the customer. While the "voice of the customer" is imperative, a customer may not be able to fully articulate his needs and desires. Even the most sophisticated customers are not likely to be able to envision all of the characteristics of a product that will satisfy and "delight" them. Expert panels can serve an important role, but they too have their limitations. Obtaining this information is a complex task. Based on this input, product creators, developers and deliverers must envision these dimensions of quality that will satisfy and delight their customer.

Furthermore, they must maintain a dialog with the customer so that they will continue to understand and respond to this dynamic "voice of the customer."

Traditionally managers have viewed quality and cost as a zero-sum game. That is, any improvement in quality will occur only at a substantial additional cost. The following quote from Vaughn (1967) illustrates this "conventional wisdom:" "The trade off is between the effects of less emphasis on quality and the cost of more of it–." The following is a counter example. A citizens' group discovered that their water company was losing 40% of its treated water, prior to delivery. This meant that they were treating 167% more water than demanded, and hence 167% additional treatment facilities were required. Rather than making any attempt to reduce losses, the leadership had committed its users to millions of dollars of debt for a land purchase to build an un-needed reservoir.

Juran (1988) categorized quality associated costs (and estimates of the associated percentage for one industry) into four broad groups, those due to Internal Failures (30%), External Failures (40%), Appraisal (25%), and Detection and Prevention (5%). He also discussed how these percentages are dependent upon the maturity of the product line and effort expended on quality improvement. Juran's classic model for optimum quality levels also emphasized that there is a tradeoff between quality and cost. He stated that "failure costs decline until they are over-taken by the increasing costs associated with appraisal and prevention. At this point total costs increase." Juran also made clear the cost of quality through the phrase, hidden factory, where he exhibited the additional resources necessary to deliver products and services.

Cole (1992) made an excellent case for a fundamental paradigm shift regarding quality and costs and timeliness, based on the achievements of the Japanese. His conclusions are given in Table 1. Compare Cole's views with the old quality paradigm, "you get what you pay for." The truth is that high cost, alone, is not a guarantee that a product will be of high quality. Indeed, some times the contrary is true, resulting in what *Consumer Reports* refers to as "best buys." The six achievements of the Japanese, cited by Cole, have an important impact on conclusions drawn from quality cost models. Specifically, they indicate that the point at which it is no longer cost effective to improve quality is at a much lower defective rate than previously thought.

Total Quality Management, Table 1 Cole's underlying reasons for Japanese achievements in quality

"-realized that the costs of poor quality were far larger than had been recognized."
"-recognized that focusing on quality improvement as a firm-wide effort improved a wide range of performance measures."
"-established a system that moved toward quality improvement and toward low-cost solutions simultaneously."
"-focused on preventing error at the source, thereby dramatically reducing appraisal costs."
"-shifted the focus of quality improvement from product attributes to operational procedures."
"-evolved a dynamic model in which customer demands for quality rise (along with their willingness to pay for these improvements)."

Juran (1988) noted that many disagreements about achieving quality result from the fact that there are two fundamentally different quality issues, one income oriented and the other cost oriented. Features that produce customer satisfaction are income oriented. They are the key to attracting new customers and through satisfaction of retaining them. Cost oriented quality issues are the defects and failures that incur. They cause dissatisfaction and the loss of customers. As customers become aware of a product and indeed a producers track record through publications such as *Consumer Reports*, they also impact the ability of attracting and retaining customers. Furthermore, they impact the profitability of the firm through the dollars lost internally in defectives and rework and externally through warranty costs and other required services.

Establishing, appraising or judging the quality of a product are far more difficult than simply defining it. In his highly acclaimed book *Management of Quality*, Garvin (1988) elaborated eight dimensions of quality, including performance, features, reliability, conformance, durability, serviceability, aesthetics, and perceived quality. Through his study on air conditioners, he illustrated the differences in the perception of quality of various constituencies, noting that customers, companies (as represented by first line supervisors), service personnel and *Consumer Reports* view quality quite differently and elaborated on the reasons for these different perceptions.

While top-level management communicates in dollars, operations level personnel must be bilingual,

communicating in both dollars and things, that is, in product units and performance measures. Taguchi popularized the use of loss functions to provide a link between these two languages. They provide a means for expressing the deviation of product characteristics from their targeted values in dollars. These loss functions can be determined through internal costs of a product at each stage of design, development, manufacture and delivery.

Quality is achieved by elaborating the important product characteristics, their targets and specifications. The ability of a product to meet these specifications depends upon its design, development and the processes employed in its manufacture. Product and process information is often gathered through capability studies, where measurements are obtained on important product characteristics, and control charts are employed to address the stability of the processes and the predictability of future performance. These product characteristics are frequently summarized by a statistical distribution, or even more succinctly, by the process capability, six sigma.

Process capability indices are typically employed to combine this voice of the customer with the voice of the product/process into a dimensionless measure. Pignatiello and Ramberg (1996) reviewed this approach, stressing the importance of an appropriate data collection scheme and the statistical analysis and summarization of results. These indices, which are dimensionless quantities, are then employed in quality improvement project selection.

Total Quality

The term quality has traditionally been associated with manufacturing, and more explicitly, with the products, processes, functions, and facilities associated with manufacturing. The modern total quality viewpoint extends this factory oriented view of quality to encompass all products, goods and services whether they are for sale or not.

Total quality proponents embrace training and education as universal, in direct contrast to the Taylor system, a system to which U.S. leadership in productivity has been attributed. Taylor made a strategic decision to separate planning and execution. This decision was based on his assessment that the then immigrant work force was uneducated and that it was not economically feasible to educate them in a timely manner. A more highly educated work force represents an untapped resource for improving quality and productivity. Total quality proponents recognized this improvement in the educational level, and the responsibility for not only utilizing this resource, but improving it through the continuing education of the work force. Furthermore, they recognized these workers as stakeholders, and that by empowering these stakeholders, productivity and quality can be further enhanced.

Total Quality Management

While neither embraced the term Total Quality Management, its origins can be traced to the work of W. Edwards Deming and Joseph J. Juran, and through the implementation of their quality philosophy, concepts and methods in Japanese industry. Kolesar (1994, 2008) discusses the contributions of Deming and Juran to the Japanese quality revolution following WWII. The importance of TQM became fully recognized in the U.S. only after its successful Japanese implementation. The domination of their products, as a direct result of their outstanding quality, especially in the auto industry, could not go unrecognized. With this recognition, Deming and Juran gained the attention of enlightened U.S. corporate and government leaders.

Deming is perhaps best known for the Shewhart/Deming PDCA cycle, and his 14 point manifesto, which is fundamental to TQM philosophy. The PDCA cycle, now called the PDSA cycle, meaning Plan, Do, Study, and Act, provides a fundamental structure for achieving quality. Gitlow et al. (1995) give an excellent discussion of Deming's 14 points and employed the PDSA approach for achieving quality improvement. Scherkenbach (1986, 1991) provides a balanced view of the key characteristics of the philosophy of Deming given in Table 2. For example, one of Deming 14 points is "reduce waste," which Scherkenbach has balanced with "add value."

Kolesar (2008) states, "Juran's 1954 lectures have been credited with being seminal contributions to the Japanese quality control movement." Juran (1988) recognized the importance of including quality in the management game plan, as well as the

Total Quality Management, Table 2 Key characteristics of the Deming philosophy, from W.W. Scherkenbach (1991)

Reduce waste	Add value
Constancy of purpose	Continual improvement
Improvement	Innovation
Team	Individual
Long-term	Short-term
Inputs	Outputs
Synthesis	Analysis
Knowledge	Action

need for developing managerial processes in managing quality. He noted financial management included three processes: financial planning (producing the budget), financial control (assuring that the budget will be met), and financial improvement (ways of increasing income and decreasing costs). Translated to quality, these are known as the Juran Trilogy: Quality Planning, Quality Control and Quality Improvement. A major advantage facilitating the implementation of these ideas is that senior management already understands them in the financial arena. Juran also stated "universal sequences for accomplishing these processes, the quality planning road map, quality control and the quality improvement processes." Fundamental to his methodology is the recognition of the presence of chronic quality wastes resulting from disconnected alarm systems.

Senge (1993) presents a TQM paradigm that is based on the three cornerstones: Guiding Ideas, Infrastructure, and Theory, Tools and Methods. He noted that guiding ideas are based on a vision. Without this vision, everything is mechanical and pedestrian. Leaders expressing this vision and these guiding ideas must practice them. When they make a decision differently, their colleagues and subordinates will know! However, these ideas and the behavior and actions of the leaders is not enough. An infrastructure is necessary for diffusing these ideas. Conflicts in goals must be resolved and this implies the importance of accountability and an appropriate reward structure. Finally, there is the theory, tools and methods cornerstone. Again, a necessary and important part of the structure, but certainly not sufficient on its own. OR/MS tends to be tool oriented.

Tables 3 and 4 list these essential tools, which seem so simple that they are frequently neglected in college courses. These tools of TQM are communications enhancers that assist one in listening and talking to processes, products, systems and people. Smith (1998) described these tools and more advanced problem solving methods within the context of diagnostic disciplines.

Transformation to Quality Organizations

Implementation of total quality management in a firm requires a transformation of the organization, and any transformation of an organization is doomed to failure if it does not recognize the importance of the human aspect. Scherkenbach (1991) elaborated a theory of transformation that emphasizes this human aspect of quality. Scherkenbach notes how differently people view the world and why they are motivated by different means. Some, such as management scientists and operations researchers, live in the logical world. They tend to proceed on the basis of logical actions. Others, including many top-level managers and workers alike, live in a physical world. This is the world of policies, procedures, standards, rewards, and punishments. They do it by the book. Still others, such as sales personnel, marketing specialists and artists live in the emotional world, typified by the statement, "The force is with you."

Scherekenbach's point is not to create stereotypes, but to enable a better understanding of why arguments made in one of these domains often do not have a substantive impact on people living in another domain, i.e., when dealing with others, it is imperative to recognize that they may not be motivated by different forces. To make progress in relationships with others, one needs to be cognizant of their view and address them in an appropriate manner. As a point of exclamation to those of us who live in the logical world, Scherkenbach quotes Schopenhauer: "No one ever convinced anybody by logic; and even logicians use logic only as a source of income."

He goes on to describe transformation through three process relationships: one for each world view, and all given in terms of different mind states or attitudes dependent, independent and interdependent. Many people function solely in either the dependent or independent mode. An important aspect of the quality transformation is to facilitate the move to the interdependent mode.

TQM and Principle-Based Management

Each of us holds an important key to any quality transformation process in which we are involved. Covey (2004) suggested that we begin the quality transformation by taking action on ourselves first; then proceed through the four steps of his inside-out principle based management. He described these four steps as self, interpersonal, managerial and organizational. At the self level, he stresses the need to carefully develop our vision, decide what our life is about and develop those principles that will serve as our guidelines in making all of our decisions in life. Next is the need to act on this vision in a consistent manner that builds an internal source of security. Immediate or complete success should not be expected since this is a learning process. Incorporating and practicing the Shewhart/Deming PDSA cycle in our own work is an important method for improving the quality or our own work.

As we achieve some comfort with ourselves, and create a more positive opinion of ourselves, we will be able to move on to the interpersonal level. Covey stated that quality at the interpersonal level means that we live by the correct principles in our relationship with other people. Here Covey used the analogy of a bank account, that is, we make deposits to and withdrawals from an emotional bank account. He stated three important ground rules for achieving quality in interpersonal relationships. First, when we have a problem with a person, we should go directly to them and explain it. The second relates to the conduct of meetings. His ground rule is that no one is allowed to make a point in a meeting until they restate the point of their predecessor, and state it in a manner that is satisfactory to that person. He notes that this eliminates the majority of disagreements, since most of them are simply misunderstandings. Through this mechanism potential misunderstandings can be quickly clarified, avoiding arguments, further miscommunications and withdrawals from the emotional bank account. Furthermore, having greatly reduced the number of misunderstandings, there is a better chance to disagree agreeably when new disagreements take place. An important question is do we have the courage to practice this ground rule and continue to practice it even if the rest of group does not.

Finally, when we do make mistakes, we need to have the courage to say that we were wrong. No excuses. We must apologize to the person; we must also apologize to the other people involved. At the managerial level, quality means that we attempt to empower people. In this way they become increasingly independent of us. They supervise themselves, and we become a source of help, rather than a micromanager. Empowerment begins with self-control and self-inspection and extends to self-directing work teams. These teams plan processes, establish schedules, assign personnel and maintain discipline through peer pressure. They accomplish the work that was once limited to managers and specialists. Juran (1988) suggests that this system could be the successor to the Taylor system. It offers the opportunity to step off of the productivity and quality plateaus, which have been directly traced to the lack of involvement of the total work force, a result of not questioning the assumptions underlying Taylor's original separation of planning and execution. A craftsperson created a product from start to finish, and thus recognized the impact of each step on the following one. The production worker, as the execution of production was broken into individual components, had a smaller and decreasing opportunity to comprehend his role in achieving quality. As a result, inspection departments and later quality

departments emerged, acting as policing units in the goal to achieve quality.

At the organizational level, the key is in the structures and the leadership styles. Are the leaders in harmony with the mission statement? Was everyone involved in the development of the mission statement?

TQM and the Malcolm Baldrige Award

The Malcolm Baldrige Award framework provides an excellent road map for implementing TQM, as well a method for evaluating a firm's progress (NIST 1999). The framework emphasizes dynamic relationships between eleven categories of core values and concepts. These underlying core values and concepts are: customer-driven quality, leadership, continuous improvement and learning, employee participation and development, fast response, design quality and prevention, long-range view of the future, management by fact, partnership development, corporate responsibility and citizenship and results orientation.

The stated goals are customer satisfaction, customer satisfaction relative to competitors, customer retention and market share gain as measured by product and service quality, productivity improvement, waste reduction/elimination, supplier performance and financial results. Leadership is viewed as the "driver" category of core values and concepts, driving the two categories: business results and customer focus and satisfaction through a system of processes. The system of processes consists of four "well-defined and well-designed processes" for achieving the firm's performance requirements and the firm's customer requirements. These four system categories are information and analysis, strategic planning, human resource development and management, and process management. The criteria, which are updated annually, are disseminated by the American Society for Quality Control and the National Institute of Standards and Technology.

TQM and Six Sigma

Six Sigma is a relatively new program for accomplishing institutionalizing quality. The fundamental concept was created by a Motorola reliability engineer. Lean six sigma, a more recent development, incorporates fundamental industrial engineering and business "lean practices," with six sigma quality principles. Ramberg (2000) describes six sigma programs, and details its history in "Six Sigma: Fad or Fundamental."

The Status of TQM

One of the first evaluations of TQM was conducted by Senge. In his 1993 ASQ Annual Conference keynote address, titled "The Health and Well Being of the TQM Movement," he posed the following questions: "Are fundamental breakthroughs being made? Are they being made in your organization?" Following this opening, he summarized surveys by Arthur D. Little and McKinsey, and made the following conclusions. Out of 500 firms surveyed, less than a third were accomplishing anything! Two thirds of the TQM programs had ground to a halt! He went on to diagnose TQM failures and successes. Based on his case studies, he concluded that there were only a few major reasons for failure. The three major ones were: conflict between time and effort; wavering goals, and employee perception that their job was at risk.

Even where TQM has "succeeded," there are questions about the measures used to judge that success. That is, in many cases, even where the TQM indicators improved, the health of the company (e.g., as judged by its price) did not get any better, even over a reasonably long term. That is, TQM did not improve the health of the organization as judged by its stockholders. Reporting on the root cause of these problems, Senge concluded that a major reason was that most organizations viewed TQM as programmatic. Presented or implemented in this manner, TQM is certain to be DOA.

Comparative studies measuring the impact of TQM on a firm's business performance also began to appear. Jarrell and Easton (1994) reported some evidence that long-term performance of firms adopting TQM is improved. This result is consistent across the accounting and stock price performance measures examined. Similar, but overall stronger results, were found when the analysis was limited to a subsample of pilot firms identified as having more mature and well-integrated TQM systems. Hendricks and Singhal (1999) concluded that effective implementation of TQM "pays off in a big way." They made this

conclusion by comparing the business performances of firms judged to have successfully implemented TQM with a control group of firms.

van der Wiele et al. (2000) examined TQM through a "fad, fashion, and fit" analysis. Utilizing a range of research studies, which began in the late 1980s, they identified three stages in the evolution by which a fad can achiever a fit with previous management practice. In stage 1, the fad must be clearly defined and measurable. For TQM this clarification was ISO 9000 and the Baldridge Award. Stage 2 is the move to a fashion, which happens when major pressures toward widespread adoption of the fad are present. Again, ISO 9000 serves as an example, because suppliers experienced a pressure from major customers to achieve certification. van der Wiele et al. (2000) state, "As a consequence, the ISO 9000 series became a fast-spreading fashion." They elaborate that "Stage 3 is the move either from fad to fit or from fashion to fit. Fit into normal management practice means that the original fad will have effected the normal way of working within whole organizations and not just a small part such as would be the case in the adoption of a mere fashion." Their fieldwork shows that such a change will only occur when there is strong internal motivation and emotional involvement to implement TQM. They also point out that, "Should such a move take place from fad or fashion to fit, then the chances are that organizational performance will also be perceived to have been effected in a positive way."

Prajogo and Brown (2004) examining the relationship between TQM practices and quality performance in Australian organizations. They compared organizations that adopted formal TQM programs with those without a formal program. They concluded that the lack of a formal program did not necessarily mean TQM principles were not being practiced. Their findings also showed that the firms adopting formal TQM programs implemented several TQM practices at a higher level than those that did not have TQM programs. However, they did not observe a significant difference between organizations implementing formal TQM programs, and those organizations simply adopting TQM practices, suggesting that it is the adoption of quality practices that matters rather than formal programs per se.

While some researchers have given a rather pessimistic view on the future of the quality management movement, Kujala and Lillrank (2004) note that quality management has survived the failure of some of its success stories, such as those of Motorola and Xerox. They affirm that TQM remains to be properly defined, and that its scientific foundations are still not transparent.

Cheng (2007) explored a model for integrating TQM and Six Sigma with business strategy. He concluded that, "Implementing Six Sigma has become a common theme in organizations of all sizes, within a TQM infrastructure."

To summarize, it seems that TQM and its derivatives are fitting into management infrastructure. However, it is important for quality proponents that TQM is not the only thing. TQM will continue to require definition and structural development based on scientific foundations. Most recent of these has come from the Six Sigma movement, and more recently from Lean Six Sigma. Transformational leadership remains a requirement for continued success.

Traffic Analysis

Denos C. Gazis
PASHA Industries, Katonah, NY, USA

Introduction

Traffic analysis has flourished since the 1950s, stimulated from the need to address the ever-growing traffic problems of cities around the world. In true scientific tradition, it has yielded an understanding of the fundamental characteristics of automobile traffic, which in turn spawned significant contributions in the management and optimization of traffic facilities. This article outlines some of the most important developments in one area of traffic analysis, that of traffic flow, including certain associated queueing phenomena. Aspects of control of traffic networks that are outside the scope of this article can be found in Gazis (1992).

A Kinematical Theory of Traffic Flow

One of the earliest, and most durable, contributions to the understanding of traffic flow was given by Lighthill and Whitham (1955). They viewed the traffic as a special fluid which obeys some basic laws consistent with the physical nature of traffic, such as its unidirectional influence of a vehicle only on the traffic behind it, the constraints on flow imposed by human limitations, etc. The Lighthill-Whitham theory is based on two basic postulates:

1. Traffic is conserved, in the sense that traffic units by and large are neither created nor annihilated; and
2. There is a fundamental relationship between traffic flow and traffic density, resulting from the physical characteristics of the traffic system.

The first postulate is expressed in the relationship

$$\frac{\partial k}{\partial t} + \frac{\partial q}{\partial x} = 0 \tag{1}$$

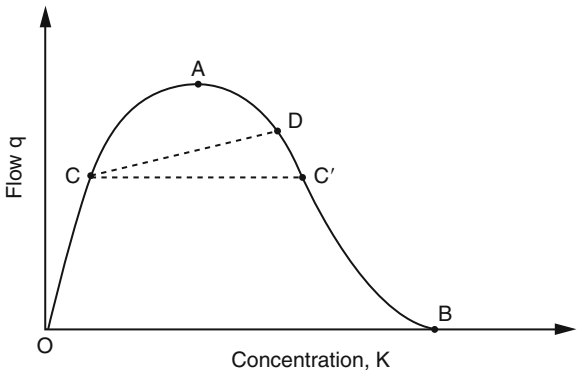
where q is the traffic flow in vehicles per unit of time t, k is the density of traffic in vehicles per unit of distance x, and v is the (average) speed of the traffic fluid. The second postulate is expressed by the relationship

$$q = f(k)$$

between flow q and density k such as that shown in Fig. 1. At zero density, there is zero flow. The flow is also zero at some jam density, k_j, because traffic grinds to a halt as vehicles are packed bumper to bumper. Between these two extremes, traffic flow builds up to a maximum and then decreases down to zero.

A number of interesting properties of traffic can be described on the basis of these two postulates. They relate to observable phenomena such as wave propagation, i.e., the movement along the traffic stream of a transition point corresponding to a change in traffic characteristics, the queueing caused by an obstruction of the traffic movement, etc.

Wave Propagation — Traffic moving at a steady-state flow rate q_1 and density k_1 may shift to a different flow rate q_2, and a corresponding density k_2, by a change in roadway quality, obstruction, or other external influence. When this happens, vehicles situated in a transition region undergo maneuvers adjusting their speed and inter-vehicle spacing, and



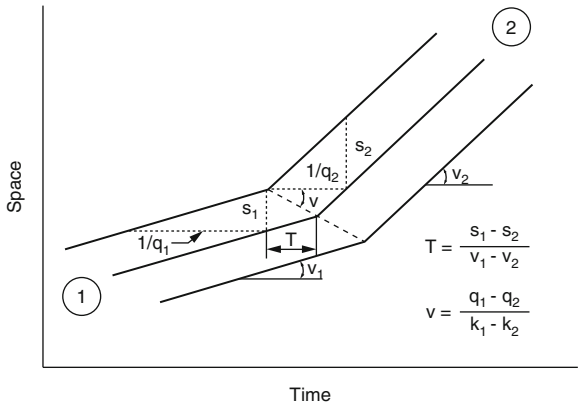
Traffic Analysis, Fig. 1 Flow vs. concentration relationship

this transition region generally moves either forward or backward in space depending on the nature of the change. The adjustments of speed and spacing are gradual, but for the purpose of deriving the characteristics of wave propagation may be assumed abrupt as suggested by Lighthill and Whitham (1955). This assumption leads to the conclusion that a change from one steady-state flow condition to another is associated with a "shock wave," an expression that pervades the traffic engineering literature.

The shock wave marks the transition from one speed to another, and moves always backwards with respect to the traffic stream, since vehicles exert an influence only on vehicles behind them. (The influence of an occasional tailgating vehicle pushing the vehicle in front is ignored as an unimportant aberration). The speed of movement of the shock wave along a roadway, may be obtained on the basis of Eq. (1), and is given by

$$v = \frac{q_1 - q_2}{k_1 - k_2} \tag{3}$$

It should be pointed out that the result given in Eq. (3) depends only on the postulate of conservation of traffic, and is totally independent of any specific relationship between flow and concentration, or even on the existence of such a relationship. It results from kinematical considerations shown in Fig. 2. The transition from one steady state flow situation to another results in a propagation of the change of the corresponding speed along the roadway. The phase velocity of this propagation depends only on the values of the initial and final pairs of flow, q, and



Traffic Analysis, Fig. 2 Transition from one steady-state-flow situation to another

concentration, k, and is given by Eq. (3). If, in addition, a relationship between flow and concentration is assumed (Fig. 1), different domains of traffic quality, and corresponding characteristics of wave propagation, can be defined as follows:

1. The range from zero flow at zero density to maximum flow (Section OA, Fig. 1) corresponds to relatively uncongested traffic flow. A small increase in density in this domain moves forward along the roadway;
2. The range from maximum flow to zero flow at "jam density" (Section AB, Fig. 1) corresponds to relatively congested, stop-and-go traffic. A small increase of density in this domain moves backwards along the roadway; and
3. Any transition from one steady state flow to another (as from point C to point D, Fig. 1) is associated with a wave propagation given by the slope of segment CD.

Queueing — Queueing may be caused by a reduction in roadway capacity at a fixed point on the roadway, or by an obstruction causing traffic to shift from the uncongested to the congested branches of the (q, k) curve, even without reduction in flow rate, (line CC′ in Fig. 1). The rate of growth of the queue can be estimated using the same methodology described above. For example, a total obstruction of flow q and density k causes a queue formation, with the tail-end of the queue moving backwards along the roadway with speed equal to

$$v = \frac{q}{k_j - k} \tag{4}$$

Additional results from the kinematic treatment of traffic — An extensive literature exists on applications of the Lighthill-Whitham model to various traffic phenomena. A word of caution is appropriate with regard to such applications. The Lighthill-Whitham model describes well only transitions from one steady state to another. Any attempt to apply the model to a sequence of traffic maneuvers that do not allow enough relaxation time between changes of speeds violates the basic spirit of the model.

An interesting extension of the above kinematical treatment of traffic was applied by Gazis and Herman (1992) for the treatment of a moving obstruction such as that caused by a vehicle moving more slowly than the other vehicles in the traffic stream. The character of this " moving bottleneck" is different from that of a fixed bottleneck, and the Gazis-Herman treatment derives the characteristic queueing behavior associated with it. Gazis and Herman obtain a description of the queueing caused by a slow vehicle on a two-lane highway. Both lanes are affected by such a vehicle, one by direct trapping of vehicles behind the slow one, and the other by interference from vehicles escaping from the queue behind this vehicle. The result is that queueing takes place in both lanes in the vicinity of the slow vehicle, with the affected vehicles moving at an average speed only marginally higher than that of the slow one, until they come abreast of this slow vehicle and are able to escape at their normal speed. Gazis and Herman also propose an explanation of the phenomenon of a phantom bottleneck, the seemingly unexplainable regions of congestion that drivers often traverse. Some of them may be caused by a moving bottleneck caused by a vehicle that slows down temporarily and then resumes its normal speed; for example, a heavily loaded truck temporarily slowing down along an uphill portion of the roadway. The Gazis-Herman treatment provides a rational way of estimating the minimum allowable speed on a highway, which would not affect its throughput.

A Boltzmann-like Model of Traffic Flow

In 1959, Prigogine suggested a model of traffic flow founded on statistical mechanics, analogous to the Boltzmann model of gases (Prigogine 1961). The Prigogine model was subsequently developed extensively by Herman, Prigogine and their

collaborators (Prigogine, Herman and Anderson 1962, 1965; Prigogine and Herman 1971). They considered a stream of traffic as an ensemble of units associated with certain statistical properties. In particular, a vehicle was associated with a desired speed which it would follow as long as it was not constrained by another vehicle in front with a lower desired speed.

Thus, traffic is described in terms of a probability density for the speed, v, of an individual car, $f(x, v, t)$. This density may vary as a function of time, t, and a coordinate x along the highway. The basic equation for this function f is assumed to be

$$\frac{\partial f}{\partial t} + \upsilon \frac{\partial f}{\partial x} = \left(\frac{\partial f}{\partial t}\right)_{relaxation} + \left(\frac{\partial f}{\partial t}\right)_{interaction} \tag{5}$$

The first term of the righthand side of Eq. (5) is a consequence of the fact that $f(x, v, t)$ differs from some desired speed distribution $f^0(v)$. A car tries to "relax" to its desired speed as soon as it finds an opportunity to do so. The second term of the righthand side corresponds to the slowing down of a fast vehicle by a slow one. True to his tradition as a leading expert in statistical mechanics, Prigogine frequently referred to this second term as the collision term — a rather unsettling choice of words in this context!

The form for these two terms was chosen for mathematical convenience and plausibility, leading to the equation

$$\frac{\partial f}{\partial t} + \upsilon \frac{\partial f}{\partial x} = \frac{f - f_0}{\tau} + (1 - p)k(V - \upsilon)f \tag{6}$$

where τ is a characteristic relaxation time, p is the probability of a car's passing another car, and V is the average speed of the stream of traffic. The second term of the right-hand side of Eq. (6) corresponds to the interaction term, and tends to zero at very light traffic concentration when the probability of passing is close to unity, in which case the relaxation term is dominant. If, in addition, a highway with constant properties along its length is assumed, then $\partial f/\partial x = 0$ and the solution of Eq. (6) is

$$f(\upsilon, t) = f^0(\upsilon) + \left[f(\upsilon, 0) - f^0(\upsilon)\right] e^{-t/\tau} \tag{7}$$

If interested only in solutions of Eq. (6) that are independent of time and space, then the lefthand side of this equation is zero. The equation may then be solved to yield an equation of state whose general form, for small values of the concentration, corresponds to an approximately linear increase of flow with concentration, e.g.,

$$q = V^0 k \tag{8}$$

where V^0 is the average of the desired speed. As k increases, the flow q falls below the straight line (8) due to the increasing influence of interactions.

In the range of high concentrations, q is independent of f^0 and depends only on τ and p, according to the equation

$$q = \frac{1}{\tau(1 - p)}. \tag{9}$$

The complete solution of Eq. (6) for steady-state flow, independent of time and space, is shown in Fig. 3. For any given f^0, the flow q rises with k, reaches a maximum, and then decreases until it intersects a curve corresponding to Eq. (9). This curve may be viewed as a universal curve of collective flow, characterized by high densities and very little passing. One very realistic feature of this theory is the fact that it predicts probable stoppage of some vehicles in the domain of collective flow, in agreement with the common experience of stop-and-go traffic at high concentrations.

It is appropriate to make an observation concerning the linkage of the Herman-Prigogine and Lighthill-Whitham theories in the range of very high densities. Since traffic at those densities is of a stop-and-go nature, it is not really steady-state traffic in the sense of being associated with constant speed and density. Rather, it is associated with alternating states of following slow platoons and escaping from them. Given this fact, it becomes clear that one should not try to apply the Lighthill-Whitham method in describing shock waves and wave propagation involving transitions into this domain of traffic movement, since the L-W theory describes well only clean transitions between two steady-state situations.

Herman and Prigogine (1979), together with several collaborators, went on to use the results of their model to develop a two-fluid approach to town traffic. This approach postulates that traffic in towns is a mixture of

two fluids, one that moves and one that is stopped. Any individual vehicle traverses a network in a stop-and-go fashion, moving part of the time and being stopped part of the time. The quality of service in a particular urban network can be described in terms of two parameters that can be determined by circulating a test vehicle through the network and measuring the percentages of time during which the vehicle is moving, or is being stopped. Thus the two-fluid model yields a simple description of the system-wide traffic quality in congested urban networks. It allows comparison between different urban networks, and it offers the potential of identifying important elements of the network, related to its geometry or control features, which may be targeted for improvement of the service quality.

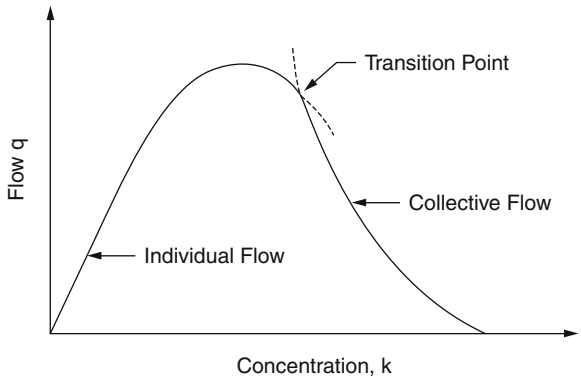
A Car-following Theory of Traffic Flow

Reuschel (1950) and Pipes (1953) proposed models to describe the detailed motion of cars proceeding close together in a single lane. This microscopic, car-following theory of traffic flow was extensively developed by Herman et al. (1959). The theory is based on the fact that when drivers do not have the freedom to pass a vehicle in front, they follow it in a way that is controlled by the overriding need to avoid coinciding with the leader in space and time. In trying to achieve this reasonable objective, drivers react to a limited set of inputs. The postulate of the car-following theory, confirmed by experiments, was that drivers reacted mostly to the relative speed between their car and that of the one in front. Experiments showed a high correlation between the acceleration of a car and its speed relative to that of a leader, after a time-lag of the order of 1 second. This led to the linear car-following model

$$\frac{d^2x_n(t+T)}{dt^2} = \lambda\left[\frac{dx_{n-1}(t)}{dt} - \frac{dx_n(t)}{dt}\right] \qquad (10)$$

in which n denotes the position of a car in a line of cars (a platoon), λ is a constant gain factor, T is the reaction time-lag, and x_n is the position of the nth car on the highway.

This model was used to investigate the stability of a traffic platoon when a perturbation in its movement is introduced. The movement of the platoon is said to be locally stable if the amplitude of a perturbation, for any given car in the platoon, decreases in time. It is asymptotically stable if the amplitude of the perturbation decreases as it propagates upstream. The value of the product λT is the determinant of stability or instability, local or asymptotic. When $\lambda T < 1/e$, a perturbation is damped exponentially as it is passed on to the following car, signifying a very stable situation. For λT between the values of $1/e$ and $\pi/2$, the perturbation produces oscillations of decreasing amplitude between pairs of cars, signifying still a locally stable situation. For $\lambda T > \pi/2$, a perturbation produces oscillations of increasing amplitude, signifying a locally unstable situation.



Traffic Analysis, Fig. 3 Flow vs. concentration relationship according to the Boltzmann-like model of traffic flow

With regard to asymptotic stability, the dividing line is at $\lambda T = 1/2$. For values of λT below 1/2, the amplitude of a perturbation decreases as it propagates backwards; for values of λT greater than 1/2, it increases. This means that between $1/e(\sim 0.368)$ and 1/2 is a situation that is locally stable but asymptotically unstable. Any pair of cars in a platoon is able to absorb a perturbation, but it amplifies it as it passes it backwards, until the perturbation is so large that it causes a collision.

The linear car-following model may be satisfactory in describing fluctuations around a steady-state, constant speed situation. It cannot be expected to describe equally well transitions from one steady state to another involving large changes of speed. For this reason, Gazis et al. (1961) proposed a nonlinear model in which the gain factor is not constant but depends on the speed of the follower and the relative spacing between leader and follower according to the relationship

$$\lambda = \frac{[v_n(t+T)]^l}{[x_{n+1}(t) - x_n(t)]^m} \tag{11}$$

where c is a constant, $v = dx/dt$ is the speed, and (l, m) are integer exponents identifying particular nonlinear models.

Various values of pairs (l, m) were used to define car-following models and investigate their predictions concerning transitions between one steady-state flow situation and another. Integrating over time Eq. (10), with λ described by Eq. (11), leads to the functional relationship between changes of speed and concentration. Together with appropriate boundary conditions, for example the condition of zero speed at jam density, bumper-to-bumper concentration, one can then obtain a phenomenological relationship between flow and concentration such as that shown in Fig. 1. Various pairs (l, m) have been used which yielded quite plausible relationships, consistent with observations.

The preceding discussion outlines most of the key contributions in the car-following treatment of traffic flow. Additional studies have been contributed by Gazis (1965) within the framework of control theory to account for physical constraints on the system, such as limited acceleration or deceleration capability of cars.

Concluding Remarks

As is the case for every scientific endeavor, much can be done to improve the theories of traffic analysis. For example, car-following theories ignore interaction of cars with other than the car just in front, whereas there is evidence that drivers are very much conscious of happenings several cars in front of them, and this consciousness tends to improve the stability of traffic. Another observation that must be made about virtually all traffic models described here is that they effectively correspond to flat, straight, and infinitely long highways. It is clear that the geometry of highways, including curves and inclination, has a strong effect on the behavior of traffic. A systematic study of such effects would greatly advance understanding of traffic movement, and produce necessary tools for future improvements in traffic management.

The analytical description of traffic flow has already had a profound influence on traffic engineering practice, and the advent of activities in the area of Intelligent Transportation Systems (ITS) points to an increasing reliance on analytical investigations of traffic systems toward improvement of their operation. One needs an improved understanding, and an improved analytical description of traffic phenomena, such as the onset of congestion, queueing, and inter-vehicle signal propagation, in order to create the theoretical under-pinning toward the use of high technology for the improvement of traffic systems, which is the central thrust of ITS. Some improvement will come from direct application of analytical results. For example, the development of automatic highways will undoubtedly draw from knowledge based on car-following models. Other improvements may come from the improved understanding of traffic phenomena that traffic analysis provides, leading to improved heuristic schemes for the control and optimization of traffic systems.

Traffic Equations

In a queueing network, the set of linear equations that results from balancing flow into each node with the flow out. These traffic equations are derived by recognizing that the total input seen at a node comes from summing the flow of new arrivals from outside the network with the flow of arrivals that are due to departures from service completions at nodes within the network:

$$\lambda_i = \gamma_i + \sum_j \lambda_j r_{ij}$$

where λ_i is the total input flow rate seen at node i, γ_i is the external input rate to node i, r_{ij} is the probability that a service completion at node i is routed to node j, and the summation is taken over all nodes in the network.

See

▶ Conservation of Flow
▶ Networks of Queues

Transition Function

A function describing the transition probabilities of a Markov process $\{X(t),\ t\ \in T\}$ into a subset A of the state space as $p(s, x; t, A) = \Pr\{X(t)\ \in\ A|X(s) = x\}$, for state x and times $s < t$ in the time domain T.

See

- ▶ Markov Chains
- ▶ Markov Processes

Transition Matrix

The matrix of (single-step) stationary transition probabilities of a Markov chain $\{X_n\}$, $\boldsymbol{P} = [p_{ij}]$, where $p_{ij} = \Pr\{X_{n+1} = j|X_n = i\}$ is the conditional probability that the chain moves to state j from state i in one step.

See

- ▶ Markov Chains
- ▶ Markov Processes

Transition Probabilities

The conditional probabilities describing the movement from state to state of a Markov process $\{X(t), t\ \in T\}$. In general, the transition probabilities are written as $\Pr\{X(t)\ \in\ A|X(s) = x\}$ for times $s < t$ in the time domain T and state x and event (set) A in the state space. For a homogeneous discrete-time Markov chain (DTMC) $\{X_n, \text{n} \geq 0\}$, the stationary transition probabilities are $\Pr\{X_{n+1} = j|X_n = i\} = p_{ij}$, for states i and j in the space state.

Transportation Problem

A linear-programming problem of the following form is called a transportation problem:

$$\text{Minimize} \sum_i \sum_j c_{ij} x_{ij}$$

subject to

$$\sum_j x_{ij} = a_j \quad i = 1, \ldots, m \quad \text{(origins/supply)}$$

$$\sum_i x_{ij} = b_j \quad j = 1, \ldots, n \quad \text{(destinations/demand)}$$

$$x_{ij} \geq 0.$$

The variables $\{x_{ij}\}$ represent a shipment of a homogeneous product from origin i to destination j, where the $\{a_i\}$ are the amounts of the product to be shipped from the origins i, and the $\{b_j\}$ are the amounts demanded by the destinations j. The form presented here assumes $\sum_i a_i = \sum_j b_j$, but the problem can also be formulated with the origin constraints as $\geq$ inequalities and the destination constraints as $\leq$ inequalities, without the restriction that the total supply equal the total demand. It can be shown that if the $\{a_i\}$ and $\{b_j\}$ are integers, than an optimal basic feasible solution exists that is all integer. The transportation problem is a special network problem whose network representation is called a bipartite graph. The special case with $m = n$ and all $\{a_i\}$ and $\{b_j\}$ equal to 1 is the assignment problem. A transportation problem can be solved by direct application of the simplex method, but due to its mathematical structure, the problem can be solved by an efficient modification of the simplex method called the transportation (primal-dual) simplex method. It can also be solved by specialized network algorithms.

- ▶ Northwest-Corner Solution
- ▶ Transportation Simplex (Primal-Dual) Method
- ▶ Unbalanced Transportation Problem

Transportation Problem Paradox

Some transportation problems exhibit the paradox that an optimal solution can be improved if the total amount of units shipped is more than the total amount shipped by the optimal solution. In other words, one can ship more for less.

Transportation Simplex (Primal-Dual) Method

The dual problem to the primal equation form of the transportation problem can be stated as follows:

$$\text{Maximize} \sum_i a_i u_i + \sum_j b_j v_j$$

subject to

$$u_i + v_j \leq c_{ij} \quad \text{for all } (i, j).$$

Here the $(m + n)$ set of dual variables u_i and v_j are unrestricted (free) variables. Note that the primal has a redundant equation due to the equality of the total supply and demand. Thus, a feasible basis matrix to the transportation problem is of dimension $(m + n - 1) \times (m + n - 1)$. It can be shown that any feasible basis matrix can be arranged into a triangular form. For a given basis, the simplex method requires that the corresponding dual constraints must hold at equality, i.e., $u_i + v_j = c_{ij}$ for all variables x_{ij} in the basis. This $(m + n - 1) \times (m + n)$ set of dual equations can be reduced to an $(m + n - 1) \times (m + n - 1)$ system by arbitrarily setting one of the dual variables, say $u_1 = 0$. This corresponds to removing, as a redundant constraint, the first equation of the transportation problem. The resulting dual square set of equations also has a triangular form that allows for the efficient calculation of the $\{u_i\}$ and $\{v_j\}$ that correspond to the current basic solution. These values of u_i and v_j are used to calculate the $(u_i + v_j)$ terms for the nonbasic

variables, and if each one is less than or equal to its corresponding c_{ij}, then by duality theory and complementary slackness, the current basis is optimal. If the latter condition does not hold, the usual simplex criterion is used to select a variable to enter the basis and a new basic feasible solution is generated by simple adjustments to the flows in the network that describe the current basic feasible solution. This network is a tree that connects all origins and destinations, and the addition of the new variable (or arc to the tree) enables the new solution to be calculated readily. This primal-dual process is repeated until an optimal solution is found. Such a solution exists because the transportation problem always has feasible solutions and the solution set is bounded.

Transposition Theorems

Transposition theorems deal with disjoint alternatives of solvability of linear systems. For example, Stiemke's transposition theorem is the following: For a matrix $\boldsymbol{A} \neq \boldsymbol{0}$, the following statements are equivalent: (1) $\boldsymbol{Ax} = \boldsymbol{0}$, $\boldsymbol{x} > \boldsymbol{0}$, has no solution, and (2) $\boldsymbol{\mu A} \leq \boldsymbol{0}$, $\boldsymbol{\mu A} \neq \boldsymbol{0}$ has a solution.

Traveling Salesman Problem

Karla L. Hoffman[1], Manfred Padberg[2] and Giovanni Rinaldi[3]

Introduction

The traveling salesman problem (TSP) has commanded much attention from mathematicians and computer scientists specifically because it is so easy to describe and so difficult to solve. The problem can simply be stated as: if a traveling salesman wishes to visit exactly once each of a list of m cities (where the cost of traveling from city i to city j is c_{ij}) and then return to the home city, what is the least costly route the traveling salesman can take? A complete historical development of this and related problems can be found in Hoffman and Wolfe (1985), Applegate et al. (2006), and Cook (2011).

The importance of the TSP is that it is representative of a larger class of problems known as combinatorial optimization problems. The TSP problem belongs in the class of such problems known as *NP*-complete. Specifically, if one can find an efficient (i.e., polynomial-time) algorithm for the traveling salesman problem, then efficient algorithms could be found for all other problems in the *NP*-complete class. To date, however, no one has found a polynomial-time algorithm for the TSP. Does that mean that it is impossible to solve *any* large instances of such problems? To the contrary, nowadays many practical optimization problems of truly large scale are solved to optimality routinely. From 1992 to 2006, Concorde, a software created by D. Applegate, R.E. Bixby, V. Chvátal, and W.J. Cook (Applegate et al. 1995, 2006), solved (among many others) a traveling salesman problem that models the production of printed circuit boards having 7,397 holes (cities), a problem over the 13,509 largest cities in the U.S., one over the 24,978 cities of Sweden, and, finally, a 85,900 city problem arising from a VLSI

application. So, although the question of what it is that makes a problem difficult may remain open, the computational record of specific instances of TSP problems coming from practical applications is optimistic.

How are such problems tackled? Obviously, one cannot consider a brute-force approach. For example, for a 16-city traveling salesman problem, there are 653,837,184,000 distinct routes that would need to be evaluated. Rather than enumerating all possibilities, successful algorithms for solving the TSP problem eliminate most of the routes without ever explicitly considering them.

Formulations

The first step to solving instances of large TSPs must be to find a good mathematical formulation of the problem. In the case of the traveling salesman problem, the mathematical structure is a graph where each city is denoted by a point (or node) and lines are drawn connecting every two nodes (called arcs or edges). Associated with every line is a distance (or cost). When the salesman can get from every city to every other city directly, then the graph is said to be complete. A round-trip (route) of the cities corresponds to some subset of the lines, and is called a tour or a Hamiltonian cycle in graph theory. The length of a tour is the sum of the lengths of the lines in the round-trip.

Depending upon whether or not the direction in which an edge of the graph is traversed matters, one distinguishes the asymmetric from the symmetric traveling salesman problem. To formulate the asymmetric TSP on m cities, one introduces zero-one variables

$$x_{ij} = \begin{cases} 1 \text{ if the edge } i \to j \text{ is in the tour} \\ 0 \text{ otherwise} \end{cases}$$

and, given the fact that every node of the graph must have exactly one edge pointing towards it and one pointing away from it, one obtains the classic assignment problem. These constraints alone are not enough since this formulation would allow subtours, i.e., it would allow disjoint loops to occur. For this reason, a proper formulation of the asymmetric traveling salesman problem must remove these subtours from consideration by the addition of subtour-elimination constraints. The problem then becomes

$$\begin{aligned} \min \quad & \sum_{j=1}^{m} \sum_{i=1}^{m} c_{ij} x_{ij} \\ \text{s.t.} \quad & \sum_{j=1}^{m} x_{ij} = 1 \quad \text{for } i = 1, \ldots, m \\ & \sum_{j=1}^{m} x_{ij} = 1 \quad \text{for } j = 1, \ldots, m \\ & \sum_{i \in K} \sum_{j \in K} x_{ij} \leq |K| - 1 \quad \text{for all } K \subset \{1, \ldots, m\} \end{aligned}$$

where K is any nonempty proper subset of the cities $1, \ldots, m$. The cost c_{ij} is allowed to be different from the cost c_{ji}. Note that there are $m(m-1)$ 0–1 variables in this formulation.

To formulate the symmetric traveling salesman problem, one notes that the direction traversed is immaterial, so that $c_{ij} = c_{ji}$. Since direction does not now matter, one can consider the graph where there is only one arc (undirected) between every two nodes. Thus, let $x_j \in \{0,1\}$ be the decision variable where j runs through all edges E of the undirected graph and c_j is the cost of traveling that edge. To find a tour in this graph, one must select a subset of edges such that every node is contained in exactly two of the edges selected. Thus, the problem can be formulated as a 2-matching problem in a graph having $m(m-1)/2$ 0–1 variables, that is, half of the number of the previous formulation. As in the asymmetric case, subtours must be eliminated through subtour elimination constraints. The problem can therefore be formulated as

$$\begin{aligned} \min \quad & (1/2) \sum_{j=1}^{m} \sum_{k \in J_{(j)}} c_k x_k \\ \text{s.t.} \quad & \sum_{k \in J_{(j)}} x_k = 2 \quad \text{for all } j = 1, \ldots, m \\ & \sum_{j \in E(K)} x_j \leq |K| - 1 \quad \text{for all } K \subset \{1, \ldots, m\} \\ & x_j = 0 \text{ or } 1 \quad \text{for all } j \in E, \end{aligned}$$

where $J(j)$ is the set of all undirected edges connected to node j and $E(K)$ is the subset of all undirected edges

connecting the cities in any proper, nonempty subset K of all cities. Of course, the symmetric problem is a special case of the asymmetric one, but practical experience has shown that algorithms for the asymmetric problem perform, in general, badly on symmetric problems. Thus, the latter need a special formulation and solution treatment. In addition, as an ATSP instance can be easily turned into a symmetric one with twice the number of nodes, any algorithm for STSP can be used to solve an ATSP.

Algorithms

Exact approaches to solving such problems require algorithms that generate both a lower bound and an upper bound on the true minimum value of the problem instance. Any round-trip tour that goes through every city exactly once is a feasible solution with a given cost that cannot be smaller than the minimum cost tour. Algorithms that construct feasible solutions, and thus upper bounds for the optimum value, are called heuristics. These solution strategies produce answers but often without any quality guarantee as to how far off they may be from the optimal answer. Heuristic algorithms that find a feasible solution in a single attempt are called constructive heuristics, while algorithms that iteratively modify and try to improve some given starting solution are called improvement heuristics. When the solution one obtains is dependent on the initial starting point of the algorithm, the same algorithm can be used multiple times from various (random) starting points. Often, if one needs a solution quickly, one may settle for a well-designed heuristic algorithm that has been shown empirically to find near-optimal tours to many TSP problems. Research by Golden and Stewart (1985), Jünger, Reinelt and Rinaldi (1994), Johnson and McGeoch (2002), and Applegate et al. (2006) describes algorithms that find solutions to extremely large TSPs (problems with hundreds of thousands, or even millions of variables) to within 1 or 2% of optimality in very reasonable times. The heuristic algorithm of Lin and Kernighan appears so far to be the most effective in term of solution quality, in particular with the variant proposed by Helsgaun (2000), which was able to find, for the first time, the optimal solution (although without a quality guarantee) of several instances of TSPLIB, a well known library of TSP problems described in Reinelt (1991). For genetic algorithmic approaches to the TSP, see Potvin (1996); for simulated annealing approaches see Aarts, Korst and Laarhoven (1988); for neural net approaches, see Potvin (1993); for tabu search approaches, see Fiechter (1990); and for a very effective evolutionary algorithm, *see* Nagata (2006). Probabilistic analysis of heuristics are discussed in Karp and Steele (1985); performance guarantees for heuristics are given in Johnson and Papadimitriou (1985) and Arora (2002), where an amazing result concerning the polynomial-time approximability is described for Euclidean TSP instances (where the nodes are points in the plane and the traveling costs are the Euclidean distances between the points). For an analysis of the heuristics for the ATSP, see Johnson et al. (2002).

In order to know about the closeness of the upper bound to the optimum value, one must also know a lower bound on the optimum value. If the upper and lower bound coincide, a proof of optimality is achieved. If not, a conservative estimate of the true relative error of the upper bound is provided by the difference of the upper and the lower bound divided by the lower bound. Thus, one needs both upper and lower bounding techniques to find provably optimal solutions to hard combinatorial problems or even to obtain solutions meeting a quality guarantee.

So how does one obtain and improve the lower bound? A relaxation of an optimization problem is another optimization problem whose set of feasible solutions properly contains all feasible solution of the original problem and whose objective function value is less than or equal to the true objective function value for points feasible to the original problem. Thus, the true problem is replaced by one with a larger feasible region but that is more easily solvable. This relaxation is continually refined so as to tighten the feasible region so that it more closely represents the true problem. The standard technique for obtaining lower bounds on the TSP problem is to use a relaxation that is easier to solve than the original problem. These relaxations can have either discrete or continuous feasible sets. Several relaxations have been considered for the TSP. Among them are the n-path relaxation, the assignment relaxation, the 2-matching relaxation, the 1-tree relaxation, and the linear programming relaxation. For randomly generated asymmetric TSPs, problems having up to 7,500 cities

have been solved, in the early 1990s, using an assignment relaxation which adds subtours within a branch and bound framework and which uses an upper bounding heuristic based on subtour patching, (Miller and Pekny 1991). For the symmetric TSP, the 1-tree relaxation and the 2-matching relaxations have been most successful. These relaxations have been embedded into a branch-and-bound framework.

The process of finding constraints that are violated by a given relaxation is called a cutting plane technique and all successes for large TSP problems have used cutting planes to continuously tighten the formulation of the problem. To obtain a tight relaxation the inequalities utilized as cutting planes in many computational approaches to the TSP are often facet-defining inequalities.

One of the simplest classes of cuts that have been shown to define facets of the underlying TSP polytope is the subtour elimination cut. Besides these constraints, comb inequalities, clique tree inequalities, path, wheelbarrow and bicycle inequalities, ladder, crown, domino and many other inequalities have also been shown to define facets of this polytope. The underlying theory of facet generation for the symmetric traveling salesman problem is provided in Grötschel and Padberg (1985), Jünger, Reinelt and Rinaldi (1994) *and* Naddef (2002); analogous results for the ATSP polytope are provided in Balas and Fischetti (2002). The algorithmic descriptions of how these inequalities are used in cutting plane approaches are discussed in Padberg and Rinaldi (1991), in Jünger, Reinelt and Rinaldi (1994), *and in* Applegate et al. (2006) where it is also shown how the polynomial-time equivalence between optimization and separation can be turned into a powerful algorithmic tool to generate inequalities not necessarily belonging to one of the known types.

Cutting plane procedures can then be embedded into a tree search in an algorithmic framework referred to as branch and cut and proposed in Padberg and Rinaldi (1991), where it is shown how such approach made it possible to solve some still unsolved instances of sizes up to 2,392 nodes. Some of the largest TSP problems solved have used parallel processing to assist in the search for optimality. This is the case of the software Concorde, where all the known algorithmic ideas for the TSP (and many new ones) have been carefully implemented. With this code, Applegate et al. (2006) managed to solve all problems of the TSPLIB to optimality; for the largest one, of 85,900 nodes, they used 96 workstations for a total of 139 years of CPU time.

As understanding of the underlying mathematical structure of the TSP problem improves, and with the continuing advancement in computer technology, it is likely that many difficult and important combinatorial optimization problems will be solved using a combination of cutting plane generation procedures, heuristics, variable fixing through logical implications and reduced costs, and tree search.

Applications

One might ask, however, whether the TSP problem is important enough to have received all of the attention it has. Much of the attention that the problem has received is because it is a relatively simple problem to describe and yet a difficult (from a complexity viewpoint) optimization problem to solve. However, there are important cases of practical problems that can be formulated as TSP problems and many other problems are generalizations of this problem. Besides the drilling of printed circuits boards described above, problems having the TSP structure occur in the analysis of the structure of crystals (Bland and Shallcross 1987), in the overhauling of gas turbine engines (Pante et al. 1987), in material handling in a warehouse (Ratliff and Rosenthal 1981), in cutting stock problems (Garfinkel, 1977), in the clustering of data arrays (Lenstra and Rinooy Kan 1975), in the sequencing of jobs on a single machine (Gilmore and Gomory 1964), in the assignment of routes for planes of a specified fleet (Boland et al. 1994) and in genome sequencing (Ben-Dor and Chor 1997; Ben-Dor et al. 2000). Related variations on the traveling salesman problem include the resource-constrained traveling salesman problem, which has applications in scheduling with an aggregate deadline (Pekny and Miller 1991). This paper also shows how the prize collecting traveling salesman problem (Balas 2002) and the orienteering problem (Golden et al. 1987; Fischetti et al. 2002) are special cases of the resource constrained TSP. Most importantly, the traveling salesman problem often comes up as a subproblem in more complex combinatorial problems, perhaps

the best-known application being the vehicle routing problem. This is the problem of determining for a fleet of vehicles which customers should be served by each vehicle and in what order each vehicle should visit the customers assigned to it. For relevant surveys, see Christofides (1985), Fisher (1987), and the book *The Vehicle Routing Problem*, edited by Toth and Vigo (2001).

Concluding Remarks

The seminal paper on the TSP is Dantzig, Fulkerson and Johnson (1954). Books by Lawler et al. (1985), Reinelt (1994) and Gutin and Punnen (2002), and the survey and annotated bibliography by Jünger, Reinelt and Rinaldi (1994, 1997), summarize most of the research up through 2002 and provide extensive references. For a deep understanding of how algorithms for TSP work, see the book by Applegate et al. (2006), which besides providing a wide overview on TSP history and on its applications, also gives a detailed description of how all the components of the Concorde software are built: a valuable source for algorithm designers. Finally, the book by Cook (2011) is for a more general audience, requiring almost no mathematical background to read, but very nicely and completely describing the TSP from several interesting viewpoints. The computer program Concorde, the TSPLIB, and many other sources of information on the TSP are available electronically at a Web site that can be easily located through Web search.

Tree

In a network, a tree is a subnetwork (graph) that has no cycles and connects all nodes of a subnetwork, that is, a unique path exists between each node. A tree that connects all n nodes of a network is called a spanning tree and has $(n - 1)$ arcs.

Triangular Matrix

A square matrix $\boldsymbol{A} = (a_{ij})$ such that either all the elements a_{ij} above the diagonal are 0 or all the elements below the diagonal are 0. The former is called a lower triangular matrix and the latter an upper triangular matrix.

Trim Problem

Problem of determining how rolls or sheets of material should be cut to minimize the amount of wasted material (trim) while meeting the demand for different sizes of cuts. The problem originally arose in the context of cutting large rolls of newsprint into desired smaller sizes. The trim problem can be formulated and solved as a linear or

integer program. It was the problem that motivated column generation procedures.

► Computational Complexity

Unbalanced Transportation Problem

A transportation problem in which the total amount to be shipped (supply) is not equal to the total demand. The unbalanced problem can be stated as a standard transportation problem by the addition of a fictitious destination when the supply is greater than the demand, or by adding a fictitious origin if the demand is greater than the supply. In the first case, the demand at the fictitious destination is the difference between the total supply and total demand, while in the second case, the supply at the fictitious origin is the difference between the total demand and total supply.

See

► Transportation Problem

Unbounded Optimal Solution

A solution to a constrained optimization problem in which the objective function value can be shown to increase (or decrease) without bound on the feasible region. A real-world problem whose mathematical model exhibits an unbounded optimal solution must have an incorrect formulation.

Unconstrained Optimization

Ariela Sofer
George Mason University, Fairfax, VA, USA

Introduction

Unconstrained optimization is concerned with finding the minimizing or maximizing points of a nonlinear function, where the variables are free to take on any value. Unconstrained optimization problems occur in a wide range of applications in science and engineering. A rich source of unconstrained optimization problems are data-fitting problems, in which some model function with unknown parameters is fitted to data, using some criterion of best fit. This criterion may be the minimum sum of squared errors, or the maximum of a likelihood or entropy function. Unconstrained problems also arise from constrained optimization problems, since these are often solved by solving a sequence of unconstrained problems.

In mathematical terms, an unconstrained minimization problem can be written in the form

$$\text{minimize } f(\boldsymbol{x}),$$

where $\boldsymbol{x} = (x_1, \ldots, x_n)^T$ is a vector of unrestricted variables in the n-dimensional space $\Re^n$. Ideally, one would like to find a global minimizer of the function, i.e., a point $\boldsymbol{x}^*$ that yields the lowest value of f. Such a solution satisfies

$$f(\boldsymbol{x}^*) \leq f(\boldsymbol{x}) \quad \text{for all } \boldsymbol{x}.$$

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

If the inequality above holds strictly, i.e., $f(\boldsymbol{x}^*) < f(\boldsymbol{x})$ for all $\boldsymbol{x}$, then $\boldsymbol{x}^*$ is a strict global minimizer.

In many cases, finding a global minimizer is extremely difficult. For this reason, most algorithms attempt only to find a local minimizer of the function, i.e., a point $\boldsymbol{x}^*$ that satisfies $f(\boldsymbol{x}^*) \leq f(\boldsymbol{x})$ for all $\boldsymbol{x}$ in some neighborhood of $\boldsymbol{x}^*$. If the objective f is a convex function (see the next section), a local minimizer will also be a global minimizer; however, for nonconvex functions this property does not generally hold.

There is no inherent difference between minimization problems and maximization problems, since maximizing f can be accomplished by minimizing $-f$ and then multiplying the optimal objective values by -1. For this reason it is sufficient to focus only on unconstrained minimization problems.

Background

Much of the research in unconstrained optimization has focused on functions with continuous derivatives. Throughout this discussion it is assumed that the objective function f is twice-continuously differentiable (i.e., its second partial derivatives exist and are continuous). The gradient of f at $\boldsymbol{x}$, denoted by $\nabla f(\boldsymbol{x})$, is the vector of first partial derivatives $\partial f(\boldsymbol{x})/\partial x_j$, and the Hessian of f at $\boldsymbol{x}$, denoted by $\nabla^2 f(\boldsymbol{x})$, is the matrix of second partial derivatives $\partial^2 f(\boldsymbol{x})/\partial x_i \partial x_j$. When f is twice-continuously differentiable, the Hessian matrix is symmetric.

If there is a single fundamental tool in optimization of differentiable functions, it is the Taylor series, which provides an approximation to the function in a neighborhood of a point. The Taylor series is used in the derivation of the optimality conditions, in the development of solution methods and in analysis of their convergence.

Let $\bar{\boldsymbol{x}}$ be a given point, and suppose that $\boldsymbol{p}$ is some direction in $\Re^n$. The first-order Taylor series expansion of f at $\bar{\boldsymbol{x}}$ is

$$f(\bar{\boldsymbol{x}} + \boldsymbol{p}) = f(\bar{\boldsymbol{x}}) + \boldsymbol{p}^T \nabla f(\bar{\boldsymbol{x}}) + O(\|\boldsymbol{p}\|)^2,$$

where $O(q)$ indicates a term that goes to zero at least as fast as q does. Ignoring the last term in the expansion leads to a linear approximation to f in a neighborhood of $\bar{x}$; the error will be of order $O(\|\boldsymbol{p}\|)^2$. Similarly, the second-order Taylor series expansion of f is given by

$$f(\bar{\boldsymbol{x}} + \boldsymbol{p}) = f(\bar{\boldsymbol{x}}) + \boldsymbol{p}^T \nabla f(\bar{\boldsymbol{x}}) + \tfrac{1}{2}\boldsymbol{p}^T \nabla^2 f(\bar{\boldsymbol{x}})\boldsymbol{p} + O(\|\boldsymbol{p}\|)^3.$$

Ignoring the last term in this expansion leads to a quadratic approximation to f, with an error of order $O(\|\boldsymbol{p}\|)^3$. This approximation is referred to as the quadratic model.

The quantity $\boldsymbol{p}^T \nabla f(\bar{\boldsymbol{x}})$ is called the directional derivative of f along $\boldsymbol{p}$ at $\bar{\boldsymbol{x}}$. If it is negative, then p is termed a direction of descent. A small step $\varepsilon > 0$ taken in such a direction will lead to a point with a lower objective value: $f(\bar{\boldsymbol{x}} + \varepsilon \boldsymbol{p}) < f(\bar{\boldsymbol{x}})$. The quantity $\boldsymbol{p}^T \nabla^2 f(\bar{\boldsymbol{x}})\boldsymbol{p}$ is called the curvature of f along $\boldsymbol{p}$. If the curvature is positive, the function is locally convex along the direction $\boldsymbol{p}$ at $\bar{\boldsymbol{x}}$.

Convexity of the objective function is a desirable property in unconstrained minimization. Geometrically, it means that the function is locally convex in every direction. The formal definition does not actually require the function to be differentiable. A function f is defined to be convex if it satisfies

$$f(\alpha \boldsymbol{x} + (1-\alpha)\boldsymbol{y}) \leq \alpha f(\boldsymbol{x}) + (1-\alpha) f(\boldsymbol{y})$$

for all $0 \leq \alpha \leq 1$ and for all $\boldsymbol{x}, \boldsymbol{y}$. The function is strictly convex if this inequality is strict (for $0 < \alpha < 1$ and $\boldsymbol{x} \neq \boldsymbol{y}$). A function f is concave if $-f$ is convex.

If f is twice continuously differentiable function, f is convex if and only if its Hessian $\nabla^2 f(\boldsymbol{x})$ is positive semidefinite for all $\boldsymbol{x}$. This means that $\boldsymbol{p}^T \nabla^2 f(\boldsymbol{x})\boldsymbol{p} \geq 0$ for all $\boldsymbol{p}$, so the function is locally convex along every direction $\boldsymbol{p}$. If the Hessian $\nabla^2 f(\boldsymbol{x})$ is positive definite for all x, then the function f is strictly convex. However the Hessian of a strictly convex function need not be positive definite everywhere, as is demonstrated by $f(x) = x^4$ at the origin $x = 0$.

Convexity is an attractive property since any local minimizer of an unconstrained convex function is also a global minimizer of the function. Furthermore, any local minimizer of an unconstrained strictly convex function is also the unique global minimizer of the function.

Optimality Conditions

Using the Taylor series approximation, it is possible to derive conditions that must be satisfied by a local

minimizer $\boldsymbol{x}^*$ of f. The conditions state that the function must have zero slope and nonnegative curvature along any direction at $\boldsymbol{x}^*$, which are summarized in the necessary conditions. The first-order necessary condition states that the gradient at $\boldsymbol{x}^*$ must vanish, so that

$$\nabla f(\boldsymbol{x}^*) = 0.$$

The second-order necessary condition states the Hessian must be positive semidefinite, so that

$$\boldsymbol{p}^T \nabla^2 f(\bar{\boldsymbol{x}}) \boldsymbol{p} \ \forall \boldsymbol{p}.$$

(In the case of a local maximizer, the Hessian must be negative semidefinite).

To illustrate these conditions, consider the two-dimensional function $f(\boldsymbol{x}) = x_1^2 + x_2^2$. The function attains its minimum at $x^* = (0,0)^T$. The gradient of f is $\nabla f(\boldsymbol{x}) = (2x_1, 2x_2)^T$, and indeed vanishes at $\boldsymbol{x}^*$; the Hessian at $\boldsymbol{x}^*$ is twice the identity matrix, and hence is positive definite. Thus, the necessary conditions for a minimizer are satisfied at $\boldsymbol{x}^*$.

A point at which the gradient is equal to zero is called a stationary point. Although such a point may be a local minimizer, it may also be a local maximizer, or neither of the above (in such case it is called a saddle point). As an example, $\boldsymbol{x}^* = (0,0)^T$ is a stationary point of the functions $f_1(\boldsymbol{x}) = -x_1^2 - x_2^2$ and $f_2(\boldsymbol{x}) = x_1^2 - x_2^2$; it is a local maximizer of f_1, and a saddle point for f_2.

It is possible to develop a condition that guarantees that a stationary point is a local minimizer. The second-order sufficiency condition states that if

$$\nabla f(\boldsymbol{x}^*) = 0, \text{and } \boldsymbol{p}^T \nabla^2 f(\bar{\boldsymbol{x}}) \boldsymbol{p} > 0 \ \forall \boldsymbol{p},$$

then $\boldsymbol{x}^*$ is a strict local minimizer of f.

As an example, consider the quadratic function

$$f(\boldsymbol{x}) = \tfrac{1}{2} \boldsymbol{x}^T \boldsymbol{Q} \boldsymbol{x} + \boldsymbol{c}^T \boldsymbol{x},$$

where $\boldsymbol{Q}$ is a symmetric invertible matrix. Any stationary point must satisfy $\nabla f(\boldsymbol{x}) = \boldsymbol{Q}\boldsymbol{x} + \boldsymbol{c} = 0$. Since $\boldsymbol{Q}$ is invertible there is a unique solution $\boldsymbol{x}^* = -\boldsymbol{Q}^{-1}\boldsymbol{c}$. The point $\boldsymbol{x}^*$ is a strict local (and global)minimizer of f if $\boldsymbol{Q}$ is positive definite, and a strict local (and global) maximizer of f if $\boldsymbol{Q}$ is negative definite. It is a saddle point if $\boldsymbol{Q}$ is indefinite.

Methods

The vast majority of algorithms for unconstrained minimization are iterative descent methods. At each iteration, a direction of descent (called the search direction) is computed at the current solution estimate $\boldsymbol{x}_k$; a step is then taken from $\boldsymbol{x}_k$ alongthe search direction, to obtain a new point a new point $\boldsymbol{x}_{k+1}$ such that $f(\boldsymbol{x}_{k+1}) < f(\boldsymbol{x}_k)$. The process is repeated till some test for convergence is satisfied. The effectiveness of an algorithm is, of course, dramatically affected by the choice of the search direction. A key question, of course, is how to obtain a good search direction. The underlying idea of most methods, is to compute a direction that minimizes some local approximation to the function. Typically, this local model is obtained from the Taylor series.

In Newton's method, the search direction at the current point $\boldsymbol{x}_k$ is the vector $\boldsymbol{p}_k$ that minimizes the local quadratic model:

$$\underset{\boldsymbol{p}}{\text{minimize}} \ f(\boldsymbol{x}_k) + \boldsymbol{p}^T \nabla f(\boldsymbol{x}_k) + \boldsymbol{p}^T \nabla^2 f(\boldsymbol{x}_k) \boldsymbol{p}.$$

If the Hessian $\nabla^2 f(\boldsymbol{x}_k)$ is positive definite, the minimizer of the quadratic model is the solution to the linear system of equations

$$\nabla^2 f(\boldsymbol{x}_k) \boldsymbol{p} = -\nabla f(\boldsymbol{x}_k),$$

known as the Newton equations. The resulting iteration takes the form

$$\boldsymbol{x}_{k+1} = \boldsymbol{x}_k + \boldsymbol{p}_k,$$

where $\boldsymbol{p}_k$ is the solution to the Newton equations.

If the initial point $\boldsymbol{x}_0$ is sufficiently close to a local minimizer $\boldsymbol{x}^*$, and if $\nabla^2 f(\boldsymbol{x}^*)$ is positive definite, then under mild conditions the iterates generated by Newton's method converge to $\boldsymbol{x}^*$. Furthermore, the rate of convergence is quadratic. This means that for large k, the error at an iteration is proportional to the square of the error in the previous iteration:

$$\|\boldsymbol{x}_{k+1} - \boldsymbol{x}^*\| \leq \gamma \|\boldsymbol{x}_k - \boldsymbol{x}^*\|^2$$

for some positive constant γ. Roughly this means that towards the end, the number of significant digits in the iterates double at each iteration. The mild conditions

mentioned are requirements that ensure the Hessian matrix does not fluctuate wildly. A commonly used condition is Lipschitz continuity of the Hessian, namely that

$$\left\|\nabla^2 f(\boldsymbol{x}) - \nabla^2 f(\boldsymbol{y})\right\| \leq L\|\boldsymbol{x}-\boldsymbol{y}\|$$

for all $\boldsymbol{x}$ and $\boldsymbol{y}$ in $\Re^n$ and some finite constant L.

The rapid convergence of Newton's method near the solution makes it an extremely attractive method, and indeed, the method can be highly effective. However, the algorithm may fail if started from an initial point that is not sufficiently close to a minimizer. Why? First, if the Hessian $\nabla^2 f(\boldsymbol{x}_k)$ is not positive definite, the Newton direction may not be a descent direction, and if the Hessian is singular, the method is not even defined. Second, even if $\boldsymbol{p}_k$ is a descent direction, there is no guarantee that $f(\boldsymbol{x}_{k+1})$ will actually be lower than $f(\boldsymbol{x}_k)$. Thus, modifications to the basic Newton method are required to guarantee that the method will converge regardless of the starting point.

There are two major approaches to guarantee global convergence (convergence from any initial point): line search methods and trust-region methods. Both approaches use the basic Newton method near the solution to exploit its rapid local convergence property. But they differ in the strategies they employ to guarantee convergence when far from the solution. Both approaches insist, however, on using a descent direction at each iteration.

Line search methods update the new estimate of the solution as $\boldsymbol{x}_{k+1} = \boldsymbol{x}_k + \alpha_k \boldsymbol{p}_k$, where the step length α_k is a positive scalar chosen so that $f(\boldsymbol{x}_{k+1}) < f(\boldsymbol{x}_k)$. Ideally, this step length would be chosen to minimize $f(\boldsymbol{x}_k + \alpha \boldsymbol{p}_k)$ with respect to α. However, finding such a step length is too time consuming. A more practical approach is to use a step length that approximately minimizes f along $\boldsymbol{p}_k$. One commonly used condition (known as the Wolfe condition) is to accept a trial step α_k if

$$\left|\boldsymbol{p}_k^T \nabla f(\boldsymbol{x}_k + \alpha_k \boldsymbol{p}_k)\right| \leq \theta \left|\boldsymbol{p}_k^T \nabla f(\boldsymbol{x}_k)\right|,$$

where θ is some scalar satisfying $0 < \theta < 1$, i.e., if a step of length α_k taken along $\boldsymbol{p}_k$ yields a substantial decrease in the magnitude of the directional derivative. This condition alone cannot guarantee convergence, since it does not guarantee decrease in the objective value. It is therefore common to impose an additional sufficient decrease condition on α_k:

$$f(\boldsymbol{x}_k + \alpha_k \boldsymbol{p}_k) \leq f(\boldsymbol{x}_k) + \eta \alpha_k \boldsymbol{p}_k^T \nabla f(\boldsymbol{x}_k)$$

where $0 < \eta < 1$. This is known as the Armijo condition. If the Wolfe and Armijo conditions are used in tandem, and if $\eta < \theta$, then under appropriate conditions, global convergence of the algorithm is guaranteed.

Line search versions of Newton's method must also incorporate some strategy to handle the case when the Hessian is not positive definite. One standard technique is to modify the Hessian matrix by a diagonal matrix, denoted $\boldsymbol{E}_k$, whose diagonal componentsare large enough to ensure that the modified Hessian is indeed positive definite. The modified Newton direction is then computed as the solution to the system

$$\boldsymbol{B}_k \boldsymbol{p}_k = -\nabla f(\boldsymbol{x}_k),$$

where

$$\boldsymbol{B}_k = \nabla^2 f(\boldsymbol{x}_k) + \boldsymbol{E}_k.$$

The approach generates descent directions and can overcome the numerical difficulties associated with near-singular Hessians.

Trust region methods differ from line search methods in that they determine a priori the maximum length of the search direction, say Δ. The direction is taken as the minimizer of the quadratic model, whose length does not exceed Δ for the trial step $\boldsymbol{p}_k$:

$$\underset{\boldsymbol{p}}{\text{minimize}}\ q(\boldsymbol{p}) = f(\boldsymbol{x}_k) + \nabla f(\boldsymbol{x}_k)^T \boldsymbol{p} + \tfrac{1}{2}\boldsymbol{p}^T \nabla^2 f(\boldsymbol{x}_k)\boldsymbol{p}$$
$$\text{subject to } \|\boldsymbol{p}\| \leq \Delta.$$

The motivation for this approach is that the quadratic model obtained from the Taylor series gives an adequate fit to the function for points that are close to $\boldsymbol{x}_k$, but may not give an adequate fit for points far away.

The length Δ is the radius of the trust region, the region in which the quadratic model is trusted. It is adjusted from iteration to iteration, based on the agreement between the function f and the quadratic model. It is increased if the agreement is considered

to be good, and decreased if it is considered to be poor. The criterion used for determining this is the value of

$$\rho = \frac{f(\boldsymbol{x}_k) - f(\boldsymbol{x}_k + \boldsymbol{p}_k)}{f(\boldsymbol{x}_k) - q(\boldsymbol{p}_k)},$$

which is the ratio of actual reduction in the function value to that predicted by the quadratic model. If this ratio is large, it is assumed that the quadratic model can be trusted in a wider region and Δ is increased. If it is small, the quadratic model is deemed inadequate (hence the model cannot be trusted) and Δ is decreased.

Global convergence is achieved under mild conditions. If f is twice continuously differentiable and the set $\{\boldsymbol{x} : f(\boldsymbol{x}) \leq f(\boldsymbol{x}_0)\}$ is bounded, the method converges to a stationary point. In practice, however, the solution to the trust region problem is relatively expensive and often only approximate solutions are attempted.

Modified Newton's methods (both line-search and trust-region variants), are effective for solving small-or moderate-sized problems. As the number of variables increases, however, the cost of each iteration can become prohibitive. The solution of the $n \times n$ system of Newton equations is expensive, on the order of n^3 arithmetic operations. Furthermore, computation of the n^2 second partial derivatives can also be expensive and is prone to human error. Thus, the benefits of fast local convergence are offset by the high costs of each iteration.

Some remedies for these concerns are possible. For example, it is possible to automate the derivative calculations Also, many large problems have sparse Hessian matrices, and special numerical linear algebra techniques for sparse matrices can reduce the storage and computational costs of using Newton's method.

Another alternative is algorithms that compromise on Newton's method by using first derivative only to compute an approximate Newton direction. The driving motivation in these algorithms is to reduce the expensive cost per iteration of Newton's method while retaining reasonably good convergence rates. While one can no longer expect a compromise on Newton's method to achieve a quadratic rate of convergence, it is still possible to achieve superlinear convergence, where

$$\lim_{k \to \infty} \frac{\|\boldsymbol{x}_{k+1} - \boldsymbol{x}^*\|}{\|\boldsymbol{x}_k - \boldsymbol{x}^*\|} = 0.$$

To achieve this, the search direction must approach the Newton search direction in the limit, as the solution is approached. Specifically, if $\nabla^2 f$ is Lipschitz continuous, and if the sequence $\{\boldsymbol{x}_k\}$ generated by

$$\boldsymbol{x}_{k+1} = \boldsymbol{x}_k + \boldsymbol{p}_k.$$

converges to $\boldsymbol{x}^*$, where $\nabla^2 f(\boldsymbol{x}^*)$ is positive definite, then $\{\boldsymbol{x}_k\}$ converges to $\boldsymbol{x}^*$ superlinearly and $\nabla f(\boldsymbol{x}^*) = 0$ if and only if

$$\lim_{k \to \infty} \frac{\|\boldsymbol{p}_k - \boldsymbol{p}_k^N\|}{\|\boldsymbol{p}_k\|} = 0,$$

where $\boldsymbol{p}_k^N$ is the Newton direction at $\boldsymbol{x}_k$.

These results motivate a general Newton-type framework for unconstrained optimization algorithms, which attempt to find an approximate Newton direction. The search direction is obtained by solving the system

$$\boldsymbol{B}_k \boldsymbol{p}_k = -\nabla f(\boldsymbol{x}_k),$$

where $\boldsymbol{B}_k$ is a positive definite approximation to the Hessian.

The simplest of all such approximations sets $\boldsymbol{B}_k$ to be the identity matrix. The resulting search direction is $\boldsymbol{p}_k = -\nabla f(\boldsymbol{x}_k)$. A line search is needed, so that the resulting iterates are $\boldsymbol{x}_{k+1} = \boldsymbol{x}_k - \alpha \nabla f(\boldsymbol{x}_k)$. The method is known as the steepest descent method. (Technically it is not a Newton-type method since $\boldsymbol{B}_k$ is usually a poor approximation to the Hessian).

The method is simple, requires only one derivative calculation, does not require the computation of second derivatives, does not require that a system of linear equations be solved to compute the search direction, and does not require matrix storage. So in every way it reduces the costs of Newton's method—at least, the costs per iteration.

On the negative side, it has a slower rate of convergence than Newton's method, only converging at a linear rate, so that

$$\|\boldsymbol{x}_{k+1} - \boldsymbol{x}^*\| \leq c \|\boldsymbol{x}_k - \boldsymbol{x}^*\|.$$

The trouble is that the constant c can be very close to 1, so that the improvements from iteration to iteration can be imperceptible. In fact, even for the simple quadratic function $f(\boldsymbol{x}) = \frac{1}{2}\boldsymbol{x}^T \boldsymbol{Q} \boldsymbol{x}$, using an

exact line search, it can be shown that the improvements in the objective value from one iteration to the next are of order

$$1 - \left[\frac{\kappa(\boldsymbol{Q}) - 1}{\kappa(\boldsymbol{Q}) + 1}\right]^2,$$

where $\kappa(\boldsymbol{Q})$ is the condition number of $\boldsymbol{Q}$. If $\kappa(\boldsymbol{Q})$ is large (close to 1, as is often the case in practice), convergence is so slow that $\boldsymbol{x}_{k+1} - \boldsymbol{x}_k$ is below the precision of computer arithmetic and the method fails. As a result, even though the costs per iteration are low, the overall costs of solving the optimization problem are high. The method is usually not a viable option for large difficult problems.

A more successful Newton-type family of methods are the quasi-Newton methods. Quasi-Newton methods are a class of methods that are motivated by Newton's method but avoid the expense of computing second derivatives. The search direction is obtained by solving the system

$$\boldsymbol{B}_k \boldsymbol{p} = -\nabla f(\boldsymbol{x}_k),$$

where $\boldsymbol{B}_k$ is an approximation to the Hessian $\nabla^2 f(\boldsymbol{x}_k)$. The matrix $\boldsymbol{B}_{k+1}$ is updated from $\boldsymbol{B}_k$ using gradient information from previous iterations.

In the one-dimensional case, quasi-Newton methods simply replace the second derivative by the slope of the secant line to the first derivative:

$$f''(\boldsymbol{x}_{k+1}) \approx \frac{f'(\boldsymbol{x}_{k+1}) - f'(\boldsymbol{x}_k)}{\boldsymbol{x}_{k+1} - \boldsymbol{x}_k},$$

so that

$$f''(\boldsymbol{x}_{k+1})(\boldsymbol{x}_{k+1} - \boldsymbol{x}_k) \approx f'(\boldsymbol{x}_{k+1}) - f'(\boldsymbol{x}_k).$$

To make $\boldsymbol{B}_{k+1}$ resemble the Hessian in the n-dimensional case requires that it satisfy the secant condition

$$\boldsymbol{B}_{k+1} \boldsymbol{s}_k = \boldsymbol{y}_k,$$

where

$$\boldsymbol{s}_k = \boldsymbol{x}_{k+1} - \boldsymbol{x}_k \text{ and } \boldsymbol{y}_k = \nabla f(\boldsymbol{x}_{k+1}) - \nabla f(\boldsymbol{x}_k).$$

The secant condition, however, does not uniquely define the matrix $\boldsymbol{B}_k$, so numerous methods have been proposed for updating $\boldsymbol{B}_{k+1}$ from $\boldsymbol{B}_k$. The most popular—and arguably most successful—of these methods has been the BFGS (Broyden, Fletcher, Goldfarb, Shanno) method, for which the update formula for the Hessian approximation is given by

$$\boldsymbol{B}_{k+1} = \boldsymbol{B}_k - \frac{(\boldsymbol{B}_k \boldsymbol{s}_k)(\boldsymbol{B}_k \boldsymbol{s}_k)^T}{\boldsymbol{s}_k^T \boldsymbol{B}_k \boldsymbol{s}_k} + \frac{\boldsymbol{y}_k \boldsymbol{y}_k^T}{\boldsymbol{y}_k^T \boldsymbol{s}_k}.$$

The matrix $\boldsymbol{B}_0$ is usually set to the identity matrix. Under appropriate conditions on the line search, it is possible to guarantee that if the BFGS method is applied to a bounded strictly convex function, then the BFGS method converges superlinearly to the unique global minimizer.

Quasi-Newton methods have been successful at solving a wide variety of practical problems, and are perhaps the most widely used methods for nonlinear optimization. However, their storage requirements and iteration costs can make them less suited for problems that have many variables. Limited memory quasi-Newton methods are a modification to quasi-Newton methods that require much less storage and much lower arithmetic costs per iteration. Rather than store the matrix $\boldsymbol{B}_k$, they store a few vectors that provide the information to store a matrix close to $\boldsymbol{B}_k$.

Another class of methods suitable for large problems are truncated-Newton methods. These methods are a compromise on Newton's method. They obtain the search direction by finding an approximate solution to the Newton equations, using some iterative method such as the conjugate-gradient method. The iterative method is stopped before the exact solution has been found, hence the name of the method. The methods do not require explicit computation of the Hessian, and only require the storage of a few vectors. They have been used successfully to solve problems with large number of variables.

Concluding Remarks

The theory and methods of unconstrained optimization are discussed in extensive detail in Dennis and Schnabel (1983), Gill, Murray and Wright (1981), Nash and Sofer (1996), Griva, Nash, and Sofer (2008), Nesterov (2004), and Nocedal and Wright (2006). For a guide to software for numerical

optimization, see Moré and Wright (1993) and the online NEOS Optimization Software Guide. This article focused on methods for computing local optima of differentiable functions; for a survey of methods for optimizing nondifferentiable functions, see Lemarechal (1989), and for a survey of derivative-free methods, see Kolda, Lewis and Torczon (2003). A survey of methods for global optimization is given in Rinnooy Kan and Timmer (1989) and in Horst, Pardalos and Thoai (2000).

Unconstrained Solution

A solution that is independent or free of constraints.

Uncontrollable Variables

In a decision problem, variables and other elements of a decision problem that are not under the control of the decision maker.

See

- ▶ Decision Maker (DM)
- ▶ Decision Problem
- ▶ Mathematical Model

Underachievement Variable

A nonnegative variable in a goal-programming problem constraint that measures how much the left-hand side of the constraint is less than the right-hand side.

See

- ▶ Goal Programming

Underdetermined System of Linear Equations

An $m \times n$ system of linear equations $\boldsymbol{Ax} = \boldsymbol{b}$ in which $m < n$. Such systems may have an infinite number of solutions or be inconsistent. The equation form of a linear-programming problem is under-determined.

Undirected Arc

In a network, an arc where flow can go in either direction.

Unimodular Matrix

An $m \times n$ matrix $\boldsymbol{A}$ such that any nonsingular square matrix formed by columns of $\boldsymbol{A}$ has a determinant value equal to +1 or −1. The matrix of the transportation problem is unimodular.

Unique Solution

The optimal solution to an optimization problem that has one and only one optimal solution.

See

► Multiple Optimal Solutions

Unrestricted Variable

A variable that can take on any value.

See

► Free Variable

Unsymmetric Primal-Dual Problems

The two linear-programming problems with the following:

Primal

$$\text{Minimize} \quad \boldsymbol{c}^T\boldsymbol{x}$$
$$\text{subject to} \quad \boldsymbol{A}\boldsymbol{x} = \boldsymbol{b} \quad \boldsymbol{x} \geq \boldsymbol{0}$$

Dual

$$\text{Maximize} \quad \boldsymbol{b}^T\boldsymbol{y}$$
$$\text{subject to} \quad \boldsymbol{A}^T\boldsymbol{y} \leq \boldsymbol{c}$$

Note that the variables of the dual problem are unrestricted.

Urban Services

Kenneth Chelst
Wayne State University, Detroit, MI, USA

Introduction

Urban services cover a broad range of activities. These include sanitation and water systems; street cleaning to remove trash, snow, and ice; public housing; urban transportation systems; libraries (Reisman and Xu 1994); public health clinics; and other local government services. This article describes representative applications of operations research that improve the efficiency of these services. Emergency services such as police, fire, and emergency medical services are covered elsewhere in this volume.

Routing

One planning function common to many of the services listed above is the need to design efficient vehicle routes that minimize the cost of the service, primarily through minimization of travel time (Laporte 2009). Garbage collectors travel up and down streets, stopping in front of each house to pick up trash. Street sweepers move along curbsides sweeping up garbage while avoiding parked cars. Snowplows and salt trucks make their way through snow-covered arteries preparing them for smooth and safe traffic flow. This last example is the most complicated form of routing because highways and wide streets will require multiple passes over the same route.

This class of routing problems is much more complicated than designing routes to deliver mail (see Chinese Postman Problem). In an urban context, route planning can involve a large number of vehicles,

one- and two-way streets, and opportunities for U-turns. The commonality of problem structure has led to the development of GeoRoute, a software program with separate modules to address multiple decisions that involve traversing the streets of a region.

Snow Clearance

Langevin et al. (2006, 2007) wrote a four-part comprehensive review of operations research models and decision support systems designed for the planning and management of snow clearance and removal. They begin with an overview of issues associated with each class of decisions: spreading chemicals or sand, snowplowing, and snow removal. Planning for road clearance and snow removal involves a number of interrelated decisions. The building block for all decisions is the establishment of service levels for each road segment within the region. The service level defines the degree to which snow and ice will be removed from the road surface and over what time frame. Regression models and cost-benefit analysis have been used to establish service levels.

Strategic decisions include determining the size of the fleet of vehicles and the location of chemical storage depots and snow disposal sites. Related decisions involve the selection of de-icing agent and the process for disposing of snow. A linear mixed-integer programming model has been proposed as an integrated approach to decisions regarding depot location and sector design.

Operational decisions focus on developing efficient routes designed to meet service levels within specified time constraints. The planning of routes begins by dividing a region into sectors to be serviced by one or more vehicles. The sectors are generally designed to balance workloads and to be efficient in terms of travel to and from de-icing storage facilities and snow disposal sites. Once sectors have been defined, routes within each sector are specified.

Salt spreaders are typically on the road in the early stages of a snowstorm with the goal of keeping roads free of ice as much as possible before massive amounts of snow overwhelm the road network. Snowplows move in next to clear larger amounts of snow. This, too, may start before the storm has ended. The routing of chemical dispersers and snowplows is complicated by the need for real-time decisions. Routes need to be adjusted as weather and road conditions evolve during the course of the snowstorm. These routes may be further complicated by accidents blocking access to specific routes. The growing availability of routine real-time road conditions and GPS on vehicles makes the routing process more dynamic. Lastly, after large storms, snow blowers hit the roads accompanied by trucks that carry the snow to disposal sites. Planning snow removal routes involves two dimensions, with allocation of both snow blowers and snow removers. There needs to be a steady stream of trucks accompanying the snow blower.

A wide variety of OR models and software systems have been developed to address different decisions within this broad problem context. Some of the systems are descriptive simulations linked to mapping software that enable decision makers to evaluate the impact of their decisions on road clearance, capital investment, and operating costs. Others are constructive: they design routes, recommend storage locations, and establish work-shift schedules. Some attempt to place many of the decisions into a complex, large-scale optimization model. In almost every instance, these tools are embedded in user-friendly decision support systems that enable the decision maker to use his experience to make informed decisions that take into account local conditions.

Solid Waste Collection and Disposal

Solid waste management begins with citizens disposing of their garbage in bins to be emptied by trucks routed through streets and neighborhoods. If the city recycles, there will be multiple receptacles to be emptied. Both constrained p-median and set-covering models have been developed to optimize the locations of these bins (Devotta et al. 2008). The next task is to devise efficient routes (Beltrami and Bodin 1974). The garbage collection problem has an added complexity due to randomness in the volume of trash. As routes are planned, it is not possible to predict exactly how many stops a truck will make before it reaches capacity A related strategic decision is the size of the

collection trucks. This decision becomes more complex with disparate recyclables. In this case, the storage compartment must be divided to accommodate different types and amounts of recyclables. Once the garbage has been collected, it is transported either directly to a final disposal site, a transfer site, or an intermediate processing facility. Classical location models have been used to identify both transfer sites and end points (Eiselt 2007).

In New York City, operations research has had a broad impact on the sanitation department that goes beyond route planning. Workload forecasting models were developed to plan personnel needs, reduce overtime, shift vacations to off-peak seasons, and plan for the hiring of new personnel. Analyses were carried out to assess the impact of increasing the capacity of trucks. A simulation model was developed to understand the impact of even one illegally parked car on the effectiveness of a street sweeper. This information was used to help coordinate efforts with the traffic enforcement division. One innovation involved the creation of Project Scorecard, a program designed to sample 6,000 blocks each month to track how dirty the streets were and not just how much garbage was collected. The OR group also carried out a variety of studies to determine the impact of different regulations for separation of trash to facilitate recycling. In summary, operations research has fundamentally changed the way New York City makes decisions about street cleaning and the way the sanitation department manages its resources (Riccio et al. 1986).

Hazardous wastes management is much broader than just routing garbage collection trucks and location of facilities. There are a number of policy decisions that relate to what to recycle and how much responsibility to place on the individual. There is also the strategic decision of whether to send the waste to a landfill or an incineration facility. These issues are discussed in more detail in the article "Environmental Systems Analysis."

Public Housing

Operations research has much to offer urban services that do not involve routing or collection issues. In many urban environments, cities build and rent subsidized housing to the poor and the elderly. One of the first issues addressed by the Local Government Operational Unit of Reading, England, was ranking applicants for the 100,000 housing units owned by the City of Manchester. A housing points scheme was developed that captured the perspectives of housing department officials on relative need. Through the use of paired comparisons, they were able to answer questions such as whether an applicant with a medical problem should be given more points than one living in crowded conditions (Ricthie et al. 1996).

In the U.S., operations researchers have used queueing theory to evaluate two alternative tenant assignment policies, namely, first available unit versus priority assignment. They evaluated mean waiting times and the impact of assignment policies on racial integration. In a second study on the redevelopment of a housing project in East Boston, researchers used integer programming to plan the sequential relocation of housing tenants (Kaplan and Berman 1988).

In the 1990s, the U.S. began changing its preferred model for public housing. Instead of concentrating the poor in specialized housing units, the government initiated the Federal Housing Choice Voucher Program. Vouchers are used at the discretion of the recipients to rent apartments in the neighborhoods of their choice. These subsidies enable the poor to live closer to job opportunities and benefit from a higher communal standard of living, such as better schools and lower crime rates. The program also affords greater opportunity for racial integration on a modest scale. One disadvantage, however, is that recipients are separated from their core community and support system.

Operations researchers have developed models to address both policy and personal decisions. At the policy level, they have developed a multi-objective model to determine pareto optimal solutions for locating clusters of subsidized rental units in neighborhoods throughout a county or metropolitan region. The model explicitly accounts for multiple perspectives: those of renters of subsidized housing, nearby residents, and employers. An objective function assigns a weight to each perspective. The model includes several constraints that limit the number of units assigned to any one area.

With regard to personal decisions, OR models are applied to the decision of where to rent. A decision support system was developed for the Pittsburgh

Housing Authority to facilitate this process, designed to be used both by renters and housing authority counselors. The system applies the concepts of value-focused thinking to help the renter determine his multiple objectives. It is linked to a comprehensive GIS that includes numerous communal measures as well as listings of housing unit availability. This system helps the counselor and renter rank-order the renter's preferred housing choices and presents him with detailed neighborhood information. The system is also designed to help landlords who are interested in contributing units to the subsidized housing rental pool (Johnson 2005).

Urban Transportation Services

The issues surrounding the delivery of urban mass transit services have been studied from a broad range of disciplines. Economists have led the study of the relationship between fare structure (price) and demand. Urban and regional planners have researched the role of mass transit in urban and regional development. Statisticians have tackled the complex problem of estimating the origin–destination matrix that is critical in planning to meet route specific demand. Civil engineers have made both road and mass transit transportation planning a major component of their discipline and have often used operations research models in their studies or teamed with operations researchers. The journal *Transportation Science* is a focal point for reporting the latest research in this and related fields. In this review, the discussion is limited to the use of OR models.

Transportation services can be viewed from three perspectives, the passenger, the crew, and the infrastructure needed to provide the service (e.g., vehicles and facilities). The passenger is interested in traveling from point A to point B in the most cost- and time-efficient ways. The journey begins with travel from home or work to the bus stop or train station. Set-covering models have been used to increase accessibility to the nearest bus station (Murray 2003).

The design of transit routes and the scheduled frequency of trains or buses (e.g., headway) are the key management decisions that influence passenger experiences (Szeto and Wu 2011). Probabilistic models such as simulation in general and queueing models in particular have been developed to estimate passenger waiting times for both rail and bus services under a variety of operational strategies. In Australia, a software system called BUDI is used to address the issue of bus dispatching (Forbes et al. 1994).

It is common in bus transit for several buses to arrive at a particular stop within a relatively short period of time, followed by a relatively long wait until the next group of buses. Early research explored a range of static policies to address this phenomenon (Larson and Odoni 1981). The increased availability of real-time data on the location of each bus, however, has led to dynamic policies that recommend changes in speed so as to maintain a consistent headway between buses (Daganzo and Pilachowski 2011).

The elderly and handicapped have difficulty using mass transit to meet their travel needs. Taxis are an expensive alternative. Dial-a-Ride mini-bus systems fill the gap by picking up passengers upon request from multiple points and delivering them to different locations. These routes are constrained by time windows. Dynamic programming, clustering, and specially designed heuristic algorithms have been developed and used to efficiently manage the complex dispatching operation associated with Dial-a-Ride Cordeau and Laporte 2007).

Demand for transportation services varies significantly by time of day. Personnel and vehicle schedules must adjust accordingly to be cost-effective. Operations researchers have addressed this issue of manpower and rotation scheduling with mathematical programming models as well as HASTUS, a software package used to develop schedules for both personnel and vehicles (Blais et al. 1990). The Italian Railway Corporation has worked with the Italian Operational Research Society to sponsor university competitions for the design of effective heuristics. Random absences of personnel produce an added burden on managing an already complex system. Probabilistic models have been developed to help transportation managers pool resources to fill in unanticipated personnel shortages.

Garages and crew rosters are an important element of any municipal bus system (Ball et al. 1984; Caprara et al. 1998). Buses and drivers start and end their shifts at garages, and most maintenance occurs in these facilities. The decision as to the number and location of these garages has been analyzed by applying iteratively a minimum cost network flow model. A related question,

common to all capital-intensive systems, involves the maintenance of capital equipment. This issue falls within the broad range of operations research methods that model reliability, optimal maintenance, and replacement strategies. One statistical study of 2,000 buses in Montreal analyzed the relationship between inspection and breakdowns and suggested that the optimal inspection policy be changed from 5,000 kilometers to 8,000. Multi-criteria decision models have been used to develop component maintenance policies that focus not only on total maintenance cost but also transit vehicle availability and component reliability (Goplalaswamy et al. 1993).

Other Services

In an urban environment, one common problem that cuts across a broad range of both government and non-government services is how many facilities to build and where they should be located. Classic facility location models, both capacitated and uncapacitated, have been applied to address this decision in cities around the world. The urban setting often requires the organization of specialized delivery services that involve the scheduling and routing of multiple vehicles, usually with time constraints. One specific application area has been the delivery of meals (Johnson et al. 2002). Traveling salesman-based routing models have been used to develop and maintain efficient routes for a Meal-on-Wheels program that provides regular service to the homebound elderly. Another application is the delivery of home-care services to AIDS patients in Rome (De Angelis 1998). In general, OR models can help manage the delivery of a variety of services to the homes of an increasingly elderly urban population (Eveborn et al. 2009).

The role of operations researchers is not limited to model development; it also includes evaluation studies, discussion of performance evaluation, and concerns over equity. However, OR's overall impact on planning and managing urban services in cities worldwide has been extremely limited compared to its potential. The primary barriers to greater use are (a) an unfamiliarity among urban leaders regarding the potential of OR models to improve efficiency, (b) the limited availability of trained OR professionals in city government, and (c) a no-profit incentive or lack of accountability to drive the search for continuous improvement.

Utility Theory

Peter Fishburn
AT&T Bell Laboratories, Murray Hill, NJ, USA

Introduction

Utility theory is the systematic study of preference structures and ways to represent preferences quantitatively. The objects on which preferences are defined could be potential outcomes of a decision, decision alternatives, individual or family consumption bundles in a fixed time period, time streams of net profits, investment portfolios, the entrees on a restaurant menu, or just about anything else. The preferences themselves are usually those of an individual, but are sometimes attributed to groups or organizations.

Let A denote the set of objects on which preferences are defined and let $\succcurlyeq$ be a binary relation on A, that is, a set of ordered pairs (x, y) of objects in A. When (x, y) is a member of $\succcurlyeq$, it is customary to write $x \succcurlyeq y$ and to say that x is at least as preferred as y. If $x \succcurlyeq y$ and not $(y \succcurlyeq x)$, then x is (strictly) preferred to y; if $x \succcurlyeq y$ and $y \succcurlyeq x$ then x and y are equally preferred, or are indifferent; if neither $x \succcurlyeq y$ nor $y \succcurlyeq x$ then x and y are preferentially incomparable. Strict preference and indifference are denoted by $x \succ y$ and $x \sim y$, respectively.

Utility theory typically regards the preference relation $\succcurlyeq$ on A as deterministic and interprets $x \succcurlyeq y$ as: if you have title to y you would be willing to trade it for title to x. There are also notions of uncertain or probabilistic preference that will not be described here. An excellent introduction to probabilistic preference and stochastic utility is provided by Luce and Suppes (1965).

Two book collections offer a broad overview of utility theory. Page (1968) contains historical essays, including an English translation of a 1738 paper by Daniel Bernoulli that introduced expected utility, a philosophical piece from 1823 by Jeremy Bentham that popularized the term utility, an excerpt from the game theory classic by John von Neumann and Oskar Morgenstern in 1944 that placed expected utility on a firm axiomatic foundation, and an economist's account by George Stigler of the development of utility theory from 1776 to 1915. The collection by Eatwell, Milgate and Newman (1990) covers many facets of utility theory, including several that are areas of contemporary research.

Distinguishing Features

There are numerous specific theories of utility. Each is distinguished by three features: (1) the structure of A; (2) the assumptions made about the properties of $\succcurlyeq$ on A; and (3) the quantitative representation that reflects $(A, \succcurlyeq)$ in a numerical structure.

Assumptions for feature 1 are structural assumptions, and those for feature 2 are preference

axioms. Together they are used to deduce the quantitative representation of feature 3. The representation's numerical functions are often called utility functions. Other real-valued functions, including probability distributions and threshold functions, also occur in representations.

An important adjunct of a utility representation is a description of the class of all functions that satisfy the representation. This is the representation's uniqueness structure. Some representations have very demanding uniqueness structures; others allow great latitude for their utility functions.

Two examples illustrate these ideas. First, let $A = \{\text{beef, chicken, fish, lamb}\}$ in regard to entrees for dinner. Assume for feature 2 that $\succ$ on A is a linear (strict) order, which, for all x, y and z in A, means that

$$\begin{aligned}&\succ \text{ is irreflexive: not } (x \succ x)\\ &\succ \text{ is complete: } x \neq y \rightarrow (x \succ y \text{ or } y \succ x)\\ &\succ \text{ is transitive: } (x \succ y \text{ and } y \succ z) \rightarrow x \succ z.\end{aligned}$$

One realization of $\succ$ on A is [beef $\succ$ lamb $\succ$ chicken $\succ$ fish]. This ordering is represented by a utility function u on A which assigns a number $u(x)$ to each x in A such that $[u(\text{beef}) > u(\text{lamb}) > u(\text{chicken}) > u(\text{fish})]$. There is great latitude for u. Every real-valued function on A whose $>$ ordering mirrors $>$ is a suitable utility function for the representation.

Second, let $A = [0, M]^3$, $0 < M$, the set of all triples (x_1, x_2, x_3) with $0 \leq x_i \leq M$ for each i. Interpret x_i as the income an individual earns in year i hence. One representation for feature 3 is the additive utility model

$$(x_1,x_2,x_3) \succcurlyeq (y_1,y_2,y_3) \rightarrow \sum_{i=1}^{3} u_i(x_i) \geq \sum_{i=1}^{3} u_i(y_i),$$

where each u_i is an increasing and continuous real-valued function on $[0, M]$. This requires that $\succcurlyeq$ on A be a weak order, which, for all x, y and z in A, means that

$$\begin{aligned}&\succcurlyeq \text{ is strongly connected : } x \succcurlyeq y \text{ or } y \succcurlyeq x\\ &\succcurlyeq \text{ is transitive : } (x \succcurlyeq y \text{ and } y \succcurlyeq z) \rightarrow x \succcurlyeq z.\end{aligned}$$

Another axiom that concerns additivity says that if two triples have identical incomes in a given year, then $\succcurlyeq$ between them remains unchanged if the identical income is changed, e.g.,

$$(x_1,x_2,x_3) \succcurlyeq (x_1,y_2,y_3) \rightarrow (y_1,x_2,x_3) \succcurlyeq (y_1,y_2,y_3).$$

Other axioms relate to monotonicity of utility in income and to continuity of each utility function.

The preceding model has a very tight uniqueness structure. In particular, when u_1, u_2 and u_3 satisfy the representation, then so do v_1, v_2 and v_3 in place of u_1, u_2 and u_3 respectively if and only if there are real numbers $\alpha > 0$ and β_1, β_2 and β_3 so that, for all m in $[0, M]$,

$$v_i(m) = \alpha u_i(m) + \beta_i, \quad i = 1, 2, 3.$$

Hence, except for an origin and unit, each u_i is unique.

The next few sections describe utility theories according to a three-part classification that mixes feature 1 with extra mathematical interpretations:

- certainty: there is no explicit use of chance or uncertainty;
- chance: chance in the form of numerical probabilities appears in A, but unquantified uncertainty is excluded;
- uncertainty: outcomes of decisions depend explicitly on uncertain events with not-yet-quantified probabilities.

Differences among classes can be illustrated by an object (m_1, m_2, m_3, m_4) in which each m_i is an amount of money. If the object describes a four-year income stream, the certainty designation applies. If the object is a gamble or risky prospect that pays off m_1, m_2, m_3 or m_4, each with probability 1/4, then chance applies. And if m_1 through m_4 are the amounts won for each dollar bet on your favorite horse in tomorrow's big race when the horse wins, places, shows and finishes out of the money, respectively, then uncertainty applies.

A differentiator for feature 2 is the extent to which preferences are transitive. The most restrictive case occurs when $\succcurlyeq$ is a weak order. Then each of $\succcurlyeq$, $\succ$ and $\sim$ is transitive. A more flexible case arises when $\succ$ but not $\sim$ is assumed transitive. Intransitive indifference is illustrated by a sequence of indifference comparisons $x_1 \sim x_2$, $x_2 \sim x_3, \ldots, x_{n-1} \sim x_n$ between similar objects, the first of which is definitely preferred to the last ($x_1 \succ x_n$). The most flexible case occurs when neither $\succ$ nor $\sim$ is assumed transitive. This allows

preference cycles, such as $x \succ y \succ z \succ x$. Fishburn (1991) provides access to the nontransitive preference literature.

Certainty

A basic theorem of utility theory for $(A, \succcurlyeq)$ says that a real number $u(x)$ can be assigned to each object in A so that, for all x and y in A,

$$x \succcurlyeq y \leftrightarrow u(x) \geq u(y),$$

if and only if $\succcurlyeq$ on A is a weak order and there is a countable (finite or denumerable) subset B of A such that, whenever $x \succ y$, some z in B satisfies $x \succcurlyeq z \succcurlyeq y$. A relaxation of this ordinal utility representation that accommodates intransitive indifference and thresholds for preference is

$$x \succ y \leftrightarrow u(x) > u(y) + \sigma(y),$$

where $\sigma(y) \geq 0$ for each y. This representation assigns a utility interval $[u(x), u(x) + \sigma(x)]$ to each x and has x preferred to y if and only if the right end of y's interval is less than the left end of x's interval. One of its preference axioms is

$$(x \succ a \text{ and } y \succ b) \rightarrow (x \succ b \text{ or } y \succ a).$$

A popular structure for preference theory formulates A as a subset of n-tuples $(x_1, \ldots, x_n)$, $(y_1, \ldots, y_n), \ldots$, in $\boldsymbol{X}_1 \times \boldsymbol{X}_2 \times \cdots \times \boldsymbol{X}_n$. Index i for $\boldsymbol{X}_i$ could refer to an attribute of objects in A or a time period. This product structure gives rise to special forms for the utility function u of the preceding paragraph, including the additive decomposition

$$u(x_{1,\ldots,}x_n) = \sum_{i=1}^{n} u_i(x_i)$$

in which u_i is a marginal utility function for the ith attribute or time period. A generalization that does not presume transitivity but retains additivity is

$$(x_1, \ldots, x_n) \succcurlyeq (y_1, \ldots, y_n) \leftrightarrow \sum_{i=1}^{n} \varphi_i(x_i, y_i) \geq 0,$$

where φ_i is defined on $\boldsymbol{X}_i \times \boldsymbol{X}_i$ and has $\varphi_i(x_i, x_i) = 0$.

Fishburn (1970, 1991), Keeney and Raiffa (1993) and Wakker (1989) have extensive coverage of the preceding topics.

Chance

The primary structure for chance takes A as a set of probability distributions on an outcome set X. For p in A, $p(x)$ is the probability that risky prospect p will yield outcome x. It is usually assumed as part of feature 1 that A is closed under convex combinations: if p and q are in A and $0 < \lambda < 1$, then $\lambda p + (1 - \lambda)q$ is also in A.

Two common preference axioms for $(A, \succcurlyeq)$ are weak order and the independence condition

$$p \succ q \rightarrow \lambda p + (1 - \lambda)r \succ \lambda q + (1 - \lambda)r$$

whenever p, q and r are in A and $0 < \lambda < 1$. When an Archimedean axiom is added to weak order and independence, the existence of a von Neumann-Morgenstern linear utility function u on A can be established. It has $p \succcurlyeq q \leftrightarrow u(p) \geq u(q)$ along with the linearity property

$$u(\lambda p + (1 - \lambda)q) = \lambda u(p) + (1 + \lambda)u(q),$$

and is unique except for origin and unit, i.e., unique up to transformations $\alpha u + \beta$ with $\alpha > 0$.

If A includes all distributions with finite support and $u(x)$ is defined as $u(p)$ when $p(x) = 1$, then linearity implies the expected-utility form

$$u(p) = \sum_{x} p(x)u(x)$$

for each finite-support distribution. Additional axioms are needed to obtain $u(p) = \int u(x)\, dp(x)$ for general probability measures.

Three variations on the expected-utility theme involve risk attitudes such as risk aversion when outcomes are monetary (Raiffa 1968; Wakker 1989), multiattribute expected utility when $\boldsymbol{X} = \boldsymbol{X}_1 \times \boldsymbol{X}_2 \times \cdots \times \boldsymbol{X}_n$, including additive and multiplicative decompositions of $u(x_1, \ldots, x_n)$ (Fishburn 1970; Keeney and Raiffa 1993; Wakker 1989), and generalizations of expected utility that relax one or more of its axioms (Fishburn 1988). A representation

that does not presume transitivity and substantially weakens the independence condition is $p \succcurlyeq q \leftrightarrow \varphi(p, q) \geq 0$, where φ is skew symmetric [$\varphi(p, q) + \varphi(q, p) = 0$] and linear separately in each argument.

Uncertainty

The main structure for uncertainty (Savage 1954) takes A as the set of functions $f, g, \ldots$, called acts from a set S of states into an outcome set X. If you choose f and state s occurs, your outcome is $f(s)$. It is presumed that one and only one state will occur, that you are uncertain which it will be, and that your chosen act will not affect its occurrence.

Savage's axioms (see also Fishburn 1970) for $(A, \succcurlyeq)$, which include weak order and independence assumptions, imply the existence of a bounded utility function u on X and a probability measure π on the set of all subsets of S such that, for all acts f and g,

$$f \succcurlyeq g \leftrightarrow \int_S u(f(s))d\pi(s) \geq \int_S u(g(s))d\pi(s).$$

Moreover, u is unique except for origin and unit, and π is unique.

Deduced probabilities in Savage's model are personal or subjective probabilities. The model itself is a subjective expected utility representation. The art of applying it to real-world problems is known as decision analysis (Raiffa 1968). Multiattribute and/ or time-stream outcomes occur in most applications.

Many other utility theories have been proposed for structures similar to Savage's. One strain relaxes his model by assuming monotonicity [$A \subseteq B \rightarrow \pi(A) \leq \pi(B)$] but not necessarily additivity [$\pi(A \cup B) = \pi(A) + \pi(B)$ when A and B are disjoint] for subjective probability. Another retains Savage's properties for π but relaxes transitivity to obtain

$$f \succcurlyeq g \leftrightarrow \int_S \varphi(f(s), g(s))d\pi(s) \geq 0,$$

with φ skew symmetric on $\boldsymbol{X} \times \boldsymbol{X}$. See Fishburn (1988) and Wakker (1989) for further details and references.

V

Vacation Model

A queueing model where the server(s) will periodically stop serving a pool of customers for some period – take a "vacation" – before resuming service. (Note that during the so-called vacation, a server could possibly be serving some other source of customers elsewhere in the system). The vacation policy governs when a server stops service and when service is resumed. For example, one simple policy would be to take a vacation whenever the queue is empty and resume after a fixed period of time.

See

- ► Queueing Theory
- ► Vacation Time

Vacation Time

In vacation models, the time starting from when a server stops serving customers (goes on "vacation") and ending when the server resumes serving customers.

See

- ► Cyclic Service Discipline
- ► Vacation Model

Validation

The process of determining how well a mathematical model of a real-world system conforms to reality for the purposes of the study being undertaken. Two key aspects of validity are face validity and predictive validity. Face validity is based on an examination of the assumptions and data going into the model for logical consistency and the review of the results by experts knowledgeable in the real world situation. Predictive validity is based on examining the model's predictions for events that were not used in building the model.

Value at Risk

Financial risk measure representing the maximum amount that can be lost over a given horizon with a specified probability, abbreviated as VaR. Mathematically, a quantile (or percentile) of the probability distribution of potential portfolio loss. For continuous probability distributions, VaR at the (1-α) 100% level is the value x such that $\Pr\{L > x\} = \alpha$,

S.I. Gass, M.C. Fu (eds.), *Encyclopedia of Operations Research and Management Science*,
DOI 10.1007/978-1-4419-1153-7,

where L represents the loss and α is generally 0.05 or 0.01, corresponding to 95% and 99% levels of VaR, respectively.

- Financial Engineering

Value Function

In a decision problem, let a be a feasible alternative from the set of all feasible alternatives A. Each alternative is measured against n attributes $(X_1,\ldots, X_n)$. The decision maker's (DM) problem is to choose an alternative $a \in A$ that maximizes the payoff vector of scores $[X_1(a), \ldots, X_n(a)] = \boldsymbol{X}(a)$. The value function is a real-valued, scalar function $v(\cdot)$ with the property that $v(\boldsymbol{X}(a)) > v(\boldsymbol{X}(b))$ if and only if the DM prefers alternative a to alternative b; and $v(\boldsymbol{X}(a)) = v(\boldsymbol{X}(b))$ if and only if the DM is indifferent between alternative a and alternative b. A similar concept can be found in dynamic programming and Markov decision processes.

Variance Reduction Techniques in Monte Carlo Methods

Jack P. C. Kleijnen[1], Ad A. N. Ridder[2] and Reuven Y. Rubinstein[3]
[1]Tilburg University, Tilburg, The Netherlands
[2]Vrije University, Amsterdam, The Netherlands
[3]Technion – Israel Institute of Technology, Haifa, Israel

Introduction

Monte Carlo methods are simulation algorithms to estimate a numerical quantity in a statistical model of a real system. These algorithms are executed by computer programs. Variance reduction techniques (VRT) are needed, even though computer speed has been increasing dramatically, ever since the introduction of computers. This increased computer power has stimulated simulation analysts to develop ever more realistic models, so that the net result has not been faster execution of simulation experiments; e.g., some modern simulation models need hours or days for a single 'run' (one replication of one scenario or combination of simulation input values). Moreover there are some simulation models that represent rare events which have extremely small probabilities of occurrence), so even modern computer would take centuries to execute a single run—were it not that special VRT can reduce theses excessively long runtimes to practical magnitudes.

Preliminaries

In this contribution the focus is to estimate a quantity

$$\ell = E(H(\mathbf{Y})), \tag{1}$$

where $H(\mathbf{Y})$ is the performance function driven by an input vector $\mathbf{Y}$ with probability density function $f(\mathbf{y})$. To estimate ℓ through simulation, one generates a random sample $\mathbf{Y}_i$ with $i = 1,\ldots,N$ from $f(\mathbf{y})$, computes the sample function $H(\mathbf{Y}_i)$, and the sample-average estimator

$$\hat{\ell}_N = \frac{1}{N}\sum_{i=1}^{N} H(\mathbf{Y}_i).$$

This is called crude Monte Carlo sampling (CMC). The resulting sample-average estimator is an unbiased estimator for ℓ. Furthermore, as N gets large, laws of large numbers may be invoked (assuming simple conditions) to verify that the sample-average estimator stochastically converges to the actual quantity to be estimated. The efficiency of the estimator is captured by its relative error (RE), i.e., the standard error divided by the mean: $\mathrm{RE} = \sqrt{\mathrm{Var}(\hat{\ell}_\mathrm{N})}/\mathrm{E}(\hat{\ell}_\mathrm{N})$. Applying the Central Limit Theorem, one easily gets that $z_{1-\alpha/2}\mathrm{RE} < \varepsilon$, where $z_{1-\alpha/2}$ is the $(1-\alpha/2)^{th}$ quantile of the standard normal distribution (typically one takes $\alpha = 0.05$ so $z_{1-\alpha/2} = 1.96$) if and only if

$$P(|\frac{\hat{\ell}_N - \ell}{\ell}| < \varepsilon) > 1 - \alpha. \qquad (2)$$

When (2) holds, the estimator is said to be $(1-\alpha, \varepsilon)$ -efficient.

To illustrate, consider the one-dimensional version of (1):

$$\ell = \int h(y) f(y)\, dy.$$

Monte Carlo integration is a good way to estimate the value of the integral when the dimension is much higher than one, but the concept is still the same. Monte Carlo integration has become an important tool in financial engineering for pricing financial products such as options, futures, and swaps (Glasserman 2003). This Monte Carlo estimate samples $Y_1, \ldots, Y_N$ independently from f and calculates

$$\hat{\ell}_N = \frac{1}{N}\sum_{i=1}^{N} h(Y_i).$$

Then $\hat{\ell}_N$ is an unbiased estimator for ℓ, and the standard error is

$$\sqrt{\mathrm{Var}\left(\hat{\ell}_N\right)} = \sqrt{\frac{1}{N}\mathrm{Var}(\mathrm{h}(\mathrm{Y}))} = \sqrt{\frac{1}{N}E\left(h(Y)-\ell\right)^2}$$
$$= \sqrt{\frac{1}{N}\int \left(h(y)-\ell\right)^2 f(y)\, dy}.$$

Hence, the relative error (or efficiency) of the estimator is proportional to $1/\sqrt{N}$. This is a poor efficiency in case of high-dimensional problems where the generation of a single output vector is costly and consumes large computing time and memory. VRT improve efficiency if they indeed require smaller sample sizes. To be more specific, consider again the performance measure (1), and assume that besides the CMC-estimator $\hat{\ell}_N$, a VRT results in another unbiased estimator, denoted $\hat{\ell}^*_N$, also based on a sample of N independent and identical observations. The VRT-estimator is said to be statistically more efficient than the CMC-estimator if

$$\mathrm{Var}(\hat{\ell}^*_\mathrm{N}) < \mathrm{Var}(\hat{\ell}_\mathrm{N}).$$

Then one usually computes the reduction factor for the variance:

$$\frac{\mathrm{Var}(\hat{\ell}_\mathrm{N}) - \mathrm{Var}(\hat{\ell}^*_\mathrm{N})}{\mathrm{Var}(\hat{\ell}_\mathrm{N})} \times 100\%.$$

Notice that this factor does not depend on the sample size N. Suppose that the reduction factor is $100r\%$, so $r = 1 - (\mathrm{Var}(\hat{\ell}^*)/\mathrm{Var}(\hat{\ell}))$, and suppose that $(1-\alpha, \varepsilon)$-efficiency is desired. The required sample size for the CMC-estimator is N, given by $z_{1-\alpha/2}\mathrm{RE} = \varepsilon$, which holds iff

$$\frac{\ell^2\varepsilon^2}{z^2_{1-\alpha/2}} = \mathrm{Var}(\hat{\ell}_\mathrm{N}) = \frac{1}{\mathrm{N}}\mathrm{Var}(\hat{\ell}_1) \Leftrightarrow \mathrm{N}$$
$$= \frac{\mathrm{z}^2_{1-\alpha/2}}{\ell^2\varepsilon^2}\mathrm{Var}(\hat{\ell}_1).$$

The same reasoning holds for the VRT-estimator with a required sample size N^*. Consequently, the reduction in sample size becomes

$$\frac{N - N^*}{N} = \frac{\mathrm{Var}(\hat{\ell}_1) - \mathrm{Var}(\hat{\ell}^*_1)}{\mathrm{Var}(\hat{\ell}_1)} = r,$$

which is the same reduction as for the variance.

Generating samples under a VRT consumes generally more computer time (exceptions are antithetic and common random numbers; see next

section). Thus to make a fair comparison with CMC, the computing time should be incorporated when assessing efficiency improvement. Therefore, denote the required time to compute $\hat{\ell}_N$ by $\mathrm{TM}(\hat{\ell}_\mathrm{N})$. Then the effort of an estimator may be defined to be the product of its variance and its computing time: $\mathrm{EFFORT} = \mathrm{Var} \times \mathrm{TM}(\hat{\ell}_\mathrm{N})$. Notice that the effort does not depend on the sample size, if the computing time of N samples equals N times the computing time of a single sample. Then the estimator $\hat{\ell}^*_N$ is called more efficient than estimator $\hat{\ell}_N$ if the former requires less effort:

$$\mathrm{EFFORT}(\hat{\ell}^*_\mathrm{N}) < \mathrm{EFFORT}(\hat{\ell}_\mathrm{N}).$$

Again, a reduction factor for the effort can be defined, and one can analyze the reduction in computer time needed to obtain $(1-\alpha, \varepsilon)$-efficiency.

Estimating the Probability of Rare Events

An important class of statistical problems assesses probabilities of risky or undesirable events. These problems have become an important issue in many fields; examples are found in reliability systems (system failure), risk management (value-at-risk), financial engineering (credit default), insurance (ruin), and telecommunication (packet loss); see Juneja and Shahabuddin (2006); Rubino and Tuffin (2009). These problems can be denoted in the format of this contribution by assuming that a set A contains all the risky or undesirable input vectors $\mathbf{y}$, so that (1) becomes

$$\ell = P(A) = P(\mathbf{Y} \in A) = E(I_A(\mathbf{Y})),$$

where I_A is the indicator function of the set A (and thus in (1) $H = I_A$). The standard error of the Monte Carlo estimator is easily computed as $\sqrt{\ell(1-\ell)/N}$. Hence, the relative error becomes

$$\mathrm{RE} = \frac{\sqrt{\ell(1-\ell)}}{\ell\sqrt{\mathrm{N}}} = \frac{\sqrt{(1-\ell)}}{\sqrt{\ell \mathrm{N}}}. \qquad (3)$$

This equation implies that the sample size is inverse proportional to the target probability ℓ when requiring a prespecified efficiency; for instance, to obtain (95%, 10%)-efficiency, the sample size should be $N \geq 385(1-\ell)/\ell$. This leads immediately to the main issue of this contribution; namely $\ell << 1$ so A is called a rare event. To illustrate, suppose $\mathbf{Y} = (Y_1, \ldots, Y_n)$, where Y_j $(j = 1, \ldots, n)$ are identically and independently distributed (IID) with finite mean $\mu = E(Y_1)$ and standard deviation $\sigma = \sqrt{\mathrm{Var}(\mathrm{Y}_1)}$. Denote their sum by $S(\mathbf{Y}) = Y_1 + \cdots + Y_n$, and let the rare event be $A = \{S(\mathbf{Y}) > n(\mu + \delta)\}$ for a positive δ. A normal approximation results for $n = 500, \delta = 0.5, \sigma = 1$ that $\ell \approx 2.5\mathrm{E}\text{-}29$. A (95%, 10%)-efficient CMC-estimator would need sample size $N \approx 1.5\mathrm{E}{+}31$; which is impossible to realize. For example, the practical problem might require the daily simulation of a financial product for a period of two years in which a single normal variate needs to be generated per simulated day. Fast algorithms for normal variate generation on standard PCs require about 20 s for E+9 samples. This gives only E+5 vector samples $\mathbf{Y}$ per second. Note that the number of calls of the random number generator (RNG) is at least $N \times n$, which in this numerical example equals 7.5E+ 33; this number is large, but modern RNGs can meet this requirement (L'Ecuyer 2006).

In conclusion, the desired level of efficiency of the CMC estimator for rare event problems requires sample sizes that go far beyond available resources. Hence, researchers have looked for ways to reduce the variance of the estimator as much as possible for the same amount of sampling resources. Traditional VRTs are common random numbers, antithetic variates, control variates, conditioning, stratified sampling and importance sampling (Law 2007; Rubinstein and Kroese 2008). Modern VRTs include splitting techniques, and quasi-Mont Carlo sampling (Asmussen and Glynn 2007; Glasserman 2003).

Antithetic and Common Random Numbers

Consider again the problem of estimating $\ell = E(H(\mathbf{Y}))$ defined in (1). Now let $\mathbf{Y}_1$ and $\mathbf{Y}_2$ be two input samples generated from $f(\mathbf{y})$. Denote $X_i = H(\mathbf{Y}_i)$ with $i = 1, 2$. Then $\hat{\ell} = (X_1 + X_2)/2$ is an unbiased estimator of ℓ with variance

$$\mathrm{Var}(\hat{\ell}) = \frac{1}{4}\left(\mathrm{Var}(\mathrm{X}_1) + \mathrm{Var}(\mathrm{X}_2) + 2\mathrm{Cov}(\mathrm{X}_1, \mathrm{X}_2)\right).$$

If X_1, X_2 would be independent (as is the case in CMC), then $\mathrm{Var}(\hat{\ell})$ would be $\frac{1}{4}(\mathrm{Var}(\mathrm{X}_1) + \mathrm{Var}(\mathrm{X}_2))$. Obviously, variance reduction is obtained if

$\mathrm{Cov}(\mathrm{X}_1, \mathrm{X}_2) < 0$. The usual way to make this covariance negative is as follows. Whenever the uniform random number U is used for a particular purpose (for example, the second service time) in generating $\mathbf{Y}_1$, use the antithetic number $1 - U$ for the same purpose to generate $\mathbf{Y}_2$. Because U and $1 - U$ have correlation coefficient -1, it is to be expected that $\mathrm{Cov}(\mathrm{X}_1, \mathrm{X}_2) < 0$. This can be formalized by the following technical conditions.

(a) The sample vector $\mathbf{Y} = (Y_1, \ldots, Y_n)$ has components Y_j that are one-dimensional, independent random variables with distribution functions F_j that are generated by the inverse transformation method; i.e., $Y_j = F_j^{-1}(U_j)$, for $j = 1, \ldots, n$.

(b) The performance function H is monotone.

Under these conditions, negative correlation can be proved (Rubinstein and Kroese 2008). In condition (a) the inverse transformation requirement can be replaced by the assumption that all Y_j-components are Gaussian: when $Y \sim \mathrm{N}(\mu, \sigma^2)$, then $\tilde{Y} = 2\mu - Y \sim \mathrm{N}(\mu, \sigma^2)$, and clearly Y and $\tilde{Y}$ are negatively correlated. This alternative assumption is typically applied in financial engineering for option pricing (Glasserman 2003).

The method of common random numbers (CRN) is often applied in practice, because simulationists find it natural to compare alternative systems under 'the same circumstances'; for example, they compare different queueing disciplines (such as First-In-First-Out or FIFO, Last-In-First-Out or LIFO, Shortest-Jobs-First or SJF) using the same sampled arrival and service times in the simulation.

To be more specific, let $\mathbf{Y}$ be an input vector for two system performances $E(H_1(\mathbf{Y}))$ and $E(H_2(\mathbf{Y}))$, and the performance quantity of interest is their difference

$$\ell = E(H_1(\mathbf{Y})) - E(H_2(\mathbf{Y})).$$

To estimate ℓ, two choices produce an unbiased estimator:

1. Generate one sequence of IID input vectors $\mathbf{Y}_1, \ldots, \mathbf{Y}_N$, and estimate ℓ by

$$\hat{\ell}_N^{(1)} = \frac{1}{N} \sum_{i=1}^{N} (H_1(\mathbf{Y}_i) - H_2(\mathbf{Y}_i)).$$

2. Generate two independent IID sequences of input vectors $\mathbf{Y}_1^{(1)}, \ldots, \mathbf{Y}_N^{(1)}$, and $\mathbf{Y}_1^{(2)}, \ldots, \mathbf{Y}_N^{(2)}$, and estimate ℓ by

$$\hat{\ell}_N^{(2)} = \frac{1}{N} \sum_{i=1}^{N} H_1(\mathbf{Y}_i^{(1)}) - \frac{1}{N} \sum_{i=1}^{N} H_2(\mathbf{Y}_i^{(2)}).$$

The first method is the CRN method, and is intuitively prefered because it reduces variability:

$$\mathrm{Var}(\hat{\ell}_{\mathrm{N}}^{(1)}) < \mathrm{Var}(\hat{\ell}_{\mathrm{N}}^{(2)}).$$

To prove this inequality, denote $X_i = H_i(\mathbf{Y}_i)$. Then $\hat{\ell} = X_1 - X_2$ is an unbiased estimator of ℓ with variance

$$\mathrm{Var}(\hat{\ell}) = \mathrm{Var}(\mathrm{X}_1) + \mathrm{Var}(\mathrm{X}_2) - 2\mathrm{Cov}(\mathrm{X}_1, \mathrm{X}_2). \quad (4)$$

If X_1 and X_2 are independent (as is the case in the second method), then (4) becomes $\mathrm{Var}(\mathrm{X}_1) + \mathrm{Var}(\mathrm{X}_2)$. Hence, variance reduction is obtained if $\mathrm{Cov}(\mathrm{X}_1, \mathrm{X}_2) > 0$ in (4). This requirement is precisely the opposite of what was needed in antithetic variates. To force the covariance to become positive through CRN, the uniform random number U used for a particular purpose in generating $\mathbf{Y}_1$, is used for the same purpose to generate $\mathbf{Y}_2$. This can be formalized by the technical conditions completely analogous to those for antithetic variates.

CRN is often applied not only because it seems 'fair' but also because CRN is the default in many simulation software systems; e.g., Arena compares different scenarios using the same seed—unless, the programmer explicitly selects different seeds to initialize the various sampling processes (arrival process, service time at work station 1, etc.) for different scenarios. Detailed examples are given in Law (2007), pp. 582–594.

So while the simulation programmers need to invest little extra effort to implement CRN, the comparisons of various scenarios may be expected to be more accurate; i.e., the what-if or sensitivity analysis gives estimators with reduced variances. However, some applications may require estimates of the absolute (instead of the relative) responses; i.e., instead of sensitivity analysis the analysis aims at prediction or interpolation from the observed responses for the scenarios that have already been simulated. In these applications, CRN may give worse predictions; also see Chen, Ankenman, and Nelson (2010).

The analysis of simulation experiments with CRN should go beyond (4), which compares only two scenarios. The simplest extension is to compare a fixed set of (say) k scenarios using (4) combined with the Bonferroni inequality so that the type-I error rate does not exceed (say) α; i.e., in each comparison of two scenarios the value α is replaced by α/m where m denotes the number of comparisons (e.g., if all k scenarios are compared, then $m = k(k-1)/2$). Multiple comparison and ranking techniques are discussed in Chick and Gans (2009).

However, the number of interesting scenarios may be not fixed in advance; e.g., the scenarios differ in one or more quantitative inputs (e.g., arrival speed, number of servers) and the optimal input combination is wanted. In such situations, regression analysis is useful; i.e., the regression model is then a metamodel that enables validation, sensitivity analysis, and optimization of the simulation model; see Kleijnen (2008). The estimated regression coefficients (regression parameters) may have smaller variances if CRN is used—because of arguments based on (4)—except for the intercept (or the 'grand mean' in Analysis of Variance or ANOVA terminology). Consequently, CRN is not attractive in prediction, but it is in sensitivity analysis and optimization.

A better metamodel for prediction may be a Kriging or Gaussian Process model, assuming the scenarios correspond with combinations of quantitative inputs; e.g., the scenarios represent different traffic rates in a queuing simulation. Kriging implies that the correlation between the responses of different scenarios decreases with the distance between the corresponding input combinations; i.e., the Gaussian process is stationary (Kleijnen 2008). In random simulation (unlike deterministic simulation, which is popular in engineering) the Kriging metamodel also requires the estimation of the correlations between the 'intrinsic' noises of different scenarios caused by the use of random numbers U; see Chen et al. (2010).

An important issue in the implementation of Antithetics and CRN is synchronization, which is a controlling mechanism to ensure that the same random variables are generated by the same random numbers from the random number generator. As an example, consider comparing a single-server queue $GI/GI/1$ with a two-server system $GI/GI/2$. The two systems have statistically similar arrivals and service times, but the single server works twice as fast. The performance measure is the expected waiting time per customer (which is conjectured to be less in the two-server system). In a simulation study, the two simulation models with CRN should have the same arrival variates, and the same service-time variates. Suppose that $A_1, A_2, \ldots$ are the consecutive interarrival times in a simulation run of the $GI/GI/1$ model, and $S_1, S_2, \ldots$ are their associated service-time requirements. Then, in the corresponding simulation run of the $GI/GI/2$ model, these same values are used for the consecutive interarrival times, and their associated service times; see Kelton, Sadowski, and Sturrock (2007); Law (2007).

Antithetic and common random numbers can be combined. Their optimal combination is the goal of the Schruben-Margolin strategy; i.e., some blocks of scenarios use CRN, whereas other blocks use antithetic variates, etc.; see Chih (2013).

Control Variates

Suppose that $\hat{\ell}$ is an unbiased estimator of ℓ in the estimation problem (1); for example, C is the arrival time in a queueing simulation. A random variable C is called a control variate for $\hat{\ell}$ if it is correlated with $\hat{\ell}$ and its expectation γ is known. The linear control random variable $\hat{\ell}(\alpha)$ is defined as

$$\hat{\ell}(\alpha) = \hat{\ell} - \alpha(C - \gamma),$$

where α is a scalar parameter. It is easy to prove that the variance of $\hat{\ell}(\alpha)$ is minimized by

$$\alpha^* = -\frac{\mathrm{Cov}(\hat{\ell}, \mathrm{C})}{\mathrm{Var}(\mathrm{C})}.$$

The resulting minimal variance is

$$\mathrm{Var}(\hat{\ell}(\alpha^*)) = \left(1 - \rho^2_{\hat{\ell}C}\right)\mathrm{Var}(\hat{\ell}), \tag{5}$$

where $\rho_{\hat{\ell}C}$ denotes the correlation coefficient between $\hat{\ell}$ and C. Since $\mathrm{Cov}(\hat{\ell}, C)$ is unknown, the optimal control coefficient α^* must be estimated from the simulation. Estimating both $\mathrm{Cov}(\hat{\ell}, C)$ and $\mathrm{Var}(\mathrm{C})$ means that linear regression analysis is applied to estimate α^*. Estimation of α^* implies that the variance reduction becomes smaller than (2) suggests, and that the estimator may become biased.

The method can be easily extended to multiple control variables (Rubinstein and Marcus 1985).

A well-known application of control variates is pricing of Asian options. The payoff of an Asian call option is given by

$$H(\mathbf{Y}) = \max(0, \frac{1}{n}\sum_{j=1}^{n} Y_j - K),$$

where $Y_j = S_{jT/n}$, the expiration date T is discretized into n time units, K is the strike price, and S_t is the asset price at time t, which follows a geometric Brownian motion. Let r be the interest rate; then the price of the option becomes

$$\ell = E\left(e^{-rT}H(\mathbf{Y})\right).$$

A control variate may be $C = e^{-rT}\max(0, S_T - K)$ whose expectation is readily available from the Black-Scholes formula. Alternative control variates are S_T, or $\frac{1}{n}\sum_{j=1}^{n} S_{jT/n}$.

Conditioning

The method of conditional Monte-Carlo is based on the following basic probability formulas. Let X and Z be two arbitrary random variables, then

$$\begin{aligned} E(E(X|Z)) &= E(X) \quad \text{and} \\ \mathrm{Var(X)} &= \mathrm{E(Var(X|Z))} + \mathrm{Var(E(X|Z))}. \end{aligned} \tag{6}$$

Because the last two terms are both nonnegative, variance reduction is obvious:

$$\mathrm{Var(E(X|Z))} \le \mathrm{Var(X)}.$$

The same reasoning holds for the original problem (1), setting $X = H(\mathbf{Y})$. Also Z is allowed to be a vector variable. These formulas are used in a simulation experiment as follows. The vector $\mathbf{Z}$ is simulated, and the conditional expectation $C = E(H(\mathbf{Y})|\mathbf{Z})$ is computed. Repeating this N times gives the conditional Monte-Carlo estimator

$$\hat{\ell}_N^* = \frac{1}{N}\sum_{i=1}^{N} C_i.$$

A typical example is a level-crossing probability of a random number of variables:

$$\ell = P\left(\sum_{j=1}^{R} Y_j > b\right),$$

where $Y_1, Y_2, \ldots$ are IID positive random variables, R is a nonnegative integer-valued random variable, independent of the Y_j variables, and b is some specified constant. Such problems are of interest in insurance risk models for assessing aggregate claim distributions (Glasserman 2003). CMC can be improved by conditioning on the value of R for which level crossing occurs. To be more specific, denote the event of interest by A, so $\ell = E(I_A(\mathbf{Y}))$. Define

$$M = \min\left(r : \sum_{j=1}^{r} Y_j > b\right).$$

Assume that the distribution of Y can be easily sampled, and that the distribution of R is known and numerically available (for instance, Poisson). Then it is easy to generate a value of M. Suppose that $M = m$. Then $E(I_A(\mathbf{Y})|M = m) = P(R \ge m)$, which can be easily computed.

Stratified Sampling

Recall the original estimation problem $\ell = E(H(\mathbf{Y}))$, and its crude Monte Carlo estimator $\hat{\ell}_N$. Suppose now that there is some finite random variable Z taking values from $\{z_1, \ldots, z_m\}$, say, such that

1. the probabilities $p_i = P(Z = z_i)$ are known;
2. for each $i = 1, \ldots, m$, it is easy to sample from the conditional distribution of $\mathbf{Y}$ given $Z = z_i$.

Because

$$\ell = E(E(H(\mathbf{Y}))) = \sum_{i=1}^{m} p_i E(H(\mathbf{Y})|Z = z_i),$$

the stratified sampling estimator of ℓ may be

$$\hat{\ell}_N^* = \sum_{i=1}^{m} p_i \frac{1}{N_i}\sum_{j=1}^{N_i} H(\mathbf{Y}_{ij}),$$

where N_i IID samples $\mathbf{Y}_{i1}, \ldots, \mathbf{Y}_{iN_i}$ are generated from the conditional distribution of $\mathbf{Y}$ given $Z = z_i$, such that $N_1 + \cdots + N_m = N$. Notice that the estimator is unbiased. To assess its variance, denote the conditional variance of the performance estimator by $\sigma_i^2 = \mathrm{Var}(\mathrm{H}(\mathbf{Y})|\mathrm{Z} = \mathrm{z_i})$. The variance of the stratified sampling estimator is then given by

$$\mathrm{Var}(\hat{\ell}_{\mathrm{N}}^*) = \sum_{\mathrm{i}=1}^{\mathrm{m}} \frac{\mathrm{p_i^2}\sigma_{\mathrm{i}}^2}{\mathrm{N_i}}.$$

Because of (6)

$$\mathrm{Var}(\mathrm{H}(\mathbf{Y})) \geq \mathrm{Var}(\mathrm{H}(\mathbf{Y})|\mathrm{Z}) = \sum_{\mathrm{i}=1}^{\mathrm{m}} \mathrm{p_i}\sigma_{\mathrm{i}}^2.$$

Selecting proportional strata sample sizes $N_i = p_i N$ gives variance reduction:

$$\mathrm{Var}(\hat{\ell}_{\mathrm{N}}^*) = \sum_{\mathrm{i}=1}^{\mathrm{m}} \frac{\mathrm{p_i}\sigma_{\mathrm{i}}^2}{\mathrm{N}} \leq \frac{1}{\mathrm{N}}\mathrm{Var}(\mathrm{H}(\mathbf{Y})) = \mathrm{Var}(\hat{\ell}_{\mathrm{N}}).$$

It can be shown that the strata sample sizes N_i that minimize this variance are

$$N_i = N\frac{p_i\sigma_i}{\sum_{j=1}^m p_j\sigma_j};$$

see Rubinstein and Kroese (2008). A practical problem is that the standard deviations σ_i are usually unknown, so these variances are estimated by pilot runs. Stratified sampling is used in financial engineering to get variance reductions in problems such as value-at-risk, and pricing path-dependent options (Glasserman 2003).

Importance Sampling

The idea of importance sampling is explained best in case of estimating the probability of an event A. The underlying sample space is $(\Omega, \mathscr{F})$ for which $A \in \mathscr{F}$, and the probability measure P on this space is given by the specific simulation model. In a simulation experiment for estimating $P(A)$, the CMC estimator would be $\hat{\ell}_N = \sum_{i=1}^N I_A^{(i)}$, where $I_A^{(1)}, \ldots, I_A^{(N)}$ are IID indicator functions of event A generated under P. On average in only one out of $1/P(A)$ generated samples the event A occurs, and thus for rare events (where $P(A)$ is extremely small) this procedure fails. Suppose that there is an alternative probability measure P^* on the same $(\Omega, \mathscr{F})$ such that (i) A occurs much more often, and (ii) P is absolutely continuous with respect to P^*, meaning

$$\forall F \in \mathscr{F} \ : \ P(F) > 0 \ \Rightarrow \ P^*(F) > 0.$$

Then according to the Radon-Nikodym theorem, it holds that there is a measurable function L on Ω such that $\int_F dP = \int_F L\, dP^*$ for all $F \in \mathscr{F}$. The function L is called likelihood ratio and usually written as $L = dP/dP^*$; the alternative probability measure P^* is said to be the importance sampling probability measure, or the change of measure. Thus, by weighting the occurrence I_A of event A with the associated likelihood ratio, simulation under the change of measure yields an unbiased importance sampling estimator

$$\hat{\ell}_N^* = \sum_{i=1}^N L^{(i)} I_A^{(i)}.$$

More importantly, variance reduction is obtained when the change of measure has been chosen properly, as will be explained below. Importance sampling has been applied successfully in a variety of simulation areas, such as stochastic operations research, statistics, Bayesian statistics, econometrics, finance, systems biology; see Rubino and Tuffin (2009). This section will show that the main issue in importance sampling simulation is the question which change of measure to consider. The choice is very much problem dependent, however, and unfortunately, it is difficult to prevent gross misspecification of the change of measure P^*, particularly in multiple dimensions.

Exponential Change of Measure

As an illustration, consider the problem of estimating the level-crossing probability

$$\ell_n = P(A_n) \quad \text{with} \quad \mathrm{A_n} = \{\mathrm{Y_1} + \cdots + \mathrm{Y_n} > \mathrm{na}\}, \tag{7}$$

where $Y_1, \ldots, Y_n$ are IID random variables with finite mean $\mu = E(Y) < a$ and with a light-tailed PDF $f(y, \mathbf{v})$, in which $\mathbf{v}$ denotes a parameter vector, such as mean

and variance of a normal density. It is well-known from Cramér's Theorem that $P(A_n) \to 0$ exponentially fast as $n \to \infty$. Suppose that under the importance sampling probability measure the random variables $Y_1, \ldots, Y_n$ remain IID, but with an exponentially tilted PDF (also called exponentially twisted), with tilting factor t:

$$f_t(y, \mathbf{v}) = \frac{f(y, \mathbf{v}) e^{ty}}{\int f(y, \mathbf{v}) e^{ty}\, dy}.$$

Thus, in the importance sampling simulations the Y_k -samples are generated from $f_t(y, \mathbf{v})$. Because of the IID assumption, the likelihood ratio becomes

$$\begin{aligned} L(Y_1, \ldots, Y_n) &= \prod_{k=1}^{n} \frac{f(Y_k, \mathbf{v})}{f_t(Y_k, \mathbf{v})} \\ &= \exp\left(n\psi(t) - t \sum_{k=1}^{n} Y_k \right), \end{aligned} \tag{8}$$

with $\psi(t) = \log \int f(y, \mathbf{v}) e^{ty}\, dy$. Variance reduction is obtained if

$$\begin{aligned} &\mathrm{Var}_t(\hat{\ell}_{\mathrm{N}}^*) \le \mathrm{Var}(\hat{\ell}_{\mathrm{N}}) \quad \Leftrightarrow \quad \mathrm{Var}_t(\hat{\ell}_1^*) \le \mathrm{Var}(\hat{\ell}_1) \\ &\Leftrightarrow \quad E_t[(\hat{\ell}_1^*)^2] \le E[(\hat{\ell}_1)^2] \\ &\Leftrightarrow \quad E_t[(I_A L(Y_1, \ldots, Y_n))^2] \le E[(I_A)^2]. \end{aligned}$$

Because of (8), it is easy to show that the variance is minimized for $t = (\psi')^{-1}(a)$. In that case the importance sampling estimator is logarithmically efficient (also called asymptotically optimal; see Rubino and Tuffin (2009; Chapter 4)):

$$\lim_{n \to \infty} \frac{\log E_t\left[(\hat{\ell}_N^*)^2 \right]}{\log E_t\left[\hat{\ell}_N^* \right]} = 2,$$

where the subscript t means that the underlying probability is the change of measure. Asymptotic optimality implies that $\mathrm{RE}(\hat{\ell}_{\mathrm{N}}^*)$ grows subexponentially as $n \to \infty$, whereas for CMC the relative error grows exponentially (see (3)).

The Cross-entropy Method

A general heuristic for constructing an importance sampling algorithm is to consider only a parameterized family of changes of measures. Consider again problem (1), with PDF $f = f(\mathbf{y}, \mathbf{v})$ where $\mathbf{v}$ is the parameter vector. Thus, let Θ be all feasible parameter vectors for f. For any $\theta \in \Theta$, the change of measure P_θ induces the (single-run) importance sampling estimator

$$\hat{\ell}_\theta^* = H(\mathbf{Y}) \frac{dP}{dP_\theta}(\mathbf{Y}) = H(\mathbf{Y}) \frac{f(\mathbf{Y}, \mathbf{v})}{f(\mathbf{Y}, \theta)}.$$

The optimal change of measure is found by variance minimization. Since the estimators are unbiased, it suffices to minimize the second moment:

$$\min_{\theta \in \Theta} E_\theta \left[\left(H(\mathbf{Y}) \frac{f(\mathbf{Y}, \mathbf{v})}{f(\mathbf{Y}, \theta)} \right)^2 \right].$$

Generally, this problem is hard. A successful approach is based on cross-entropy minimization as explained in Rubinstein and Kroese (2004). First, consider the optimal change of measure, resulting in a zero-variance estimator:

$$dP^{\mathrm{opt}}(\mathbf{Y}) = \frac{H(\mathbf{Y}) dP(\mathbf{Y})}{\ell}. \tag{9}$$

This change of measure is not implementable as it requires knowledge of the unknown quantity ℓ. The cross-entropy method finds P_θ by minimizing the Kullback–Leibler distance (or cross-entropy) within the class of feasible changes of measure:

$$\min_{\theta \in \Theta} \mathscr{D}(dP^{\mathrm{opt}}, dP_\theta),$$

where the cross-entropy is defined by

$$\begin{aligned} \mathscr{D}(dP^{\mathrm{opt}}, dP_\theta) &= E^{\mathrm{opt}}\left[\log\left(\frac{dP^{\mathrm{opt}}}{dP_\theta}(\mathbf{Y}) \right) \right] \\ &= E_v\left[\frac{dP^{\mathrm{opt}}}{dP}(\mathbf{Y}) \log\left(\frac{dP^{\mathrm{opt}}}{dP_\theta}(\mathbf{Y}) \right) \right]. \end{aligned}$$

Substituting expression (9), and canceling constant terms and factors, the equivalent cross-entropy problem becomes

$$\max_{\theta \in \Theta} E_v[H(\mathbf{Y}) \log dP_\theta(\mathbf{Y})].$$

There are several ways to solve this stochastic optimization problem. The original description of the cross-entropy method for such problems proposes to solve the stochastic counterpart iteratively, see Rubinstein and Kroese (2004). This approach has been applied successfully to a variety of estimation and rare-event problems.

State-dependent Importance Sampling

The importance sampling algorithms described above were based on a static change of measure; i.e., the samples are generated by a fixed alternative statistical law; see (8). In specific problems, such as (7), the static importance sampling algorithm yields an efficient estimator. However, for many problems it is known that efficient estimators require an adaptive or state-dependent importance sampling algorithm (Juneja and Shahabudding 2006). To illustrate this concept, consider again the problem of estimating the level-crossing probability (7). The Y_k-variables are called jumps of a random walk $(S_k)_{k=0}^n$, defined by $S_0 = 0$, and for $k \geq 1$: $S_k = \sum_{j=1}^k Y_j = S_{k-1} + Y_k$. Under a state-dependent change of measure, the next jump Y_{k+1} might be generated from a PDF $f(y|k+1, S_k)$; i.e., it depends on jump time $k+1$ and current state S_k. Hence, under the change of measure, the process $(S_k)_{k=0}^n$ becomes an inhomogeneous Markov chain. Given a generated sequence $Y_1, \ldots, Y_n$, the associated likelihood ratio is

$$L(Y_1, \ldots, Y_n) = \prod_{k=1}^{n} \frac{f(Y_k, \mathbf{v})}{f(Y_k|k, S_{k-1})}.$$

The next question is: Which time-state dependent PDFs should be chosen for this kind of change of measure? The criterion could be (i) variance minimization, (ii) cross-entropy minimization, or (iii) efficiency.

1. A small set of rare-event problems are suited to find so-called zero-variance approximate importance sampling algorithms, notably level-crossing problems with Gaussian jumps, reliability problems, and certain Markov chains problems; see L'Ecuyer et al. (2010).
2. A cross-entropy minimization is applied after each state S_k for determining the PDF of the next jump (Ridder and Taimre 2011). The result is that when the level-crossing at time n can be reached from state S_k just by following the natural drift, no change of measure is applied. Otherwise, the next jump is drawn from an exponentially tilted PDF with tilting factor $t = (\psi')^{-1}((an - S_k)/(n-k))$. This would be the static solution given before when starting at time $k = 0$. This approach gives logarithmic efficiency.
3. The method developed by Dupuis and Wang (2007) considers the rare-event problem as an optimal control problem in a differential game. Applying dynamic programming techniques while using large-deviations expressions, the authors develop logarithmically efficient importance sampling algorithms. This approach works also for rare events in Jackson networks (Dupuis et al. 2007).

Markov Chains

Many practical estimation problems in statistical systems (e.g., reliability, production, inventory, queueing, communications) can be reformulated as a Markov model to estimate a quantity $\ell = P(\mathbf{Y}_T \in \mathscr{F})$. Let $\{\mathbf{Y}_t : t = 0, 1, \ldots\}$ denote a discrete-time Markov chain with a state space $\mathscr{X}$ with transition probabilities $p(\mathbf{x}, \mathbf{y})$; $\mathscr{F} \subset \mathscr{X}$ is a subset of states, and T is a stopping time. A typical example is a system of highly reliable components where the response of interest is the probability of a break down of the system.

Assume that the importance sampling is restricted to alternative probability measures P^* such that the Markov chain property is preserved with transition probabilities $p^*(\mathbf{x}, \mathbf{y})$ satisfying

$$p(\mathbf{x}, \mathbf{y}) > 0 \;\Leftrightarrow\; p^*(\mathbf{x}, \mathbf{y}) > 0.$$

This constraint ensures the absolute continuity condition. Furthermore, assuming that the initial distribution remains unchanged, the likelihood ratio of a simulated path of the chain becomes simply

$$L = \prod_{t=0}^{T-1} \frac{p(\mathbf{Y}_t, \mathbf{Y}_{t+1})}{p^*(\mathbf{Y}_t, \mathbf{Y}_{t+1})}.$$

Thus, it suffices to find the importance-sampling transition-probabilities $p^*(\mathbf{x}, \mathbf{y})$. Considering these probabilities as parameters, the method of cross-entropy is most convenient; Ridder (2010) gives sufficient conditions to guarantee asymptotic

optimality. However, many realistic systems are modeled by Markov chains with millions of transitions, which causes several difficulties: the dimensionality of the parameter space, the danger of degeneracy of the estimation, and numerical underflow in the computations. Several approaches are proposed to reduce the parameter space in the cross-entropy method (de Boer and Nicola 2002; Kaynar and Ridder 2010).

Another approach to importance sampling in Markov chains approximates the zero-variance probability measure P^{opt}. It is known that this P^{opt} implies transition probabilities of the form

$$p^{\text{opt}}(\mathbf{x},\mathbf{y}) = p(\mathbf{x},\mathbf{y})\,\frac{\gamma(\mathbf{y})}{\gamma(\mathbf{x})},$$

where $\gamma(\mathbf{x}) = P(\mathbf{Y}_T \in \mathscr{F} | \mathbf{Y}_0 = \mathbf{x})$. As these quantities are unknown (and in fact the subject of interest), these zero-variance transition probabilities cannot be implemented. However, approximations of the $\gamma(\mathbf{x})$ probabilities may be considered (L'Ecuyer et al. 2010). Under certain conditions this approach leads to strong efficiency of the importance sampling estimator.

Splitting

The splitting method may handle rare-event probability estimation. Unlike importance sampling, the probability laws remain unchanged, but a drift to the rare event is constructed by splitting (cloning) favorable trajectories, and terminating unfavorable trajectories. This idea may be explained as follows. Consider a discrete-time Markov chain $\{Y_t : t = 0, 1, \ldots\}$ on a state space $\mathscr{X}$. Suppose that the chain has a regeneration state or set $\mathbf{0}$, a set of failure states $\mathscr{F}$, and a starting state $\mathbf{y}_0$. The response of interest is the probability that the chain hits $\mathscr{F}$ before $\mathbf{0}$. More formally, if T denotes the stopping time

$$T = \inf\{t : \mathbf{Y}_t \in \mathbf{0} \cup \mathscr{F}\},$$

then

$$\ell = P(\mathbf{Y}_T \in \mathscr{F}).$$

The initial state $\mathbf{y}_0 \notin \mathbf{0} \cup \mathscr{F}$ may have either some initial distribution, or be fixed and known. The assumption is that ℓ is so small that CMC in impractical. Suppose that the state space is partitioned into sets according to

$$\mathscr{X} \supset \mathscr{X}_1 \supset \mathscr{X}_2 \supset \cdots \supset \mathscr{X}_m = \mathscr{F}, \tag{10}$$

with $\mathbf{0} \in \mathscr{X}/\mathscr{X}_1$. Usually these sets are defined through an importance function $\phi : \mathscr{X} \to \mathbb{R}$, such that for each k, $\mathscr{X}_k = \{\mathbf{y} : \phi(\mathbf{y}) \geq L_k\}$ for certain levels $L_1 \leq L_2 \leq \cdots \leq L_m$, with $\phi(\mathbf{0}) = L_0 < L_1$. Now define stopping times T_k and associated events A_k by

$$T_k = \inf\{t : X(t) \in \mathbf{0} \cup \mathscr{X}_k\}; \quad A_k = \{\mathbf{Y}_{T_k} \in \mathscr{X}_k\}.$$

Because of (10), clearly $A_1 \supset A_2 \supset \cdots \supset A_m = A = \{\mathbf{Y}_T \in \mathscr{F}\}$. Thus the rare-event probability $\ell = P(A)$ can be decomposed as a telescoping product:

$$\ell = P(A_1) \prod_{k=2}^{m} P(A_k | A_{k-1}).$$

To estimate ℓ, one might estimate all conditional probabilities $P(A_k|A_{k-1})$ separately (say) by $\hat{\ell}_k$, which gives the product estimator

$$\hat{\ell}^* = \prod_{k=1}^{m} \hat{\ell}_k, \tag{11}$$

where $\hat{\ell}_1$ estimates $P(A_1)$. The splitting method implements the following algorithm for constructing the $\hat{\ell}_k$ estimators in a way that the product estimator is unbiased. In the initial stage ($k = 0$), run N_0 independent trajectories of the chain starting at the initial state $\mathbf{y}_0$. Each trajectory is run until either it enters $\mathscr{X}_1$ or it returns to $\mathbf{0}$, whatever come first. Let R_1 be the number of "successful" trajectories; i.e., trajectories that reach $\mathscr{X}_1$ before $\mathbf{0}$. Then set $\hat{\ell}_1 = R_1/N_0$. Consider stage $k \geq 1$, and suppose that R_k trajectories have entered set $\mathscr{X}_k$ in entrance states $\mathbf{Y}_1^{(k)}, \ldots, \mathbf{Y}_{R_k}^{(k)}$ (not necessarily distinct). Replicate (clone) these states, until a sample of size N_k has been obtained. From each of these states, run a trajectory of the chain, independently of the others. Each trajectory is run until either it enters $\mathscr{X}_{k+1}$ or it returns to $\mathbf{0}$, whatever come first. Let R_{k+1} be the number of successful trajectories, i.e., trajectories that reach $\mathscr{X}_{k+1}$ before $\mathbf{0}$. Then set $\hat{\ell}_{k+1} = R_{k+1}/N_k$. This procedure is continued until all trajectories have entered either $\mathscr{F}$ or returned to $\mathbf{0}$.

This form of the splitting method has attracted a lot of interest (see the reference list in Rubino and Tuffin (2009; Chapter 3)), both from a theoretical point of view analyzing the efficiency, and from a practical point of view describing several applications. The analysis shows that the product estimator (11) is unbiased. Furthermore, the analysis of the efficiency of the splitting technique depends on the implementation of (a) selecting the levels, (b) the splitting (cloning) of successful trajectories, and (c) the termination of unsuccessful trajectories. Generally, the problem of solving these issues optimally is like choosing an optimal change of measure in importance sampling. In fact, Dean and Dupuis (2008) discusses this relationship when the model satisfies a large deviations principle.

Concerning issue (c), the standard splitting technique terminates a trajectory that returns to the regeneration state $\mathbf{0}$, or—in case of an importance function—when the trajectory falls back to level L_0. This approach, however, may be inefficient for trajectories that start already at a high level L_k. Therefore, there are several adaptations such as truncation (L'Ecuyer et al. 2007), RESTART (Villen-Altamirano, and Villen-Altamirano 1994), and Russian roulette principle (Melas 1997).

Concerning issue (b), there are numerous ways to clone a trajectory that has entered the next level, but the two ways implemented mostly are (i) fixed effort, and (ii) fixed splitting. Fixed effort means that the sample sizes N_k are predetermined, and thus each of the R_k entrance states at set $\mathscr{X}_k$ is cloned $c_k = \lfloor N_k/R_k \rfloor$ times. The remaining $N_k \mathrm{mod} R_k$ clones are selected randomly. An alternative is to draw N_k times at random (with replacement) from the R_k available entrance states. Fixed splitting means that the splitting factors c_k are predetermined, and each of the R_k entrance states at set $\mathscr{X}_k$ is cloned c_k times to give sample size $N_k = c_k R_k$.

For a certain class of models, Glasserman et al. (1999) has shown that fixed splitting gives asymptotic optimality (as $\ell \to 0$) when the number of levels $m \approx -\ln(\ell)/2$, with sets $\mathscr{X}_k$ such that $P(A_k|A_{k-1})$ are all equal (namely, roughly equal to e^{-2}) and splitting factors such that $c_k P(A_{k+1}|A_k) = 1$. However, since ℓ and the $P(A_{k+1}|A_k)$ are unknown in practice, this result can only be approximated. Moreover, one should take into account the amount of work or computing time in the analysis; for example, Lagnoux (2006) determines the optimal setting under a budget constraint of the expected total computing time.

Application to Counting

Recently, counting problems have attracted the interest of the theoretical computer science and the operations research communities. A standard counting problem is model counting, or #SAT: how many assignments to boolean variables satisfy a given boolean formula consisting of a conjunction of clauses? The related classical decision problem is: does there exist a true assignment of the formula? Because exact counting is impracticable due to the exponential increase in memory and running times, attention shifted to approximate counting—notably by applying randomized algorithms. In this randomized setting, the counting problem is equivalent to rare event simulation: let $\mathscr{X}^*$ be the set of all solutions of the problem, whose number $|\mathscr{X}^*|$ is unknown and the subject of study. Assume that there is a larger set of points $\mathscr{X} \supset \mathscr{X}^*$ with two properties:

1. the number of points $|\mathscr{X}|$ is known;
2. it is easy to generate uniformly points $\mathbf{x} \in \mathscr{X}$.

Because

$$|\mathscr{X}^*| = \frac{|\mathscr{X}^*|}{|\mathscr{X}|}|\mathscr{X}|,$$

it suffices to estimate

$$\ell = \frac{|\mathscr{X}^*|}{|\mathscr{X}|} = P(\mathbf{U} \in \mathscr{X}^*),$$

where $\mathbf{U}$ is the uniform random vector on $\mathscr{X}$. Typically ℓ is extremely small, and thus rare event techniques are required. Splitting techniques with Markov chain Monte Carlo (MCMC) simulations have been developed in Botev and Kroese (2008) and Rubinstein (2010) to handle such counting problems.

Quasi-Monte Carlo

Suppose that the performance function H in (1) is defined on the d-dimensional unit hypercube $[0,1)^d$,

and the problem is to compute its expectation with respect to the uniform distribution:

$$\ell = E(H(\mathbf{U})) = \int_{[0,1)^d} H(\mathrm{u})\,\mathrm{du}.$$

As was shown in the introduction, the variance of the CMC estimator $\hat{\ell}_{Nm}$ using a sample size $N \times m$ equals $\sigma^2/(N \times m)$, where

$$\sigma^2 = \int_{[0,1)^d} H^2(\mathrm{u})\,\mathrm{du} - \ell^2.$$

Let $P_N = \{\mathbf{u}_1, \ldots, \mathbf{u}_N\} \subset [0,1)^d$ be a deterministic point set that is constructed according to a quasi-Monte Carlo rule with low discrepancy, such as a lattice rule (Korobov), or a digital net (Sobol', Faure, Niederreiter); see Lemieux (2006). The quasi-Monte Carlo approximation of ℓ would be

$$\sum_{j=1}^{N} H(\mathbf{u}_j).$$

This deterministic approach is transformed into Monte Carlo simulation by applying a randomization of the point set. A simple randomization technique is the random shift: generate m IID random vectors $\mathbf{v}_i \in [0,1)^d$, $i = 1, \ldots, m$, and compute the quasi-Monte Carlo approximations

$$\hat{\ell}_i = \sum_{j=1}^{N} H(\mathbf{u}_j + \mathbf{v}_i \mod 1).$$

Then the randomized quasi-Monte Carlo estimator using sample size $N \times m$ is defined by

$$\hat{\ell}^* = \frac{1}{m}\sum_{i=1}^{m} \hat{\ell}_i\,.$$

The scrambling technique is based on permuting the digits of the coordinates u_j.. Other techniques of randomizing quasi-Monte Carlo point sets are less used. The main property is that when the performance function H is sufficiently smooth, these randomized quasi-Monte Carlo methods give considerable variance reduction (Lemieux 2006).

Vector Maximum Problem

► Multiobjective Programming

Vector Space

A vector *n*-space is a set of vectors or points, each with *n* components, and rules for vector addition and multiplication by real numbers. Euclidean 3-space is a vector space.

Vehicle Routing

Lawrence Bodin
University of Maryland, College Park, MD, USA

Introduction

The traditional point-to-point vehicle routing problem (K-VRP) determines a minimum cost set of routes for a fleet of K identical vehicles where the vehicles service a set of locations and each location has a known demand for service. For these problems, minimum cost can represent the 1) minimum dollars to service the locations or 2) minimum nonproductive operating cost to service the locations or 3) minimum travel distance to service the locations. If the fleet size (number of vehicles in the fleet) is known, then the routes are formed in most cases to minimize the total cost associated with the nonproductive travel time (also known as deadhead travel time) associated with the routes that are formed. If the fleet size is not known, then the routes are formed in order to minimize the total cost of the operation, where the total cost of the operation is a combination of the capital cost associated with the fleet size and the operating cost associated with the deadhead travel time of the fleet.

Generating and Executing Routes

When the routes are generated is an important consideration in solving these vehicle routing problems. In some vehicle routing problems, the routes for the vehicles are formed for a single day and these routes are determined well in advance of when the routes are executed. These problems are called fixed route problems. In the preplanned vehicle routing problems, the vehicles are assumed to carry out different routes daily since the locations to be serviced can differ from one day to the next but all of the

locations to be serviced on a given day are known in advanced. In these cases, the vehicle routing problem is solved daily. Most of the traditional papers on vehicle routing are concerned with variants of the fixed route and preplanned vehicle routing problems. These problems are the focus of this article.

However, there are other classes of vehicle routing problems that can be defined where these classes are based on when the routes are generated. In some cases, the routes begin with a skeleton routes or partial routes formed over the locations that are always serviced on that day. Then, new locations for that day are inserted onto these routes to determine a set of routes for that day. Adding locations to routes as the locations are received by the dispatcher generate a class of routing problems called the real time vehicle routing problem or real time dispatching problem.

Traditional Vehicle Routing Constraints

Traditional vehicle routing constraints include the following:

1. Each route can be no longer than a specified length.
2. The volume or weight on each route can be no larger than a specified amount, called the capacity of the vehicle.
3. Each route begins and ends at the depot so that these problems are called single depot vehicle routing problems.
4. All vehicles are identical so that this vehicle routing problem is called a homogeneous routing problem.

Time Windows

A time window at a location to be serviced is defined as a time interval $[L, U]$ where L is the earliest possible time to begin the service at the location and U is the latest possible time to begin the service at the location. If a location has a hard time window, It is normally assumed that the time window is hard, i.e., the service of the location must begin between L and U. In a route, if the vehicle can arrive at the location before L, the hard time window forces the vehicle to wait until L to begin service at the location. The time that the vehicle must wait before beginning the service at L is called the wait time of the vehicle at the location. Vehicle wait time represents nonproductive time and can be considered a cost to the organization. With hard time windows, it is assumed that it is infeasible to begin to service a location after U. If is desired that the service at a location is to be carried out between L and U but the service can begin before L or after U, then $[L, U]$ is called a soft time window at the location.

Vehicle routing problems then fall into two classes – vehicle routing problems without time windows and vehicle routing problems with time windows. If the locations in a vehicle routing problem have time windows, then the windows can be soft or hard. Further, a location without a time window can be assumed to be a location with a time window where $L = 0$ and U is very large.

Vehicle Routing Literature

Vehicle routing problems form a rich area of research and applications. There are many vehicle routing problems that can be defined, where the analysis of these vehicle routing problems depend upon the conditions placed on the problem. As such, a vast literature on vehicle routing exists. Standard references include Ball (1995a; 1995b), Bodin (1990), Bodin et al. (1983), Golden and Assad (1986, 1988) and Lawler et al. (1985). Three books on vehicle routing are Dror (1999), Hall (1999) and Toth and Vigo (1999). Each of these books and papers include extensive bibliographies.

Practical Vehicle Routing Problems

There are many applications of vehicle routing problems and effective software has been developed for solving many of these applications. Practical vehicle routing problems include the delivery of goods from a depot to a set of locations, residential and containerized sanitation pickup, scheduling of meter readers, scheduling of field maintenance personnel, delivery of newspapers and telephone books, scheduling of fuel deliveries such as propane gas and gasoline, scheduling of paratransit vehicles, and scheduling of pickups and deliveries for courier services.

Some of the more common constraints that can be encountered when attempting to solve practical vehicle routing problems are as follows:

1. The length of each route must be between a prespecified lower and upper bound.
2. Each route begins and ends at the same depot although in some problems, there can be several such depots. This problem is called the multiple depot vehicle routing problem. Further, in some

problems, the route can begin (or end) at a depot and end (or begin) at the last (or first stop) on the route.

Problems have been encountered where vehicles leave a depot (or storage facility), deliver items to several locations, go to a second depot (or storage facility), reload the vehicle, deliver items to several locations, go to a third depot (or storage facility), etc. These problems can involve developing routes over several days.

The rollon-rolloff problem is an example where (i) a tractor leaves a depot, (ii) goes to a location with an empty container, (iii) exchanges the empty container for a full container at the location, (iv) brings the full container to a landfill or storage facility, (v) exchanges the full container for an empty container, (vi) brings the empty container to a location, (vii) exchanges the empty container for a full container at the location, (viii) brings the full container to a landfill or storage facility, (ix) exchanges the full container for an empty container, etc. In the rollon-rolloff problem, there can be multiple landfills and storage facilities and the vehicle capacity is 1 (the tractor can only move one container at a time).

3. There can be several types of vehicles in the fleet where the vehicles can be different in terms of capacity, size of crew, speed, etc. This problem is called the multiple vehicle type routing and scheduling problem.
4. If some of the locations can be serviced by some, but not necessarily all, of the vehicle types and the specification of the vehicle types that can service a location can differ by location, then this problem is called the vehicle/location or vehicle/site dependency routing problem.
5. If demand at a location is not known in advance but can be stochastic, then this problem is called the stochastic vehicle routing and scheduling problem. A variant of the stochastic vehicle routing and scheduling problem, called the inventory routing problem, occurs in the delivery of such items as propane gas and fuel oil. In the case of propane gas or fuel oil, the demand (amount of propane gas or fuel oil needed at the location) is forecasted using a factor such as degree-days.
6. In paratransit, courier delivery and shared cab ride problems, each customer demanding service has a specified pickup location and a specified delivery location. The pickup has to be scheduled on the route before the delivery is scheduled on the route. Some of these problems can have transshipments; that is to say, packages are picked up and brought to a pre-specified drop location where they are unloaded and another vehicle later picks up these packages and makes the deliveries.
7. The vehicle routing problem with backhauling occurs In some vehicle routing problems when there are delivery locations and pickup locations and each route has the restriction that all (or most) of the deliveries are to be carried out before any of the pickups are to be carried out. In this way, the vehicle can be close to empty before it is filled up. An example of this problem is when a vehicle makes several deliveries and then goes to a warehouse where it reloads the vehicle to bring the items that has just been loaded on the vehicle to another warehouse or depot.

   A second example is the local delivery and pickup routes for organizations like Federal Express and UPS. In this example, the drivers make deliveries in the morning, then make later deliveries and early pickups in the midday, and then mostly pickups at the end of the day. These pickups are then returned to the depot where they are processed for delivery. This problem involves both daily scheduled pickups and daily real time dispatching.

Algorithms for Solving Vehicle Routing Problems

Virtually all vehicle routing problems fall into the class of combinatorial optimization problems called *NP*-Hard. A problem is *NP*-Hard if the number of computations needed to solve this problem grows exponentially with a parameter of the problem (Garey and Johnson (1979), Karp (1975), Lenstra and Rinnooy Kan (1981) and Papadimitriou and Stieglitz (1982)). Many of the algorithms for solving vehicle routing problems can be divided into the following three classes – heuristic approaches, metaheuristic approaches and exact procedures.

Heuristic and Metaheuristic Algorithms

Since finding the optimal solution for reasonable size problems and proving that the solution is optimal is difficult, heuristic approaches are generally employed to find a close-to-optimal solution for these problems.

Many of the papers and books in the literature describe various heuristic approaches for solving vehicle routing problems. These approaches are surveyed in Ball (1995a; 1995b), Bodin (1990), Bodin et al. (1983), Golden and Assad (1986, 1988) and Toth and Vigo (1999). Further, metaheuristics such as tabu search and neural networks (Martello et al. 1999; Toth and Vigo 1999) have been applied with some success to finding reasonable solutions to these vehicle routing problems.

A standard heuristic approach for solving many point-to-point vehicle routing and scheduling problems consists of the following steps:

(a) *Specify K, the fleet size*. The fleet size K is generally set by the user or determined by some estimation procedure.

When practical considerations are considered, determining the value of K (the number of vehicles in the fleet) may be very difficult to estimate accurately. As such, the user may not know how many routes to form. To overcome this issue, the user can always repeat the heuristic approach for different values of K and take the best solution.

(b) *Tour Construction or Partitioning of the Locations*. The locations to be serviced are aggregated into K clusters. Some of the approaches for tour construction use single location insertion heuristics and are sequential in nature (one location is assigned to a cluster on each iteration). Other approaches, such as the generalized assignment algorithm, are based on solving a mathematical program and are not sequential in nature.

In some cases, the locations are sequenced as the partitions are formed. If routes and schedules have not been formed while aggregating locations into partitions, then a route and schedule is found over the locations assigned to each of the K partitions, one cluster at a time.

Depending upon the algorithm being implemented and the constraints on the problem, at the conclusion of this step, it is possible to have some locations that are not assigned to routes and/or some of the routes to violate the upper bound on travel time.

(c) *Tour Improvement*. In Tour Improvement, the total travel time of each of the routes is reduced by reordering the locations. To accomplish this, the following is carried out:

(i) The locations on each route are reordered, one route at a time. There are very popular and effective procedures designed for carrying out this exchange process. The number of exchanges of this type is a function of the implementation of the algorithms used and the amount of computer time available.

(ii) Locations are moved between routes and the routes regenerated to reduce their lengths. The results of exchanging locations between routes is not nearly as effective as the within route exchanges described in c-i. Thus, this approach has to be used with some caution because it could use up significant computer time and find few route improvements.

(iii) Unassigned locations are inserted into routes using some of the insertion procedures described in step (b). This approach can be integrated with the approaches in c-i and c-ii.

The tour improvement step continues until no more improvements are found or the time allocated to tour improvement is exhausted.

Many of the tour construction approaches (Step B above) are sequential in nature in that one location is assigned to one of the K routes on each iteration. As such, a bad decision of assigning a customer to a route made at an early step in the tour construction part of the above approach locks in the solution being generated. This bad decision can adversely affect the subsequent assignment of locations to routes.

Moreover, the tour improvement procedures [Step (c) above] can be either too time consuming or not powerful enough to derive a close to optimal solution when starting from an initial assignment of locations to routes that is inferior (these routes are formed in the tour construction approach (Step B above). Despite these caveats, this approach, from a research standpoint and in commercially available software, has served as one of the 'workhorse' procedures for solving vehicle routing problems.

The above approach did not explicitly mention time windows. Adapting this approach to solve a VRP with time windows may not be effective if the time windows are hard and the time window duration D = U-L at some of the locations is narrow (say D < 1 hour).

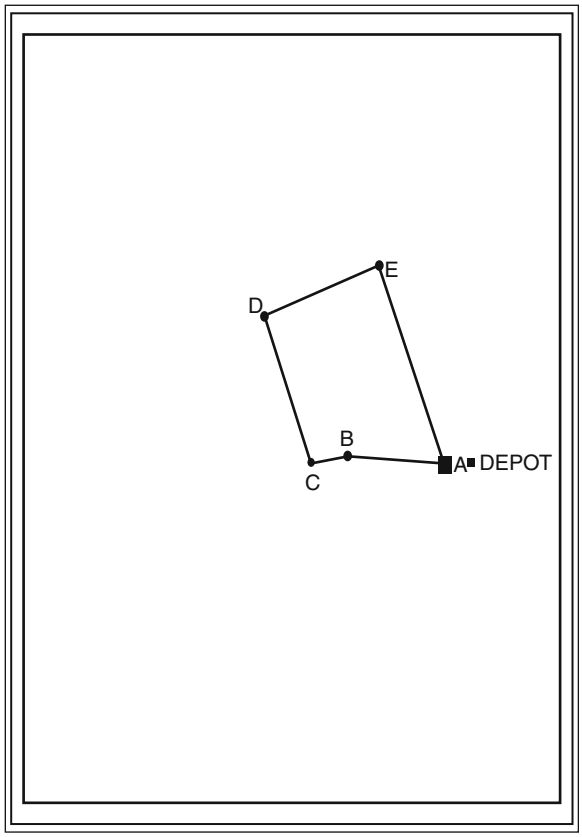
Mathematical Programming Approaches

Mathematical programming approaches have been developed for solving certain vehicle routing problems with at least 150 locations exactly. Bodin, Mingozzi and Maniezzo (1999) survey some of the

more promising approaches for solving vehicle routing exactly. Subsequent papers by Aristide Mingozzi and his colleagues describe effective exact approaches for solving various classes of vehicle routing problems. The results in these papers show that the exact approach taken in these papers get superior results to virtually all of the test problems that have been created for solving different and difficult vehicle routing problems.

Classes of Vehicle Routing Problems

The above discussion has concentrated on solving point-to-point vehicle routing problems (also known as node routing problems). In a point-to-point vehicle routing problem, the locations are distinct points to be serviced and these points are scattered over a region. It is generally assumed that in a node routing problem, the density of the service points is not too great so that the resulting travel path for the vehicle is reasonably independent of the underlying street network. Traditionally, the Euclidean distance (or travel time based on the Euclidean distance or some other metric based on Euclidean disatnace) is used as the deadhead travel time metric when solving point-to-point vehicle routing problems.



Vehicle Routing, Fig. 1 Euclidean distance route over five points

Traveling Salesman Problem

The traveling salesman problem is the one vehicle point-to-point vehicle routing problem. The optimal solution to the traveling salesman problem requires the determination of a minimum deadhead time path that services each location demanding service exactly once. This route begins and ends at the depot. A traveling salesman solution is displayed in Fig. 1. The route in Fig. 1 represents a solution to a symmetric or undirected traveling salesman problem since the travel time between each pair of locations does not depend on the direction of travel. An asymmetric or directed traveling salesman problem occurs when the travel time between each pair of locations can be different.

There has been considerable research in developing efficient and accurate procedures for solving the traveling salesman problem. Helsgaun (Helsgaun 2009 and Applegate et al. 2009) has developed extremely effective approaches for solving the traveling salesman problem with as many as 10,000,000 nodes and has demonstrated that his computationally efficient procedure has found a solution to these very large traveling saleman problems that is within .02% of the optimal solution.

Arc Routing Problems

A second class of routing problems are called arc-routing problems. In an arc-routing problem, the entities to be serviced are the arcs in a network, rather than the individual locations in node routing problems discussed earlier. The methodology for solving arc routing problems is similar to the methodology for solving node routing problems. Matter of fact, a question that often arises is should one (i) convert an arc routing problem to a node routing problem and solve the node routing problem or (ii) convert a node routing problem to an arc routing problem and solve the arc routing problem (assuming that the locations to be serviced are geocoded onto a network). At this time, there is no definitive answer to this question although

algorithms for solving node routing problems tend to allow for additional constraints to be considered as compared to arc routing problems. Dror's book on arc routing problems is devoted totally to the formulation, solution methodologies and practical applications of arc routing problems (Dror 1999). Many of the other references cited earlier also have sections or chapters on arc routing problems.

Chinese Postman Problems

The single vehicle version of an arc routing problem is called the Chinese Postman Problem (given the name by Meigu Guan or Mei-Ko Kwan, see Kwan (1962)). In the Chinese Postman problem, there are streets in a network that require service and the subgraph made up of the streets requiring service is connected. The problem is to develop a travel path (called an Euler path) that services all of the streets requiring service where the deadhead time is minimzed for the additional streets added to the required streets to allow for an Euler path to be found.

A simple approach for solving the undirected Chinese Postman Problem (all arcs in the network are undirected) is to sove a 1-match problem to determined the minimum cost additional arcs to be added into the problem to allow for an Euler path to be found over the subgraph of required arcs and deadhead arcs. In a similar vein, the determination of the minimum deadhead arcs in the directed Chinese Postman Problem is found by solving a transportation problem.

Since the algorithms for optimally solving the 1-match problem and the transportation problems are polynomial, the undirected and directed Chinese Postman problems are not NP-Hard. The Chinese Postman Problem becomes NP-Hard when some of the arcs are directed and others are not directed. In the case where the arcs to be serviced are a subset of all of the arcs in the network, then the problem is not NP-Hard if all the arcs requiring service are either directed or undirected and the network of all streets requiring service is connected.

The famous Swiss mathematician, Leonhard Euler, solved the first undirected Chinese Postman Problem in the famous problem called the Seven Bridges of Koenigsburg (Prussia). Because of this problem, Euler is generally credited with originating Graph Theory (Assad 2007). A special issue of *Networks* was devoted to celebrating Euler's 300th birthday (Golden and Shier 2007). This special issue of *Networks* also contained a delightful article on the present status of the Seven Bridges of Koenigsburg (Gribkovskaia et al. 2007).

Neighborhood Vehicle Routing Problems

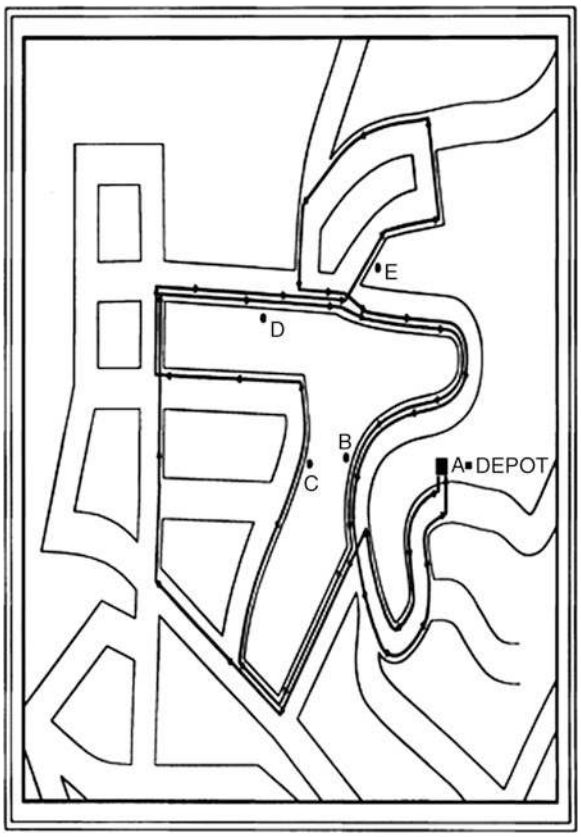
A second class of vehicle routing problems are called neighborhood routing (or arc routing) problems. In a neighborhood vehicle routing problem, the locations are arcs in the underlying network to be serviced. In solving the neighborhood vehicle routing problem, the arcs are partitioned into subsets and, within each subset, the locations are ordered to form a minimum travel time path. Traditionally, when solving neighborhood vehicle routing problems, the shortest travel time path between street segments requiring service is used as the deadhead travel time metric.

The capacitated arc routing problem is another example of a neighborhood routing problem. In the undirected (directed) capacitated arc routing problem, a network is given where every arc in this network is either directed or undirected and the network is connected. Moreover, each arc has a known demand and each vehicle has the same capacity Q. The problem is to break this network down into partitions where each arc is assigned to a partition, the demand in each partition is no greater than Q, a travel path can be found over the arcs in each partition that traverses all of the arcs in that partition and the total deadhead travel time over all of the vehicles is minimized.

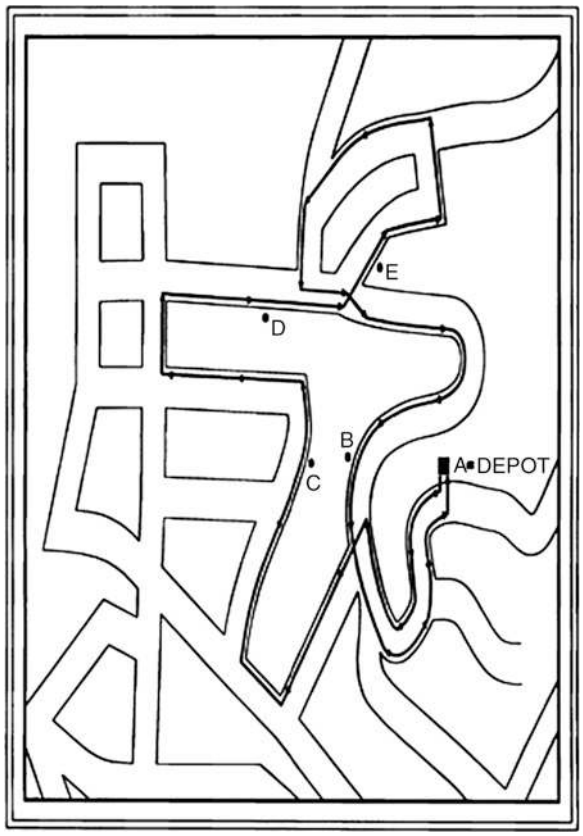
Street Routing and Scheduling Problems

As noted earlier, the original procedures for solving the point-to-point vehicle routing problems assumed that Euclidean distance was used to determine the distance or travel time between the locations to be serviced in a point-to-point vehicle routing problem. This assumption worked reasonably well as long as the locations to be serviced were scattered over a region and not too dense. However, the Euclidean distance assumption may not be realistic when solving practical vehicle routing problems where the locations to be serviced are somewhat dense and/or the street network on which the locations are geocoded have to be taken into consideration.

A five-location traveling salesman solution, A-B-C-D-E-A, using Euclidean distances was displayed in Fig. 1. Assume that location A is the depot in Figs. 2 and 3.



Vehicle Routing, Fig. 2 Actual travel path for Euclidean distance route in Fig. 1. (Notes for Fig. 2: Order of the servicing the locations on the route is maintained as in Fig. 1. No U-turns are allowed. Service is carried out on the location's side of the street without making a left hand turn. To get from location A to location B without U-turns and ensuring that service is carried out on the location's side of the street, the route has to go around several blocks)



Vehicle Routing, Fig. 3 Travel path when shortest paths are computed over the street network. (Notes on Fig. 3: No U-turns are allowed. Service is carried out on the location's side of the street without making a left hand turn)

In Fig. 2, the same traveling salesman solution (A-B-C-D-E-A) is displayed but the locations to be serviced are superimposed on a street network. In this solution, the vehicle would drive past locations and not service these locations and then have to service these locations later in the route, increasing the total travel time of the route.

The solution in Fig. 3 is generated by solving a traveling salesman problem where the shortest travel time path between each pair of locations is used rather than Euclidean distances. In this solution, no U-turns are allowed and the vehicle is forced to traverse each street segment on the right hand side. In this solution, the vehicle always services locations as it drives past these locations.

A special class of practical vehicle routing problems are called street routing and scheduling problems. Street routing and scheduling problems consist of point-to-point routing problems where locations to be serviced are dense and arc routing problems. In street routing problems, the locations to be serviced are located on a digital map and the deadhead travel times are computed as shortest paths rather than Euclidean distances. In arc routing problems, most street segments in the region are to be serviced. Street routing and scheduling problems are described in detail in Bodin, Mingozzi and Maniezzo (1999).

Geographic Information Systems and Digital Street Networks

To solve street routing and scheduling problems requires an accurate digital street networks and

a Geographic Information System (GIS). A digital street network is a street segment by street segment representation of a geographic region. A *GIS* is a system of computer hardware, software and procedures designed to support the capture, management, manipulation, analysis, modeling and display of a digital street network. With an accurate GIS, the user is able to address match the locations to be serviced on the digital street network, to compute the travel times between locations as shortest travel-time paths, and to give accurate street-by-street travel directions for each vehicle route. On the other hand, the Euclidean distance approach for solving vehicle routing problems only gives an ordering of the locations of a route could be derived.

Most commercially available vehicle routing systems use a digital street network and a GIS in their routing and scheduling procedures. The generation of accurate travel paths is essential for having these travel paths accepted by the drivers and management. Users do not want strange turns on their routes and they wish to be able to give accurate locations for all of the locations that they service. In this regard, early procedures for solving street routing and scheduling problems were concerned about adverse turns in their travel paths and developed approaches for reducing U-turns and left-hand turns on their travel paths (assuming vehicles are driven on the right hand side of the street) (McBride (1982)). UPS announced that they had developed the travel paths for their drivers that emphasized right hand turns. As a result, they saved $600 million per year (Farber (2005)).

Concluding Remarks

Due to the increase in the capabilities of computers and the increase in functionality and sophistication of software, it is now possible to derive better solutions to larger (in terms of number of locations to be served) and more varied (in terms of the constraints that can be considered) vehicle routing problems. Moreover, the computer systems that solve these systems have improved graphics, user interfaces and underlying geographic data. Since the cost of distribution is a major cost component of many organizations, computerized vehicle routing systems are becoming a necessary part of an organization's logistics/distribution system.

Verification

For a mathematical model, especially a computer-based one such as a simulation model, verification is the process by which the computational procedure (computer program or software) is checked to determine if it is error free (debugged) and the determination that the model, as represented by the calculations or software, does what the analyst intended. A model is said to be verified if it (the computation) correctly executes the intended calculations.

Verification, Validation, and Testing of Models

Osman Balci
Virginia Polytechnic Institute & State University, Blacksburg, VA, USA

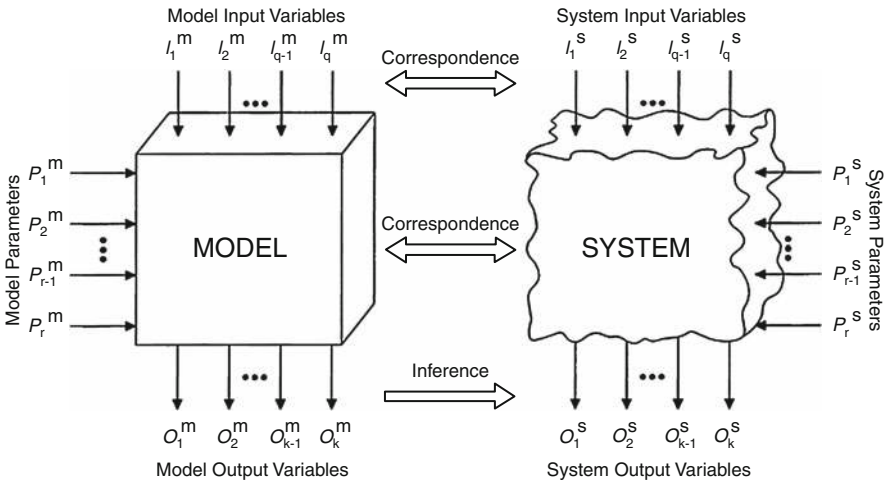
Introduction

Operations research/management science (OR/MS) models lacking a sufficiently accurate representation produce erroneous results that can be catastrophic when making critical decisions based on the model results. Thus, principles and techniques for verification, validation and testing (VV&T) of the OR/MS models are critical for their successful implementation and utilization. After presenting some background information, the principles are introduced and a taxonomical brief overview of the techniques is given.

Background

A model is a representation and an abstraction of anything such as a system, concept, problem, or phenomena. It can have inputs, parameters, and outputs as illustrated in Fig. 1. The term system is used to refer to whatever the model represents.

Model Verification is substantiating that the model is transformed from one form into another, as intended, with sufficient accuracy. Model verification deals with building the model right. The accuracy of transforming a problem formulation into a model specification or the accuracy of converting a model representation in micro flowchart into an executable computer program is evaluated in model verification.



Verification, Validation, and Testing of Models, Fig. 1 Model and system characteristics

Model Validation is substantiating that the model, within its domain of applicability, behaves with satisfactory accuracy consistent with the study objectives. Model validation deals with building the right model. It is conducted by executing/running the model under the same input conditions that drive the system and by comparing model behavior with the system behavior. (Note that a linear programming model is executed and a simulation model is run).

Model Testing is demonstrating that inaccuracies exist in the model or revealing the existence of errors in the model. In model testing, the model is subjected to test data or test cases to see if it functions properly. Test failed implies the failure of the model, not the test. Testing is conducted to perform verification and validation. Some tests are intended to judge the accuracy of model transformation from one form into another (verification). Some tests are devised to evaluate the behavioral accuracy (i.e., validity) of the model. Therefore, the whole process is commonly referred to as model VV&T.

Model VV&T is conducted to prevent occurrences of three major types of errors in OR/MS modeling studies (Balci 1998b): Type I Error is the error of rejecting the model credibility when in fact the model is sufficiently credible; Type II Error is the error of accepting the model credibility when in fact the model is not sufficiently credible; and Type III Error is the error of solving the wrong problem. The probability of committing the Type I Error is called Model Builder's Risk and probability of committing the Type II Error is called Model User's Risk. Committing the Type I error increases the cost of model development. The consequences of committing the Type II and Type III errors may be catastrophic. Therefore, a cost-risk analysis should be conducted whenever possible (Balci and Sargent 1981).

Principles

The principles presented here are established based on the experience described in the published literature and the author's experience (Balci 1998b, 2010). The principles are listed below in no particular order.

Principle 1: The model VV&T must be conducted throughout the entire modeling life cycle starting with problem formulation and culminating with the presentation of model results. The VV&T activities throughout the entire life cycle are intended to reveal and rectify quality deficiencies during the life cycle phase in which they occur.

Principle 2: The outcome of model VV&T should not be considered as a binary variable where the model is absolutely correct or absolutely incorrect. Since a model is an abstraction of an entity, perfect representation is never expected. The outcome of model VV&T should be considered as a degree of credibility on a scale from 0 to 100, where 0 represents absolutely incorrect and 100 represents absolutely correct.

Principle 3: A model is built with respect to the study objectives and its credibility is judged with respect to those objectives. The study objectives dictate how representative the model should be. Sometimes, 60% representation accuracy may be

sufficient; sometimes, 95% accuracy may be required. The adjective "sufficient" must be used in front of the terms such as model credibility, model validity or model accuracy to indicate that the judgment is made with respect to the study objectives.

Principle 4: The model VV&T requires independence to prevent developer's bias. The organization which is contracted to conduct the modeling study is not qualified to perform the final model VV&T (acceptance testing). The sponsor of the modeling study should identify an independent agent to conduct the final model VV&T. To emphasize this principle, VV&T is called independent VV&T or independent V&V (IV&V) by many authors in the literature.

Principle 5: The model VV&T is difficult and requires creativity and insight. Knowledge of the problem domain, expertise in the modeling methodology, and prior modeling and VV&T experience are required. It is not possible for one person to fully understand all aspects of a large and complex model especially if the model is a stochastic one containing hundreds of concurrent activities.

Principle 6: Model credibility can be claimed only for the prescribed conditions for which the model is tested. The accuracy of the input–output transformation of a simulation model is affected by the characteristics of the input conditions. The transformation that works for one set of input conditions may produce absurd output when conducted under another set of input conditions.

Principle 7: Complete model testing is not possible. Exhaustive (complete) testing requires testing the model under all possible inputs. Combinations of feasible values of model input variables can generate millions of logical paths in model execution. Due to time and budgetary constraints, it is impossible to test the accuracy of millions of logical paths. Therefore, in model testing, the purpose is to increase confidence in model credibility as much as dictated by the study objectives rather than trying to show 100% credibility.

Principle 8: The model VV&T must be planned and documented. Testing is not a phase or step in model development life cycle; it is a continuous activity throughout the entire life cycle. The tests should be identified, test data or cases should be prepared, tests should be scheduled, and the whole testing process should be documented. All test data and cases must be preserved for use in model maintenance and regression testing.

Principle 9: Type I, II and III errors must be prevented. Committing a Type I Error unnecessarily increases the cost of model development. The consequences of Type II and Type III Errors can be catastrophic especially when critical decisions are made on the basis of model results. Committing a Type III Error implies solving the wrong problem and causes the study results to be irrelevant.

Principle 10: Errors should be detected as early as possible in the life cycle of a modeling study. Correcting errors detected in later phases of the life cycle is much more expensive. Some vital errors may not be detectable in later phases resulting in the occurrence of Type II or Type III error.

Principle 11: Multiple response problems must be recognized and resolved properly. The validity of a model with two or more output variables (responses) cannot be tested by comparing the corresponding model and system output variables one at a time, that is, O_1^m versus O_1^s, O_2^m versus O_2^s, etc. as shown in Fig. 1. A multivariate statistical procedure must be used to incorporate the correlations among the output variables in the comparison.

Principle 12: Double validation problem must be recognized and resolved properly. If data can be collected on both system input and output, model validation can be conducted by comparing model and system outputs obtained by running the model with the same input data that drives the system. Determination of the same is yet another validation problem within model validation. Therefore, this is called the double validation problem.

Principle 13: Successfully testing each submodel (module) does not imply overall model credibility. The credibility of each submodel is judged to be sufficient with some error that is acceptable with respect to the study objectives. Each submodel may be found to be sufficiently credible, but this does not imply that the whole model is sufficiently credible. The allowable errors for the submodels may accumulate to be unacceptable for the whole model. Therefore, the whole model must be tested even if each submodel is found to be sufficiently credible.

Principle 14: Model validity does not guarantee the credibility and acceptability of modeling study results. Model validity is a necessary but not a sufficient condition for the credibility and acceptability of

model results. Model validity is assessed with respect to the modeling study objectives by comparing the model with the system as it is defined. If the study objectives are incorrectly identified and/or the system is improperly defined, the model results will be invalid; however, the model may still be found to be sufficiently valid by comparing it with the improperly defined system and with respect to the incorrectly identified objectives.

Principle 15: Formulated problem accuracy greatly affects the acceptability and credibility of model results. If the problem is formulated incorrectly, no matter how excellent the problem solution is, the modeling study results will be irrelevant.

Techniques

Figure 2 shows a taxonomy that classifies more than 77 VV&T techniques into four primary categories: informal, static, dynamic, and formal (Balci 1998a). The use of mathematical and logic formalism by the techniques in each primary category increases from informal to formal from left to right. Likewise, the complexity also increases as the primary category becomes more formal. The categories and techniques in each category are briefly described below (Balci 1998b).

Informal Techniques

These techniques are among the most commonly used ones. They are called informal because the tools and approaches used rely heavily on human reasoning and subjectivity without stringent mathematical formalism. The informal label does not imply any lack of structure and formal guidelines for the use of the techniques.

Audit is undertaken to assess how adequately the modeling study is conducted with respect to established plans, policies, procedures, standards and guidelines. The audit also seeks to establish trace-ability within the modeling study.

Desk Checking (also known as Self-Inspection) is the process of thoroughly examining one's work to ensure correctness, completeness, consistency and unambiguity. It is considered to be the very first step in VV&T and is particularly useful for the early stages of development.

Documentation Checking is conducted to ensure correctness, completeness, consistency, and unambiguity of all model documentation and to justify that all documentation is up-to-date with respect to model logic specification.

In Face Validation, the project team members, potential users of the model, people knowledgeable about the system under study, based on their estimates and intuition, subjectively compare model and system behaviors under identical input conditions and judge whether the model and its results are reasonable.

Inspections are conducted by a team of four to six members for any model development phase such as model requirements specification, detailed model design, or model code. An inspection goes through five distinct phases: overview, preparation, inspection, rework and follow-up.

Reviews are conducted in a similar manner as the inspections and walkthroughs except in the way the team members are selected. The review team also involves managers. The review is intended to give management and study sponsors evidence that the model development process is being conducted according to stated study objectives.

Turing Test is based on the expert knowledge of people about the system under study. The experts are presented with two sets of output data obtained, one from the model and one from the system, under the same input conditions. Without identifying which one is which, the experts are asked to differentiate between the two. If they succeed, they are asked how they were able to do it. Their response provides valuable information for model validation.

Walkthroughs are conducted by a team composed of a coordinator, model developer and three to six other members. Except the model developer, all other members should not be directly involved in the development effort.

Static Techniques

These techniques are concerned with accuracy assessment on the basis of characteristics of the static model design and source code. Static techniques do not require machine execution of the model, but mental execution can be used.

Cause-Effect Graphing assists model correctness assessment by addressing the question of "what

Verification, Validation, and Testing of Models, Fig. 2 A taxonomy of model VV&T techniques

causes what in the model representation?" It is performed by first identifying causes and effects in the system being modeled and by examining if they are accurately reflected in the model specification.

Calling Structure Analysis is used to assess model accuracy by identifying who calls whom and who is called by whom. The who could be a module, procedure, subroutine, function, or a method in an object-oriented model.

Concurrent Process Analysis is especially useful for parallel and distributed models. Model accuracy is assessed by analyzing the overlap or concurrency of model components executed in parallel or as distributed. Such analysis can reveal synchronization problems such as deadlocks.

Control Flow Analysis requires the development of a graph of the model where conditional branches and model junctions are represented by nodes and the model segments between such nodes are represented by links. A node of the model graph usually represents a logical junction where the flow of control changes, while an edge represents towards which junction it changes. This technique examines sequences of control transfers and is useful for identifying incorrect or inefficient constructs within model representation.

State Transition Analysis requires the identification of a finite number of states the model execution goes through. A state transition diagram is created showing how the model transitions from one state to another. Model accuracy is assessed by analyzing the conditions under which a state change occurs.

Data Dependency Analysis involves the determination of what variables depend on what other variables. For parallel and distributed models, the data dependency knowledge is critical for assessing the accuracy of process synchronization.

Data Flow Analysis is used to assess model accuracy with respect to the use of model variables. It can be used to detect undefined or unreferenced variables and, when aided by model instrumentation, can track minimum and maximum variable values, data dependencies and data transformations during model execution. It is also useful in detecting inconsistencies in data structure declaration and improper linkages among submodels.

In Fault/Failure Analysis, fault implies incorrect model component and failure implies incorrect behavior of a model component. The analysis uses model input–output transformation descriptions to identify how the model might logically fail. The model design specification is examined to determine if any failure-mode possibilities could logically occur and in what context and under what conditions. Such model examinations often lead to identification of model defects.

Model Interface Analysis is conducted to examine the (sub)model-to-(sub)model interface and determine if the interface structure and behavior are sufficiently accurate.

User Interface Analysis is conducted to examine the user-model interface and determine if it is human engineered so as to prevent occurrences of errors during the user's interactions with the model. It is also used to assess how accurately the interface is integrated with the model. This technique is particularly useful for accuracy assessment of interactive models used for training purposes.

Semantic Analysis is conducted by the model's programming language compiler and attempts to determine the modeler's intent in writing the code. The compiler informs the modeler about what is specified in the source code so that the modeler can verify that the true intent is accurately reflected. The compiler generates a wealth of information to help the modeler determine if the true intent is accurately translated into the executable code.

Structural Analysis is used to examine the model structure and to determine if it adheres to structured principles. It is conducted by constructing a control flow graph of the model structure and examining the graph for anomalies, such as multiple entry and exit points, excessive levels of nesting within a structure and questionable practices such as the use of unconditional branches (i.e., GOTOs).

Symbolic Evaluation is used to assess model accuracy by exercising the model using symbolic values rather than actual data values for input. It is performed by feeding symbolic inputs into the (sub) model and producing expressions for the output which are derived from the transformation of the symbolic data along model execution paths.

Syntax Analysis is carried on by the model's programming language compiler to assure that the mechanics of the language are applied correctly.

Traceability Assessment is used to match, one to one, the elements of one form of the model to another. For example, the elements of the model requirements specification are matched one to one to the elements of the model design specification. Unmatched elements may reveal either unfulfilled requirements or unintended design functions.

Dynamic Techniques

These techniques require model execution and are intended for evaluating the model based on its execution behavior. Most dynamic VV&T techniques require model instrumentation. The insertion of additional code (probes or stubs) into the executable model for the purpose of collecting information about model behavior during execution is called model instrumentation. Probe locations are determined manually or automatically based on static analysis of model structure. Automated instrumentation is accomplished by a preprocessor that analyzes the model static structure (usually via graph-based analysis) and inserts probes at appropriate places. Dynamic VV&T techniques are usually applied using the following three steps. In Step 1, the executable model is instrumented. In Step 2, the instrumented model is executed, and in Step 3, the model output is analyzed and dynamic model behavior is evaluated.

Acceptance Testing is conducted either by the model sponsor or an independent contractor hired by the sponsor after the model is officially delivered and before the sponsor officially accepts the delivery. The model is operationally tested by using the actual hardware and actual data to determine whether all requirements specified in the legal con-tract are satisfied.

Alpha Testing refers to the operational testing of the alpha version of the complete model at an in-house site which is not involved with the model development.

In Assertion Checking, an assertion is a statement that should hold true as the model executes. Assertion checking is a verification technique used to check what is happening against what the modeler assumes is happening so as to guard model execution against potential errors. The assertions are placed in various parts of the model to monitor model execution. They can be inserted to hold true globally—for the whole model; regionally—for some submodels; locally—within a submodel; or at entry and exit of a submodel.

Beta Testing refers to the operational testing of the beta version of the complete model at a "beta" user site under realistic field conditions.

Bottom-up Testing is used in conjunction with bottom-up model development strategy under which model construction starts with the submodels at the leaf nodes and culminates with the submodels at the highest level.

Comparison Testing (also known as back-to-back testing) may be used when more than one version of a model representing the same system is available for testing. All versions of the model built to represent exactly the same system are run with the same input data and the model outputs are compared. Differences in the outputs reveal problems with model accuracy.

Authorization Testing is used to test how accurately and properly different levels of access authorization are implemented in the model and how properly they comply with the established rules and regulations.

Performance Testing is used to test whether (a) all performance characteristics are measured and evaluated with sufficient accuracy, and (b) all established performance requirements are satisfied.

Security Testing is used to test whether all security procedures are correctly and properly implemented in conducting a classified experiment with the model.

Standards Testing is used to substantiate that the model is developed with respect to the required standards, procedures, and guidelines.

Debugging is an iterative process the purpose of which is to uncover errors or misconceptions that cause the model's failure and to define and carry out the model changes that correct the errors. This iterative process consists of four steps. In Step 1, the model is tested revealing the existence of errors (bugs). Given the detected errors, the cause of each error is determined in Step 2. In Step 3, the model changes believed to be required for correcting the detected errors are identified. The identified model changes are carried out in Step 4. Step 1 is re-executed right after Step 4 to ensure successful modification because a change correcting an error may create another one. This iterative process continues until no errors are identified in Step 1 after sufficient testing.

Execution Monitoring is used to reveal errors by examining low-level information about activities and events that take place during model execution.

Execution Profiling is used to reveal errors by examining high-level information (profiles) about activities and events that take place during model execution.

Execution Tracing is used to reveal errors by watching the line-by-line execution of a model.

Fault/Failure Insertion Testing is used to insert a kind of fault (incorrect model component) or a kind of failure (incorrect behavior of a model component) into the model and observe whether the model produces the invalid behavior as expected. Unexplained behavior may reveal errors in model representation.

Field Testing places the model in an operational situation for the purpose of collecting as much information as possible for model validation.

Functional Testing (also known as Black-Box Testing) is used to assess the accuracy of model input–output transformation. It is applied by feeding inputs (test data) to the model and evaluating the corresponding outputs. The concern is how accurately the model transforms a given set of input data into a set of output data.

Graphical Comparisons is a subjective, inelegant and heuristic, yet quite practical approach especially useful as a preliminary approach to model VV&T. The graphs of values of model variables over time are compared with the graphs of values of system

variables to investigate characteristics such as similarities in periodicities, skewness, number and location of inflection points, logarithmic rise and linearity, phase shift, trend lines and exponential growth constants.

Data Interface Testing is conducted to assess the accuracy of data inputted into the model or outputted from the model during execution. All data interfaces are examined to substantiate that all aspects of data input/output are correct.

Model Interface Testing is used to detect (sub) model-to-(sub)model interface errors or invalid assumptions about the interfaces. This form of testing deals with how well the (sub)models are integrated with each other and is particularly useful for object-oriented and distributed models.

User Interface Testing is used to detect user-model interface errors or invalid assumptions about the interfaces. This form of testing is particularly important for testing human-in-the-loop, interactive and training models.

Object-Flow Testing is used to assess model accuracy by way of exploring the life cycle of an object during model execution.

Partition Testing is used for testing the model with the test data generated by analyzing the model's functional representatives (partitions). It is accomplished by: (1) decomposing both model specification and implementation into functional representatives (partitions), (2) comparing the elements and prescribed functionality of each partition specification with the elements and actual functionality of corresponding partition implementation, (3) deriving test data to extensively test the functional behavior of each partition, and (4) testing the model by using the generated test data.

Predictive Validation requires past input and output data of the system being modeled. The model is driven by past system input data and its forecasts are compared with the corresponding past system output data to test the predictive ability of the model.

Product Testing is conducted by the model developer after all submodels are successfully integrated and before the acceptance testing is performed by the model sponsor.

Regression Testing is used to substantiate that correcting errors and/or making changes in the model do not create other errors and adverse side-effects. It is usually accomplished by retesting the modified model with the previous test data sets used.

Sensitivity Analysis is performed by systematically changing the values of model input variables and parameters over some range of interest and observing the effect upon model behavior. Unexpected effects may reveal invalidity.

Boundary Value Testing is employed to test model accuracy by using test cases on the boundaries of the model input domain.

Equivalence Partitioning Testing partitions the model input domain into equivalence classes in such a manner that a test of a representative value from a class is assumed to be a test of all values in that class.

Extreme Input Testing is conducted by running/exercising the model by using only minimum values, only maximum values, or arbitrary mixture of minimum and maximum values for the model input variables.

Invalid Input Testing is performed by running/exercising the model under incorrect input data and cases to determine whether the model behaves as expected. Unexplained behavior may reveal model representation errors.

Real-Time Input Testing is particularly important for assessing the accuracy of models built to represent embedded real-time systems. Real-time input data collected from a real system is used for testing the model's timing relationships and correlations between input data points.

Self-Driven Input Testing is conducted by running/exercising the model under input data randomly sampled from probabilistic models representing random phenomena in a real or futuristic system.

Stress Testing is intended to test the model validity under extreme workload conditions. This is usually accomplished by increasing the congestion in the model.

Trace-Driven Input Testing is conducted by running/exercising the model under input trace data collected from a real system.

Statistical Techniques can be used to conduct model validation by comparing model and system output data obtained by running both model and system under the same input data. Some example statistical techniques for model validation include Confidence Intervals/Regions, Hotelling's T^2 Tests, Multivariate Analysis of Variance, Nonparametric Goodness-of-fit Tests, Nonparametric Tests of Means, and Time Series Analysis.

Branch Testing is conducted by executing the model under test data so as to execute as many branch alternatives as possible, as many times as possible and to substantiate their accurate operations.

Condition Testing is conducted by executing the model under test data so as to execute as many (compound) logical conditions as possible, as many times as possible and to substantiate their accurate operations.

Data Flow Testing uses the control flow graph to explore sequences of events related to the status of data structures and to examine data-flow anomalies. For example, sufficient paths can be forced to execute under test data to assure that every data element and structure is initialized prior to use or every declared data structure is used at least once in an executed path.

Loop Testing is conducted by executing the model under test data so as to execute as many loop structures as possible, as many times as possible and to substantiate their accurate operations.

Path Testing is conducted by executing the model under test data so as to execute as many control flow paths as possible, as many times as possible and to substantiate their accurate operations.

Statement Testing is conducted by executing the model under test data so as to execute as many statements as possible, as many times as possible and to substantiate their accurate operations.

Submodel/Module Testing requires a top-down model decomposition in terms of submodels/modules. The executable model is instrumented to collect data on all input and output variables of a sub-model. The system is similarly instrumented (if possible) to collect similar data. Then, each submodel behavior is compared with corresponding sub-system behavior to judge submodel validity.

Symbolic Debugging assists in model VV&T by employing a debugging tool that allows the modeler to manipulate model execution while viewing the model at the source code level.

Top-Down Testing is used in conjunction with top-down model development strategy under which model construction starts with the submodels at the highest level and culminates with the submodels at the leaf nodes

Visualization/Animation of a model greatly assists in model VV&T. Displaying graphical images of internal and external dynamic behavior of a model during execution enables one to discover errors by watching.

Formal Techniques

These techniques are based on formal mathematical proof of correctness. If attainable, formal techniques provide the most effective means of model assessment. Induction, Inference, and Logical Deduction are acts of justifying conclusions on the basis of premises given. Lamda Calculus is a system of transforming the model representation into formal expressions for which mathematical proof techniques can be applied. Predicate Calculus provides rules for manipulating predicates (combinations of simple relations), which are derived from the model representation. Predicate Transformation is used to define the model semantics with a mapping that transforms model output states to all possible model input states. This definition provides the basis for proving whether or not the model is sufficiently correct. Proof of Correctness is employed to express the model in a precise notation and then mathematically proving that: (a) the executed model terminates and (b) it satisfies the requirements of its specification.

Concluding Remarks

In modeling studies, it is well to remember the dictum that "Nobody solves *the* problem. Rather, everybody solves the model that he [or she] has constructed of the problem" (Elmaghraby 1968). This dictum clearly identifies the crucial importance of model credibility. If the model does not represent the problem with sufficient accuracy, the modeling study becomes useless. The model VV&T principles and techniques presented here indicate that assessment of model credibility is an onerous task requiring multifaceted and interdisciplinary knowledge and experience. The applicability of the techniques should be judged with respect to the model type (e.g., mathematical programming model, stochastic optimization model, simulation model). Applying VV&T techniques increases confidence in model credibility. The amount of credibility required or when to stop testing is determined with respect to the study objectives.

Virtual Reality

An extension of the simulator concept in which the computer-simulated external physical world is dynamic rather than static. Actions by the user(s) may change the simulated external world in the same way those actions would affect the real world through the use of the real equipment. The primary sensory environment of virtual reality systems is visual, but sound is prevalent in many systems, with touch/feel also found in some systems. Such systems are routinely used for test pilots and military combat training. Another major application is computer gaming.

Visualization

Peter C. Bell
University of Western Ontario, London, Ontario, Canada

Introduction

Operations research/management science (OR/MS) is frequently involved in the development and use of visualization techniques at various stages of the problem-solving cycle. Jones (1994, 1996) provides many examples, including the use of natural language and informal diagrams at the problem conceptualization stage; spreadsheets, and block structured languages at the problem formulation stage; spreadsheets and relational databases during data collection; interactive optimization, and network flow graphics during problem solution; objective plots and matrix images at the solution analysis stage; and

animation, hypertext, hypermedia, and presentation graphics for results presentation.

The use of visualization techniques such as these is not new: many of the earliest examples of OR/MS problem solving made use of visual concepts. Graphs were routinely used to summarize the results of modeling studies, flowcharts were used to sketch out the flow of an algorithm, and graphical techniques have long been a mainstay of teaching about the simplex method. However, visualization has moved from a position at the periphery of OR/MS to being an important driver of new developments in the field.

The emergence of visualization into the centre stage of OR/MS parallels developments in computing, which have seen the industry's early emphases on number-crunching speed and storage capacity superseded by those of user-friendliness and marketability. These developments have led to spreadsheet software with a ubiquitous visual presentation based on rows and columns, the WIMP (Windows/Icons/Mouse/Pull-down-menu) user interface, and a large variety of user-friendly software for the production of colorful dynamic computer-generated pictures. Just as these developments have proved marketable for the computer industry, so have they proved marketable within OR/MS, with the consequence that OR/MS software that produces vivid visualizations is now widely available.

Sophisticated computer-generated graphics represent the most elaborate extreme of the spectrum of visualization possibilities. Many other methods are employed that use many different spatial techniques to add information content to data. At the opposite end of this spectrum are some very simple tools where the picture elements are characters spatially arranged to have limited visual characteristics. For example, text, the arrangement of data in a table, a set of corporate accounts, and the block structure in a computer code all use a simple visual layout to improve understanding of the numbers and characters. Between these two extremes are a host of tools that have traditionally been characterized in two main groups: presentation graphics and iconic graphics.

Presentation Graphics

Presentation graphics are pictures (bar charts, line graphs, or pie charts) that are used to illustrate or summarize data. The use of these types of tools predates the computer era. From the earliest days of OR/MS, presentation graphics have been used to summarize data, to illustrate the results of OR/MS work, and to aid in communicating data or results to decision makers or management. Considerable research has been done that addresses issues such as when a graph is more useful than numbers, what type of graph is most useful in which situation, and when the use of color adds value to a presentation graphic (Desanctis 1984). The results of this body of research suggest that the nature of the task is very important in determining the appropriateness of numerical display or various presentation graphic forms (Vessey 1991).

Iconic Graphics

Iconic graphics include picture elements that map to elements of the real world. A road map is an iconic graphic consisting of lines that are icons, representing roads, and blocks that represent urban areas. Other common iconic graphics include floor plans, PERT charts, and network flow diagrams. Again, iconic graphics have a long history within OR/MS, but research on the value of iconic formats is lacking. For many people, the value has been obvious: try driving from New York to San Francisco using only numeric data on road and town locations! Often, however, there are alternative iconic representations for a problem, but research has been slow to provide answers to resolve these choices. As a consequence, the market has been the determining factor in deciding which iconic formats survive and which die, with the result that the survivors are often high on color and razzle-dazzle but perhaps not the most useful.

Iconic graphics can be categorized as static or dynamic. An important application area for static iconic graphics has been transportation systems routing and planning. Models that link mathematical programming models to computer-generated road or street maps have been used to solve truck routing and scheduling problems, mass transit system route planning and scheduling problems, and school bus routing problems (Florian et al. 1987; Bodin and Levy 1994).

Dynamic iconic graphics, or animations, were first applied to the study of operations problems by Hurrion (1980) and have proved to be a huge market success.

A major application area for animation is simulation modeling, where animation is now routinely used to illustrate the progress of a simulation code. The use of animation seems to aid code debugging, model verification and model validation (Sargent 2011), and the presentation of the results of simulation studies to decision makers. Visual interactive simulation couples animation with interactive access to the running simulation model to produce decision support systems with visual user interfaces that provide useful tools to aid problem formulation and interactive problem solution (Bell 1991). The use of animation and interaction with simulation models is now so pervasive that every major simulation modeling software package includes these capabilities.

Animated sensitivity analysis uses dynamic graphics to illustrate the sensitivity of an optimal solution to changes in a parameter (Jones 1992). As the parameter is changed, a visual screen display is updated 30 times/second to illustrate the response of the optimal solution to the change.

Impact of New Technologies

The traditional view of visualization has been considerably expanded by new technologies. Text is a graphic format (the location of the characters has meaning), as is hypertext. These tools provide a host of visual formats, including choice of font, size, and layout. Both text and hypertext are used as a front-end for OR/MS models. Again, there exists a broad spectrum of possibilities from simple examples, such as the use of textual data on punched cards as input to mathematical programming software, to hypertext systems that provide the ability to navigate through a complex optimization problem (Kimbrough et al. 1990).

The emergence of multimedia and virtual reality development tools at reasonable cost has driven new developments within OR/MS. As these technologies have become more commonplace, there have appeared many new kinds of OR/MS models that take advantage of the new delivery systems available for OR/MS work (Lembersky and Chi 1984).

While the emergence of visualization as an important field within OR/MS appears to have been market driven, a body of research evidence has appeared which supports a view that visualization helps decision makers solve problems. Surveys of model builders (Kirkpatrick and Bell 1989) and of decision makers who have used visual and interactive models (Bell et al. 1995) strongly support a view that model developers and decision makers believe that these types of tools lead to improved decision making, and explain the market success of software that provides animation capability for simulation models. Task-based behavioral research comparing dynamic iconic graphic tools with non-visual tools has demonstrated the superiority of the graphic tools for some specific tasks (Bell and O'Keefe 1995; Chau and Bell 1995).

Finally, there is a growing body of evidence that suggests that the use of visualization and interaction in conjunction with OR/MS models and new information technology tools will have a revolutionary effect on OR/MS. These tools facilitate, or may even require, the use of innovative problem-solving methodologies (Bell and O'Keefe 1994), and the development of areas of new theory and new algorithms to support these methodologies (Bell 1994). Jones (1994, 1996) are recommended for further reading.

Vogel's Approximation Method (VAM)

A method for finding a first feasible solution to a transportation problem. The procedure begins by finding the two lowest cost cells for each row and column in the transportation problem array. Subtracting the smaller of these costs from the other produces a Vogel number for each row and column. Select the largest Vogel number and make the first assignment to the corresponding lowest cost cell, where the assignment is the maximum amount that can be sent from the corresponding origin to the corresponding destination. After each assignment, the Vogel numbers are recomputed based on the remaining rows and columns in the array. The procedure is repeated until all assignments (shipments) are made. Although VAM tends to find a good (low cost) first feasible solution, the extra computational work required has proven to be a detriment to its use in computer-based software for solving transportation problems.

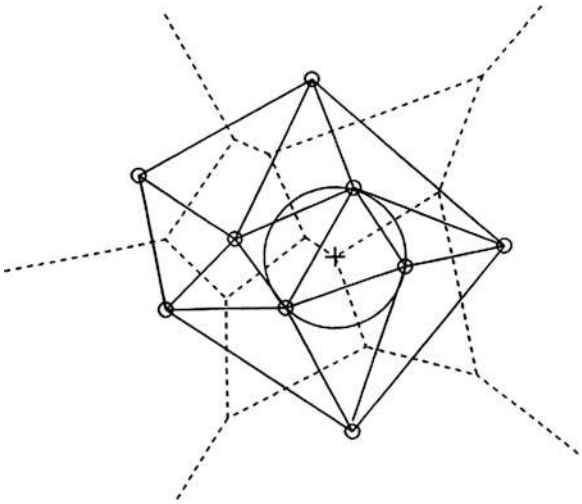
Voronoi Constructs

Isabel M. Beichl[1], Javier Bernal[1], Christoph Witzgall[1] and Francis Sullivan[2]
[1]National Institute of Standards & Technology, Gaithersburg, MD, USA
[2]Supercomputing Research Center, Bowie, MD, USA

Introduction

Given a finite set S of "sites" p_i located in Euclidean space $\mathfrak{R}^d$, the Voronoi polyhedron $V(p_j)$ of site p_j is the set of all points $p \in \mathfrak{R}^d$ which are at least as close to site p_j as to any other site p_i. Such a Voronoi polyhedron (also called Thiessen polygon or Wigner-Seitz cell) is convex, its facets determined by perpendicular bisectors — (hyper)planes or lines of



Voronoi Constructs, Fig. 1 Planar Voronoi diagram (dashed lines) and Delaunay triangulation of nine sites. The circle around one of the Delaunay triangles illustrates the empty circle criterion

equal Euclidean distance from two distinct sites. The Voronoi polyhedra $V(p_i)$, $p_i \in S$ cover the space $\mathfrak{R}^d$ and define a polyhedral cell-complex known as a Voronoi diagram (Voronoi 1908) or Dirichlet tesselation (Dirichlet 1850). For a survey, consult Aurenhammer (1991); also see the texts by Okabe, Boots, and Sugihara (1992); Goodman and O'Rourke (2004).

The cells of the dual complex are convex and, in general, simplicial. By partitioning nonsimplicial cells of the dual complex into simplices, the Delaunay triangulation results (Fig. 1). It provides a canonical scheme for triangulating the convex hull of an arbitrary set $S \subset \mathfrak{R}^d$ of sites, with these sites as vertices. Under the assumption that sites are realizations of a homogeneous Poisson process, statistics for geometrical parameters of Voronoi diagrams and Delaunay triangulations have been derived (Miles 1970; Stoyan et al. 1987).

Delaunay Triangulation

For each site $p_i \in S$, the Delaunay triangulation contains an edge from p_i to each of its nearest Euclidean neighbors $q \in S$. In particular, edges in that triangulation connect all pairs of points of minimum distance in S. The 1-skeleton of the Delaunay triangulation contains the relative neighborhood graph, which in turn contains a Euclidean minimum spanning tree. The Delaunay triangulation thus provides a convenient tool for solving various proximity problems (Shamos and Hoey 1975). Delaunay triangulations avoid narrow triangles (see below) as much as possible, are essentially unique, and are readily determined. They are often the triangulations of choice for constructing piecewise-linear surfaces and for applications of finite-element techniques in engineering.

Delaunay triangulations are characterized by the empty sphere criterion: the circumsphere of a simplex in a Delaunay triangulation does not contain any of the triangulation vertices in its interior (Delaunay 1934). This criterion determines a triangulation uniquely in the absence of degeneracy, i.e., the occurrence of several simplices sharing a circumsphere.

In two dimensions, the empty circle criterion is equivalent to the requirement that the ascending sequence of angles, formed by selecting a smallest interior angle from each triangle in the triangulation, lexicographically maximizes the corresponding sequences for all triangulations of the same vertex set (equiangularity). The requirement that the sequence of *all* interior angles be lexicographically maximum is, in the presence of degeneracy, stronger, and can therefore serve in some instances as a tie-breaker in the presence of degeneracy.

The Delaunay triangulation of a set $S \subset \mathfrak{R}^d$ of n sites can be obtained as a projection of the face lattice of the convex hull of n suitable points in $\mathfrak{R}^{d+1}$. Those points can be chosen on a sphere — stereographic projection — or on a rotational paraboloid whose axis is perpendicular to the space of the triangulation. This implies that the Voronoi/Delaunay problem in d dimensions is computationally subsumed under the strong formulation of the convex hull problem in $d + 1$ dimensions.

To check whether a given triangulation satisfies the empty sphere criterion, it is not necessary to verify that criterion for each simplex by scanning all sites which are not vertices of the simplex: only pairs of facet-adjacent simplices whose union is convex need to be examined as to whether anyone of the two vertices not in the common facet might lie in the interior of its opposite circumsphere. This corresponds to establishing convexity of a (hyper) surface by examining the angles at which adjacent facets are joined. In two dimensions, the above

criterion reduces to checking each strictly convex quadrangle formed by edge-adjacent triangles as to whether the correct diagonal of the quadrangle belongs to the triangulation (Lawson 1977). Based on this observation, several simple and efficient methods such as the insertion method swap diagonals in quadrangles. Alternatively, divide-and-conquer as well as plane sweep techniques yield $O(n \log n)$ algorithms for planar Delaunay triangulation of n sites. Determination of Voronoi diagrams in linear expected time is discussed in Bentley, Weide, and Yao (1980), and Dwyer (1991).

In many applications, it is desirable to construct a planar triangulation with some prescribed edges while preserving the advantages — avoiding unnecessarily narrow triangles, essential uniqueness — of the Delaunay approach. In that case, the empty circle criterion can be generalized by testing for potential inclusion only those sites whose "visibility" from any point of the triangle is not blocked by a prescribed edge. This generalized empty circle criterion defines a constrained Delaunay triangulation, which is unique except for sites on the peripheries of empty circles (De Floriani and Puppo 1988).

A second important generalization of the Voronoi diagram is the power diagram (see Aurenhammer 1987) or radical Voronoi diagram (Gellatly and Finney 1982). Here sites may be enlarged to spheres of positive radius. The intersection, real or imaginary, of two spheres lies on and defines the "radical" (hyper) plane of that pair. These (hyper)planes then play the same role as the perpendicular bisectors in the classical Voronoi diagram. The radical Voronoi diagram of site spheres of radius $r_i \geq 0$ centered at locations $p_i \in \Re^d$ respectively, can be obtained by intersecting the classical Voronoi diagram for the sites (p_i, r_i) in $d + 1$ dimensions with the original d-dimensional space. Radical Voronoi diagrams are used in crystallography in order to account for differences in atomic radii.

There are numerous other generalizations of the Voronoi/Delaunay construct. Alternatives to the Euclidean norm, as well as general sets instead of single point sites, are considered. There are order-k, furthest site, weighted, discrete, and abstract Voronoi diagrams. Voronoi constructs based on the Euclidean metric are instances of cell-complexes derived from arrangements of hyperplanes. Data structures, algorithms and combinatorial results concerning such cell-complexes in general are presented by Edelsbrunner, O'Rourke, and Seidel (1986) and in the text by Agarwal (1991).

W

Waiting Time

In a single queue, the time from customer entrance into the queue until completion of service; in a queueing network, the total elapsed time between customer arrival to the network and final departure from the network. Sometimes, however, waiting time refers only to the time from arrival until the *beginning* of service. These two different quantities are often differentiated by referring to the former as the system or sojourn time and the latter as the queueing time or delay in queue.

Warehouse Problem

A warehouse has a fixed capacity C and an initial stock s_0 of a certain product that is subject to known seasonal fluctuations in selling price and cost. The problem is to determine the optimal pattern of purchases, storage, and sales for the next n months. The problem can be formulated as a linear-programming problem. Its dual has an interesting form that enables the dual solution to be determined readily.

Water Resources

Roman Krzysztofowicz
University of Virginia, Charlottesville, VA, USA

Introduction

Methodologies and techniques of operations research and management science have been applied to a vast array of water resource problems since the early 1960s. Conversely, water resource problems stimulated several methodological developments, notably in statistics of extremes, dynamic programming algorithms, and multi-objective optimization methods. Four classes of problems are discussed herein, techniques that have been employed are noted, and exemplary models are sketched. Fundamental to building operational models is the science of water transport processes.

Hydrology and Hydraulics

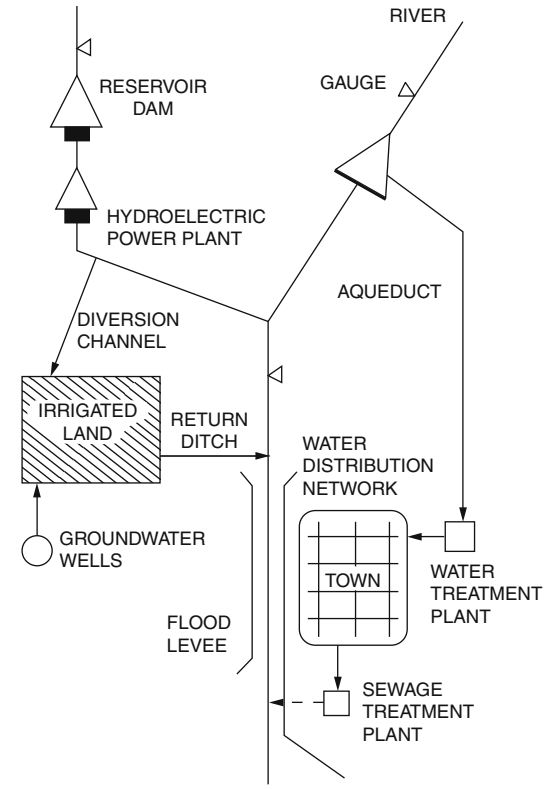
Variability of the quantity and quality of natural waters and their renewability in space and time are governed by the water cycle – a sequence of processes through which water is transported between the atmosphere, the land, and the ocean: precipitation, evaporation, transpiration, infiltration, groundwater flow, and river flow. Hydrology develops models of these natural processes; the models can be used to describe or predict the quantity and quality of water available in a given place and time (Musy and Higy 2010). This information, in turn, constitutes an input into models of water resource systems. Hydraulics develops models of flow in channels and lakes, and through constructed facilities such as spillways, sluices, fish ladders, turbines, pumps, pipelines, aqueducts, culverts, navigation locks, and floodways (Mays 2005). These models serve as building blocks of control and management models.

Planning Water Resource Development

The purpose of water resource development is to alter the natural water cycle so as to ensure the quantity and quality of water in places and times dictated by socioeconomic objectives of human activities. Specific purposes are: (i) flood control, (ii) hydroelectric power generation, (iii) water supply for domestic, municipal, industrial and agricultural uses, and (iv) low-flow augmentation for navigation, recreation, water quality control (by diluting wastewater and contaminated runoff) and aquatic life maintenance (by increasing volume and decreasing temperature of rivers during summer).

For comprehensive planning, the natural boundary of a water resource system is a river basin (source of surface water) and the underlying aquifer (source of groundwater). Figure 1 depicts an exemplary system. Planning involves tasks such as deciding the type, location and size of facilities, sequencing investments, and developing control policies; facilities may be operated individually or conjunctively (as two reservoirs in a cascade, or wells and reservoirs supplying irrigation water to the same district).

The planning process begins with identification of a time horizon (usually several decades) and objectives



Water Resources, Fig. 1 Water resources

(usually multiple ones). Next, the available water resources are characterized: groundwater supply and the rate of its recharge are estimated; river flows at gauge sites are modeled, for example, as time series (Hipel 1985); extreme events such as floods (Krzysztofowicz 2002) and droughts (SHH Special Issue 1991) are modeled stochastically. Predictive models of water demands for various purposes are developed. Alternative system plans are designed, and operations of individual projects or subsystems are described via simulation models or optimization models (in the form of integer, linear, nonlinear, chance-constrained, stochastic, or dynamic programming). Finally, all models are synthesized into a comprehensive river basin planning model, which provides a decision support for a multi-objective analysis (WRB Special Issue 1992). The purpose of the analysis is to screen a large number of alternative plans and to select a few which are Pareto-optimal. The choice of a plan for implementation is usually left to the political process (Loucks and van Beek 2005).

Operation of Hydrosystems

One of the most active and challenging research areas has been optimal control of reservoirs, aqueducts, irrigation systems, water distribution networks, urban drainage and sewage systems. Control policies are almost always discrete-time (with the time interval of an hour, day, week, month or year), but otherwise they may be discrete- or continuous-state, finite- or infinite-horizon, stationary or nonstationary (e.g., periodic as the annual regime of river flows).

In a generic single reservoir control problem, the state x_n denotes the storage at the beginning of time interval n, the input ω_n represents the inflow during interval n, the control u_n is the release decided at the beginning of interval n, and the output y_n represents the outflow during interval n. With any finite ($n = 1, \ldots, N$) trajectories $\boldsymbol{x} = \{x_n\}$ and $\boldsymbol{y} = \{y_n\}$, there is associated a performance measure $g(\boldsymbol{x}, \boldsymbol{y})$, whose form is dictated by reservoir purposes (e.g., generated hydropower, prevented flood damages). In a deterministic case, inflows $\{\omega_n\}$ are assumed to be known; hence $y_n = u_n$, and one wishes to find a policy $\boldsymbol{u}^* = \{u_n^*\}$ maximizing $g(\boldsymbol{x}, \boldsymbol{y})$ subject to the state dynamics, $x_{n+1} = x_n - u_n + \omega_n$, and constraints on storage and release. In a stochastic case, inflows follow a probabilistic law (usually of Markovian structure), and one wishes to find a strategy $\mu^* = \{u_n^*\}$, a sequence of control rules, $u_n = \mu_n^*(x_n)$, that maximizes the expectation $E[g(\boldsymbol{X}, \boldsymbol{Y})]$, subject to nonlinear state dynamics, output operators, and possibly probabilistic constraints.

The complexity of hydrosystems is reflected in the many control models described in the literature. They can be classified according to these features: (i) single reservoir vs. multi-reservoir, (ii) single purpose vs. multi-purpose, (iii) deterministic inflows vs. stochastic inflows, (iv) climatic statistics vs. hydrologic forecasts, (v) linear objective functions vs. non-linear objective functions, (vi) separable objective functions vs. non-separable objective functions, (vii) single objective control vs. multi-objective control, (viii) short-term control (hourly, daily, weekly) vs. long-term control (monthly, yearly), (ix) one-level control vs. hierarchical control, (x) terminal condition vs. infinite horizon.

Deterministic control problems are often formulated as dynamic programs (DP) solved via discrete DP, successive approximation algorithms such as state incremental DP and differential DP (Yakowitz 1982), or approximating linear-quadratic controllers (Protopapas and Georgakakos 1990). Among other techniques one finds linear programming (Yeh et al. 1980), and its chance-constrained variations, network flow algorithms, both linear and nonlinear (Rosenthal 1981), and multi-objective optimization. Stochastic control problems are almost exclusively formulated as dynamic programs solved via discrete DP, policy iteration methods, or approximating linear-quadratic controllers. Various quasi-stochastic approaches have also been tried, such as sampling DP, simulation methods, combined simulation-optimization methods, and heuristic control strategies (Faber and Stedinger 2001). Despite these advances, stochastic control of hydrosystems remains at the forefront of research–the challenges stemming from the dimensionality of the state space, spatial and temporal dependence of hydrologic inputs, nonlinear state dynamics, nonlinear and multiple objective functions.

Mitigation of Floods

Structural solutions, such as dams, diversion channels with retention basins, and levees, offer protection against floods up to a certain magnitude. Risk and benefit-cost analyses have guided decisions concerning the degree of protection and size of structures. Heuristic rules, simulation, and optimization methods have been employed to develop strategies for operation of reservoirs during floods.

Nonstructural solutions, such as floodplain zoning, flood insurance, and flood warning systems, aim at reducing the negative consequences of floods. Risk and decision analyses have been proposed for delineating land use zones, setting insurance rates, issuing flood warnings, and evaluating economic benefits of flood forecasts (Krzysztofowicz and Davis 1984).

A decision-theoretic model of a flood warning system provides an example (Krzysztofowicz 1993). Having received forecast (s, t) of (H, Λ), the uncertain flood crest H and time to crest Λ at a river gauge, a manager must decide whether to issue ($w = 1$) or not to issue ($w = 0$) a warning for a zone of the floodplain above elevation y. Thereafter the zone is

flooded ($\theta = 1$) or not ($\theta = 0$). Each decision-event vector (w, θ) leads to disutility

$$D_{w\theta}(s,t) = \int_y^\infty \int_0^\infty d_{w\theta}(h,\lambda)\,\phi\,(h,\lambda|s,t)d\lambda dh,$$

where ϕ ($\cdot$, $\cdot|s$, t) is the posterior density of (H, Λ), conditional on the forecast, and $d_{w\theta}$ (h, λ) is the disutility of all economic, social, and behavioral outcomes resulting from flood crest h occurring at time λ. The expected disutility associated with decision w, termed the risk function, is

$$R(s,t,w) = D_{w0}(s,t)Pr\{\theta = 0|s,t\} + D_{w1}(s,t)Pr\{\theta = 1|s,t\}.$$

For each (s, t), the optimal warning rule W^* prescribes decision $w = W^*(s,t)$ which minimizes the risk $R(s,t,w)$.

Management of Water Quality

Water pollution comes from either point sources, which can be directly monitored (e.g., industrial wastewater discharges), or nonpoint sources, from which loadings can only be estimated (e.g., contaminated runoff from agricultural fields and urban areas). The preference of downstream users for clean water and the preference of upstream entities (such as municipalities, industries, and agricultural producers) for free discharging of contaminants create a societal conflict whose resolution requires legislative, economic, and institutional means.

Management models are typically formulated in support of planning by a regional authority faced with decisions such as locating and sizing waste-water treatment plants and effluent disposal fields, setting charges for release of wastewater, locating and operating monitoring networks, and devising enforcement policies. These decision problems are multi-objective and hierarchical in nature (Loucks and van Beek 2005). At the upper level, the authority's objectives are (i) to minimize the total cost, (ii) to equitably allocate the cost to entities, and (iii) to improve the quality of waste-receiving waters. At the lower level, an entity's objectives are (i) to minimize its cost and (ii) to optimize its compliance with effluent standards and discharge regulations. Game-theoretic models are developed to predict the compliance behavior of entities, and thus the effectiveness of policies (WRB Special Issue 1992). Water quality models – simulating the physical, chemical, and biological processes taking place in water bodies – are employed to predict impacts of alternative management plans on concentration of constituents (e.g., biochemical oxygen demand, dissolved oxygen deficit, nitrogen, phosphorus, metals, organics, bacteria), which collectively define water quality (Young 1993).

Weak Duality Theorem

- ▶ Strong Duality Theorem

Weakly-Coupled Systems

A linear-programming problem that has a few variables that connect (couple) the constraints or subsets of constraints. Such systems usually arise in time dimensioned large-scale problems that exhibit a block-angular structure. The dual of such systems are weakly-coupled in the sense of having a few constraints that tie the blocks together. Special adaptations of the simplex method exist that take advantage of such structures in their computations.

Wicked Problems

As first described by Professor Horst Rittel, University of California Architecture Department, the term wicked problem refers "to that class of social system problems which are ill-formulated, where the information is confusing, where there are many clients and decision makers with conflicting values, and where the ramifications in the whole system are thoroughly confusing" (Churchman 1967, B141). Such problems, however, are not restricted just to social system problems; they are encountered especially in systemic problems in many areas of business, industry, and government.

In their paper, "Dilemmas in a General Theory of Planning," Rittel and Weber (1973, pp. 161–166) point out that there are ten distinguishing properties of wicked problems:

1. There is no definitive formulation of a wicked problem.
2. Wicked problems have no stopping rule.
3. Solutions to wicked problems are not true or false but good or bad.
4. There is no immediate and no ultimate test of a solution to a wicked problem.
5. Every solution to a wicked problem is a "one-shot operation," because there is no opportunity to

learn by trial and error, every attempt counts significantly.
6. Wicked problems do not have an enumerable (or an exhaustively describable) set of potential solutions, nor is there a well-described set of permissible operations that may be incorporated into the plan.
7. Every wicked problem is essentially unique.
8. Every wicked problem can be considered to be a symptom of another problem.
9. The existence of a discrepancy representing a wicked problem can be explained in numerous ways. The choice of explanation determines the nature of the problem's resolution.
10. The planner has no right to be wrong.

Winner's Curse

The selection bias that occurs in an auction or other situation in which bidders with independent estimates of the value of an item compete to buy it. Even though all of the competitors' estimates are unbiased, the winner will have tended to overestimate the value. Also used, less precisely, to denote an expected loss by a winning bidder.

See

► Bidding Models

Wolfe's Quadratic-Programming Problem Algorithm

An adaptation of the simplex method that solves quadratic-programming problems with positive definite or positive semidefinite quadratic forms. It is based on the simultaneous solution of the linear constraints of the problems and associated Karush-Kuhn-Tucker conditions. It uses a restricted basis entry for the solution of necessary complementarity conditions.

► Quadratic Programming

Work Schedule

A schedule of hours and days to be worked. This issue is of special importance to emergency services which are usually provided 24 hours-a-day, 7 days-a-week.

See

► Emergency Services

Worst-Case Analysis

For an algorithm and associated problem, the determination of an upper bound on the number of steps that the algorithm can take on any instance of the problem. For an optimization problem and an associated heuristic or suboptimal algorithm, worst-case analysis may include a statement regarding bounds on how far the objective function value for the solution returned by the algorithm can be from the true optimal value.
